The template content is the assembly of data elements consisting of items and options or text boxes, which are arranged in a tree structure. The template module displays all the elements in the same layer at once. When a value that has some subordinate elements is selected, these elements are displayed under the selected value. Because the template form changes according to the selected values, we call it 'dynamic template' (Fig. 1).

Although the structured data is processed easily by computer systems, it is difficult for users to understand. Therefore, we adopted a strategy of converting the structured data into narrative form, using the following rule: Each item and value has 4 types of character string: prefix, body, conjunction, and suffix. Linefeed can be set after each character string. If several values are selected for one item, conjunction is set between these values. If there are several items linked with one value, conjunction is set between these pairs of item and value, and the suffix of the value is set after those [16].

We adopted XML for the expression of the template contents master. This master includes the information about a structure of describing element, a way for expression on template of these elements, and a way for conversion of entered data to narrative form.

The main part of the elements in DTD of the template master is as follow.

<!ELEMENT ATOM-LIST (ATOM-STYLE,ATOM*)>

<!ELEMENT ATOM (ATOM-TYPE,DISPLAY-STRING,DOCUMENT-STRING,VALUE-LIST?)>

<!ELEMENT VALUE-LIST (VALUE-STYLE,VALUE*)>

<!ELEMENT VALUE (VALUE-TYPE,DISPLAY-STRING,DOCUMENT-STRING,ATOM-LIST?)>

<!ELEMENT DOCUMENT-STRING (DOC-BODY?,DOC-PREFIX?,DOC-CONJUNC-TION?,DOC-SUFFIX?)>

<!ELEMENT DOC-PREFIX (#PCDATA)>

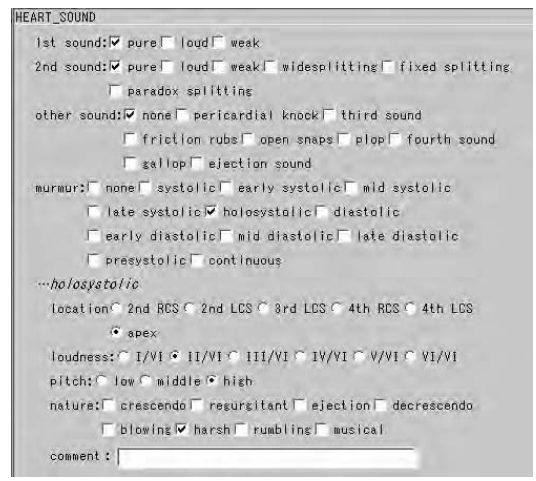
<!ELEMENT DOC-BODY (#PCDATA)>

<!ELEMENT DOC-CONJUNCTION (#PCDATA)>

<!ELEMENT DOC-SUFFIX (#PCDATA)>

DISPLAY-STRING is the character string expressed on the template. DOCUMENT-STRING is the character string on the narrative form, which consists of DOC-PREFIX, DOC-BODY, DOC-CONJUNCTION and DOC-SUFFIX. ATOM is an item of the describing element. ATOM-LIST includes ATOM, and ATOM includes VALUE-LIST. VALUE-LIST includes VALUE, and VALUE includes ATOM-LIST. In this format, the nested structure is presented.

Because the entered patient data is sometimes recalled with the original template and then revised, we adopted a method in which entered patient data is included in the template contents master. We put the SELECTED attribute of VALUE-LIST element in the template master. Before the value is selected, no is set to SELECTED attribute. When the value is selected, it changes to yes. When a character string is entered in a text box, it is set as the element of DISPLAYSTRING and DOCUMENT-STRING of VALUE-TYPE.



Narrative form

1st sound pure, 2nd sound pure, no other sound

holosystolic murmur (apex Levein II/IV high pitch harsh)

diastolic murmur (2nd LCS Levein I/IV high pitch regurgitant)

Figure 1 - An example of the dynamic template.

When the user selects "holosystolic" in " murmur", then the portion under "...holosystolic" appears. After data is entered by this template, the narrative form is generated.

Storage of data into the EMR database

In the EMR database, all kinds of patient data are stored. We call a cluster of information a 'medical event', which is stored in one record of the database. The describing object is one of the medical events. The data in XML and narrative text data are stored in each field, respectively.

EMR database is not suitable for data analysis, because the procedure for such analysis affects the response of the daily online transaction procedure. Furthermore, the patient data is included in the XML. Thus, in order to

search the objective data, all the records have to be checked. To overcome this problem, the data in EMR is transferred to the DWH. In this process, the XML data is parsed to extract patient data, which is stored in the database of DWH (Fig. 2). The structure of the database of DWH is quite simple. One record is made to correspond to one value. The main fields of this database file are as follows: patient ID, date, template name, xPath name, xPath code, value code, value name, suffix. The xPath code and the xPath name indicate the traced items and values in the tree structure. The xPath code (or the xPath name) is expressed by the traced items and values codes (or names) connected with "\", e.g. \A01\V0101\A02.

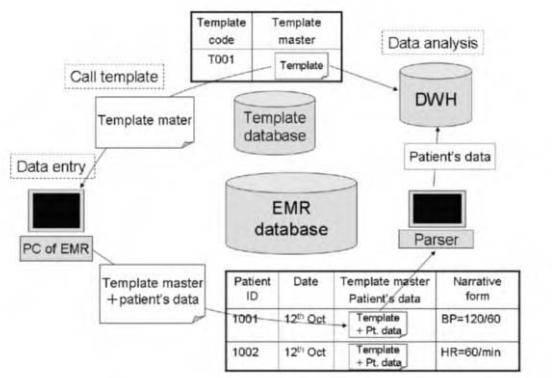


Figure 2 - Flow of template master and patient's data

Search assisting system

We developed an application system for searching the objective data from this database of DWH. In this system, users easily designate the objective data using a GUI. When users select an objective template, the system shows the names of items and values in the template. Thus, users can easily set the combination of search conditions in one template. The character string entered in the text box can also be the object of a search. In the case of numerical values, the conditions "more than" or "less than" can be set. The application system makes a SQL request according to the user's designation and searches the objective data from the DWH database. When the system finds the description that meets the condition, a progress note including the description is shown. Additionally, the system shows the progress notes of other days for the same patient.

Results

Availability of template

Preparation of input templates that are useful and convenient for every member of the hospital staff is essential before a hospital initiates an EMR system. The task is so large for each hospital that we formed an organization to support the preparation of template contents and their supply. The template contents that are developed for hospital use are then stored in the database, from which the staff of the hospital can select useful ones for their practice. The dynamic template module is used in 35 hospitals as of October 2006. Different styles of templates were sometimes produced for a concept. As of that time, 3725 templates (3242 concepts) had been produced and stored in the database. The numbers of template in each class are shown in Table 1. In the description of progress notes, the number of templates for "physical findings" is much greater than the numbers for "symptom", "assessment" or "plan". Not only doctors, but also nurses, pharmacists and nutritionists used templates. Templates are frequently used in examination reports, operation reports, and summaries.

Table 1 – The classification of templates

Classification of Template	No. of Concepts	No. of Template
Symptom	37	46
Physical finding	399	494
Assessment	157	168
Plan	24	26
Disease relating description	618	766
Patient history	184	211
Summary	62	64
Examination report	267	313
Operation report	55	62
Medical checkup	79	92
Description for rehabilitation	134	157
Description by social worker	23	23
Description by nurses	956	1013
Description by pharmacists	12	12
Description by nutritionists	44	44
other	191	234
Total	3242	3725

We examined 100 templates randomly selected from the database. When we count the same item linked with multiple values as 1, the average number of items in one template is 34.8. The average number of layers in one template is 8.1. We examined the maximum depth of layers in one template, and found 1 layer in 17%, 2 layers in 43%, 3 layers in 24%, 4 layers in 25%, and 6 layers in 1% of templates. The total number of items in the database is estimated as about 112,800.

Data warehouse and search assisting system

The DWH and search assisting system were implemented in Osaka University Hospital, and their usefulness was

evaluated. Without the search assisting system, users have to examine the xPath code of the value they want to search beforehand. Furthermore, it is quite difficult to write SQL for a combination of search conditions in one template. Contrasted with this, users can now search the objective data easily by this searching system.

Discussion

General descriptions in medical records, such as progress notes, examination reports, operation reports and summaries, are so diverse and complicated that these data are generally entered as free text in EMR. In order to use these data for research, clinical evaluation and so on, natural language processing is one of the possible methods [17,18]. However, to achieve good results by this method, all of the words in the entire medical field, including abbreviations and frequent typing errors, have to be entered into this system beforehand. This would entail tremendous amount of work.

The strategy of template-based data entry is a practical method from the viewpoint of data analysis [12]. The simple templates that are generally adopted, however, limit what users wish to express, and users have no choice but to tolerate these limitations.

Descriptions in medical records are the observation records of patients. When the observation object is normal, the user just enters “nothing particular”. However, when something abnormal is found, they describe the object in detail. For the observation records, a tree structure is suitable: an abnormal object is described by several features, which may be further described by other properties [19,20]. Thus, a tree structure is necessary for the template. If the structured data is expressed as it is in EMR, it is not acceptable for users because it is quite different from the expression in free text. A person prefers an expression in which obviously understandable words are omitted, rather than a strictly redundant expression. To overcome this problem, we convert the structured data into narrative form [16]. By using this template, users can enter what they want to record in shorter time without the risk of typing errors. This strategy is quite acceptable for users.

The dynamic template is implemented in the EMR system produced by NEC and 35 hospitals actively use this module. Before starting to use EMR system, hospital staff prepared templates useful for their daily practice. During operating the EMR, templates were revised and new ones were added according to the users’ requirement. More than 3725 templates have been produced and more than 100,000 items were entered in the template master. More templates about physical findings or examination reports have been produced than those about symptoms. Template-based data entry is suitable for actively acquired data. On the other hand, it is not suitable for passively acquired data such as symptoms. The concept, which has many options (e.g. portion of skin in dermatology), is difficult to handle with templates. Although the dynamic template is not effective for every type of description in medical records, its popularity and practical accomplishments show that the strategy of dynamic templates, i.e. tree-structured template and conversion of structured data into narrative form, is acceptable in many fields.

For general descriptions in medical records, many types of template have to be prepared. To bring this about, trial and error is inevitable, even after active use in daily practice [21]. Thus, it is necessary to have a system that enables users to produce templates easily and revise them even after releasing. Generally a template is made based on its own database file [14,15], which must be set on each occasion to produce a new template. If the template is revised, the corresponding database file must also be revised. Because this method disperses a patient data in many database files, it is not suitable for EMR system, which must enable users to refer quickly to any patient data.

In our method, the template content master that regulates the content of a template and the patient’s data are simultaneously expressed in XML. After entering patient data by the template, the XML data and the narrative form of patient data are stored in the EMR database. Although this schema is practical for EMR systems, data analysis is virtually impossible. Thus, we developed a parser system that retrieves the data in XML from the EMR database and extracts patient data from it. The parser system then stores the patient data in the DWH database, in which one record corresponds to one value. Because patient data is originally in tree structure, xPath code and name is used to designate each property. This database schema is independent from the template contents; therefore, the user can produce and revise templates freely without thinking of the database schema.

Using this DWH, data entered by the template can be used for analysis. It is, however, difficult for users to find the xPath code of the objective data. Furthermore, in this database schema, it is difficult to execute combined search conditions in one template. Accordingly, we developed a search assisting system which assists in finding the xPath code in the template, and thus enables the user to easily set combinations of search conditions. Although this database schema is not the best for data analysis, the user can search the objective data from the database with the support of the search assisting system.

By using this method, general descriptions in medical records can be structured and analyzed. Although it has been said that structured data entry is essential for advanced functioning in EMR, there are a few reports that it succeeded when limited to a few a fields [14,15,22] or a few department [23,24]. We achieved active use of the structured data entry system in every department in many hospitals.

Abstract

Patient records contain most crucial documents for managing the treatments and healthcare of patients in the hospital. Retrieving information from these records in an easy, quick and safe way helps care providers to save time and find important facts about their patient's health.

This paper presents the scalability issues induced by the indexing and the retrieval of the information contained in the patient records.

For this study, EasyIR, an information retrieval tool performing full text queries and retrieving the related documents has been used.

An evaluation of the performance reveals that the indexing process suffers from overhead consequence of the particular structure of the patient records. Most IR tools are designed to manage very large numbers of documents in a single index whereas in our hypothesis, one index per record, which usually implies few documents, has been imposed. As the number of modifications and creations of patient records are significant in a day, using a specialized and efficient indexation tool is required

Keywords:

information retrieval, patient records

Introduction

The ideal patient record should be unique and persistent over time, consolidated within a distributed computerized patient record (CPR). Whatever its technical, architectural and conceptual organization, accesses should only be constrained by access policies. However, not all the information contained in the records is relevant for each encounter. Care providers waste precious time at searching and browsing the patient record to collect all information pertinent to the actual situation. The problem is emphasized when specific information is scattered in numerous documents. Therefore, creating an efficient tool that allows retrieving relevant information from patient documents should improve the efficiency of care providers.

This paper presents the methodological approach for using an Information Retrieval (IR) tool in order to index the patient records and allowing fast retrieval. The specificity of our approach arises from the specific structure of the patient records. Contrarily to common IR task where all the documents are stored in a unique and large corpus, we have to work with numerous small corpora that must be indexed independently.

Two key measures have been used to evaluate performance, efficiency and effectiveness. As no gold standard was available, an ad-hoc method of automatic query generation has been used to generate the required data. The structure of the dataset has been modified to analyze the consequence of the patient records corpus structure on the indexing process.

Background

Patient records in Geneva University Hospital

The Geneva University Hospitals (HUG) is a consortium of hospitals in four campuses and more than 30 ambulatory facilities in the state. The HUG have about 2,000 beds, 5,000 care providers, over 45,000 admissions and 850,000 outpatients' visits each year. Over than 20,000 computerized records are open daily. More than 4,000 care providers do use this system, including physicians, nurses, medical secretaries, social care providers, physiotherapists, nutritionists, music therapists, etc. Beside order entry, clinical documentation is an important pillar of the CPR. More than 50,000 images, 25,000 lab results, 8,500 documents are stored every day. The clinical database contains more than 130 millions patient facts. All data is available online, there are no archives.

Information retrieval

The purpose of a "document retrieval system" is to select, from a relatively large collection of documents, a manageable number of documents that is likely to satisfy an expressed need for information [1]. It deals with the representation, storage, organization and access to information items. To accomplish the retrieval task, the system needs to build, usually prior to queries, a representation of each document in the collection. This representation consists of a table containing links that allow knowing which terms occur in the documents with which frequency [8].

During the search process, the system typically computes the degree of match between the terms contained in the index and a corresponding set of terms derived from the query [6]. This degree of match based on the frequency of the words in the document itself (TF) and in the corpus

(IDF) provides the basis for deciding whether a document should or not be retrieved.

IR evaluation

Two very different aspects of an IR system can be measured: efficiency and effectiveness [2].

Efficiency can be measured in terms of the resources required by the system for the whole IR process, including storage space and computing resources. Effectiveness attempts to measure the success of an IR system. It should provide a domain neutral measure of the ability of the system to retrieve all relevant documents [5].

The most widespread method of evaluating effectiveness of an IR system involves providing precision–recall values for a set of queries posed on a specific documents collection [4]. Recall measures the proportion of relevant documents retrieved and precision measures the proportion of retrieved documents which are relevant.

Test collection

The final application of our system is dedicated to index the patient records; however, experiments done in this paper are performed on OHSUMED dataset to facilitate measures and reliability.

In this paper, two different kinds of corpus are considered, the source and the experimental corpus. The source corpus denotes the collection from which all the documents supporting the experiments are extracted. The experimental corpus refers also a collection of documents but this collection possesses a special structure. Indeed, in the experimental corpus, the entire documents collection is split into several groups. One group can therefore be assimilated to a given patient record. Note that the total number of documents is independent from the number of groups.

The choice of OHSUMED as the source corpus has been motivated by the easiness of manipulation of the documents for the creation of the different datasets required for our experiments. This corpus is homogenous, meaning that its documents share similar properties like length, word distribution, and word frequency. This homogeneity avoids biasing the experiments and allows focusing only on the quality of retrieval. Additionally, using a standardized corpus accessible to other groups fosters comparisons of alternative methodologies.

As the OHSUMED corpus and the patient records corpus share important common properties regarding the IR process, we believe that we will be able to predict the behavior of our system on the patient records by looking at the results obtained on the OHSUMED corpus.

Patient records

The documents used for the study covers all aspects of clinical documentation, such as admission notes, discharge letters, activity reports, nurses' data entries, consultations and interventions reports. Over 1,500 different categories of documents are used.

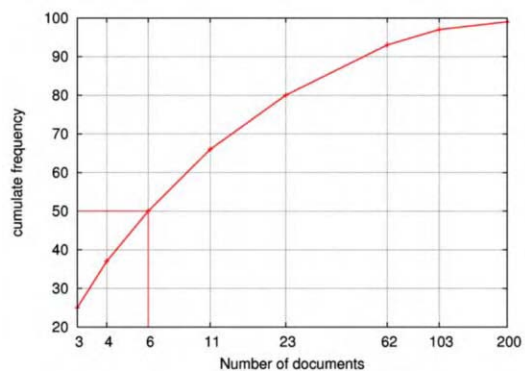

Figure 1 - Distribution of the records size in the patient records corpus

In regard to this distribution, we can stress two issues. First, as most of the records contain few documents (50% of the records have less than 7 documents), there will be little interest in using a tool not returning the exact answer. The second concern is related to records containing numerous documents. In this situation, constraint applied on small record is relaxed as returning a small subset of documents containing the answer could be sufficient. Even if the first answer is not the good one, reducing the possible research space brings a significant gain of time for the care providers.

OHSUMED

The choice of an alternate dataset has been focused on OHSUMED. OHSUMED is a bibliographical document collection, developed by William Hersh and Colleagues at the Oregon Health Science University. It is a subset of the Medline database consisting of 348,566 references from 270 medical journals from the years 1887 to 1991. All of the references have titles, but only 233,445 have abstracts [7].

We refer to the title plus abstract as a document.

Comparison OHSUMED - Patient record

In order to study the similarity of the two corpuses, we selected 8,192 documents from each corpus and compared the frequency of the words of the subsets. Our comparison focused on the frequency distribution of the words contained in the two corpuses as it is the most influential feature on the IR process. Indeed, the observed variation on the inverted index size induced by the modification of the number of patient records is strongly influenced by the distribution of the words in the corpus. While increasing the number of patient records indexed independently, the low frequency words have a different effect on the inverted index size compared to the high frequency words. The former will not be retrieved in independent index whereas the latter will be part of several ones.

We notice in Figure 2 that OHSUMED and the patient record corpora are mainly similar in number of words per document. However, patient record corpus contains less unique words than the OSUHUMED. It is certainly due to

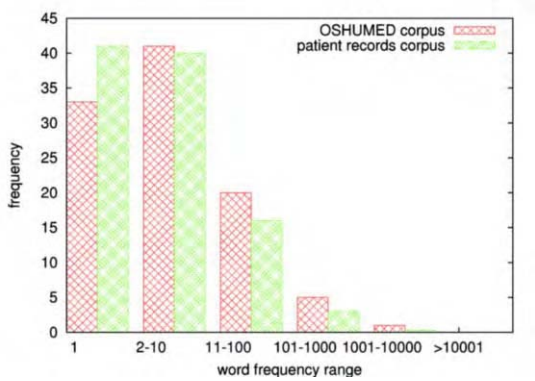

Figure 2 - Frequency of the words contained in the corpus for 8,192 documents

the fact that an important part of the OHSUMED corpus is related to genetics. As there is little consensus on naming genes and proteins, different spelling and acronyms are used and artificially increase word diversity. Beside these the patient records cover mainly the same subjects as the ones addressed in OHSUMED.

Test collection construction

The test collection is composed of three parts, the collection of documents, the queries and the relevance assessments.

The test documents selected from the OHSUMED corpus are structured in order to mimic the existing structure of the patient records corpus. We vary the number of groups while keeping a constant number of documents in order to study the impact of the corpus structure on the performance [3]. As the number of documents is fixed, each increase in groups is accompanied by a proportional decrease in the number of documents per group.

Queries and relevance assessments are dependent of the field of the application. Usually, experts are required to construct relevant and interesting queries for specific domains. We avoid this requirement by automatically generating the queries and their related relevance assessments by considering "known-item-search". The goal in a "known-item search" is to retrieve just a unique document that has been used to build the query. It simulates a user seeking for a particular, partially remembered document in the collection by using a part of a document as a query

The care providers behave quite similarly as the way "known-item-search" works. They have a precise idea of what they search and are often interested in only one particular document that contains the relevant information. Given these similarities, the effectiveness obtained using "known-item-search" is well suited to estimate the usefulness of the tool in a real situation.

The queries are generated by selecting random parts of the documents. Building queries using randomness has the advantage of creating more complex queries than the ones built selecting simply a subpart of the text. Queries built through this process reflect quite properly the ones used in real life situation where they are never exactly similar to the content of the text. Moreover using randomness prevents to match too easily the queries in the initial text.

Methods

Indexing and retrieval strategies

The indexing of the documents is performed with EasyIR, an existing tool [9-10]. This tool has shown good performance on indexing and retrieval in the genetic and biomedical field and should be suitable to be applied on medical terminology.

The specificity of the application arises from the necessity of processing the generated data in real time. In our situation, numerous documents are daily added in the patient records and queries can be performed immediately after. Given these constraints various indexation triggering strategies have been suggested.

a) Indexation launched when a query is performed
b) Indexation performed at fixed, but short, intervals
c) Indexation triggered by a notification when a document is saved

Indexation at fixed time has been dismissed, as it would lead to a lot of useless processing without ensuring proper indexation when needed. Indexation at query time could be interesting, as it requires less indexation process. However, as it inducing a delayed answer when queries are performed, it has a severe impact on perceived performance. Consequently, the last strategy, notification-based triggering appears to be the best solution.

Evaluation metrics

The most basic evaluation of a "known-item search" task, consists in looking at the rank at which the target documents are retrieved. This measure called the "mean-reciprocal-rank" is the mean of the reciprocal of the rank at which the known item was found, averaged over all the queries, and using 0 as the reciprocal for queries that did not retrieve the known document.

Another evaluation measure used is the recall at first retrieved document. It consists in computing the recall of the system when the first returned answer of the system is returned. In our application, recall at first retrieved document is a very useful method to evaluate the utility of our tool. When care providers perform searches in patient records containing few documents, they expect to obtain directly the correct document; therefore the tool must have a high recall at first retrieved document to be really useful.

Trial

Indexing and retrieval - efficiency

The objective is to measure the time cost induced by an increasing number of groups given a fix number of documents. The number of groups grows according to an exponential scale with a parallel decrease in the number of documents in each group.

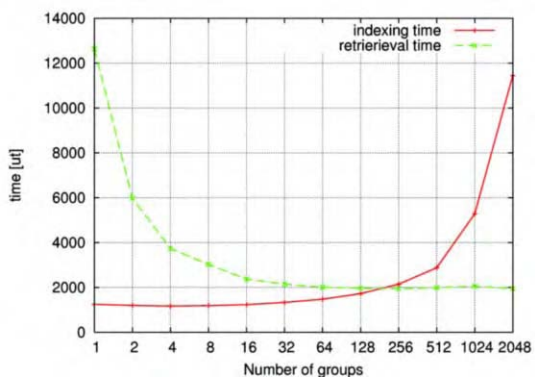

Figure 3 – efficiency given an increasing number of groups for 8,192 documents

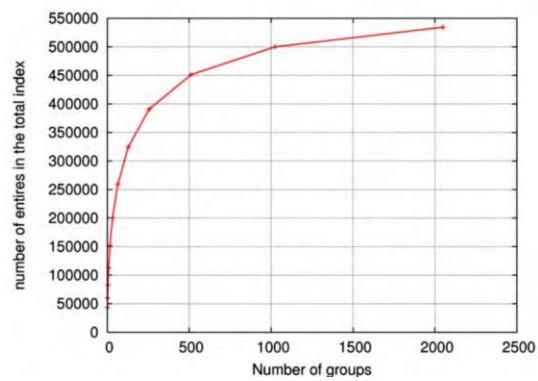

Figure 4 - Total number of entries in the database given the number of groups for 8,192 documents

The measures have been performed using the 8,192 documents with the number of groups varying from 1 to 2,048.

The results show a linear increase in time required for indexation given the number of groups (Figure 3). As the total number of document does not change, this increase in time can be attributed to the indexation initialization overhead.

The time required for retrieval follow a totally inverted tendency in comparison to the indexing process. During retrieval process, as the numbers of queries are constant, it is faster to perform queries on small indexes (Numerous groups). Indeed, if we perform 1,024 queries on an index containing 8,192 documents, it will last longer than performing these 1,024 queries on 1,024 different indexes of 8 documents.

Explanations of the indexing overhead

In this paper, the total index of an experimental corpus refers to the merge of all the individual entries of the index table of each group that compose the corpus. As during the indexing process every group of documents is indexed separately, a separated index table is generated for each group and therefore the total index will contain redundant entries. Indeed, if an entry belongs to two individual indexes it will be present twice in the total index. As the total index contains all the entries which have to be stored on the database, its size is a good estimator of the space required in memory.

As shown in the Figure 4 the number of created entries grows in a logarithmic manner regarding to the number of groups. This is the consequence of the distribution of the frequencies of the words in the corpus that follows a logarithmic decrease (there are many infrequent words and few very frequent words). A word can not occur in a larger number of groups than its document frequency. Therefore, the closer we approach this threshold, the lower the probability of this word occur in an additional separated group and increase the size of the total index. Once a word occurs in a number of groups equal to its frequency, increasing the number of group will not bring any further increase in size of the total index.

In order to analyze the consequences of the size variation of the total entry table on the program overhead, we decomposed the indexation process in three main tasks.

The first step consists in extracting all the words from the documents using tokenization in order to build the vocabulary. This does not lead to significant overhead variation according to the number of groups, as the complexity of this task is only dependent from the total number of words in the whole corpus.

After word tokenization, extracting the term frequency and inverse document frequency values of every term is required to compute the weights. As the inverse document frequency is dependant of the documents contain in every group, this computation is not done once per word but once per entry. Therefore, this process brings clearly an overhead.

The last step consists in storing the indexes in the database. Obviously, there is an overhead linked to the number of groups for this task. As the size of the total index is bigger with a large number of groups, the necessary time to store the total index in the database is bigger too.

Retrieval - effectiveness

Effectiveness evaluation has been done with the mean reciprocal rank and also with recall at first retrieved document.

Table 1 - Recall at top returned documents for different size of experimental corpus given 1,024 queries

Number of document per group	recall at first retrieved document	MRR
8	96%	0.964
16	95%	0.961
32	94%	0.956
64	92%	0.935
128	88%	0.901
256	86%	0.885
512	82%	0.847
1,024	80%	0.819
2,048	74%	0.769
4,096	73%	0.758
8,192	69%	0.722

The Table 1 sho*ws that the fewer documents contained in groups, the better the recall. It is encouraging to see that the tool is effective with small groups. However, results are less impressive with larger groups. Even if the analysis of the data shows that it is extremely rare to have more than 1,000 documents in a patient record this case must be take in consideration.

Mean reciprocal rank results confirm the tendency observed with recall at first returned document measure: the top returned documents of small groups contain most of the time relevant results whereas queries in larger groups must be improved.

Situation with patient records

Given the structure of the patient records corpus one can expect that a significant computational power will be required to offer acceptable efficiency. Indeed, experiments show that when the structure is similar to the one of the patient record the indexing time suffer of a consequent overhead. However given this structure there will be no problem for the retrieval as groups containing few documents allow very quick answer

For effectiveness the 3% of the patient records containing more than 100 documents will be problematic, however this problem should be marginal, at least in the beginning.

Conclusion

Indexing patient records is an unusual information retrieval task as it implies to work with numerous corpuses of relatively small size. Working with such data has revealed weaknesses of systems initially dedicated to manage large corpuses. Highly dedicated tools are needed to answers requirements for real-time and sensitivity. As performing information indexing in patient records is time-consuming, the finest tuning possible should be done in order to increase the efficiency.

The increasing time required when the documents are split into several groups has been a surprising result. However by analyzing the process, we have identify the sources of this overhead and are now able to apply the best solution to solve it.

On the retrieval side, we show that the tool offers satisfying time response and offer good retrieval effectiveness, at least for small patient records.

Experiments done are sufficient to identify weaknesses and strengths of traditional information retrieval tools and define the improvements needed.

Abstract

Many digital libraries use hierarchical indexing schema, such as MeSH to enable concept based search in the retrieval phase. However, improving or outperforming the traditional full text search isn't trivial. We present an extensive set of experiments using a hierarchical concept based search retrieval method, applied in addition to several baselines, within the Vaidruya search and retrieval framework. Concept Based Search applied in addition to a low baseline is outperforming significantly, especially when queried on concepts in the third level and using disjunction within the hierarchical trees.

Keywords:

medical text retrieval, concept based search

Introduction

Many digital libraries are indexed using a hierarchical conceptual structure; examples include PUBMED, in which documents are classified along the Medical Subject Headings (MeSH) concepts, and the National Guideline Clearinghouse (NGC[1]) library, each of whose documents is classified using multiple concepts from MeSH and the Unified Medical Language System (UMLS) [1]. Several sites allow browsing through the concepts using the hierarchical structure from the root to the most specific concepts (leaves), which forces the user to navigate the hierarchy. Others enable to query for concepts from MeSH relying on the pre-indexing of the documents along the concepts. Some studies proposed limiting the search to a specific concept (category) [2, 3] and its subconcept contents. In the medical domain, unlike the web, documents are often classified by a multitude of concepts, often as many as a dozen or even tens of concepts, a property which can be further exploited for better retrieval.

The NIH had invested huge amount of money during the past decades in building a set of controlled vocabularies and accessory tools to enable the implementation of concept indexing and retrieval. However, no study had shown that using the conceptual structures outperforms or improves the traditional full text search. One of the famous studies was made by Hersh, in which an attempt to adopt Salton's *tfidf* approach to the conceptual resulted unsuccessfully [4]. Recently we presented *Vaidurya*, a concept based and context sensitive search engine, developed originally, within the Digital Electronic GuidEline Library (DeGeL) [5], to search for textual and marked up clinical practice guidelines, however, we extended it recently to handle general clinical documents. A detailed description of Vaidurya is provided in [6], as well as an extensive and rigorous evaluation, in which a small portion of this study results appear, however, in this study a wider evaluation is provided, in which both concepts based logic operators are evaluated as we will elaborate later. Vaidurya enables the user to query explicitly for concepts given a logic relation between them. In this study we present a novel hierarchical concept based retrieval method including a wide and detailed evaluation of the approach.

We start with a background review of concept based search (CBS) and MeSH. Then we describe briefly the search methods implemented in Vaidurya. We describe our research hypotheses, the experimental plan, and the results. Eventually we discuss the results and conclude.

Background

Concept based search

In the medical domain, CBS refers to a text retrieval approach, in which documents are mapped to concepts, representing a meaningful abstract subject, based on its contents. Hersh's SAPHIRE system [4] uses an approach, in which concepts used for indexing, are automatically extracted from the document. Commonly both documents and queries are mapped, in the case of the biomedical domain into vocabularies such as MeSH and UMLS. However, users are not always familiar with the concepts in these vocabularies, rendering it somewhat limited. It has been previously noted, that the particular implementation of concept-based search described above does not necessarily improve the retrieval performance [7] compared to traditional text retrieval methods. Other studies have tried to exploit the UMLS meta-thesaurus to expand queries, thus extracting the concepts from the query terms [7]. The authors found that query expansion degraded aggregate retrieval performance, but some specific instances of syn-

1 www.ngc.org

onyms and hierarchy-based query expansion improved individual query performance. Aronson [8] compared his methods to Srinivasan's [9] and showed an improvement by expanding text-based queries with both phrases and concepts from the UMLS Metathesaurus. Neither used the hierarchical relationships of the Metathesaurus, yet reported an improvement over a non-query-expanded baseline. Rada [10] developed an algorithm to estimate the conceptual distance between documents and queries using MeSH and suggested that MeSH can be utilized to improve retrieval performance.

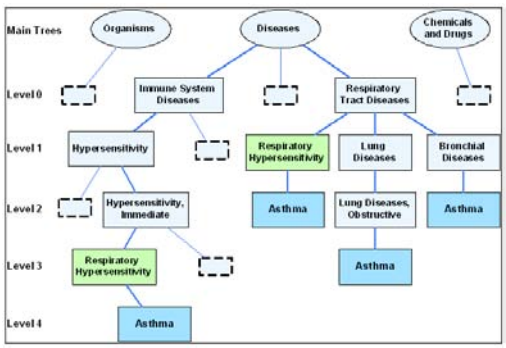

Figure 1 - The concept "Asthma" in MeSH, decomposed to tree-numbers, appearing in several locations in different concept trees

Medical subject headings

The MeSH thesaurus is organized hierarchically and includes 15 concept "trees", consisting of descriptors (concepts). Examples of such trees include *Anatomy* and *Diseases*. At the most general level of the hierarchical structure there are very broad concepts (e.g, 'Anatomy', 'Mental Disorders'). More specific headings are found at lower levels of the eleven levels hierarchy (e.g., 'Ankle' and 'Conduct Disorder'). The same concept may appear as multiple *tree-numbers* within MeSH, thus, in effect, having multiple ancestors. For example, the concept *Asthma* has *four* tree-numbers in MeSH, having three different parents (figure 1). Note that intermediate concepts such as *Respiratory Hypersensitivity* can also appear more than once as different *tree numbers*, possibly at different levels (figure 1).

Vaidurya

Vaidurya is a concept based and context sensitive search engine, developed originally, within the Digital Electronic GuidEline Library (DeGeL) [5], to search for textual and marked up clinical practice guidelines, including three types of implemented search methods: (1) full-text search, using standard key terms; (2) context-sensitive search, which exploits the semantic markup performed on guidelines in *DeGeL*, can be used also for search in a structured document; and (3) concept-based search, consisting on hierarchical concepts indexing structure. The documents can be classified manually or automatically using machine learning based method as we proposed in [11].

Full text search in Vaidurya

Documents are represented and indexed using the *vector space model* introduced by Salton [12], commonly used in free text search, in which each document is represented by a *bag-of-words*. After the document terms are extracted, stop-words (e.g., "and", "the", "are") are removed and the left terms are stemmed to their root using porter algorithm,, a vector of terms is created, such that each index in the vector represents a term frequency in the document, known as ***term-frequency*-inverse-document-frequency** (**TF*IDF**). Term frequency (*tf*) represents the term appearances in the specific document, normalized by the most appeared term (tf^{max}), while the *idf = log(N/n)* represents the appearance of the term in the entire documents collection, where N is the size of the collection, and n is the number of documents in which the term appears. The free text retrieval is based on the *cosine similarity* [12] which measures the distance between a query and a document within the Euclidean space of the terms. More details about the free text retrieval in vaidurya is at [6].

Context sensitive search in Vaidurya

To perform a context-sensitive search, Vaidurya assumes the existence of an internal hierarchical structure of the document (i.e., an ontology that defines an internal contextual model). The internal structure enables the user to query for keywords appearing only in specific contexts (i.e., within segments of text labeled only by the specified tag), thus potentially improving the search and retrieval accuracy. Thus a contextual query includes a set of keywords for each queried context element. In the retrieval process each document gets a rank according to the match for each queried context. This study focuses on the concept based search in Vaidurya, however, more details are provided at [6].

Materials and methods

Concept based search in Vaidurya

In general, our study focused on a very broad class of search methods, which we refer to as *double-operator* methods. Our assumption is that a conceptual hierarchy is always composed of one or more *concept trees*, determined by the roots at level 1 of the hierarchy (level 0 being the root concept). For example, the 15 concepts trees in MeSH.

To perform a concept-based search, Vaidurya includes optional specification of one or more concepts or subconcepts, using the logical operators *conjunction* (AND) and *disjunction* (OR), defining the constraints on the desired relations between the queried concepts, explicitly specified by the user. The first, called *outer-op*, defines the relation among *different* concept trees; the second, called *inner-op*, is defined within the *same* concept tree (Figure 2). Formally, a concept based query $Q^{cb} = \{[t^1<inner^1, c^1_1, c^1_2,.., c^1_{n1}>, t^2<inner^2, c^2_1,.., c^2_{n2}>,..,t^m<inner^m, c^m_1,.. c^m_{nm}>], outer^{op}>$ is denoted by a pair, in which the first element specifies a collection of the queried concepts trees, $T = \{t^1, t^2,.., t^m\}$, in each one of the m concept trees t^1 to t^m. Each queried tree ^{i} is defined by a set of queried concepts

c^i_k, in which *i* is the tree id and *k* is the queried concept id, and a local $inner^i$ operator AND or OR. The second element defines the *outer* logic operator.

During the retrieval process, first, the documents, classified along each queried concept c^i_j and *its descendents*, are retrieved. Then, based on the application of *inner-op*, a set of documents are retrieved for each queried hierarchy, in the case of AND the documents of each concept are intersected and in the case of OR they are unified. Eventually, the application of the *outer-op* logical operator on the documents retrieved for each tree, intersecting in the case of AND, and unifying in the case of OR, results in the final set of documents retrieved for the CBS having the same rank, which is later integrated with additional types of queries, such as full text or context sensitive search, using a weighted average formula.

Four concept based retrieval algorithms were used in this study, defined by the *outer* and *inner* logical operators: (1) *OR-OR*, in which both logic operators set to disjunction. (2), OR-AND, in which the outer is set to disjunction and the inner to conjunction (3) *AND-OR*, in which the outer operator is set to conjunction and the outer operator is set to disjunction, and (4) *AND-AND*, in which both logic operators set to conjunction. In this study the inner operator in all the trees were set to the same value.

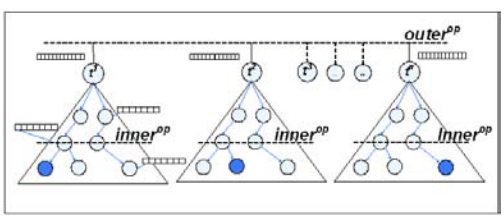

Figure 2 - The inner-op is located within the queried concepts tree and the outer-op defines the relation between the trees, in the final retrieval stage

Evaluation

Test Collection

For our detailed evaluation of the relative value of concept-based and context-sensitive search required a test collection in which documents are structured and classified along hierarchical concepts, we have therefore used the NGC CPGs collection. The NGC website is a repository of CPGs classified by MeSH concepts. The CPGs are classified along two tree-like hierarchical concepts, Disorders and Therapies. Each concept tree has roughly 2,000 unique concepts in a tree-like structure; overall, 5407 concepts were used at the time of the evaluation. In several regions, the concept trees were 10 levels deep, but the average depth was around 4-6 levels. There were 1136 CPGs; each CPG might have multiple classifications indexed by both of the concept trees, including indices that belong to the same tree but at different levels (nodes), not necessarily leaves. CPGs have on average 10 classifications per guideline.

In order to use the NGC collection for an information-retrieval evaluation, we created a set of information needs, queries, and corresponding judgments. Several physicians at the Palo Alto Veterans Administration Health Care System, E&C-Medical Intelligence Ltd Company and a physician from the Medical Crops of the Israeli Defense Forces defined 13 information needs (e.g., treatment of hypothyroidism in a particular population subset). Altogether, *six* physicians participated in the creation of the information needs, queries, and judgments. Each time, a subset of the physicians defined an information need; that group then agreed on the final information need. Eventually, these physicians scanned (*manually*) all of the guideline collection and identified CPGs that were relevant to the information needs (i.e., judgments). In order to evaluate the concept-based search and context-sensitive search methods, in addition to the full-text search, each information need was queried through a combination of a full-text query (FTQ), i.e., a list of keywords searched within the whole document, a context-sensitive query (CSQ), i.e., a query that searches for terms within three predefined context elements (knowledge roles that exist in the NGC ontology), and a concept-based query (CBQ), i.e., a list of concepts, all at the k^{th} level of the concept tree. Thus, each query consisted of three components, each in a different format, each of which could be used, on its own or in combination with one or more other components, to query the guideline database. The typical FTQ consisted of two or three terms after stop-word removal.

We selected three elements from the NGC document structure: "Target Population," "Intervention and Practices considered," and "Diseases and condition(s)" for the CSQ and full-text query. These elements are particularly meaningful when searching for a guideline to answer a clinical question that applies to one's patient, and thus were suggested by the participating clinicians. For the CBQ two types of queries were formulated: (1) concepts from the 2nd level of the conceptual hierarchy, and (2) concepts from the 3rd level of the conceptual hierarchy. In this study we queried the CBQ using the four combinations of the *outer* and *inner* logic operators.

Evaluation measures

In order to evaluate the retrieval performance, we used the traditional precision and recall metrics. *Precision* is the proportion of relevant documents (defined for a specific query within the entire collection, also called judgments) within the set of the retrieved documents, and *recall* is the proportion of relevant-retrieved documents (judgments) retrieved from the set of relevant documents (total judgments), for a specific query. We also interpolated the averaged precision at eleven-points of recall levels 0.0, 0.1,..,1.0.

Experimental plan

In this study we wanted to examine the contribution of the CBQ to the FTQ and CSQ. We also wanted to examine the best level of querying, as well as estimating the best logic operators settings.

Hypothesis I – *adding concept-based search to full-text or context-sensitive search will improve the respective baseline performance.*

Hypothesis II – *Querying concepts from the third level will outperform querying at the second level*.

Hypothesis III - *There are significant differences among the results of the four types of searches*.

To examine these hypotheses three main experiments were designed, in which we used CBQ in addition to a given baseline: (1) *FTQ*, (2) *single CSQ*, and (3) *three CSQs*. In each experiment we evaluated eight combinations of the CBQ resulting from three variables: (1) the queried level of the hierarchy second or third, (2) the *outer* logic operator having *AND* or *OR*, and (3) the *inner* logic operator having *AND* or *OR*, resulting in the four options: *OR-OR*, *OR-AND, AND-OR and AND-AND*. Table 1 presents all the eight combinations including an acronym which we will use in the report of the results.

Table 1 - The eight concept based queries combinations

Level	Outer	inner	Acronym
2	OR	OR	2OO
2	OR	AND	2OA
2	AND	OR	2AO
2	AND	AND	2AA
3	OR	OR	3OO
3	OR	AND	3OA
3	AND	OR	3AO
3	AND	AND	3AA

Experiments and results

We present the results of three experiments, in which the eight CBQs were applied in addition to a given baseline. As a result of the limited length of the paper we present only the four best CBQs in the figures, while report the order of the others performance in the text. We sorted the CBQs according to their average precision at 0, 0.5 and 1 recall level.

Experiment 1 - CBQ in addition to FTQ

In experiment 1 we evaluated each of the eight combinations, in addition to full-text queries. Figure 3 presents the four outperforming CBQs, in addition to the FTQ baseline. Generally at most of the recall levels all the four CBQs, including 3OO, which was significantly greater at the 0.05 significance level when compared at 0.5 recall level, 3AO, 3OA and 2OO in decreasing order, outperformed the FTQ baseline, while beyond the 0.6 recall level the FTQ outperformed. In addition the additional four CBQs (not appearing in figure 3) were 2OA, 2AO, 3AA and 2AA. The four outperforming CBQs can be characterized by querying the 3rd level of the hierarchy, which outperformed the 2nd level. Three of them have OR set to the *outer*, and to the *inner* logic operators. Note that the 3OO outperformed at most of the recall levels while the 3AO outperformed at the low recall levels.

Experiment II - CBQ in addition to single CSQ

In experiment 2 we evaluated each of the eight combinations, in addition to a single context query. Figure 4 presents the four outperforming CBQs, in addition to the single CSQ baseline. Generally, at most of the recall levels all the four CBQs, including 3OA, 3OO, 3AO and 2OO, in decreasing order, outperformed the single CSQ baseline (1CSQ), while beyond the level of 0.3 recall the 2OO was bellow the baseline. In addition the additional four CBQs (not appearing in figure 4) were 2OA, 2AO, 3AA and 2AA. The four outperforming CBQs can be characterized by querying the 3rd level of the hierarchy, which outperformed the 2nd level. Three of them have OR set to the *outer*, and to the *inner* logic operators. Note that while all the four outperforming CBQs were the same, as in experiment 1, but in a slight different order, the best CBQ in the experiment two was 3OA.

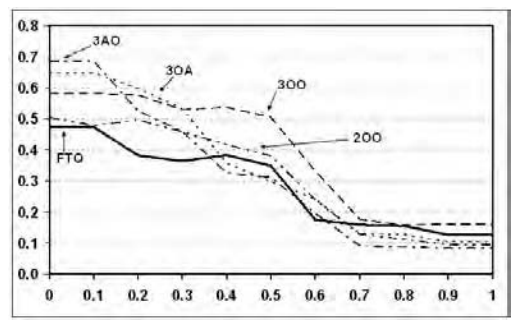

Figure 3 - CBQs applied in addition to the full text queries baseline, in which 3OO, 3AO, 3OA and 2OO outperform the baseline

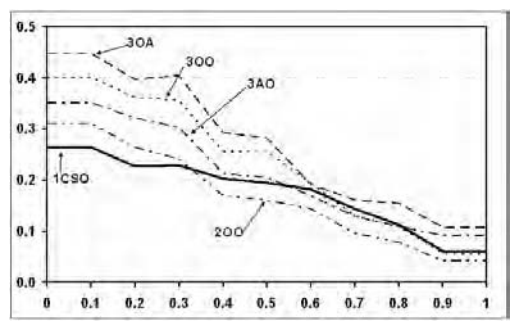

Figure 4 - CBQs applied in addition to single context queries baseline, in which 3OA, 3OO, 3AO and 2OO outperform the baseline at most of the recall level

Experiment III - CBQ in addition to three CSQs

In experiment 3 we evaluated each of the eight combinations, in addition to three context queries. Figure 5 presents the four outperforming CBQs, in addition to three CSQs baseline. Generally, along all the recall levels all the four CBQs, including: 2OO, 3OA, 2OA and 3OO, in decreasing order, performed lower than the three CSQs baseline (3CSQ). In addition the additional four CBQs (not

appearing in figure 5) were 3AO, 3AA, 2AO and 2AA. Unlike the previous experiments, in which CBQs improved the baseline, here it decreased. We will refer to this in the discussion and conclusion section; however, again three of the four outperforming CBQs appear in the first and second experiments. In this experiment while there were two CBQs querying at the 2nd and 3rd hierarchy level, as well as the inner operator, the outer operator is OR at all the four top CBQs. Note that while 2OO was the fourth at both previous experiments, it is the first here (within the CBQs).

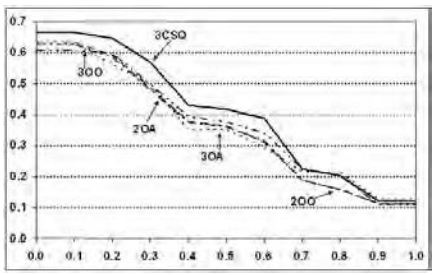

Figure 5 - CBQs applied in addition to three context queries baseline, in which the CBQs (2OO, 3OA, 2OA and 3OO) constantly decreased the baseline (3CSQ)

Discussion

We presented Vaidurya, focusing on its concept based search methods, the hypotheses of the research, the corresponding experiments, in which CBQs in eight settings were applied to varying baselines. Testing hypothesis 1, in which we expected to have an improvement when applying CBQs in addition to varying baselines, shown a significant improvement when applied in addition to FTQ. An improvement was found in addition to a single CSQ, while decreased when used in addition to three CSQs. The reason for the difference between these three scenarios might be that the initial baseline precision in the last case (i.e., when using the three CSQs) was much higher than that when using FTQ or a single CSQ (see figures 3, 4 and 5). In addition, note that the improvement was *greater* when the baseline was *lower* (see figures 3 and 4). Referring to hypothesis 2, querying at the third level outperformed the second level, especially in experiments 1 and 2, while in the third it was even. Referring to hypothesis 3, three CBQs 3OA, 3OO and 2OO appeared within the four outperforming CBQs repeatedly within the three experiments. While 2OO was the last (within the four outperforming CBQs) in experiments 1 and 2, it was the first in experiment 3, which may be explained as well by the high level of the baseline performance.

To summarize, an improvement by applying CBQ in addition to a textual search can be achieved, especially when querying at the third level, setting the *outer* logic operator to OR or AND, and setting OR to the *inner* logic operator. Note that using AND-AND achieved the lowest performance.

Previous studies examining CBS have shown that it does not necessarily improve, and might even worsen, the search-engine's performance [4]. This phenomenon might be due to the fact that current automated extraction modules are not yet sufficiently accurate, and users usually are not familiar with all the concepts when entering keywords. In the case of our CBS the user can manually specify queried concepts from a given predefined ontology of concepts. The limitations of this study are mainly caused by the size of the test collection, which is relatively small. However, in contrast to huge test collections, in which judgments are specified automatically, based on an ensemble of search engines, in our test collection the reviewers browsed manually each of the CPGs and indicated their relevance to the query. We are currently in the process of extending this method to enable a user enter *simply* a textual query which will be converted to a conceptual representation and will be queried in addition to the FTQ. Preliminary evaluation results on the Trec-Genomics are encouraging.

StructConsult: Structured Real-Time Wet Read Consultation Infrastructure to Support Patient Care

Craig Morioka[a], John David N. Dionisio[b], Alex Bui[a], Suzie El-Saden[a], and Hooshang Kangarloo[a]

[a] *Medical Informatics, University of California, Los Angeles, United States*
[b] *Department of Electrical Engineering and Computer Science, Loyola Marymount University, United States*

Abstract

Our research addresses how to improve physician to physician communication of patient information, and how to prevent lapses of patient care as they are referred to other clinicians within the healthcare system. The wet read consultation is defined as a rapid response to a clinical question posed by a referring physician to a clinical specialist. This research involves the development of an imaging-based wet read consultation system called StructConsult (SC), which facilitates communication between non-imaging specialist (i.e., primary care physician (PCP), emergency room (ER) physician, or referring physician), and an imaging specialist-radiologist. To facilitate data mining and effective recall, SC utilizes a data model based on the Digital Image Communications in Medicine (DICOM) standard for grayscale presentation state and structured reporting. SC requires information from four sources: (a) patient-specific demographics, clinical hypothesis, and reason for exam, (b) sentinel image capture from a DICOM image study, (c) direct capture of radiologist's image operations and annotations, and (d) radiologist's response to the chief compliant, and the reason for examination. SC allows users to add additional functionality to a Picture Archiving System to improve patient care.

summarization of patient data, DICOM presentation state, DICOM structured reporting, wet read consultation, teleradiology

Introduction

Radiology is the one specialty that is inherently suited for the practice of telemedicine. In particular, the most common application of telemedicine in radiology is teleradiology. Teleradiology is the transmission of medical images to a remote location for the interpretation of radiographic images. Emergency departments, off-site outpatient imaging centers, and even rural hospitals are utilizing picture archiving and communication systems (PACS) to send images to radiology departments for immediate interpretations and/or second opinions [1-5]. The primary scenarios for the use of teleradiology involve off-hour and weekend interpretation of imaging studies from emergency departments. Second opinions and overreads are also performed via teleradiology when the junior radiologist is unsure of the diagnosis and requires an expert opinion. A survey by Hunter et al. indicated that 60% of 287 academic radiology departments provide teleradiology services [3]. Kalyanpur et al. published an article on private radiology groups that have stationed board certified radiologist in India, in order to have 24 hour read outs of CT imaging studies [4]. This new emergent business model is known as NightHawk or Global Radiology Practices [5]. This allows the radiology group the ability to increase the number of procedures performed as well as their revenue. Primary care physicians usually treat patients for most maladies without consultation. For more difficult cases, the rate of referral by PCPs can be as high as 28.1% per 1000 patients [6]. The consultation process involves communication between physicians. Unfortunately, the communication process can cause serious problems for the patient. The Applied Strategies for Improving Patient Safety collaborative states that communication errors between clinicians, staff, and patients account for over 70% of all errors made in physician practices [7]. Breakdown in communication between clinicians accounts for 80% of all malpractice lawsuits [8]. The Physician Insurers Association of America (PIAA) report that communication errors between referring physicians and radiologists create the fourth most common compliant lodged against radiologists [9]. The PIAA reviewed 144 communication claims, and found that 10% of the written reports never reached the correct physician or patient. In another 10% of the claims, the radiologist's issuance of a delayed written report affected the patient outcome in 75% of the cases. For 60% of the claims against radiologist, the most egregious mistake involved failure to deliver urgent or significant unexpected findings to the referring physician. In a recent study on generalist-subspecialist communication concerning children with chronic conditions, Stille et al. describe specific improvements in order to enhance communication between physicians [10]. The study advocated timely communication, understanding the reasons for the referral and the nature of the child's condition, or appropriate definition of what role the generalist and specialist should play in the treatment of the child. Physicians described numerous examples where communication had direct effects on patient outcomes. Efforts to

improve communication between pediatric generalists and specialists in the care of children with chronic conditions should emphasize the importance of timely information transfer, in order to avoid worsening the patient's compromised health. The content of messages between physicians is also important, but lack of response when needed is more of a problem. Improving generalist/subspecialist communication has great potential to improve the quality of care. Forest et al. found that the top reason for referral was advice related to diagnosis and/or treatment [11,12]. Non-radiology medical clinicians — primary care, internal medicine, and emergency room physicians — typically do not have the proper training nor experience to diagnose difficult radiographic cases [13]. In research studies evaluating general clinicians versus radiologists, radiologists outperformed general clinicians in accuracy of image diagnosis [14,15]. A radiology consult provides two benefits: 1) the consultation helps the referring physician understand the patient's present condition, and 2) the consultation provides the referring physicians with new medical knowledge. The goal of SC is to provide structured clinical consultations that address the specific clinical hypothesis posed by the referring physician. SC stores both the chief complaint, reason for the imaging exam, and the imaging evidence which substantiates the radiologist's response to the reason for exam.

Materials and methods

SC addresses the communication barrier between referring physician and radiologist by enhancing the clinical workflow. The key components of the workflow that are improved include: the image order process, radiologist's wet-read and response to reason for exam, and summarized structured report for the referring physician. The major software components of SC involve: image order, image capture, image order reconciliation, radiologist's wet-read and response to reason for exam, and summarized structured report for the referring physician. Figure 1 illustrates the component or "wiring" structure of the SC software. The software consists of four end-user applications. Three of the applications are based on Java Swing, distributed via Java Web Start in the *op-client.war* archive, while one application is Web-based, deployed through the *op-ros-web.war* Web archive.

- The *referral order system* is the Web application used for entering image orders and viewing their resulting images and annotations.
- The *imaging study reconciler* binds image orders to acquired imaging studies.
- The *reading/annotation workstation* displays the current worklist and corresponding imaging studies for reading, markup, and reporting. When an imaging study has been read and signed, it is "prepped" by the pre-genearation (*pregen)* component for presentation by the referral order Web application.
- The *administration utility* provides a user interface for configuring and setting up the SC installation, and user access and privilege.

The three server-side components are shown near the center of the diagram:

op-ros-ejb.jar is the central set of services provided by the software, as shown by the interfaces that it implements: Admin, UserAdmin, Info, Login, Order, Reconciliation, Station, Image Server, and Results. Other components rely on one or more of these interfaces to accomplish their respective tasks. The four end-user applications rely *only* on this component for all server-side interactions.

pregen is the *results generation daemon* that prepares an imaging study for presentation on the Web application. When an imaging study is signed, the daemon converts the study's selected key images from DICOM to a Web-compatible format such as JPEG or PNG, at the same time compositing any annotations that were made by the study's reader.

image server is the bridge between DICOM devices and SC. It is the gateway that receives incoming studies from these devices and notifies the other SC components of the studies' availability. Received studies are stored on a file server that is mounted over the network on both the reading/annotation workstation and results generation daemon's file systems.

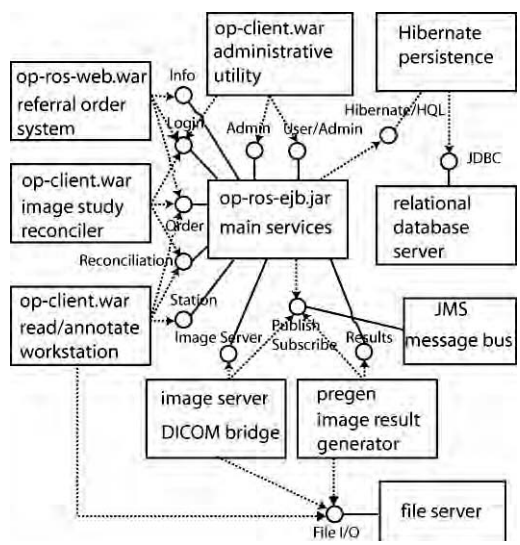

Figure 1 - Component diagram of StructConsult software

The overall design of the SC software follows recommended Enterprise Java Beans patterns, resulting in appropriate separation of classes, excellent portability, and flexibility of configuration and deployment. Every component of the suite has been tested on Windows XP, Mac OS X, and Linux. For optimal security, reliability, and stability, server-side components are typically hosted on a Unix-based operating system such as Linux or Mac OS X. Client machines tend to run end-user-centric operating systems such as Windows XP or Mac OS X. The components can also be deployed completely using established open source software (e.g., Apache, JBoss, PostgreSQL, Samba), thus

reducing the overall cost of an SC installation, especially when compared to existing commercial solutions.

StructConsult Organization

Image order

One of the major problems in medicine is improving physician communication between a referring physician and radiologist. The most prevalent criticism from referring physicians was that the radiology report did not answer the clinical question that they expected based on the patient's chief complaint. Referring physician consultations with subspecialists can be more effective when the referring physician provides a specific question, clinical hypothesis, or specific reasons for exam concerning the patient condition [12]. Once the chief complaint and reason for exam are captured, the structured information is then used by the radiologist at the review station to determine which images in the image study will provide evidence linked to each particular reason for exam. The user interface for the referring physician is intended to capture two important pieces of information: 1) chief complaints, and 2) clinical hypothesis. The chief complaint is entered — *abdominal pain*. The reason for exam is also entered as a list of "Rule-out the following:" *heart attack, ulcer, appendicitis*, etc. Figure 2 shows the referring physician user interface. The referring physician enters the chief complaint (upper right panel) and finally enters the reasons for exam, or clinical hypothesis for the patient (lower right panel).

Image capture

After the image order is complete, the patient is sent to an imaging center to receive their exam. As part of SC, there is a DICOM image server that receives images from the patient scanning devices, or from the PACS server. DICOM image object definitions that can be received by our image server include the following: computed radiography, computed tomography, magnetic resonance, ultrasound, secondary capture, presentation state, and structured report objects.

Image order/image study reconciliation

The image order/image reconciliation process allows the administrator the ability to match up an image order with an image study. The SC infrastructure makes no assumption about the healthcare infrastructure. As healthcare within the United States can be fragmented, it cannot be assumed that the entire healthcare process is within the same healthcare entity. A patient may visit their PCP, or referring physician, who is unaffiliated with the image scanning facility. SC provides a manual method to reconcile a particular image order and image study. This reconciliation process can only begin once the image order is complete, and the patient's image study has been received by SC's image server. A worklist is provided to the SC administrator to identify outstanding imaging orders that need to be reconciled with the image study. The user selects the image order in one column, and then matches the appropriate image study in the other neighboring column. Patient demographic information is provided to help user ascertain the likelihood of a match between the order and the study.

DICOM presentation state

The image viewer developed by our research group reads DICOM compliant radiographic image studies. When reviewing the images, the radiologist can capture the viewing conditions and image operations performed as a DICOM presentation state (PS). The DICOM PS captures the *viewing state* of the radiologist while the image study was dictated. The operations necessary to reproduce the same viewing conditions involve the exact image(s) reviewed, look-up table (LUT) values of the image displayed, scale size, rotation, linear measurements, and annotations. The objective of the PS is to capture the radiologist's viewing conditions at the time the image study was reviewed. Once the user saves the DICOM PS, the DICOM PS object is sent to the image server for storage. The DICOM standard allows DICOM PS objects to be transmitted, stored, and retrieved from a DICOM compliant server.

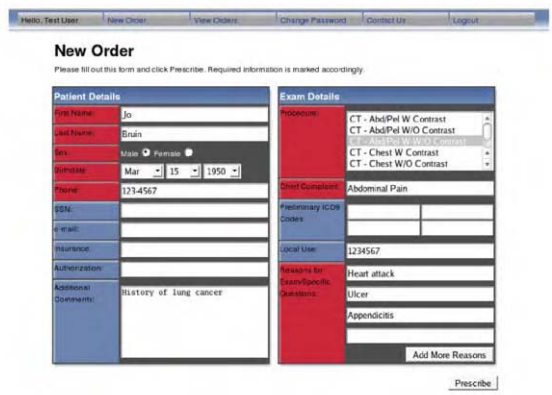

Figure 2 - Referring physician order entry Web page

Radiologist review workstation

The radiologist review workstation allows the user to see patient demographic information, chief complaint, and reason for exam (see Figure 3). The reason for exam is shown in the upper panel in the right corner. The radiologist indicates for each reason for exam the following response: rule-in, rule-out, or unsure. When a reason for exam response is selected, the images that correspond to a particular reason for exam are captured as a presentation state. The response to a reason for exam is also captured as part of the structured report. The structured report can also capture free-text data keyed in by the radiologists as additional comments. Once a particular image study is chosen, the SC image review workstation allows the radiologist to examine the entire image study (see Figure 4). The toolbar along the top of the viewer allows basic image operations: horizontal and vertical flip, window and level, pan, scale, and rotation. The viewer also allows the user to draw line annotations, text, and different types of measurements (point, line, and area). Finally, the image viewer can present studies using different image layouts.

DICOM structured report

The referring physician's clinical hypothesis, DICOM PS of the image study, and the clinical findings that rule-out a clinical hypothesis are stored as a DICOM structured report (SR). The structured report is the underlying framework for capturing the clinical questions and responses for the patient. The primary components of a DICOM SR document consists of meta-information that describes the creator of the document, date of creation, time of creation, institution, and a unique identifier for this DICOM SR object. Other structured information captured by DICOM SR include: patient's chief complaint, referring physician's reason's for exam, radiologist's response to reason for exam, reference to specific DICOM image(s) referred to by DICOM PS, and reference to DICOM PS.

Summarized view of structured text and image

Once the radiologist has structured their response to the chief complaint and reasons for exam by capturing the image(s), text comments, and structured responses, the information is stored in our image server as a DICOM SR object and within the PostgreSQL database. The results view of SC allows clinicians a summarized view of the patient. Patient demographic information, previous clinical documents, responses to the reason for exams, and the key images are stored as a Web-accessible page summarizing the patient's condition. Figure 5 depicts our Web-accessible DICOM SR summarized view. The patient's summary is a Web page that can be accessed anywhere given a user ID and password. The upper left panel in Figure 5 depicts the patient demographics with name, medical record number, gender, and patient's birth date. The worklist to the right of the patient demographics is a list of available documents for the respective patient. All available clinical reports and labs can be selected from this panel. The text panels below the worklist show the most recent oncologist, radiology, and pathology reports. For this lung cancer patient, all responses to the reason for exams were positive and indicated by the red check mark shown on the right side of in the image box. The small thumbnail images along the top of the image panel are the DICOM PS key images captured by the radiologist. The user can select the smaller thumbnail image, which will appear in the larger image viewing panel. This summarized view of the radiologist's responses to the referring physician's clinical hypothesis completes the communication between clinicians.

Results

The SC system has been deployed at a primary care clinic/imaging center. Harris Family Medical Center and University Center Imaging (UCI) in Melbourne, Florida have registered 48 referring physicians. The number of SC image orders from 01-01-2006 to 11-01-2006 was 11,093. This accounts for 32.4% of all images ordered. A majority of the image orders are still paper-based, but as the referring physicians become more comfortable using the Web-based system, a larger number of online image orders is expected. A survey was administered to the referring physicians using the SC system. Five of the referring physicians completed the survey. There were 5 questions asked of the users:

1. What was the availability of the Web-based image report?
2. Compare the Web-based system to the traditional phone order/fax report system.
3. What was the accuracy of the report content of the Web-based report compared to the faxed version?
4. When accessing the Web report from a browser, how long did it take?
5. What was the turnaround time of the Web report compared to the traditional phone order/fax report?

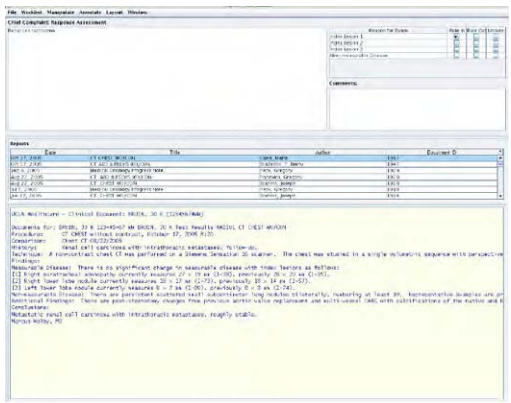

Figure 3 - Radiologist review workstation depicts structured capture of reasons for exam (i.e., index lesion 3 is checked rule-in, upper right corner). Previous radiology reports are also available for review

Each question was based on a 5-point rating scale (1 = superior performance, 2 = better performance, 3 = performance was equal, 4 = poor performance, and 5 = very poor performance). Questions 1 (*avg*=1.2, *std*=0.4, p=0.034, n=5), 2 (*avg*=1.5, *std*=1.0, p=0.046, n=4), and 4 (*avg*=1.2, *std*=0.5, p=0.034, n=5) were statistically significant using a Wilcoxon signed-rank test. Questions 3 (*avg*=1.8, *std*=1.0, p=0.052, n=4), and 5 (*avg*=1.6, *std*=0.9, p=0.052, n=6) were very close to significance.

Discussion

The trend in the replies indicated that the users chose a score of 1, 2, or 3 indicating equal or better performance for the Web-based system for all questions. There were no user responses that indicated that the Web-based system was poor or very poor when compared to the conventional paper order/fax report. The goal of our SC system is to provide structured clinical consultations between referring physicians and radiologists. The SC infrastructure provides improved communication support for the referring physician, particularly for patients with complex medical conditions requiring close monitoring to insure proper quality of care. Utilizing our SC system insures that the communication between clinicians is accurate and justifi-

able. SC stores both the reason for the exam, and the imaging evidence that substantiates the radiologist's response. Our system is not limited to only radiology consults; potentially one could provide accessible services to other subspecialists. Another benefit of the SC infrastructure is the ability to create teaching files, as the radiologist captures key images through DICOM PS. A long-term goal of this research is to generate summarized views of patient data accumulated over long period of care. The SC infrastructure will provide the structured image data necessary to complete this task.

Abstract

For making medical decisions, healthcare professionals require that all necessary information is both correct and easily available. We address the issue of integrating anatomical pathology department information into the electronic healthcare enterprise. The pathology workflow from order to report, including specimen processing and image acquisition was modelled. An integration profile - pathology general workflow- was created in the framework of the Integrating the Healthcare Enterprise (IHE). This Integration Profile relies on 8 transactions based on HL7 or DICOM standards. An important issue was to define information entities (order, imaging study and report) and real-world objects (specimen, tissue sample, slide, etc). Joint efforts between IHE and DICOM WG26 has resulted in a proposed common model for "specimen" usable for both HL7 and DICOM transactions related to anatomic pathology.

Keywords:

pathology, standards, imaging, integration

Introduction

Information systems in anatomical pathology departments gather medical data (text, images, etc.) throughout various procedure steps from specimen processing to report editing. Since information systems are not typically integrated, information acquisition is time consuming with double data entry. Orders, images and reports are spread out over different systems which do not interoperate. Although standardization efforts conducted by HL7 [1] and DICOM [2] are progressing to provide integration solutions, HL7 or DICOM messages contain many optional data fields so that being DICOM or HL7 compliant does not imply direct integration. The goal of the Integrating the Healthcare Enterprise (IHE) initiative is precisely to specify how data standards should be implemented to meet specific healthcare needs and to make systems integration more efficient and less expensive [3]. Based on working groups including users and manufacturers, IHE defines "Integration Profiles", that are real-word situations describing exchange of information called "Transactions", from various functional components of a distributed healthcare environment, called "Actors". IHE provides implementation guides for "Transactions", using established standards as DICOM or HL7. IHE has developed in North America, Europe and Asia. The annual definition cycle of new profiles by users and suppliers, ending in the organization of international platforms of interoperability tests (called "connectathons"), confers its unique efficiency, transforming basic standards into "plug and play" solutions.

In some cases, IHE recommends selection of specific options supported by these standards; however, IHE does not introduce technical choices that contradict conformance to these standards. If errors in or extensions to existing standards are identified, IHE's policy is to report them to the appropriate standards bodies for resolution within their conformance and standards evolution strategy.

In Europe, in 1996, the Association for the Development of Informatics in Cytology and Pathology (ADICAP) with the collaboration of different software vendors proposed a European de facto standard for image folders [4].

In the US, Laboratory Digital Imaging Project (LDIP) began in 2005 with a goal to establish an open access, voluntary use specification that will permit images generated in pathology and in clinical laboratories to be widely shared across different applications, databases, and operating systems for the purpose of enhancing image annotation, integration, archiving, publication, and analysis. This effort is intended to be complementary to DICOM, rather than as an alternative to it.

Relying on this experience, the aim of ADICAP is now to promote the use of international standards (DICOM, HL7) in the development of information systems in anatomical pathology. In 2005, ADICAP and SEAP (Spanish association of Anatomic Pathology), with the collaboration of the Group promoting the Modernization of Hospital Information Systems in France (GMSIH), launched the IHE pathology initiative in Europe.

Although specific DICOM objects are defined for pathology, modification and/or extension are necessary for two main reasons. First, the current DICOM specimen module is not sufficiently detailed to capture the complexity of pathology practice, and second, some pathology-related image formats (whole-slide images, multispectral images, flow cytometry, etc) do not have applicable DICOM Information Object Definitions. A specific DICOM working group (DICOM WG26) has been recently created to address these issues. A specific working group (HL7 Pathology Special Interest Group) has been also recently created within HL7 to address the pathologists' needs, in synergy with DICOM WG26, focusing on the orders and reports aspects of the pathology workflow.

The objective of this paper is to present a methodology to integrate anatomical pathology department into the healthcare enterprise. We first describe the IHE-Pathology efforts to model the anatomical pathology workflow in order to define new Integration Profiles. We also describe IHE-Pathology and DICOM 26 joint efforts to define a common model of "specimen" usable for both HL7 and DICOM transactions. DICOM Information Object Definitions for whole slide images is out of the scope of this paper.

Methods

Modeling anatomical pathology workflow

ADICAP, with the collaboration of the GMSIH, solicited participants to work on the Pathology Technical Framework: 12 pathologists and haematologists, 6 professional associations and 12 vendors. 7 working sessions were organized between September 2005 and January 2006. The working group first defined the pathologists' needs and then created a corresponding Integration Profile for anatomic pathology. They identified the Actors and Transactions involved in this profile. Then, they reviewed the literature about order forms and reports in anatomic pathology in order to describe the main requirements for the structure and content of orders, imaging folders and reports.

Defining HL7 and DICOM based transactions

DICOM currently has Information Object Definitions dedicated to anatomical pathology, namely VL Photographic Image (XC) for gross imaging and VL Slide-Coordinates Microscopic Image (SM) for microscopic imaging. Following creation of the DICOM Pathology Working Group (WG-26), five IHE-Pathology-DICOM working sessions were organized between September 2005 and November 2006 to define modification/extension needed for the DICOM specimen module.

Results

General pathology workflow (pathology technical framework - volume 1)

The diagnostic process in anatomical pathology (figure 1) differs from that in the clinical laboratory since it relies on image interpretation. It also differs from that in radiology since it is specimen-driven and when digital imaging is performed many types of imaging equipments (gross imaging, microscopic still imaging, whole slide imaging, multispectral imaging, etc.) may be involved for a single examination. Moreover, images of the same study may be related to different specimen (parts and/or slides) from one or even different patients (e.g., Tissue Micro Array). Finally, slides are always available to acquire more images, if needed. In radiology, the diagnostic process is patient-driven, an examination (study) usually involves a single image acquisition modality and all images of the study are related to one and only one patient.

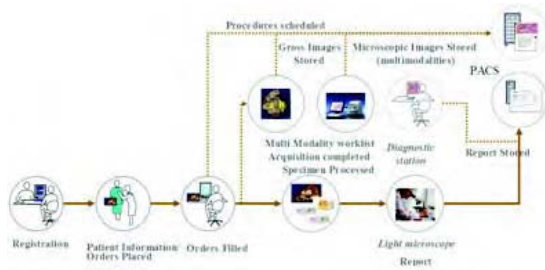

Figure 1 - Anatomic pathology workflow

The Integration Profile "Pathology General Workflow" was proposed for a first IHE cycle: (Specimen, Order and Report Management Workflow) and Pathology Image Workflow. This Integration Profile involves 8 Transactions exchanged by 8 Actors: 3 transactions dedicated to Order Management (Order Placer Management, Order Filler Management, Procedure Scheduled and Update), 4 transactions dedicate to Image Management and one procedure for Report Management. For each transaction, the workgroup proposes the use of the most suitable format (HL7 version 2, - HL7 version 3 (Clinical Document Architecture (CDA)) and DICOM).

General principles were defined with respect to information entities: Order, Image Study and Report. The order for the pathological examination is communicated between the Order Placer (of the Order Entry system) and the Order Filler (of the PIS). In the pathology department environment, the Order Filler also identifies the set of procedures and sub-procedures (procedure steps) that have to be performed in the process of fulfilling the order.

Order

Quality assurance about order forms provides a list of mandatory items [5]: order identification (Order ID), order date & time, identification of the ordering physician and the ordering care department (including call back telephone number), patient identification (PID, name, visit number, etc.), identification of the care unit of the patient (if different from the ordering care department), priority of the order, (date & time when the results are expected to be available), etc. Each order may contain one or more Requested Procedure possibly reported by different pathologists. A Requested Procedure is a unit of work resulting in one report with associated codified, billable acts. For each Requested Procedure, the basic or special

techniques involved in the processing of the corresponding specimen(s) may require different devices (automatons, image acquisition modality, etc). Each Requested Procedure may contain one or more Procedure Steps. A Procedure Step is the smallest unit of work in the workflow that is scheduled (work to do) and/or performed (work done) by a person or a machine (automaton, image acquisition modality, etc) on an object (specimen, tissue sample, tissue section, etc.) Figure 2 depicts an example of cases resulting from an order and of the breakdown in Requested Procedures and in Procedure Steps.

Report

Since 1993, Association of Directors of Anatomic and Surgical Pathology has published recommendations for pathologic reporting [6]. A generic model of structured report can be derived from these templates. In complement, studies about quality assessment of reports provide lists of mandatory items and stress the positive role of checklists to enhance the reporting process [7,8]. According to "evidence-based pathology", only features that are reproducible and relevant – with a demonstrated diagnostic or prognostic signification – should be reported in description and corresponding evidence available"[9,10]. A crucial issue is to identify a technical solution to handle templates of structured reports including findings and their evidences.

Image

In pathology, the image folder (study) is defined at the level of the pathological examination or case. For each case, images acquisition may require different modalities (gross imaging, microscopic imaging, etc). A new series is created whenever an imaging procedure step is performed on a new specimen or slide or when a new type of image is created of the same specimen or slide.

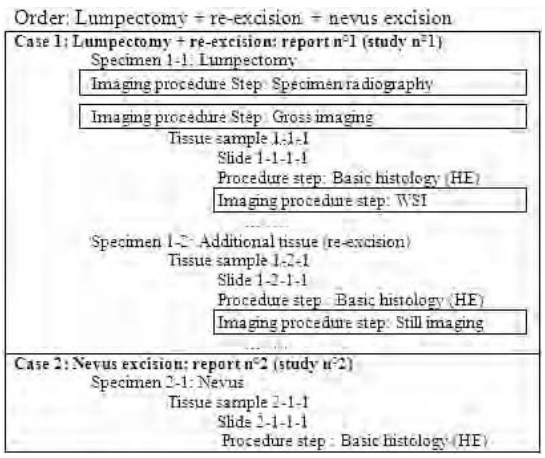

Figure 2 - Extract of the structure and content of an order: the breakdown in cases (corresponding to reports) and procedure steps and the organization of the corresponding images in studies and series

Actors and transactions

Figure 3 - General pathology workflow

Six specific transactions exchanged between 7 actors are required to perform the General Pathology Workflow and are schematically represented in Figure 3. Placer Order Management (PAT1) contains all the messages required between the Order Placer and the Order Filler for the management of the life cycle of the order. Its main goal is to keep a consistent vision of the order, (content and status), between the two actors. Filler Order Management (PAT2) contains all the messages required between the Order Filler and the Order Placer for the notification of a new filler order, as well as the creation of the placer order that reflects it.

Modality Worklist Provided (PAT3) is based on a query entered at the Acquisition Modality. In case of a general query, the list of Scheduled Imaging Procedures with selected demographic information and information about specimens is returned to the Acquisition Modality. In case of a query using the barcode identifying a given specimen being source of an imaging procedure (either part or slide), the specific information about this specimen is returned.

The Procedure Scheduled and Update (PAT4) allows the Order Filler to send the Image Manager and Report Manager information about the scheduled procedure or procedure update.

Report Management (PAT7) carries changes of the observation results and order status from Order Filler to the Enterprise Report Repository i.e. corrections, cancellations.

Using the Image Availability Query (PAT9), the Order Filler or the Report Manager asks the Image Manager if a particular image or image series is available. The worklist provider informs other interested actors of the on-going status and completion of performed work.

The transaction Modality Image Stored is based on two transactions already defined in the radiology domain (RAD8, RAD10) and allows an Acquisition Modality or an Evidence Creator sending acquired or generated images to the Image Archive. Acquisition Modality or Evidence Creator requests that the Image Manager confirm ownership for the specified DICOM objects (images, Key Image Notes, Evidence Documents or any combination thereof)

stored in the Image Archive, thus allowing the sender to delete those objects.

HL7 and DICOM based transaction (pathology technical framework – volume 2)

Prior to the specification of the transaction a common model of "real world objects" (specimens, containers (blocks, cryomolds or cryotubes, slides, etc) was defined.

Specimen identification mechanism

The specimen identification mechanism must allow keeping track of all these "real world objects" (figure 4).

"Specimen" is the role played by any discrete physical object that is the subject of pathologic examination. This includes objects at all levels of processing, including fresh tissue, dissected organs, tissue embedded in paraffin, and sections made from embedded tissue. This extends the common definition of a specimen beyond the object itself received for examination (e.g., from surgery).

"Container" is a physical object which can be labeled (eg with a pathology department accession number, or a block label or a slide label, etc) and contains a tissue sample which may be analyzed or further processed.

"Box" refers to a container which contains Part(s). "Part" refers to a separately identified physical object (tissue) collected in care department upon which a pathologic or laboratory procedure is requested to be performed.

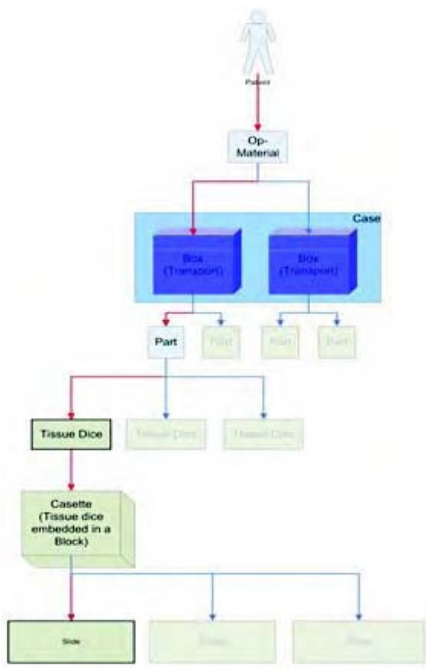

Figure 4 - Typical : Specimen can be identified by containers' ID

"Cassette" refers to a "container" which contains Tissue dice(s) that are embedded in Block (one cassette corresponds to one block that corresponds to one or more tissue dice(s)). "Tissue dice(s)" within a block are tissue samples resulting from sampling processes within the pathology department obtained from one or more parts. They have been processed and embedded in a medium to allow the creating of tissue sections which are mounted on slides for imaging. Tissue dice(s) may be identified (Tissue dice ID, optional). The corresponding Cassette is mandatory identified (Cassette ID)

"Slide" refers to a container which holds a tissue section, a smear, a touch prep, etc. The slide is typically glass for visual light microscopy, but is usually a grid for electron microscopy. "Tissue sections" are created from Tissue Dice(s) embedded in blocks. "Touch preps" are prepared by placing a slide into contact with unprocessed tissue. "Smears" are created from taking a liquid containing cells (peripheral blood or other bodily fluids such as ascites) and spreading this liquid into a thin layer.

Tissue item(s) within a tissue section or a smear may be identified (Tissue item ID, optional). The corresponding Slide is required to be identified (Slide ID)

"Tissue Microarray" (TMA) is a composite specimen which is typically created by taking a small core of tissue from many different tissue blocks and re-embedding them in a new block in an organized manner. Slides created from this TMA block thus have small fragments of many different tissues all of which may be processed at the same time, under the same conditions by a desired technique. These are typically utilized in research (figure 5).

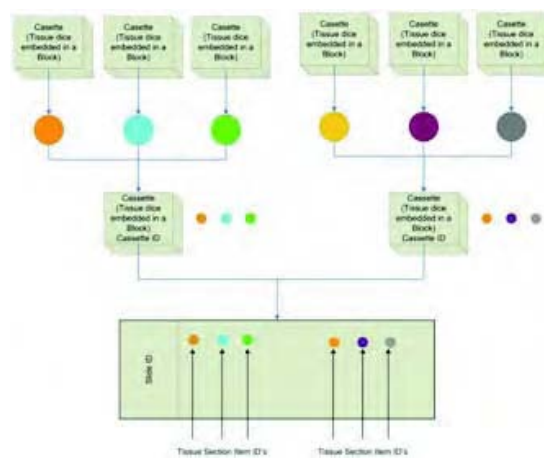

Figure 5 - TMA : Tissue items ("spots") on slide come from tissue dice(s) ("cores") sampled from different tissue blocks (from different parts and from different patients)

Specimen description

Specimen(s) and container(s) description requires a controlled vocabulary. A first step consisted in aligning DICOM Specimen Module and HL7 v2.5 Specimen (SPM) and Container (SAC) segments. Eleven DICOM tags of the Specimen Module correspond to items of the HL7 v2.5 SPM segment: Specimen ID; Specimen Type, and Type Modifier; Specimen Collection Method, Site and Date/Time; Specimen description; Specimen Handling

Code; Specimen Received Date/Time; Specimen Condition; Container Type and Condition and Parent Specimen ID. Four DICOM tags of the Specimen Module could be expressed using items of the HL7 v2.5 SAC segment: Container length, Container width, Container thickness and Container length, width, thickness units.

We haven't found any existing item in HL7 v2.5 to express specimen state identifier and specimen state description. We have no more found a satisfactory solution to solve the specimen identification issue in case of TMA.

Discussion

Quality assessment studies in anatomical pathology show that each of the different steps from specimen processing to report editing may be source of errors and that information systems integration supports error reduction [11-13]. This work is done in the framework of the IHE-pathology initiative to define the requirements of systems integration in anatomical pathology.

The results show that a first significant IHE cycle in anatomic pathology could involve the new integration profile "General Pathology Workflow". The main contributions of this work were to analyze the specificity of the anatomical pathology workflow with respect to laboratory and radiology workflows and to define the structure and content of cases, orders, image folders and reports. There was an issue to make explicit the links between information entities (orders, image folder, reports, etc.) and real-world objects (specimens and containers, etc).

The anatomic pathology specimen model that we have described was developed to be consistent with the Specimen Information Module included in HL7 version 3, which is based on the HL7 Reference Information Model (RIM). The HL7 model was designed for clinical laboratory specimens, but is sufficiently generic to be useful for anatomic pathology specimens. We consciously attempted to maintain consistency with the HL7 v3 Specimen Common Message Element Type (CMET), and in our definition of a specimen, we consciously adopted the terminology of the focal class specimen as a "Role" with an identifier, in accordance with the v3 model.

Although the main output of the anatomical pathology workflow is a timely and clear report of a diagnostic opinion, images will be more and more associated as evidence to textual reports. DICOM seems to be a convenient format for image archiving and communication within the anatomical pathology department. For integration into the Electronic Healthcare Record, HL7 Clinical Document Architecture (CDA) seems to be the suitable format but solutions available to link textual items to DICOM images in an HL7 CDA document must be clarified.

Our perspective is that vendors implement IHE-pathology principles. Thanks to an on going collaborative work involving IHE-Pathology, DICOM WG26 and HL7 pathology SIG, an implementation guide (Pathology Technical Framework) will be available for a first IHE cycle in 2008.

Acknowledgments

This work has been supported by the ADICAP and the College of American Pathologists.

Abstract

The requirements of highly specialized clinical domains are often underrepresented in hospital information systems (HIS). Common consequences are that documentation remains to be paper-based or external systems with insufficient HIS integration are used. This paper presents a solution to overcome this deficiency in the form of a generic framework based on the HL7 Clinical Document Architecture.

The central architectural idea is the definition of customized forms using a schema-controlled XML language. These flexible form definitions drive the user interface, the data storage, and standardized data exchange.

A successful proof-of-concept application in a dermatologic outpatient wound care department has been implemented, and is well accepted by the clinicians. Our work with HL7 CDA revealed the need for further practical research in the health information standards realm.

Keywords:

medical record systems, computerized, generic architecture, systems integration, hospital information systems; CDA, openEHR, HL7, semantic interoperability

Introduction

The potential advantages of computerized patient records (CPR) versus conventional paper-based files have been known for many years [1]. CPRs were envisioned to improve both routine care and research in a multiple ways. The possible benefits range from obvious ones, like readability or availability, to visionary decision support scenarios. Studies were able to support many theoretical CPR advantages, while increased experience with CPRs and clinical information systems also reveals deficiencies. Ginneken [2] identifies low user-acceptance as a barrier that slows down the adoption of CPRs. This low user-acceptance results from lack of integration and missing flexibility in content and use. Other impediments mentioned are an inability to adapt to change, the lack of data exchange standards, or an insufficient financial return on investment.

The aim of this paper is to share our experiences from designing and implementing a generic clinical information system architecture. This project was initiated to implement a special-purpose application in clinical dermatology. In order to make our decisions comprehensible and to prove our concept, the context and realization of this implementation will be illustrated.

Problem

The outpatient clinic for patients with chronic wounds is a subunit of Freiburg university hospital's dermatology department and needed an application to document their treatment. Up until this point paper files had been used to record visit findings and procedures. As the chronic wound clinic is a multi-provider facility, the main problems with the paper records were difficulties with legibility and conventions about how and what should be recorded. Further issues were the limited data reusability for research (no standardized recording practice and primarily no electronic format) and the non-existence of discharge letter writing assistance (e.g. partially pre-filled letter template).

Within the hospital an in-house developed information system is in use [3]. The system provides hospital wide services such as a central document and picture archive (e.g. discharge letters, radiology images), access to lab data, and management of administrative patient data via a range of client applications. The communication between distributed components is based on HL7 v2 [4]. Besides these general functions a number of custom extensions have been developed to reflect the information needs of single sub-/departments (e.g. a module to document the vein status).

An external solution had also been considered for the chronic wound clinic. After determining scope (2 forms with around 200 data items) and basic requirements (analyzing existing paper recordings, conducting a series of three observation and interview sessions, and review of the existing products in the market) it became clear that no commercial product in the small market of chronic wounds documentation systems could fulfill the special needs. Lacking customisation flexibility, unsolved integration problems, incomplete features, and unacceptable conditions of use by one vendor were the main reasons for the decision to develop an in-house solution.

Health information interoperability standards

Establishment of semantic interoperability between distributed health information systems is probably one of the most important challenges of health informatics today [5]. Most expected CPR advantages [1] are based on this premise. It is widely accepted that only well designed health information standards can solve this problem.

There are currently two major standard initiatives that aim to achieve semantic interoperability of medical information: CEN 13606 [6, 7] & *open*EHR (http://www.openehr.org/, accessed 29 Nov 2006) and HL7 v3 (http://www.hl7.org/, accessed 29 Nov 2006). While it is undisputed that standardized information structures have to be exchanged, the approaches to about how this can be done differ.

HL7 Clinical Document Architecture: HL7's central design artefact is the Reference Information Model (RIM) from which message specifications are derived via a cascade of intermediary models. The idea is that this approach secures shared semantics. The HL7 Clinical Document Architecture release 2 (CDA r2, [8]) is an ANSI-approved exchange standard for medical documents. It has been developed according to the HL7 methodology and is fully based on the RIM. CDA r2 documents are XML instances with two main parts: a *header* setting the document context and the *body* containing the clinical report in a semantically enriched HTML-like markup. The CDA r2 specification purposely has a wide scope to be able to express any clinical document. Further constraint mechanisms are needed to enforce a particular structure. Currently, further constraints are defined by narrative 'implementation guides'. In the future formal constraint expressions, called 'HL7 Templates', are envisioned for this task. In order to ease the adoption of the standard an incremental approach regarding the semantic enrichment is supported. The concept of levels reflects this design, while only a CDA r2 Level 3 document is envisioned to guarantee full semantic interoperability. CDA r2 Level 1 only expects a standard conforming document header while there are few restrictions for the body. In CDA r2 Level 2 the coarse body structure (sections) needs to be understood by the receiving system through definition of meaning in the form of terminology codes. Level 3 can be achieved by adding semantic markup (entries) for every narrative clinical statement. To adhere to the CDA's human readability principle, level 3 markup can't contain more information than the narrative.

CEN 13606 and openEHR: The *open*EHR Foundation is a not-for-profit company behind an open community effort to produce specifications (requirements, technical and clinical models) and reference implementations. The aim is to achieve an "open, interoperable health computing platform, of which a major component is clinically effective and interoperable electronic health care records (EHRs)" [9]. While not a standards body itself, *open*EHR is dedicated to work with standards organizations. The revised European standard CEN 13606 is influenced by *open*EHR. Like the *open*EHR architecture, it promotes a stable reference model, whose classes can be aggregated and further constrained by standardized, formal clinical content models called *archetypes* [10]. This so-called two-model approach separates medical knowledge from technical knowledge to achieve semantic interoperability and future-proof health information systems. Part two of the CEN 13606 standard has adopted the *open*EHR Archetype Description Language (ADL).

Design decisions

As a consequence of the depicted situation the following in-house solution design goals were rated with the highest priority:

- Customisation – to fit to clinical information requirements and workflow needs
- Integration – into the existing hospital IT environment
- Data sustainability and semantic interoperability – through standard conformance
- Generic methodology and components – to foster reusability in other clinical areas
- Pragmatism – to develop a solution that takes the limited resources into account and allows early utilization

Material and methods

The design goals mentioned above determined the choice of development technologies and the applied methodologies. To allow the possibility of reusing the system for similar documentation problems within the department of dermatology (e.g. the clinic for dermatological autoimmune diseases) it was decided to build a generic architecture that can be adapted flexibly according to new needs. XML instances of a form description language implemented in RELAX NG were pictured to drive a GUI generator. Flexibility regarding data entry items implies flexibility of the underlying database. This requirement excluded the use of the central hospital database facilities and we used a variable XML format instead. In order not to create an isolated "data island" we decided to build a XSLT transformation mechanism that could export our data to the standardized CDA r2 format. Integration with the hospital information system (HIS) was to be achieved by regular sending of CDA documents as payload in HL7 v2 messages. Administrative patient data should be similarly imported from the administrative data module of the HIS. We conceived the architecture as a web application framework whose core features (form definition language, data storage) are based on XML technologies and tools. The presented initial version also uses technologies such as PHP5 (form generator) and MySQL (4 tables: patient data, user data, XML form definition and XML form data). The necessary security is achieved as the application can currently only be accessed from within the firewalled hospital intranet. Additionally LDAP authentication and https encryption were installed.

After the development of the generic architecture, analysis and deployment of the chronic wound application were the next steps. A number of form definition iterations were planned to achieve a customized solution. This approach follows the idea of rapid prototyping [11] and allows early

user involvement to secure a high-level of user-acceptance.

Results

Overall architecture

Following the classic web paradigm the system architecture consists of a web server and database containing the application (PHP5) and a web browser on the client side to interact with the application. The application consists of: a form generator that creates HTML forms based on a formal XML form definition and modules for tasks such as user authentication, transformation to CDA r2, or integration with the HIS.

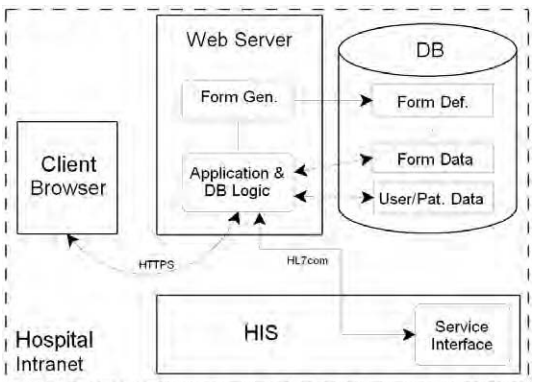

Figure 1 - Architecture of the system framework

HTML form generation

The form generator component was written in PHP5 and dynamically generates HTML forms based on XML instances of a formal form definition language. These forms are used for editing and viewing. There is no restriction in the number of forms.

Form definition language: A RELAX NG schema grammar restricts the form definition elements to 6 types that can be arranged using 3 layout patterns. Additionally the form can be divided in sections and subsections. Each sub-/section XML tag has optional attributes to specify a terminology (e.g. LOINC or SNOMED) and the suitable code. The element types comprise the normal HTML input fields (text, checkbox, dropdown, upload) and widgets for date input (calendar) and for image display with planimetry. Each element has a mandatory label and an optional suffix. The available layout patterns are 'beneath' (field elements below each other), 'float' (field elements next to each other), 'table' (configurable tabular layout).

GUI features: The Graphical User Interface (GUI) is rendered according to the form definition file. By default, every section is displayed in its own tab (see Figure 2 for a screenshot from the chronic wound application).

Data storage

The structure of the form content data depends on the form definition. To store submitted form data, a simple XML file is generated by mapping element names to their current values. This file is stored in the MySQL database together with metadata for retrieval.

Transformation to the HL7 CDA level 2

Based on former experiences with the first release of CDA [12, 13], we developed the framework according to the CDA r2 specifications. Provided correct code mappings exist in the form definition, an XSLT script that creates a CDA r2 Level 2 document can be derived automatically from the form definition. The CDA body content is created from the flexible form definition and the corresponding form data, while the metadata in the CDA header is based on information that is invariably required by the stable module.

Integration with the HIS

Integration with the existing HIS infrastructure is guaranteed by import of master data and export of CDA documents once they are approved by the supervising physician. Technically, import and export works by transferring XML documents via a HL7 v2 service interface provided by the HIS.

Implementing the chronic wounds application

Using the results from the scope and basic requirements analysis (conducted prior to the framework realization), an initial form definition was built by one author with good medical and IT knowledge. Consequently, 5 half-hour sessions with one medical user and one author were sufficient to reach the final definition.

In order to cover the use cases of the chronic wound clinic it was decided to have two types of forms: an 'initial assessment' form and a 'follow-up' form. The 'initial assessment' form contains the detailed patient history and information about special tests, that aren't performed during every visit. It is primarily filled during the first visit, but it can also be updated later. A new 'follow-up' form is completed during each subsequent visit, documenting the current status and determining the further procedure.

Discussion

Proof of concept

The first application of the presented framework has been successful. It is used daily by 3 nursing staff and 4 physicians. During the first 2 months of use about 500 visits of 150 patients have been documented. Although the system doesn't

Figure 2 - Chronic wound web-application GUI

provide all possible features yet (see the section 'Future'), early positive user reactions show that the system provides major improvements to the former solution. A study to analyse the system usability and the added value of the solution is planned.

The user involvement during requirements and implementation iterations was very valuable for both parties (medical and technical) and we can confirm similar experiences mentioned in the literature [2, 14]. Having the possibility to make quick adaptations to the form definition and displaying the result instantly helped the clinicians immensely to assess the current form and recommend improvements. The generator driven evolutionary approach described by Lenz and Kuhn [15] is similar in the rapid prototyping respect but manages system integration differently.

Integration

The presented architecture is potentially autonomous, but an integration with the central HIS components proved to be possible. The decentralized integration strategy is based on the standardized messaging exchange format HL7 v2. An direct extension of the HIS would have meant a prolonged development cycle and a high degree of inflexibility (limited existing data structures), which possibly could have lead to compromises in design.

CDA standard

Standard support is crucial for inter-organizational information exchange and must be a goal of every modern clinical information system. We decided to use the HL7 CDA r2 standard. Its document orientation suits the form-based framework well, and more importantly, it was a pragmatic choice that could be implemented relatively easily on top of ubiquitous XML tools. Currently, the generated CDA documents conform only to Level 2. The generation doesn't impose major difficulties provided suitable codes are found and set in the form definition. First experiments with Level 3 markup showed that it will not be easy to automatically create semantically correct CDA entry statements. Especially the necessary combination of several entries or the expression of post-coordinated SNOMED terms showed much arbitrariness.

Total semantic interoperability means that a receiving system can derive the same meaning from a standardized information unit (e.g. a CDA document) as the sending system. This must be true for any CDA document. In our opinion for this long-term goal the CEN 13606/*open*EHR approach using coherent, standardized content models (archetypes) seems currently better suited. HL7 is aware of this "gap", which HL7 templates are supposed to fill. Further research regarding CDA r2 Level 3 compared to CEN 13606/*open*EHR is needed.

Future

Besides the necessary research mentioned in the preceding discussion sections, various practical and technical improvements to the framework could be explored and implemented to further address issues like the ones mentioned in the introduction (e.g. data reuse). Routine care would benefit greatly from a letter writing assistance tool or a history feature where certain entries can be viewed over time (e.g. numerical values as a chart). An "XML2relational" data dump tool would allow analysing the collected data with conventional statistics programs. At the moment, only one version of each form is valid. A variable versioning mechanism would overcome this restriction. Technically, a re-implementation of the architecture based on pure XML technologies such as XForms, the Apache Cocoon Framework, and a XML database would be interesting.

Conclusion

This article describes a generic system architecture framework for health care applications. Through an autonomous concept special-purpose, form-based solutions that are customized to the needs of clinical users can be developed.

The HL7 CDA r2 standard was used to ensure system integration. A proof-of-concept implementation for routine care shows its applicability.

To what extend HL7 CDA or alternatives like *open*EHR can enable full semantic interoperability needs to be explored in further practical trials.

Acknowledgments

We would like to thank the medical and the nursing staff of the dermatological chronic wounds unit for their assistance and feedback during development.

Analyzing the Key Variables in the Adoption Process of HL7

Alejandro E. Flores, Khin Than Win

Health Informatics Research Centre, University of Wollongong, Australia

Abstract

The intention of this paper is to provide an analysis of variables that could affect the adoption of HL7 message standard. Based on the review of 33 cases where HL7 was successfully implemented the authors present relevant evidence related to inherent limitation of HL7. The result from this study indicates that it is necessary to enhance the standard to overcome particular limitations and facilitate the implementation of inter-institutional software interfaces based on HL7.

Keywords:

Health Level Seven, adoption, connectivity and standardization

Introduction

Health Level seven (HL7) consortium was founded in 1986 to research and develop a set of standards for electronic data exchange in the heath care domain. The HL7 standard is a structured specification that can be used for interconnection and exchange of health records [1]. HL7 is the most widely used messaging standard for clinical and administrative data exchange among health care applications in the information technology industry [2]. HL7 has established a set of information and message models for the development and implementation of interfaces for communication and transmission of medical data among heterogeneous health information systems [2][3]. The aim of HL7 is to produce standards for a particular health care domain considering the holding of a strict and well-defined framework that ensure consensus, openness and balance of interest, and allow the development of specifications for the implementation of messages model and software interfaces[1].

At the actual level of development, the most intractable barrier for the use of HL7 has been the lack of standards for exchanging fine-grained, highly heterogeneous, structured clinical data among information systems that had been implemented under different platforms [2][3]. Moreover, the additional consideration of specific health information domain and inclusion of new information and communication technology adds levels of complexity to the initial hitch [4]. Therefore, it is necessary to explore the HL7 message standard and its application to different health care domains to establish limitations of HL7 standard, and to outline alternative courses of action that permit the overcoming of those restrictions [4].

The aim of this paper is to identify advantages and disadvantages of HL7 standard by the analysis of 33 specific cases. It will permit to identify benefits of the use, understand the adoption process and recognize limitation and barriers that should be considered during the implementation of HL7 standard. This will also offer an initial answer to why it is important to consider the development of new set of communication models based on HL7 in order to overcome the new requirement of connectivity and communication for specific application in the health care domain.

Methods

As the main purpose of this research is to identify the key attributes that facilitate or limit the adoption of HL7. The methodology used in this study was based on an analytical generalization [5] based in the analysis of 33 articles related to the use of HL7 during the design and development of software interfaces for electronic health information systems.

Framework

The Technology Acceptance Model (TAM) [6][7] was used as a framework for this analysis. The variables considered for this analysis were: (1) benefits, (2) adoption and (3) barriers. The variable cost was not considered because of the limited information provided by the authors of the studied papers.

Scope

The search was limited to articles published since 2000. The articles selected include implementation experiences in: (1) Electronic Health Records (EHR) Systems, (2) Cardiology Information Systems, (3) Electro Physiology Information Systems, (4) Radiology Information Systems, (5) Administrative, Support and Knowledge Information Systems, (6) Tele-medicine Services, (7) Regional Health Information Systems, and (8) Home Monitoring Health Information Systems.

Search strategy

The search was realized in March 2006 and repeated in July and October 2006. The second and third searches were conducted to include recent cases where HL7 has been used as a framework for the development of commu-

nication interfaces in the health care domain. The following key words were used during the search process: (1) HL7, (2) Health Level Seven, (3) health information standard, (4) interconnectivity, (5) software interfaces and (6) communication. The databases ScienceDirect, Proquest 5000, IEEE Xplore and SpringerLink were used as knowledge sources during the search process due to the immediate access for the authors.

More than 150 articles were identified during the search process. However, only 63 of them were considered for review based on the relevance over the adoption of HL7 in the health care domain. Three elements were considered as relevant to pick up the list of 63 articles: (1) the article presents information related to the development and implementation of software interfaces for data exchange among health care system, (2) the main standard used for the development was HL7, and (3) the information presented by the authors has been obtained during the implementation of projects since the year 2000.

The Table 1 shows the criteria used to select the final list of 33 articles. The scope of these criteria was to narrow the articles selected to those that present the most recent information about HL7 implementation.

Table 1 - Selection Criteria

Criteria	Considerations
Version	HL7 v. 2.5 and HL7 v. 3.0
Implementation	Modeling, Implementation of Communication Interfaces, Software, and Web-based software and interface.
Message Format	XML
Publishing Date	Year 2000 and after.
Elements Implemented	HL7 messages, new vocabulary, and model representation based on the Reference Information Model (RIM) and/or Clinical Document Architecture (CDA).

Results

The articles selected were classified into the four implementation categories described in table 1. The analysis was conducted considering the following variables: (1) Benefits/Limitations (performance and time saving, adaptability, and extensibility, modeling and implementation support; (2) Adoption of HL7 in health care; (3) Technical barriers for adoption of HL7

Benefit and limitation of HL7

Performance and time saving

The performance and time saving during the exchange of data is a main decision variable for the adoption of international information and communication standards. Moreover, the inclusion of international standards for exchange of information among health information systems, such as HL7, may have a direct and positive impact in the time processing and performance of medical data exchange.

Langer [8] indicated that the implementation of HL7 standard enhances the performance and interoperability of health information systems and diminishes the time required for data exchange and access between hospital units and departments. Moreover, they consider that the incorporation of HL7 messages allows the friendly and easy access to multiple instances of patient's records and clinical information, which permit to enhance the quality of the health care delivery service. Ko et al. [9] agreed that the use of HL7 improves performance and efficiency of connectivity and interoperability among health information systems. However, they pointed out that large implementations, such as integrated institutional web-based application or inter-institutional health information systems, increase the risk of informatics attacks and could provoke loss of robustness, security and flexibility of the systems.

Müler et al. [10] indicated that the implementation of communication standards is a cost factor in modern health care systems. This implies that a better and faster exchange of medical information could ameliorate medical care services. They also agree that HL7 framework, in special the Clinical Document Architecture (CDA), allows the development of efficient and well defined interfaces that enhance the exchange of medical documents in local health information structures and diminishes the time of transference.

In almost all the cases analyzed, the implementation of HL7 has permitted the enhancement of performance and diminution of time during the transaction and data exchange among electronic health information systems. However, the inclusion of security schemes should be considered to ensure the safe delivery of messages and information and overcome possible information threats and loss of robustness of the systems.

Adaptability

Since its beginning HL7 has been developed as a standard for software interface that should be able to connect different and highly heterogeneous software environments. For this reason adaptability has become a keystone attribute that must be accomplished by HL7.

Most of the authors state that HL7 has presented high adaptability to the domains actually included in the standard scope [11][10]. In this sense, the HL7 Reference Information Model (RIM) has been successfully adapted to electronic health records systems, department information system and administrative and financial applications [11]. However, it has presented limited adaptability to nursing information systems, inter-institutional application

and specific health care systems such as general practice and radiology [4]. The Act[1] class of the RIM has been unable to represent nursing activities and the HL7 vocabulary is limited for nursing information [4]. The actual data structure and vocabulary definition is unable to map complete data information for General Practice's information systems [12] and, even though, HL7 has demonstrated excellent performance during the exchange of radiology clinical information, it is still limited for large image exchange [13].

According to Müler et al. [10] CDA can be easily adapted to overcome local health system requirements such as electronic health records systems, decision support systems and knowledge applications [14]. However, some issues, related to adaptability requirements, efforts and cost to meet inter-institutional needs, should be addressed to provide a better support in the implementation of software interfaces for the exchange of clinical document among different actors of the health care domain [15][10]. They also suggested that CDA can be adapted to different inter-institutional scenarios by including additional data structures and vocabulary that allow overcome the two basic limitations: (1) CDA is limited to the scope of HL7 definitions [16] and any additional extension to the data or vocabulary definition is limited to local solutions [10]. Finally, Müler et al. pointed out that the inclusion of CDA permits diminish the cost associate to the exchange of clinical documents and could enhance the delivery of primary and secondary health care services.

Bicer et al. [17] discussed about the necessity to develop message exchange frameworks that provide support semantic interoperability between different versions of HL7 message standard. This is one of the most common problems during the exchange of data between software interfaces developed under both version 2.x and version 3 of HL7.

In conclusion, HL7 has few adaptability issues for health information domains such as electronic health record, administrative and financial systems, and departmental information systems. However, due to limitations in the referential data representation and vocabulary, HL7 has restrictions that have to be considered for implementing health information systems in particular domains such as nursing system, general practice and inter-institutional application.

Modeling, extensibility and implementation support

HL7 allows the incorporation of information structures and extension to the vocabulary and messages specifications. Moreover, the information model and vocabulary should be adapted during the process of software implementation to achieve local needs [4][11]. However, those extensions are limited in exchange of information among different health providers [10].

According to Fernandez and Sorgente [14], the ad hoc variation of the HL7 Unified Modeling Language (UML) is incompatible with existing standards. Moreover, the HL7 documentation is wide and complex making it difficult to understand. In addition, entities, roles and associations had been represented and structured for implementation not for abstract representation, e.g. roles are job descriptions without security specifications and associations that do not have names or semantic values. Indeed, they had been replaced by separate class representations. Moreover, to add extend class representations HL7 uses arbitrary names based on prefixes of the original classes and not stereotypes as usual in UML representations. In general, HL7 artifacts do not completely follow the UML patterns and software engineering rulers. This issue makes the standard unnecessarily complex for the elaboration of model representations and model extensions.

The RIM provides explicit semantic and lexical representations of messages and fields. Additionally, it facilitates the data integration among health care applications, providing structural information models and a health base vocabulary [14]. Moreover, the RIM facilitates the mapping process over basic health care informational representations and model [20]. However, these representations are relatively limited if the standard is applied to some particular health care domains such as nursing systems [4], general practice's information systems [12] or radiology information systems [21].

The HL7 CDA gives a framework for design and interoperability of clinical documents [20]. Furthermore, the CDA provides support and representation for messages based on text, image, sound and multimedia contents, and allows the enhancement of vocabulary and information structure to reach particular requirement. However, it does not provide guides or recommendation for the development of structural or vocabulary extensions and most of the representations require adjustment and modification to local needs [22]. Additionally, any local extension to the model, vocabulary or documents structures must be considered as optional data or field during the interchange of data among health care providers [4]. This implies that, due to the message definition, some relevant information could not be interpreted by the destination bode.

Lebak, Yao and Warren [23] suggest that HL7 should provide a better support for large scale system implementations that consider interconnection among different actors of the health care. It implies the consideration of a framework that includes support for the development and deployment of integrated, interconnected and secure software interfaces. [23], the integration of electronic health records, and provides a wide set of elements that support the modeling and implementation of robust inter-institutional software interfaces based on HL7 standard [15].

In Summary, the had hoc UML model representation used by HL7 artifacts do not follow the object oriented standards, this makes more complex the standard for develop-

1 The RIN Act class is used to represent intentional acts that are performed to benefit the patient and associated clinical activity.

ers and increases the time and cost associated to the development of HL7 message interfaces. HL7 provides extensibility capabilities. However, extensions of HL7 standard are limited to local implementation. Moreover, inter-institutional implementations, such as Regional Health Information Systems, should consider this limitation to include homogenized message structures and message interpretations.

Adoption of HL7 in health care

The use and adoption of HL7 allows the implementation of integrated health care systems. In addition, HL7 provides a native and robust interoperability framework for software development and deployment. Moreover, HL7-CDA reduces the cost of moving existing documents to new standards [10] and enhances the work flow between health information systems. For these reasons most authors explicitly agree that HL7 is a recommended and required standard for information exchange among health care applications. However, the adoption of HL7 should consider several issues that should be addressed to the implementation plan. Some of them are adoption limitation over ad hoc UML modeling of HL7 [18], complexity of the implementation over large information systems, high cost, restrictions of vocabulary and the consideration of other communication standards that provide better support over specific domain, e.g. The Digital Imaging and Communications in Medicine (DICOM) for radiology exchange of information [13].

Technical barriers for adoption of HL7

HL7 provides a wide range of guidelines and specification for implementation of data structures and messages for software interfaces among health informatics applications [2]. Instead, HL7 has several technical limitations related to information model specifications, message definitions, document structures and vocabulary applied to specific health care domains.

First, according to the definitions of HL7 standard, the message should contain a basic set of fields, which must hold the critical information required for exchange; additional information should be provided using the optional fields [1]. This fact does not represent a real inconvenience for local implementations [22][11]. However, this issue could increase the costs and efforts required during the development and deployment of HL7 messages for inter-institutional applications [10].

Second, the RIM has presented issues during the data mapping and development of messages in some health care domains [4][12][20]. According to Danko et al. [4], the RIM class Act is unable to represent complete model structures for nursing information systems. Moreover, they suggested the additional attributes to the RIM-Act class and the enhancement of the HL7 vocabulary to include nursing information. Furthermore, these limitations also affect the development of software solutions in other domains such as general practice [12], and the exchange of referral and discharge letters [11].

Thirdly, the CDA has been developed to provide a framework for document representation and message elaboration based on HL7 standards. However, the CDA framework is in a development stage. This implies that CDA does not provide a complete data representation for some specific health domains or local requirements [11]. Moreover, limitations of HL7 vocabulary and data structure make necessary the development of local solutions, which are not totally compatibles for inter-institutional information exchange [4][11]. In addition, actual vendor's software does not provide complete support for integration of certain external data, and local implementations are restricted to internal needs [10]. These issues add levels of complexity to the development process and increase the cost if implement HL7-CDA messages interfaces over inter-institutional health information systems.

Finally, additional limitations are related the cost and time required for implementation and the complexity of the existent HL7 artifacts [13]. The implementation of HL7 messages based on CDA over XML requires an important amount of time and cost of development. In addition, the deployment of large health information system makes the development and implementation process highly difficult and requires additional resources [14].

In conclusion, HL7 has provided a helpful framework for developing and implementing health information messages interfaces. However, there still exist some issues to address in order to improve the standard.

Discussion

This paper has presented an analysis based on HL7, both version 2.5 and version 3.0, implementations experiences over different health care domains since the year 2000. Those experiences ratified that HL7 provides a wide range of capabilities for the enhancement of message communication among health information systems. However, those experiences also had made manifest that HL7 has structural and technical limitation that could make difficult the adoption process. Those limitations are related to the message modeling and implementation, data structure representation and vocabulary presented in the RIM and CDA.

HL7 standard provides a basic framework for message modeling and implementing. However, in most of the cases analyzed the authors recommend to update the standard to overcome local needs. Furthermore, it is necessary to consider the development of a framework that provides guidelines for the development of inter-institutional message solutions. Additionally, it is also necessary to develop a message exchange framework that enhances the compatibility between version 2.x and version 3.0 HL7 messages.

Both the RIM and CDA have been implemented and used to enhance the data, information and document exchange among local and inter-institutional health information systems. At the local level both provide a framework for message design and extensibility implementation, and system deployment [1][10]. However, the data definition and vocabulary incorporated to the HL7 standard is limited to

the existing in the RIM and CDA definition [20][10][19]. Moreover, the existing data and vocabulary definitions limit the mapping of data and generation of messages. These limitations can be overcome by incorporating extension to the models and vocabulary at the local level. Nevertheless, it is important to consider that according to the HL7 message standards [1][4], extensions must be considered optional attributes or optional values during the exchange of messages. These issues increase the complexity and cost of the development and implementation of health information software solution at inter-institutional level.

Conclusion

HL7 has demonstrated to be an important advance in the development of health information software for medical data exchange. However, the implementation of HL7 in specific cases, requires the development of new information models, message model and vocabulary that allows the implementation of those interfaces [4][12][13]. Moreover, the development of communication interfaces on specific scenarios would permit to enhance the actual information structure of HL7 standard. On the other hand, the definition and specification of HL7 message information models, for specific health domain software, allows the implementation of robust software interfaces. These interfaces would enhance the information exchange and interoperability among different local and inter-institutional health care software applications.

An XML Model of an Enhanced Data Dictionary to Facilitate the Exchange of Pre-Existing Clinical Research Data in International Studies

Stephany N. Duda[a], Clint Cushman[b], Daniel R. Masys[a]

[a] *Vanderbilt University, Nashville, USA*
[b] *University of California, San Diego, USA*

Abstract

Pre-existing clinical research data sets exchanged in international epidemiology research often lack the elements needed to assess their suitability for use in multi-region meta-analyses or other clinical studies. While the missing information is generally known to local investigators, it is not contained in the files exchanged between sites. Instead, such content must be solicited by the study coordinating center though a series of lengthy phone and electronic communications: an informal process whose reproducibility and accuracy decays over time. This report describes a set of supplemental information needed to assess whether clinical research data from diverse research sites are truly comparable, and what metadata ("data about the data") should be preserved when a data set is archived for future use. We propose a structured Extensible Markup Language (XML) model that captures this information. The authors hope this model will be a first step towards preserving the metadata associated with clinical research data sets, thereby improving the quality of international data exchange, data archiving, and merged-data research using data collected in many different countries, languages and care settings.

programming languages, software design,
knowledge representation (computer),
database management systems

Introduction

The meta-analysis of clinical research and community health data from different regions of the world is the focus of an increasing number of international collaborations [1]. Merging such diverse data is particularly challenging in medicine, since geographic differences in patient and disease characteristics, medical resources, language, and cultural beliefs can have a profound effect on the comparability of clinical information [2]. Varying regional standards for measurement units, "normal" ranges, treatments and procedures, and medical definitions may prevent data from being interpreted correctly. These differences are magnified when each participating site has collected the data independently as part of routine patient care. Successful harmonization of diverse, global data requires additional information that is known locally but not generally included in study records or patient care databases. Such metadata, or "data describing data," may help answer the following questions that arise when already-existing data are considered for combined analysis:

- Are the observations stored in a given variable in one data set equivalent to those stored in a variable in another data set, or are the variables similar but not identical for the purposes of a particular form of analysis?
- What computer program has been used to store and format the data?
- What is the "normal" range for this observation?
- What are the valid values that this variable may take?
- Who owns the data, and under what circumstances can it be used for analysis?
- From what geographic region are the data derived?
- In what language are the text-based data represented?
- What quality control measures have been applied to the data set to ensure that it is accurate and complete?

Historically, limited metadata related to these questions have been recorded in narrative form or made available by person-to-person communication with the owners of the research data. Over time, however, this information may be lost in the shuffle of old project records and in job transitioning among investigators and staff. The information loss resulting from reliance on memory, paper memos, and generally uneven documentation affects how accurately data sets can be combined for joint analysis, and how reliably data may be reused years after their creation [3].

If such "hidden" metadata can be identified, recorded, and transmitted alongside clinical research data sets in a well-structured format, it may reduce information loss and enhance the usability of research results. Extensible Markup Language (XML) is an established standard for this type of structured information exchange: its hierarchical text format is flexible, simple to implement, and easily interpreted by both humans and computers [4]. Web-based

applications and fields such as business, chemistry, and mathematics have employed XML extensively for information sharing, encoding semantic content, and data modeling [5-7]. In biomedicine, XML has been used to encode clinical guidelines, support electronic messaging between hospitals, and annotate nucleotide sequences [8-11]. The structure and syntax of such XML models is often described using XML Schema, the World Wide Web Consortium's recommended means of expressing XML schemata[12].

We report here the development of methods for capturing and storing clinical research metadata in an XML format. Preliminary work will focus on data collected by the International Epidemiologic Databases to Evaluate AIDS (IeDEA), an initiative of the U.S. National Institutes of Health to "establish international regional centers for the collection and harmonization" of HIV data and the management of region-wide analyses [13]. Participating sites include hospitals and clinics located throughout the Americas, Asia, Africa, and Oceania. The IeDEA collaboration will focus on regional analyses in its first three years, after which sites may choose to submit their data sets worldwide data pooling and analysis.

The majority of IeDEA member sites are based in developing countries, where the process of collaborative research differs significantly from that in developed nations [14]. Consequently, an appropriate data model must take into account the information exchange needs and capabilities of clinical research centers in the developing world. We assert that a simple, structured model designed to capture and preserve clinical research metadata can improve the quality of international data exchange and merged-data research, as well as preserve study metadata for future research projects.

Approach to model development

Six IeDEA-participating sites submitted descriptions of their pre-existing patient care and research databases. We reviewed these descriptions and developed a list of elements required to represent the characteristics of the content. Approximately thirty participants, including statisticians, HIV researchers, epidemiologists, database managers, and international clinical trials specialists, reviewed the proposed element list and suggested additional fields they might use to determine the compatibility and usefulness of different data sets. The resulting metadata fields were categorized and mapped to a collection of XML examples and a corresponding XML Schema.

The authors and collaborators identified the following design objectives for the metadata model, based on the input of the researchers and descriptions of locally-developed databases at IeDEA sites.

Design objectives for model

Flexibility: An ideal model for collaborative international data exchange must be adaptable to a range of data storage formats, from elaborate databases in fully-electronic clinical trials data management systems to the locally-developed systems of treatment centers in the developing world. While some sites may upload database files to their regional coordinating centers, others will struggle to deliver Microsoft Excel spreadsheets or plain text files. The internal structure of the data exchange format must accommodate all possibilities.

Document Independence: The metadata solution should not rely on any single data management system to repackage data and metadata into a cohesive unit. Instead, the metadata document should accompany data files originating from preexisting local databases – such as those maintained at IeDEA's participating sites – when they are submitted to collaborators or study coordinating centers.

Transparency: The syntax for recording research metadata should be easy to generate and interpret, for humans and computers alike. The information should be accessible to individuals without a specialized data viewer and it should be possible to automate part of the metadata documentation process.

Design objectives for model content

Data Descriptors: The model describing a clinical research data set should contain traditional data dictionary content, such as variable names, ranges, datatypes, and special values for missing or pending measurements. It is particularly important to capture this information for clinical databases in developing countries, where often no formalized data dictionary exists.

Measurement: The documentation for numeric values such as laboratory results should include the measurement unit and a description of the measurement method used.

Geography: The model should include some marker of location that indicates, geographically, the site(s) where the data have been collected and the location of the sponsoring or coordinating organization. This geographic code should be able to pinpoint the country, region, or city from which the data originated, but also allow fuzzy mappings to protect the privacy of individuals in small villages or accommodate the address-less locations of traveling or wilderness clinics.

Contacts: The name, contact information, and website of the organization (clinic, hospital, research center) responsible for producing and maintaining the clinical research data should be recorded in the metadata, along with a list of persons responsible for preparing the data or metadata.

Terms of Use: A section of text should clarify under what conditions the data set may be used.

Quality: The data exchange model should include a description of the quality assurance measures applied to each variable as it exists in the current data set. Examples of quality assurance tests include range and valid values checking (either manually or using an algorithm), double data entry with comparison, and source document verification.

Ontologies: The XML model should allow users to map locally defined variables to existing concepts in multiple controlled vocabularies and vocabulary versions. The

resulting structure should be able to represent compound concepts, also known as data tuples or post-coordinated terms.

Proposed model

The model overview contains XML samples and brief descriptions of the more complex elements in the document hierarchy. The full XML Schema is available online at http://ccasanet.vanderbilt.edu/xml.php. The website is hosted by CCASAnet, the Caribbean, Central, and South America Network for HIV research, which is one of seven IeDEA-funded regional coordinating centers and is located at Vanderbilt University [15].)

Model overview

The XML structure has a single root element, <metadata>, that encloses all other metadata-related elements. The first levels of the hierarchy are shown in Figure 1 - Root structure of the XML model for exchanging pre-existing international research data1:

```
1<metadata>
2   <about_dataset>
3       <db_software>...</db_software>
4       <owning_organization>
        See Figure 2 - XML description of
the organization that owns the data set2
5       </owning_organization>
6       <contact_people>
7           <contact_person>...
                </contact_person>
8       </contact_people>
9       <dataset_composition>
        See Figure 3 - XML structure for
storing information about the data set's
patient cohort3
10      </dataset_composition>
11  </about_dataset>
12  <dataset>
13      <datafile>
14          <variables>
15              <variable>
                    See Figure 4 - XML
structure for variables in a data set4
16              </variable>
17          </variables>
18      </datafile>
19      <datafile>...</datafile>
20  </dataset>
21</metadata>
```

Figure 1 - Root structure of the XML model for exchanging pre-existing international research data

As seen above, the XML elements are partitioned into two sections of meta-content: metadata related to the *data set as a unit* (<about_dataset>, line 2), and metadata related to the *observations contained in the data set* (<dataset>, line 12).

Metadata associated with the data set unit can answer questions such as "what software was used to maintain this database?," "who owns this data?," and "whom should I contact if I have questions related to this data set?" This information is captured between the <about_dataset> tags. The <dataset> tag, in contrast, encompasses the metadata related to the observations in the dataset.

The four fields within the <about_dataset> tag include <db_software>, which contains the product name and version of the database software used, and <owning_organization>, which contains the name, contact information, and geographic location of the hospital, clinic, or research institution that owns the data. The syntax of the <owning_organization> hierarchy is shown in Figure 2 - XML description of the organization that owns the data set2. Geographic location markers, or geocodes, are recorded in latitude and longitude, as these measures are easy to compute using publicly accessible web tools such as EarthTools or Getty Thesaurus of Geographic Names Online [16, 17]. Data owners may also stipulate a Terms of Use clause, <terms_of_use>, that restricts the applications of their data.

```
1<owning_organization>
2   <name></name>
3   <contactinfo>
4       <address></address>
5       <city></city>
6       <country></country>
7       <phone></phone>
8       <fax></fax>
9       <email></email>
10      <url></url>
11  </contactinfo>
12  <geocode>
13      <name></name>
14      <description>
            </description>
15      <latitude></latitude>
16      <longitude></longitude>
17      <coordinate_source>
            </coordinate_source>
18  </geocode>
19  <terms_of_use></terms_of_use>
20</owning_organization>
```

Figure 2 - XML description of the organization that owns the data set

A third element, <contact_people>, on line 6 of Figure 1, contains the names, titles, roles, and contact information for people associated with the creation, maintenance, or packaging of the data set. A high-level description of the data set, a description of the study cohort, and a set of geocodes demarking the data's source regions are part of the fourth and final descriptive metadata element, <dataset_composition>, shown below:

```
1<dataset_composition>
2   <description></description>
3   <study_cohort></study_cohort>
4   <data_region>
5       <geocodes>...</geocodes>
6   </data_region>
7</dataset_composition>
```

Figure 3 - XML structure for storing information about the data set's patient cohort

The second section of the data exchange model describes the data files that accompany the XML metadata docu-

ment. Each file is described within its own <datafile> tag (Figure 1, line 13), and the set of such tags constitutes the <dataset> structure of the model. These files may be database tables, spreadsheets, or even text files, but they contain variously formatted table information. All variables or equivalent table columns appearing in a data file are represented in the <variables> tag. The <variable> structure is detailed in Figure 4 - XML structure for variables in a data set4.

```
1<variable>
2    <name></name>
3    <description></description>
4    <datatype></datatype>
5    <length></length>
6    <count></count>
7    <measurement>...</measurement>
8    <quality>

```

Figure 4 - XML structure for variables in a data set

The XML fields in lines 2 through 6 of Figure 4 include a variable name, description, datatype, type length, and count. The <measurement> field, shown on line 7, records the measurement unit, if applicable, and a description of the measurement method used to ascertain a numeric or subjective value. The subsequent <quality> tag (line 8) encloses a list of quality assurance measures applied to the variable, along with the quality test date and result. Special value codes for missing and pending data and counts of these code occurrences are recorded in the <value_types> field beginning on line 16, along with valid ranges for numeric variables and sets of valid values, discussed below.

```
1<valid_values_set
    location="inline|file|external">
2    <name></name>
3    <description></description>
4    <values_list>
5        <value></value>
6        <value></value>
7    </values_list>
8    <filename></filename>
9    <filetype></filetype>
10   <url></url>
11</valid_values_set>
```

Figure 5 - XML structure for internal and external valid values lists

The <valid_values_set> tag set, highlighted in Figure 5 - XML structure for internal and external valid values lists5, specifies a list of names, codes, or numbers considered to be valid content for a given variable. An *inline* list of valid values is often one developed locally, by the database designers. In this case, all valid codes are specified between the <values_list> tags, beginning on line 4 of Figure 5. A valid value set of type *file* indicates a value list included in a separate document transmitted along with the data set. A reference to *external* authorities suggests the valid values for this field are governed by controlled vocabularies such as SNOMED, ICD-9, or LOINC.

Each <variable> also contains a <content_mappings> structure that allows users to associate the variable semantics with one or multiple ontologies, specified by the vocabulary and version tags. The <content_mapping> structure is shown in Figure 6 - XML structure for ontology mappings6. Multiple <concept> tags within a single content mapping indicate a concept tuple, or post-coordinated term.

```
1<content_mapping>
2    <concept>
3        <vocabulary></vocabulary>
4        <version></version>
5        <term_name></term_name>
6        <content_id></content_id>
7    </concept>
8</content_mapping>
```

Figure 6 - XML structure for ontology mappings

The hierarchy of subsequent closing tags is specified in Figure 1 - Root structure of the XML model for exchanging pre-existing international research datagure 1. Many structures, such as <content_mappings>, are optional, and any text field can take a language attribute. Repeatable elements such as <contact_person> or <variable> are fully specified in the XML Schema available online.

Discussion

The XML model described in this paper meets the specified design objectives and constitutes a complete structure for international clinical research data exchange. The metadata fields include traditional data dictionary values, mappings to controlled vocabularies, and markers of geographic location, as well as specifics about local data entry and storage methods, definitions, measurements, quality control procedures, data ownership, and use restrictions. In addition, the model employs a flexible data exchange language (XML) that is system-independent and interpretable by both humans and computers.

By making this metadata uniformly available among IeDEA collaborators, researchers can analyze count and content metadata to determine in advance whether sufficient data are present to perform an analysis across global regions. Thus, the decision to make the data itself available for pooled analysis still remains with the owners of the data, while still allowing outside researchers to see what categories of information are available.

Although current database modeling and healthcare messaging standards exist, these exchange formats are either too rigid or too complex to use to describe data collected outside the controlled environment of a clinical trial. Data dictionaries are often focused on database structure and fail to capture information outside of the database syntax, while medical messaging and data exchange formats such as HL7 are designed for the exchange of patient care documents among electronically-enabled hospitals and care providers, rather than the merging of clinical research data.

We intend to validate the XML model presented here using real-world data sets contributed by IeDEA member sites. In areas where the model is shown to be not sufficiently flexible, we will update the schema to accommodate new categories of metadata. In addition, we intend to develop a tool to automatically populate most fields of the XML model by pre-processing the source database, and create a secure web interface for online maintenance of the metadata. This will reduce the burden of documentation placed on the data set owners. We will test the usefulness of the metadata and its XML model for the harmonization and meta-analysis of HIV electronic clinical research data from different countries, languages and cultural traditions.

The work described here represents a two-fold approach to improving the documentation that accompanies clinical research data in international studies. We have described seven categories of metadata that researchers find useful in determining the semantics and compatibility of pre-existing research data sets, and have formulated an XML model to document this metadata in a flexible, structured format. Future work will assess whether this innovation will improve the quality of international data exchange and merged-data analyses, thereby creating a more sustainable model for research collaborations worldwide.

Abstract

Standardization of data is a prerequisite to achieve semantic interoperability in any domain. This is even more important in the healthcare sector where the need for exchanging health related data among professional and institutions is not an exception but the rule. Currently, there are several international organizations working on the definition of electronic health record architectures, some of them based on a dual-model approach.

We present both an archetype modeling framework and LinkEHR-ED, an archetype editor and mapping tool for transforming existing electronic healthcare data which do not conform to a particular electronic healthcare record architecture into compliant electronic health records extracts. In particular, archetypes in LinkEHR-ED are formal representations of clinical concepts built on a particular reference model but enriched with mapping information to data sources which define how to extract and transform existing data in order to generate standardized XML documents.

Keywords:

medical records, archetypes, standardization, data translation, information systems

Introduction

Health care is a sector where the need for sharing information is the norm rather than the exception. However, the health data of one patient is usually scattered among the different health facilities where she/he has been attended. This leads to distributed and heterogeneous data resources, all of them containing health data, making the exchange of data across systems and organizations very difficult. This situation has created a large gap between the potential and actual value of the information content of electronic health records (EHR). Closing this gap by making efficient use of the health data held by these systems, could improve significantly patient care, clinical efficiency and empower research activities.

Due to the special sensitivity of medical data and the wide range of ethical and legal constraints, data exchange must be done in a meaningful way, avoiding all possibility of misunderstanding or misinterpretation. The faithful communication in EHR crucially depends on the standardization of the EHR architecture (EHRA) used to communicate data. Currently there are several international organizations [1] working on the definition of an EHRA. Health Level 7 [2] supports two message protocols: HL7 Version 2 and HL7 Version 3. The technical committee 251[3] of the European Committee for Standardization is working on a new full European Standard and future ISO norm for the communication of the EHR called EN13606 [4][5]. The OpenEHR foundation [6] maintains an EHR architecture designed to support the constructions of distributed, patient-centered, life-long, shared care health records.

Due to the complexity and the continuous evolution of the health domain a new approach for the development of EHR systems has been proposed. The methodology is known as the dual model methodology which is based on a clear separation between information and knowledge. The former is described through a Reference Model (RM) that contains the basic entities for representing any entry in an EHR. The latter is based on archetypes, which are formal definitions of clinical concepts in the form of structured and constrained combinations of the entities of a RM. Examples of Dual Model EHRA are CEN/TC251 EN13606 and openEHR.

Currently, in most organizations there is a vast amount of health related data that does not conform to an EHRA that need to be converted into standardized EHR extracts in order to be exchanged with other organizations. In this paper we address the problem of how to use archetypes to make public these legacy data in the form of standardized EHR. We argue that archetypes are suitable for this purpose. First, archetypes allow the formal description of the semantics of legacy and un-standardized health data. On the other hand, by mapping the structure of archetype definitions to the elements of the data sources, it is possible to generate normalized EHR extracts compliant with the underlying RM.

Dual model approach

The dual model approach distinguishes a reference model and archetypes.

A reference model is an object oriented model that is used to represent the generic and stable properties of health record information. It comprises a small set of classes that define the generic building blocks to construct EHRs. It

specifies how health data should be aggregated to create more complex data structures and the context information that must accompany every piece of data in order to meet ethical and legal requirements.

An archetype is a formal definition of a distinct, domain-level concept in the form of structured and constrained combinations of the classes of the RM. What is important is that for each concept in the domain we want to use, a definition can be developed in terms of constraints on structure, types, values, and behaviors of RM classes. Basically, archetypes are means for providing semantics to data instances that conform to some reference model by assuring that data obey a particular structure (combination of classes of the reference model) and satisfy a set of semantic constraints. This is achieved by linking data structures and content to knowledge resources as terminologies and ontologies. Their principal purpose is to provide a powerful, reusable and interoperable way of managing the creation, description, validation and query of EHRs.

ADL (Archetype Definition Language) [7] is a formal language for expressing textually archetypes developed by OpenEHR that has also been adopted by CEN. ADL is a textual language for specifying constraints on data instances of an RM in a formal way. An archetype expressed in ADL is composed of four main parts: header, definition, ontology and revision history. The header section contains the archetype metadata. In the definition section is where the modeled clinical concept is represented in terms of a particular RM class. This description is built by constraining several properties of classes and attributes, such as existence, occurrences or cardinality or by constraining the domain of atomic attributes. It is important to notice that in this section only those entites that need to be constrained should appear. The ontology section is where the entities defined in the definition section are described and bound to terminologies. Finally the revision history section contains the audit of changes to the archetype.

Archetype modeling

The current ADL specification is not precise enough regarding archetype specialization; this hinders a precise understating of archetypes and their implementation. As a consequence our first work was to define a precise archetype modeling framework as a prerequisite for implementing tools providing enhanced support for archetypes. Since our main concern is the generation of standardized EHR extracts we have focused on the data definition facet of archetypes. We view the definition section of archetypes as a database schema which describes subset of instances of a class from a particular RM. In this section we present briefly the data model used to describe data instances (EHR extracts) and the schemas that formalize the definition section of archetypes, the composition and specialization of archetypes and the relationship between a business concept and its archetypes and between an archetype and its instances. An extended formal definition and additional examples can be found in [8], due to lack of space these are omitted here.

Data model

Archetypes impose a hierarchical structure to the EHR, therefore we have chosen a data model based on trees with labeled nodes to formalize their data instances. It is similar to the models presented in [9,10] but our data model supports both ordered and unordered nodes. Although archetypes do not impose an order on class attributes or attribute values, it is possible to define ordered multi-valued attributes such as attributes whose value is a list.

The representation of data instances (in our context EHR extracts compliant with a RM) is straightforward. Each object is described by a data tree. The root node is labeled with the class name and has one child for each attribute. The children are labeled with the attribute names and each of them has one child labeled with the corresponding type (class) name. This mechanism is repeated iteratively. Atomic values are represented by a leaf node labeled with a value.

Schema model

For the representation of the definition section of archetypes we have developed a type system that allows the specification of decidable sets of data trees, i.e., in our context set of instances of the RM. We assume the existence of a finite set of primitive types C, i.e., the set of primitive types defined in the reference model, an infinite set of type variables T disjoint with C and an infinite set P of label predicates.

Definition 1. A multiplicity list is a regular expression of the form:

$$t_1^{(l_1:u_1)} \ldots t_n^{(l_n:u_n)} \tag{1}$$

Where n≥1, t_iÎCÇT, l_i£u_i and $t_i^{(l_i:u_i)} = t_i^{l_i} \mid t_i^{l_i+1} \mid \ldots \mid t_i^{u_i}$

Definition 2. A constrained multiplicity list (CML) is language definition expression of the form:

$$\left(t_1^{(l_1:u_1)} \ldots t_n^{(l_n:u_n)}\right)^{|l:u|} \tag{2}$$

Where $t_1^{(l_1:u_1)} \ldots t_n^{(l_n:u_n)}$ is a multiplicity list, l≤u,

$$\sum_{i=1}^{n} l_i \geq u \quad \text{and} \quad \sum_{i=1}^{n} u_i \geq l \; .$$

Intuitively the language generated by a constrained multiplicity list is composed by all the word defined by the regular expression whose length (number of symbols) is between l and u inclusively. As an example consider the CML $\left(A^{(1:2)}B^{(1:3)}\right)^{|3:4|}$ which defines the language {ABB, ABBB, AAB, AABB}.

We formalize the definition section of archetypes as a set of type definitions (a schema).

Definition 3. A type definition has either the form $t:=l_t<r_t>$ or $t:=l_t\{r_t\}$. Where t is a type name, l_t is a label predicate and r_t is a CML over the set the type names and primitive types.

A type definition has two parts. The first is a label predicate that describes the valid labels of nodes. The second is a CML that is used to describe the sequence of children that a node may have. An expression of the form t:= l_t<r_t> defines a sets of data trees t whose root node is labeled with a label that satisfies l_t, its children are ordered and are describe by r_t. On the other hand, an expression of the form t := l_t{r_t} defines a set of data trees t whose root node is labeled with a label that satisfies l, its children are unordered and at least one permutation is described by r.

Definition 4. A schema is a set of type definitions, one of which must be declared to be the root type, i.e. whether roots of data trees can be assigned this type.

We need to define the semantics of a schema, i.e. the set of data tree that it models. Intuitively, a data tree D conforms to a schema S if it is possible to assign to every node d of D a type T_i from S, and d satisfies the label predicate and the CML of T_i.

Both RM and definition sections of archetypes can be modeled as a schema. Each type in the schema represents an RM/archetype entity, i.e. a class or an attribute, and the CML represent its structure. The label predicate describes the name of the entity or the valid domain of atomic attributes. As an example consider the class *PERSON* from Figure 1. It can be formalized by the type definition:

$$t_{\text{PERSON}} := \text{is\_}\ person(X)\left\{\left(t^{(1:1)}_{addresses}\, t^{(1:1)}_{name}\right)^{|2:2|}\right\}$$

where is_person(X) is a unary predicate that is true only when X is equal to the string "person" and $_{\text{t}}$addresses and t_{name} are the types that, respectively, model the attributes addresses and name.

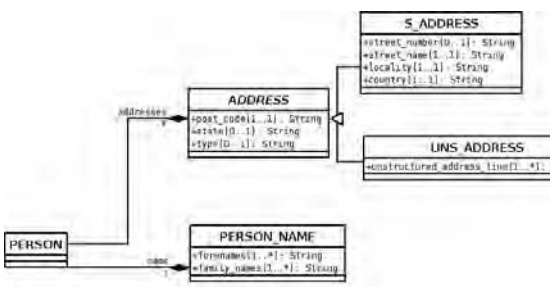

Figure 1 - Example of OO model

Let see how different types of archetype constraints are modeled with our type system. Existence constraints of attributes can be easily expressed by the CML attached to the type that models the attribute. Cardinality and occurrence constrains are mutually related. Actually, it only makes sense to constrain the occurrence of node objects that are inside a block introduced by a multi-valued attribute. Cardinality constraints can be modeled by the length constraint of CML while occurrence constraints by regular expressions. Alternative constraints for mono-valued attributes can be expressed by a CML whose length constraint is equal to |0..1| if the attribute is optional or to |1..1| otherwise, and the regular expression is of the form $t_1^{(0:1)}$.... $t_n^{(0:1)}$ where t_1,..t_n are the alternative types. Finally, domain constraints on primitive types are straightforwardly modeled as label predicates. As an example, let us consider the following ADL expression:

PERSON[at001] matches {
addresses cardinality matches {1..} matches {*
ADDRESS[at002] occurrences matches {0..1}
matches {...}
ADDRESS[at003] occurrences matches {0..}*
matches {...}
}

Which can be modeled by the following set of type definitions:

$$PERSON[at001] := is\_PERSON(X)\left\{\left(t^{(1:1)}_{addresses}\right)^{|1:1|}\right\}$$

$$t_{addresses} := is\_addresses(X)\left\{\left(t^{(0:1)}_{ADDRESS[at002]}.t^{(0:*)}_{ADDRESS[at003]}\right)^{|1:*|}\right\}$$

$$t_{ADDRESS[at002]} := is\_ADDRESS(X)\{...\}$$

$$t_{ADDRESS[at003]} := is\_ADDRESS(X)\{...\}$$

Archetype specialization

Archetypes can be defined by further constraining other archetype, i.e., by specialization, in order to obtain a more adequate or fine grained representation of a clinical concept. An archetype is specialized by providing narrower constraints on data. The overall idea is that all data instances that conform to the more specialized archetypes also conform to the more general but there can be data instances of the more general archetype which are not data instances of the specialized archetype. Multiple inheritance is not allowed. We formalize the inheritance relationship between archetypes by means of the subsumption relation [10], i.e., an archetype A is more general than archetype B if A subsumes B. The subsumption relation is also used to formalize the relationship between business concepts and archetypes, we say that an archetype A specialized a business concept B if B subsumes A. What makes the proposed subsumption relation interesting is that it not only captures the containment relationship between the set of data instances defined by two archetypes, but also captures some of the structural relationship between node objects from both archetypes.

Intuitively, subsumption is based on defining a mapping function () between types, on inclusion between both label predicates and languages defined by the CML of these types. All these can be translated to archetype specialization. Subsumption mappings specify specialization relationships between node objects and attribute object from parent and child archetypes. This is compatible with the syntactical rules used in ADL to specify the specialization of node object. In ADL specialization of coded concepts, e.g. PERSON[at0001], is indicated by using the same root, followed by an extension, e.g. PERSON[at0001.1]. Note that this defines partly the subsumption mapping, e.g. (PERSON[at0001.1]) = PERSON[at0001]. On the other hand,

inclusion of label predicates assures both that only class and attribute names from the reference model are used in archetypes, and the domain of atomic attributes in specialized archetype are a subset of the domain in the parent archetype. Finally, CML controls that super-types and subtypes have the same structure.

As stated before, RM and the definition section of archetypes can be modeled by the proposed type system. One interesting consequence is that "archetypable" classes of RMs can be considered as archetypes (from a data definition point of view). Therefore, the same logic can be applied both to the specialization of an exiting archetype or to the definition of a new one by constraining a RM class. This brings about the possibility of building flexible archetype editors capable of working with several RM or different version of the same reference model. This possibility has been explored in LinkEHR-Ed.

Mapping and data translation

Since the health data to be made public resides in the underlying data sources, it is necessary to define some kind of mapping information that links entities described in the archetype to data elements in data repositories (e.g. tables and attributes in the case of relational data sources). In the health care domain very few generic EHR data transformation efforts exist. Commercial tools with limited capabilities exist but they are mainly focused on the generation of HL7 v2.x or EDI messages and none of them supports archetypes. Furthermore, definition sections of archetypes can not be represented by XML schemas. Thus, current tools for data translation for XML schemas can not be used for this purpose.

In our scenario an archetype is considered to be a view that provides abstraction in interfacing between the data sources and the RM used to communicate the EHR extracts. Since EHR extracts have an inherent hierarchical structure, we have chosen XML as canonical data model, i.e. data sources are viewed a XML documents.

There exists two kinds of mappings: atomic attribute mappings and class mappings. Atomic attribute mappings define how to obtain a value for an atomic attribute of an archetype by using a set of values from the data sources. For this purpose rules relating a set of source paths to an archetype path identifying an atomic attribute are used. This kind of mappings preserves node paths from the root, i.e. the node contexts. It is possible for an archetype attribute to have more than one mapping and it also possible to utilize functions involving more than one source path (for instance the addition of the value of two source attributes). A rule may also contain a condition specifying the subset of values of the data source that can be used to compute values. Obviously, there must be at least one of this kind of mapping for each mandatory atomic attribute.

On the other hand, for each constrained class there exists a class mapping which contains both the query to be used to retrieve all the data necessary for generating data instances and the set of attributes that identify univocally the class instances. The combination of both components allows the conversion from source data to XML documents compliant with the RM. The query extracts the relevant information and for each different combination of values of the identification attributes a new instance of the class is generated.

Archetype designers are responsible of defining the atomic attribute mappings and the system tries to generate [11] from them a set of candidate class mappings by taking into account the structure of the RM entity being used, the archetype constraints and the integrity constraints of data sources. This approach alleviates the work of defining how to populate archetypes since it is easier for the designer to indicate which data elements of the data sources are relevant to a certain archetype attribute, rather than to specify the possible complex query required to extract and transform all the relevant information. As a result, an XQuery expression is generated, which transforms the XML view of the data source into an XML document that satisfies the constraints imposed by the archetype and at the same time is compliant with the RM.

Results

LinkEHR-Ed (http//pangea.upv.es/linkehr) is a visual tool implemented in Java under the Eclipse platform which allows the edition of archetypes that can be based on different RMs, mapping specification between archetype and data sources and the generation of data conversion scripts which generate XML documents compliant with the RM. Figure 2 describes the overall edition process. LinkEHR Ed is composed of four main components.

Reference model manager. In LinkEHR-Ed new reference models expressed as a W3C XML Schema can be imported at any time. Note that the XML Schema is supposed to describe the XML documents compliant with the RM. The import process generates archetype representations of the RM archetypable classes that will be immediately available as basis for the creation of archetypes by means of specialization. Currently, many of the characteristic of W3C XML schemas are supported, such as all the data types, name spaces, imports and includes (reference models can be defined by several files) and several structures such as complex and simple types, elements, attributes, inheritance by extension and restriction, sequence, choice, all, attributes, patterns and groups and their respective facets. Two reference models have been imported and used successfully: EN13606 and OpenEHR. The XML schema of EN13606 schema has been developed by us from the UML model due to the lack of an official one. For OpenEHR the official schema (actually a set of XML schemas) has been used [6]. This feature has been very useful in keeping in pace with their evolution without modifying a single line of code.

Semantic validation module. In LinkEHR-Ed only the logic that guides archetypes specialization, which is based on the subsumption relationship described before, is hard coded. This module, given an archetype, tests whether the archetype is valid with respect the RM entity that it constrains (i.e., it is subsumed by the RM entity) or in the case that there exists a parent archetype it test that its constraints are narrowed that those of the parent archetype (i.e., it is subsumed by the parent archetype).

Mapping module. It is in charge of managing data sources schemas, attribute mappings and the generation of candidate class mappings. Given a candidate class mapping, it generates an XQuery expression that outputs standardized XML EHR extracts satisfying all the constraints stated in the archetype.

Visual interface. LinkEHR-Ed provides two different interfaces, one for the health domain experts and one for the information technologies professionals. On the one side, the Health domain expert will be in charge of archetype definition and so they must have some knowledge about the RM they are working with. But the main idea for this perspective is to hide the underlying complexity of the system and the Dual Model architecture logic involved in the designing of an archetype as we can not presuppose any computer management skills for this expert. A set of available constraints and applicable restrictions is provided during design time. On the other side is the information technologies expert, who knows the structure of data sources of the organization and his role is to map the archetype definition tree nodes to them. A mapping definition interface fills nearly all this edition perspective. It is composed by a graphical representation of the archetype definition tree and a graphical representation of the diverse data sources available. Users can then add or modify mapping transformations between elements of both representations. In this case, LinKEHR-Ed can be seen as visual mapping and data translation tool.

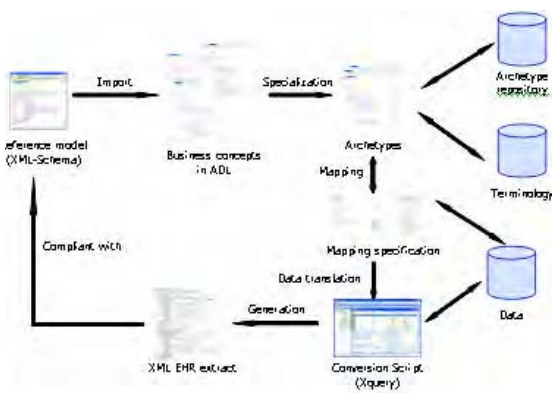

Figure 2 - Archetype edition and mapping process

Conclusion

In this paper, we have presented an archetype modelling framework and LinkEHR-Ed, a tool that allows the utilization of archetypes for upgrading already deployed systems in order to make them compatible with an EHR architecture standard. The overall objective is to maintain in-production systems and applications without any changes while providing a means for making public clinical information in the form of standardized EHR extracts, hiding technical details, location and heterogeneity of data repositories. Therefore, we use archetypes as a semantic layer over the underlying databases associating them with domain specific semantics. LinkEHR-Ed combines in an easy manner the formal representation of knowledge of a heath domain expert, represented by an archetype, with the mapping information to clinical data sources for semantic interoperability and standardization purposes.

Reaching Standards for Dissemination: A Case Study

Helen Christensen[a] **and Kathleen Griffiths**[b]

[a b] *Centre for Mental Health Research, The Australian National University, Canberra, Australia*

Abstract

At what stage are web applications ready for dissemination? A set of standards for efficacy, effectiveness and readiness for dissemination of (prevention) interventions has been developed by the Society for Prevention Research (SPR) (Flay et al., 2005)[1]. In this case study paper, we examine these standards criteria with reference to MoodGYM, an automated web application designed to reduce depression symptoms using cognitive behaviour therapy training. We examine evidence for its efficacy, its effectiveness in real world situations, and its capacity to meet recommended standards for dissemination. We conclude that MoodGYM has substantially met the standards of evidence required for dissemination. This successful application of the SPR standards to the evaluation of a web application, suggests that these prevention standards might be usefully applied to web/Internet context. Web applications might be assessed for dissemination by the International Society for Research into Internet Interventions (ISRII), or some other professional organization to assist policy makers in making decisions about the funding, adoption and promotion of applications.

Keywords:

internet, depression, efficacy, effectiveness, implementation

Introduction

Over the last 10 years, web applications have proliferated in the areas of mental health and substance abuse. This growth in the development and research of web applications is illustrated below using a review of the frequency of research papers identified using search terms for 'web therapy' trended for year from 1996 to 2003 (Figure 1)[2]. Web applications have been found to be both feasible and effective in reducing common mental health disorders such as anxiety and depression [3,4].

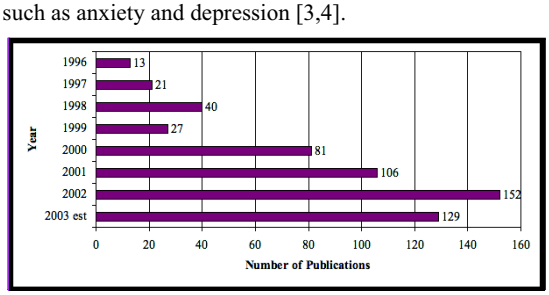

Figure 1 - Web therapy papers as a function of year

Policy makers and governments are now seriously interested in these applications, but they require guidelines for determining which applications are likely to yield positive public health outcomes, and which should be supported financially. One set of standards, which has been recently developed by the Society for Prevention Research (SPR), may be suitable, not only for prevention programs, but also for web applications designed as early intervention programs. Flay et al., 2005 [1] provide a set of 47 standards for efficacy, effectiveness and dissemination, which may prove to be useful in assessing web applications in terms of their success and their potential for implementation and wider dissemination. Currently, most web interventions are disseminated using marketing strategies, and their uptake is determined by market forces, consumer preferences and other factors. Little is known about the benefits or potential adverse effects of these interventions. Computer-based CBT programs have recently been endorsed by government bodies such as the UK-based National Institute for Health and Clinical Excellence, and it is likely that such bodies will similarly endorse Internet programs in the future. This endorsement will also be expected to drive demand.

In this case report paper we describe the research taken to establish the efficacy and effectiveness of a web intervention – MoodGYM –an application designed to reduce symptoms of depression in community users. We ask (i) whether it meets the SPR criteria for efficacy, effectiveness or dissemination, and, if not, (ii) what additional research might be required. We also (iii) comment on the potential usefulness of SPR standards in the evaluation of web applications.

In the SPR standards, the demonstration of *efficacy* requires the demonstration of positive treatment outcomes under optimal conditions: The following are required: clear description of the project, and clearly stated outcomes [decrease in depression symptoms, over a (minimum) six month period, using psychometrically sound measures, with one form of data collection not susceptible to demand characteristics]. The strongest form of control design should be used where possible (RCT), and the sample requires definition, [how it was obtained], the statistical analysis should be unbiased [intention to treat, adjustment for pretest differences, differential attrition adjustment, correction for experiment wise error]. At least two different high quality studies/replicates must exist. Desirable standards include process variable measure-

ment, and measures of side effects [See Flay for more details [1]].

Effectiveness studies focus on the importance of the project in real-world situations, implementation procedures, fidelity and adaptation (p. 153). Standards include the provision of manuals and technical support, the delivery of the project, as in the real world, with a clear statement for whom the intervention works. The level and integrity of the intervention, in addition to the level of engagement is needed, including measures of adherence, and or involvement in both the control group and the treatment group. RCT designs are required, although often more difficult to implement. The sample investigated should be the sample for which the application is targeted. A desirable standard is replication with different responses. The practical importance or public health impact of studies requires assessment. Examples include cost effectiveness, effect size measures and percent relative change. Replication is also required.

Programs worthy of *dissemination* must meet all requirements for efficacy and effectiveness, as well as additional standards for dissemination such as training of staff, and the provision of project support materials. The criteria include: the provision of provider materials, and evidence that the program can be implemented with fidelity, evidence for scalability, and exact estimates of cost. Monitoring and evaluation tools must be available to providers (p.167). A desirable standard is "a clear statement of the factors that are expected to assure the sustainability of the program or policy once implemented".

Materials and methods

Checklist and raters

A checklist of standards was constructed based on the Flay et al. criteria. We reduced the number of SPR criteria from 47 to 19 in order to summarize outcomes within the space of this report. To achieve this some sub-criteria, definitions and some outcome criteria were not included. All published or completed research reports of the MoodGYM website were collected. Two raters reported whether the MoodGYM site reached standards for efficacy, effectiveness and potential for dissemination. Any difference between raters was resolved by references to criteria and published reports.

Results

Efficacy Standards

All of the required standards for efficacy were met by the MoodGYM application, although one of two desirable standards was not met. The MoodGYM website provides a clear indication of its content and aims (http: moodgym.anu.edu.au). An efficacy trial published in 2004 compared the website to an attention placebo control condition (health coach) and to a psychoeducation site (BluePages) using participants from a community sample with elevated depression symptoms, recruited by survey using addresses from the Australian Electoral Roll [6,7]. An intention to treat analysis demonstrated that the effects of the website persisted at 12 months follow-up [8]. Figure 2 illustrates that both MoodGYM and the psychoeducation site were associated with better outcomes immediately, and at 6 and 12 months. A second study has now been undertaken of the use of the website in 29 schools around Australia, using a clustered randomized controlled trial design. Although not complete (two of the 29 schools currently in the intervention phase of the project) and the long term follow-up is yet to be collated, there is evidence of a small effect for the (Universal) intervention in students in Years 9 or 10 (mean age 14.3 yrs). An additional efficacy trial has been completed in Norway which found that MoodGYM (in combination with BluePages) reduced depression symptoms compared to a control condition [9]. A New Zealand trial is about to commence. The day-to-day implementation of these trials is under the control of researchers external to developers. The MoodGYM site measures a number of variables that might mediate the effect of the website on the reduction of depression symptoms. The major measure is the Warpy Thoughts Questionnaire. This questionnaire was developed by the Centre for Mental Health Research (CMHR), and has been validated against other scales of dysfunctional thinking. The users of the site record scores on this questionnaire three times over the course of the intervention. In the first instance, this permits the calculation of correlations between symptom change and thinking style [10]. A second desirable criterion for the efficacy of a trial is a measure of side effects. MoodGYM does not explicitly collect information on side effects. This represents a common omission in psychological therapy studies, but one that requires rectification.

Effectiveness standards

The 8 criteria for effectiveness are outlined in Table 1.

The MoodGYM application provides a user manual and a clinician manual which can be purchased from the CMHR website at http://www.anu.edu.au/cmhr/shop.php. The user manual provides basic information on access to the site and trouble shooting for technical problems. The clinician manual provides week-by-week instructions, which allow clinicians to implement the self-help program with clinical populations, and normative data on website users.

Table 1 - SPR Criteria

Simplified Standards Criteria (Society for Prevention Research)	
Criteria for Efficacy	**Rating**
Clear description of project (R)	**Yes**
One high quality RCTs (ITT, sound measures) (R)	**Yes**
Long term follow-up (at least 6 months) (R)	**Yes**
Additional long term high quality RCT (R)	**Yes**
Process variable measurement (D)	**Yes**
Measures of side effects (D)	**No**
Criteria for Effectiveness	**Rating**
Provision of manuals and technical support (R)	**Yes**

Simplified Standards Criteria (Society for Prevention Research)	
Evidence of delivery in the real world to target (R)	**Yes**
Level of exposure, engagement and adherence (R)	**Yes**
Two RCTs in identified settings (R)	**Current**
Replication with different samples (D)	**Current**
Cost effectiveness (D)	**Yes**
Dose analyses (D)	**Yes**
Demonstration of public health impact (R)	**No**
Criteria for Dissemination	**Rating**
Provision of provider support and fidelity (R)	**Yes**
Evidence for scalability (R)	**Yes**
Clear cost information available (R)	**No**
Monitoring and evaluation tools (R)	**Yes**
Factors to assure sustainability (D)	**No**

Note: R=Required, D=Desirable.

One of the advantages of the MoodGYM application is that it is both automated and self-directed. As such it requires less intensive training for those who implement it, especially in comparison to face-to-face interventions. Technical support is available via an email address posted on the site. One potential problem with the application when used outside a research trial that incorporates interviewer-instigated tracking is its failure to engage all registrants for the complete program of five modules. Studies of usage [11] and mental health change suggest that treatment benefits are obtained once two or more modules are accessed. As many spontaneous users engage with the site for more than this number of modules, we believe that adherence level is relatively acceptable for a proportion of users. Moreover, the interpretation of drop out from web applications, where there is no expectation held by most users that they are required to engage for hours of therapy online, is less straightforward than conventional drop out in non-Internet RCTs. Many users may well attain what they set out to achieve in two or three modules rather than the full six.

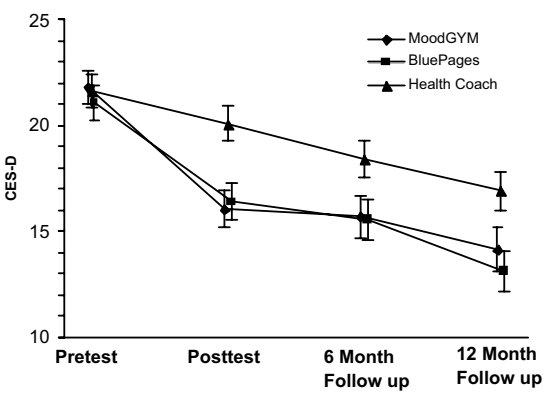

Figure 2 - Least squares means for CES-D estimated using time by condition model with unstructured covariance matrix. Note: CES_D: Higher scores indicate higher levels of depression symptoms [8]

MoodGYM has not yet met the standard of two randomized controlled effectiveness trials, although comparisons of spontaneous users and those in our first randomized controlled trial were positive [12] and the schools trial, mentioned earlier, is both an efficacy and effectiveness trial as it is implemented in real world conditions. An additional study is currently in progress, evaluating MoodGYM's effectiveness in a general practice setting. Results from these evaluations may well provide the necessary evidence of effectiveness.

A study of the cost effectiveness of MoodGYM has also been conducted. There are few cost-effectiveness studies of Internet programs, although one computerized therapy program used in general practice settings has been assessed to date [See Kaltenthaler et al, 2006] [13]. Cost effectiveness analysis is particularly interesting for Internet programs given the scalability of Internet applications and their very low marginal costs [14]. The cost effectiveness study indicated that MoodGYM (M-CBT) was dominant over conventional treatments consisting of a general practitioner-delivered anti-depressant medication (GP-DRUG) and psychiatrist led cognitive behaviour therapy (P-CBT). The above assumes a similar level of efficacy for therapist administered CBT, for anti-depressant medication and for Internet CBT. A separate randomized controlled trial of community users found that different components of the program were associated with improved outcomes [15], but, in particular, that extended CBT component of the program was associated with large effects.

A final effectiveness criterion is the demonstration of the public health benefit of the application. This has not yet been conducted.

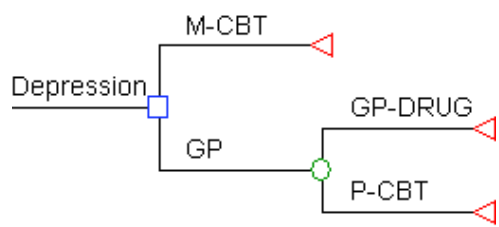

Figure 3 - Cost effectiveness comparisons. M-CBT=MoodGYM, P-CBT=Psychiatrist CBT and GP-DRUG=General Practitioner Anti-depressant medication[14]

Dissemination standards

Of the identified five standards in Table 1, MoodGYM meets three. These are fidelity, scalability, and monitoring tools. Fidelity (as in the provision of the exact user experience of the website) is guaranteed in automated web applications (although there is no guarantee that each user will access all pages in a similar way, or even receive the same pages if the application is personalized or tailored). The site is also scalable, with over 160,000 registrants, and up to 14,000 visitors a month. Moreover, organizations or researchers are able to download SPSS formatted data

from their specific trials or organisations, to allow monitoring and evaluation. MoodGYM is currently offered free of charge to users on the World Wide Web. The costs of the development and maintenance of the MoodGYM website are borne by our research group within a University. Clearly, this model of funding the site is not sustainable. The capacity to provide the service will cease when the research agenda has concluded or grants are completed. This as-yet-to-be developed model for sustainability represents the most serious threat to meeting the criteria for standards for dissemination.

Discussion

Usefulness of the efficacy, effectiveness and dissemination standards

There may be merit in examining web applications with reference to the standards developed by the Society for Prevention Research. In this study, the areas in need of further research and development to reach standards for the MoodGYM site were relatively easily identified. For example, we identified the need to investigate and include side effect assessment in our online MoodGYM satisfaction questionnaire (available from the menu), and to consider methods to estimate the public health impact of our intervention more systematically. The review of the web application against the standards criteria suggests possible areas for the refinement of the criteria. For example, it is sometimes difficult to distinguish for automated applications such as MoodGYM whether an intervention study should be classified as an efficacy study or an effectiveness study. Some aspects that differentiate an efficacy from an effectiveness trial of a psychological intervention may be less relevant in an automated application. For example, in contrast to human-delivered therapy, automated delivery of web therapy ensures fidelity of treatment content whether or not the intervention is delivered in a research or specialist environment. Another potential area in which the SPR might be profitably refined relates to the definition of an acceptable 'control' group. Although there is a large 'effectiveness' trial of the MoodGYM site which was conducted entirely online [14], it does meet the specified criteria for an effectiveness trial, as the criteria state that the comparison group must be one of waitlist, attention placebo or TAU. In this trial, which is offered directly to users, the control condition was a one-module version of the site. Perhaps effectiveness trials could be permitted to include a minimal intervention condition as a control.

Advantages of web applications

This exercise of comparing MoodGYM against the standards criteria reveals the strengths of web applications compared to non-Internet interventions. For example, because of the capacity for tracking, web applications should be particularly strong in comparison to face-to-face interventions in the following areas: determining dose responses, process evaluation and the collection of routine implementation and evaluation data. Demand characteristics might be reduced by self-report data submission. Websites can be readily disseminated, and dissemination will occur regardless of whether a website meets the SPR or other quality standards. This underscores the importance of researchers and policy makers introducing standards like these to rate the readiness of applications for dissemination.

Major problems for sustainability

A major problem we identified for the MoodGYM site was lack of sustainability. A number of methods to financially sustain the site might include a user-pays system, an employer-pays system for the workforces of large organizations, or a health company pays system delivered via health maintenance organizations. However, as developers of the site, we preferred to offer the site free of charge to individuals with mental health problems with the aim of maximising the potential public health impact of the application. To offer cost-free access, the site needs to gain support from government. The mechanisms within government to offer this support must be in place, and this itself may be a stumbling block. Because of the international nature of website applications, it is difficult to determine how users from different countries might contribute. For example, the MoodGYM site is regularly accessed by users of the UK National Health Service. There may be some capacity here for governments to agree to contribute to costs of approved sites. However, at this stage, in Australia, the sustainability for public health websites is yet to be convincingly demonstrated.

Conclusion

The standards of evidence for prevention research might be usefully applied to web/internet interventions. Web applications might be assessed for dissemination by the International Society for Research into Internet Interventions (ISRII), or some other professional organization to assist policy makers in making decisions about the funding, adoption and promotion of applications.

Acknowledgments

The authors are the developers of the MoodGYM site. The site is supported by e-hub at the Australian National University.

A Discrete Time-Space Geography for Epidemiology: From Mixing Groups to Pockets of Local Order in Pandemic Simulations

Einar Holm[a], Toomas Timpka[b,c]

Abstract

The World Health Organization urges all nations to develop and maintain national influenza preparedness plans. Important components of such plans are forecasts of morbidity and mortality based on local social and geographic conditions. Most methodologies for simulations of epidemic outbreaks are implicitly based on the assumption that the frequency and duration of social contacts that lead to disease transmission is affected by geography, i.e. the spatial distribution of physical meeting places. In order to increase the effectiveness of the present methods for simulation of infectious disease outbreaks, the aim of this study is to examine two social geographic issues related to such models. We display how the social geographic characteristics of mixing networks, in particular when these significantly deviate from the random-mixing norm, can be represented in order to enhance the understanding and prediction of epidemic patterns in light of a possible future destructive influenza pandemic. We conclude that social geography, social networks and simulation models of directly transmitted infectious diseases are fundamentally linked.

Keywords

health informatics, methodology, social geography, epidemiological modeling, simulations

Introduction

In response to the threat of a destructive influenza pandemic similar to that of 1917-1918, the World Health Organization urges all nations to develop and maintain national influenza preparedness plans [1]. Important components of such plans are forecasts of morbidity and mortality based on local social and geographic conditions. Such forecasts require both surveillance of disease activity and simulations of disease dissemination. Epidemiological simulations of contagious diseases based on social network theory, where hosts and contacts are modeled as 'actors' and 'relations', have attracted considerable attention [2,3,4]. While an arbitrary level of complexity may be included in network and agent-based simulations of spatial epidemics, computational intensity and analytical intractability mean that such models often lack transparency into the determinants of epidemiological dynamics. Another approach to simulation of epidemics is based on stochastic models. These strategies have the advantages that they are computationally less complex and also can be validated using quantitative epidemiological data. Discrete-time, stochastic simulations have been used to study both the dissemination of infectious diseases and the outcome of interventions. To deal with the unrealistic assumption of homogenous contact patterns in large populations, individuals are usually allocated at each time step to discrete places, with specific localized mixing groups, where within social mixing is assumed to be more homogenous than between [5,6]. The computations in such a mixing group simulation can hereby be reduced to mixing people in the discrete spaces with homogenous mixing, while maintaining the dynamic state of infection of each sample person at each time step. Although numerous approaches have attempted to resolve the complexity-tractability/validation trade-off between social network-based and stochastic simulations, there is today no established solution to the problem.

A social geography of infectious disease

The available methodologies for simulations of epidemic outbreaks are implicitly based on the assumption that the frequency and duration of social contacts that lead to disease transmission is affected by geography, i.e. the spatial distribution of physical meeting places of different types. However, current socio-geographic concepts and empirical findings have seldom been adequately applied to specify these assumptions. It is for example only the neighborhood around the living place that increases contact probability only for spatial reasons, i.e. the closest neighbors within some 100 meters to 1 km range [7,8]. Beyond that, the organization of workplaces and other meeting places are primarily not spatially but socially stratified. If the work place, friends, relatives, or shopping mall, etc. are around the corner or 20 km away does not significantly influence behavior; these places are still visited in favor of random places that are closer. The next distance that matters somewhat is the dwelling area (cp. village), say within some 3 km range. In Sweden, one third of the working population have their place of work within that range, often also a local shop, a primary school, and a day-care center. Obviously, the likelihood of meeting others at such a place chosen at random is larger than beyond. But more impor-

tantly, already within this spatial scale, you will almost never visit the other majority of workplaces, inhabitants, etc., except for your own specific ones. Once selected, they remain fixed with respect both to location and members for the duration of a pandemic. Next level that might matter is municipality range, approx. within 30 km (cp. the municipality). Most of everyday work (two thirds) and services are situated there. The following boundary is an extended commuting distance, approx. within 100 km (cp. county). Although, it is a relatively small fraction of the population that interacts daily on that distance. For instance, the median commuting distance all over Sweden is approx. 5 km. Beyond that, we have low frequency meetings within and outside the country more or less regardless of how many there are living in between or the distance. This low frequency travel is, however, important for the initial transmission of disease between regions.

A realistic social geographic representation is not the same as a mapping of the socio-spatial trajectories of all individuals in a population in full detail. Contrarily, most of such intrinsic peculiarities probably have minor impact on general transmission of infectious diseases and should therefore rather be modeled by help of more abstract entities with random variations. This is also the most prominent property of the mixing group model for stochastic simulations of epidemics. The most important thing is instead to represent the relevant discrete spaces of close contact, i.e. the only places where the transmission of infectious agents occur. Second is the spatial configuration of these meeting places, with Hägerstrands terminology, "the pockets of local order" [9]. They are constructed by people in order to perform activities for certain projects that must be done at a particular place and to shield these from destructive outside influences [8]. The spatial configuration is mainly a constraint on the initial set up and choice of meeting places. It can in most cases be regarded as a constant for the duration of the pandemic, not changing the set of participants at the places.

Study aims

In order to increase the effectiveness of the present methods for simulation of infectious disease outbreaks, the aim of this study is to examine two social geographic issues related to such models:

1. Contact endurance at meeting places. Most mixing groups used in simulation models represent the mixing of more or less the same set of individuals day after day during the evolution of the pandemic. The degree to witch this is the case is one of the most important distinguishing features between mixing groups and should be explicitly considered for modeling.
2. Social vs. ecological fallacy. In a mixing group simulation, populations are divided into submodules based on, e.g. municipalities or counties. Such regionalization that is heterogeneous with respect to distances, from a few hundred meters to hundreds of kilometers between random inhabitants. Depending on context this distance may or may not matters for whom you will meet, but not if it is 200 or 20000 people in between. In either case, most of those latter individuals you will never meet.

This paper reports from a research program aimed at supporting pandemic response planning by simulations of contagious disease outbreaks in local public health contexts [10,11,12]. The methods section of the paper outlines the basic theoretical concepts necessary for application of social geography in the context of influenza pandemic simulations. The results section presents an application based on the Swedish ASTRID database. The final section summarizes the paper and draws conclusions.

Materials and methods

Mixing groups as social pockets of local order

Our approach to inform models for simulation of pandemics by social geography is to transfer Hägerstrand's concept of 'pockets of local order' to homogenous localized population mixing groups. A network structure is used to represent the mixing groups as nodes with contact frequencies between individuals within them as well as the other properties of social pockets. Instead of a fixed arbitrary hierarchy of household groups and regions, we suggest a system of meeting place centered, floating, overlapping reference areas. We propose the following structure for modeling of the time individuals spend at social pockets.

1. Close neighborhood (100-1000 m^2around the family residence)
2. Dwelling area (range 3 km around the residence)
3. Municipality range (30 km around the residence)
4. Extended commuting range (100 km around the residence)
5. Rest of nation and world.

The reference spatial entity is the family residence, where the infection enters and is distributed out with the family members. In principle, each family has its own unique set of ranges with a unique localization of the different types of meeting places for each individual family member. Their closest neighbor has almost the same range attributes but the set of meeting places within the ranges are very different for the individual members of each family. Information on the location of the meeting places is almost only necessary because of our interest in the spatial outcome of the disease diffusion. For global results, the individual flows between, and the characteristics of the meeting places would be enough.

A network representation of mixing groups

A central question for epidemic modeling is how to represent a differential description of who meets whom, how close and for how long time and how to represent the interaction (flows of people) between different geographical contexts. We know relatively well people's behavior with regard to their social contracts (employments, compulsory schools, etc.) and can model visits at corresponding social pockets accordingly. What needs to be dynamically modeled is the time spent in pockets that are visited during leisure time. Following pockets of social order with rele-

vance for transmission of infectious disease can be identified:

Reference pocket with fixed location and mainly fixed set of mixing subjects

1. Family residence (by type, size)

Pockets regularly visited by social contract with the same subjects

2. Place of work (by size, type of employees and social mixing patterns)
3. Day care center (specifically)
4. Primary school (specifically)
5. Other education

Pockets visited at random occasions with the same subjects

6. Relatives' homes (grandchildren, former wife etc.)
7. Friends' homes (a large part of social interaction goes on here)

Pockets visited at random with random new subjects each time

8. Public services and entertainment

Transition pockets (random or fixed occasions, random subjects)

9. Local daily travel with public means of transport (commuting, train, air transports - short duration but sometimes close contact with new people)

Transitions (movements between communities)

10. Short and long haul recreation and leisure travel
11. Business travel (rapidly growing, partly replacing commuting and migration)

Table 1

Social pocket	n	*p (c)*	*p* (t)	Contract
Family home	1-7	0.3-0.6	0.12	Yes/No*
Workplace	20	0.06	0.12	Yes

* Relatives and friends visiting a family home do not own or rent the facility.

Table 1 displays some characteristics of such social pocket types. The contact probability ***p*(c)** reflects the probability for any person visiting the social pocket to meet one single person in the pocket, while ***p*(t)** reflects the probability of transmission of the infectious agent at a given contact. Estimates are from Swedish data and the literature [5,6,13]. This representation is mainly consistent with the mixing group model. A spatially explicit mixing group simulation can thereafter be divided into two stages. At the first stage, an abstract representation of contacts based on social contracts is generated from spatially explicit population data using fixed types of social pockets and itinerary types specific for age-group and socioeconomic categories. Each person is initiated by allocating the person first to an age-specific itinerary type, thereafter to the relevant types of social pockets, and finally to instances of social pockets, , called local pockets (localized mixing group) from the database. That allocation is based on observed or estimated cross sectional frequencies for each of the social pocket types over each of the ranges for certain groups of individuals.

Table 2

Age	1km	3km	30km	100km
0-6	Own home *17.5/7*		Day-care center *3.5/5* or Family day-care *3.5/5*	
7-15	Own home *4/7*	Primary school 5/5		
16-19	Own home *14/7*		High school *5/5* Short-distance transports 0.5/8	
20-64	Own home *14/7*			Workplace 5/5 Short-distance transports 0.5/8
65-	Own home *17.5/7*			

Using empirical data, the patterns for visiting the social pockets can thus be represented as itinerary types for regularly visited social pockets and for arbitrarily visited pockets, respectively. While the pockets visited by social contract can be represented by one particular mixing group instance (school, workplace, etc.) during the instantiation, the arbitrarily visited social pockets are randomly instantiated (as one or several local pockets) within the corresponding geographical region determined from the individual's place of residence. Table 2 shows itinerary types for pockets visited by social contract displayed by concentric geographical regions determined from the individual's place of residence. Numbers in italics indicate 8-hour time units spent in the pocket per week and number of visits per week (8-hour units/visits).

Table 3 shows itinerary types for arbitrarily visited mixing groups displayed by concentric geographical regions determined from the individual's place of residence. The examples in the results sections are based on structures and data from the ASTRID database covering the Swedish population (9 million).

Results

Mixing-group instantiation of social pockets

In our instantiation of the social geographic model for epidemiological simulations, each social pocket type I has type specific properties, such as the average disease passage between pairs of visitors (infectious or susceptible) per unit of time. In order to enable adjustments to different infectious agents, this risk is factorized into contact probability per time unit and transmission risk per contact. The specific instances i of I are given the same properties as the type, and provided a random variation reflecting observed empirical distributions. In addition each i has a location and size etc. The outcome probability for a specific infectious/susceptible pair is also affected by those persons' individual properties.

Parameterization of individuals

Parameters for each individual is derived from the ASTRID database. The basic object in this modeling approach is each individual person p in the country. All other local pockets are relational properties of the person but also when convenient objects by themselves. The approach lends from time geography, micro simulation and agent based simulation [14,15]. Each person p has a set of individual properties (age, sex, education, origin, income, mother, family etc.). Person p's family f has other properties common to its members (single, adults only, child family etc., size, location, housing type etc.) Person p also has individual relations r(I) to the social pockets types I visited by social contract (work, day care, school) and those visited less regularly but within a small set of persistent members (friends' and relatives' homes) and those visited irregularly with random members (public services, entertainment, long-distance travel, etc.). For the duration of a pandemic, p's properties, including location and social composition of family and meeting places, can be regarded as fixed, i.e. as an itinerary. For example, suppose that the partly overlapping ranges (family, 1 km^2, 3 km neighborhood, 30 km commuting distance, and 100 km regional range) are outlined for two (p and q) out of the nine million localized individuals in the database. Say that two example local pockets, a school and a workplace are in place. The school might be within reach only for q whereas both p and q might work at the work place. The floating ranges are only used as a tool for the initial allocation of persons to local pockets. When that is done, the resulting set of "arrows", the network of connections, is the only thing necessary to feed into the simulation.

Each person also is given an individual computed state with regard to the disease. The only property that has to be dynamic is the person's current infectious status. The set of people m(i) "mixing" at each specific social pocket i of type I, consists of persons being members of pocket i (p.r(i).member = true). That set is therefore also fixed for all persons and local pockets (meeting places) during simulation by the individual properties of the persons as derived from the database.

Simulation

When running the simulation, a population is first broken down in administrative-political segments (by residence) and then divided into standardized units. The division into standardized units is, among other reasons, based on the necessity to validate the simulations against historical data. For each time step (8 hours) each person in the population is exposed to a context, time and person specific computed probability to transmit and receive the disease at each mixing group and thereafter updated accordingly to the outcome of the lottery. The consequence events are then conventionally modeled without time delay either immediately after the transmission or for aggregates at the end of the time step.

After that the table for simulation is set and fixed, the main property changing value during simulation is the persons current infectious status. In a more elaborate model also other dynamic response actions can be introduced, like keeping children at home instead of at day care or school before they become infected or that hospital personnel obstruct by staying home from work in order to avoid personal risk. Such behavior responses can only be based on vague and anecdotic evidence but it is nevertheless crucial to enable such hypothetical experiments.

Discussion

Social geography, social networks and the epidemiology of directly transmitted infectious diseases are fundamentally linked. The foundations of epidemiology and early epidemiological models were based on population wide random-mixing, but in practice each individual has a finite set of contacts to whom they can pass infection; the ensemble of all such contacts forms a 'mixing network'. Knowledge of the structure of the network allows models to compute the epidemic dynamics at the population scale from the individual-level behaviour of infections [16]. We have in this study displayed how issues related to the social geographic characteristics of mixing networks, in particular how these deviate from the random-mixing norm, can be resolved in order to enhance the understanding and prediction of epidemic patterns in light of a possible future destructive influenza pandemic.

Abstract

The role of standards is constantly increasing in health services, electronic health records, and eHealth applications. There are many areas of standardization which affect the healthcare work and health information systems. On a national level, the organization of the development and support for standardization should be a key priority. This paper summarizes a national study in Finland which reviewed the current status of eHealth standardization and made recommendations for the national standardization and the use of standards. The recommendations are related to the organization model and balanced participation, international and cross-domain collaboration and quality assurance of standards-related activities. In addition, education and support services and support for introductions and pilots are recommended to improve the know-how of standards in system acquisitions.

Keywords:

standardization, interoperability, eHealth, health information systems

Introduction

The role of standards in eHealth and national initiatives

The provision and use of health services are facing increasing change pressures. The aging population, recruitment problems, biomedical advances, diversity of treatments and examinations, and increasing need of services by the elderly and by those having multiple diseases are seen as international trends [1, 2]. On the other hand, the national and international health and economic policies affect the market of the eHealth solutions. For example, the transition from hospital-centric to patient-centric and local health service provision has been seen as a pan-European trend [3]. On the other hand, specialized services such as clinical laboratories are transferred to large specialized units, for example in Finland. Electronic health information is increasingly used to improve quality and to enable new care models and treatments [1]. Healthcare networks require connections between disparate healthcare units and professionals. These needs are reflected in the requirements of eHealth applications and information systems.

One of the central challenges for electronic health services is the *interoperability* of eHealth solutions [4]. Health information systems contain lots of diverse information which have to be preserved and used for a long time. Large amount of new information and knowledge is constantly emerging in healthcare [1]. In addition, information is often sensitive or has accountability requirements. It has been observed that in general, the interoperability of eHealth applications and health information systems is far from optimal. This is partially due to the fact that *standards* are missing, their existence is not known, or they have not been implemented to an adequate extent [2].

A central goal of the national health project in Finland is to produce interoperable national electronic healthcare records. This includes national solutions for the long-term storage of electronic patient records and a secure access to the patient records by health service providers, patients and other actors [5]. The national architecture requires that the electronic patient record systems correspond to the national specifications as well as the establishment of national healthcare IT services. These services include an electronic archive and related services for the registration of documents as well as solutions for messaging. The realization of the architecture requires steering by the

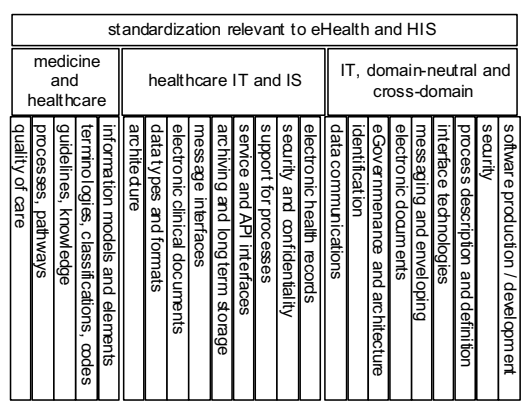

Figure 1 - Areas of standardization addressed in the study

authorities and the establishment of an actor that is responsible for the implementation of the national services. Shared standards are a key factor in pursuing these goals. In addition to Finland, similar large-scale projects are underway in many countries. One central component of these initiatives is the promotion of the standardization of the healthcare IT.

This paper presents the central results of a study which aimed to document the current status of the national healthcare IT standardization in Finland and to identify and suggest improvements in the organization and development of standardization and the use of standards.

Dynamics of standardization

To illustrate the context of this work, we briefly discuss some aspects of standardization as a basis for this study. A *standard* is a document approved by an accepted body which contains rules, guidelines or features for generic and repeated use in products, processes or services [6]. In general, standardization has many meanings and motivations [7]: the *uniformity* of production, the *compatibility* of technologies, the *objectivity* in measurement, the means for *justice* and a form of *hegemony*. Out of these goals, compatibility in the form of *interoperability* of software applications has been emphasized in recent years. Rapid change, global connectivity and the need for systems to interoperate are also increasingly evident in the future [8]. However, there is a wide range of interoperability standards available, both on healthcare-specific and domain-neutral levels. The lack of implemented standards hinders the development and use of healthcare knowledge, causes risks to the patients and sub-optimal use of resources [2].

Central tasks related to standards include the organization and steering of the standards work, the production and use of standards (experiments, introduction and use in products and procurements), education and support services, and the evaluation of standards and products conforming to them. The tasks are different in various phases of the lifecycle of standards, and they affect different participants. Standardization organizations are only responsible of some of the costs of these activities.

Most standardization organizations emphasize the creation of standards as a response to the *needs expressed by the companies and users*. On the other hand, standards are created as a result of complex *social negotiations* [7]. These viewpoints to the creation of standards (functionalistic and constructivistic) emphasize the quality and accuracy, and the acceptance and dissemination of standards, respectively.

In health information systems, standards support the *vision of open systems* which can be complemented with new products. The direct benefits of eHealth standards provided for healthcare organizations, professionals and patients include the reduction in costs and errors, and improvements in care quality, usability, work practices and the availability of information. In addition, the application developers must attain advantages from the use of standards, such as new markets, consistent and accurate requirements, improved integration with partners, specialization possibilities and reusable models for subsystems or interfaces. In addition, healthcare financiers, medical research and the government benefit from standardization [3,2].

However, several problems related to standardization have been identified. Standards and standard families are incompatible and overlapping. Despite many standards available nationally and internationally, the introduction and assignment of different standards has not been completed. As the participation in the standards work is voluntary, not all relevant areas of standardization have been considered. In addition, the participation has been based on personal interest and it has not been properly coordinated, organized or resourced.

Materials and methods

In November 2004, the challenges and problems of standardization were considered in a meeting by the representatives of the Finnish Ministry of Social affairs and Health, Ministry of Trade and Industry, the Association of Finnish Local and Regional Authorities, the Technical Research Centre of Finland (also representing HL7 Finland), the National Research and Development Centre for Welfare and Health, the Finnish Agency for Technology and Innovation TEKES, the University of Kuopio and the Savonia University of Applied Sciences. In conclusion, it was acknowledged that standardization is an important enabler of the health service provision, the development of the national economy, and the growth of the small and medium enterprises. The lack of sustained solutions for the development, utilization and participation in standardization was identified as a central challenge. The action was taken to produce a report which would review the previous studies and recommendations and combine them with a wider view of standardization. The result of the study would be recommendations for the improvements in the development of activities related to standardization on a national level.

The work was scheduled from December 2004 to March 2005 for two projects funded by the Finnish Agency of Technology and Innovation TEKES. A *literature survey* was first performed, and national and international recommendations for eHealth standardization were reviewed, e.g. [3,4,9,10,2]. The study also produced a description of central *international and national actors* in eHealth standardization and a description of the *different areas of standardization* related to eHealth and health information systems. In addition, a previously defined framework for the evaluation and selection of standards was updated. The standardization areas were intentionally described from a wider view than only health IT to identify relationships and improvements beyond healthcare-specific considerations (see Figure 1). The standardization areas were divided in three main classes: the standards requiring specific medical or healthcare knowledge, the standards requiring a combination of IT and healthcare skills, and the IT or domain-neutral standards relevant in healthcare. These classes have some correspondence with the specificity levels and perspectives of the health informatics

profiling framework by ISO TC 215 [10]. The notion of complementary standards to allow the modular construction of solutions [4] was one of the guiding principles in the identification and classification work.

After the identification of the main actors and areas, data collection was designed to survey the *current status* and the *target state* of the field. A recent web-based survey from the SerAPI project which included questions related to the responsibilities of integration and standardization was used as a basis. The survey was continued with an e-mail survey to named experts in different organizations (hospital districts, companies, organizations in the board of the project). This survey had four main categories and 60 detailed points. The main categories were the goals and policies, areas of standardization, activities related to standardization and the objectives for improvement. Each respondent received questions from two or three categories to lower the response threshold.

The questions of the e-mail survey were also discussed in several meetings with various experts. The number of responses in the web-based survey was 10 (of 18) and in the e-mail survey and meetings 13 (of 18), the total response rate being 66,7 %. In addition to the surveys, interviews were performed with several experts responsible of the different areas of official and industry standardization. Furthermore, the participants of the project board reviewed the work in two mid-project meetings. The results of the literature survey and the data collection were then used by the authors who wrote the descriptions of current and target state, and other parts of the report.

The main result of the study was the description of current status and issues and a set of recommendations related to the standardization of healthcare IT. For the recommendations, the material of the study was combined with the personal experience of the authors. The results of the study were published in a 92-page report in Finnish for further actions [11].

Even though the work covered many areas, the application of standards was delimited to consider mainly *health information systems*. This was due to the fact that the majority of challenges of the national project and of the hospital districts were related to the interoperability of these systems. Excluded were also the devices and device interfaces, for example the medical equipment. In addition, the scope of the work was limited to open standards and specifications, and it did not consider internal implementation technologies of applications or development models such as open source.

Results

The results of the surveys and interviews

The respondents of the surveys and interviews saw the quality assurance and applicability of standards as a key factor in relation to the *goals and policies* of standardization. In addition, the usability requirements and pragmatism of standards were emphasized. Fast introduction and implementation were highlighted by software companies, as well as consistent solutions across different business domains. However, the opportunities of international markets were not among the most central goals. There were conflicting views regarding the special consideration of the existing systems in relation to standards, as well as the need for accurate identification of specific fine-grained standards versus widely applicable frameworks.

According to the respondents, the most central *areas of standardization* were the consistency in the support and specification of healthcare processes, the structure of information, data types, semantic consistency and the storage of electronic patient documents. In addition, unified information models and desktop integration were among the most important areas in some responses. Terminologies, codes, knowledge, shared IT services and workflow support were advocated to some extent. There were different opinions about the necessity of the standardization of architectures, security solutions and many technical or domain-neutral aspects. The code sets and information models were seen as enablers for more advanced standards such as guidelines and processes[1]. According to the responses, eHealth solutions should be based on generic technologies and cross-domain standards, but the specific requirements of healthcare were identified in relation to security, safety and privacy, for example.

Many respondents saw a clear need for many different types of *participants* in the standardization. Healthcare organizations were emphasized in the standardization of healthcare-specific information, processes and guidelines. In the technology standardization (including healthcare IT), the role of companies and standardization organizations was highlighted. The role of authorities was also seen central, especially in relation to the healthcare-specific aspects and architectural guidance.

Goals, problems and challenges

Based on the literature survey and the results from the data collection, the national problems and challenges were identified and the target state was specified. In eHealth standardization, no organization can master all areas. This stresses the importance of coordination, the utilization of experts in different areas and the relationship between international and national standardization. In addition, clear relationships between healthcare information and processes, healthcare IT and technical standardization, and the requirement to base the solutions on the actual needs of the market are central. Some research results suggest that global standards succeed only if they can be adjusted to the local processes and activities, and they are applied or modified according to the local requirements [7, 12]. This observation was supported by our study.

The local or national *definition of responsibilities, guidelines and resources* is needed for the selection and production of standards and recommendations [9]. The selection and production of specifications, steering of these activities, support for their use in products and pro-

1 This statement has been emphasized also in other research [7].

curements, and education and conformance evaluation are central parts of these activities.

The *coordination and ownership* of standardization activities was identified as one of the key challenges in standardization. The various earlier recommendations for the organization models of standardization have not been realized. The collaboration and knowledge of different activities should be increased. Even though standardization requires participation from the industry and their customers, the government can maintain a working standards infrastructure. This support can be realized as clear recommendations about the selected standards, clarification of responsibilities and guidelines such as national architecture for electronic health records. The linkage between the standardization and system introductions, and the creation of conditions which balance the participation in standards activities can also be centrally supported [9].

The *quality assurance and the evolution of requirements* require special attention in standardization. There is a contradiction between the fast introduction of standards and their quality [9]. The subtle balance between accuracy and flexibility depends on the type of the specification. The conformance and certification require accurate specifications and dedicated services. Implementation examples, support for the projects which introduce standards, and guidelines for the procurement are useful means for the quality assurance.

The *relationship between official and industry standardization* has not been clearly defined. Industry standardization has been more agile in responding to the needs of the users. The free availability of key specifications promotes their use. In addition, the *commitment and participation* in standards-related work has been increasing very slowly. In particular, the companies and healthcare organizations have not participated actively in the international standardization. In general, successful standards require demand from the market, and standards can not be easily enforced by the officials.

New standards and specifications which are potentially relevant for healthcare, health IT or technology aspects, are continuously emerging. Constant *learning* by the users and developers is required. The careful selection of the specifications to be studied, and education about standards are necessary to keep the workload reasonable. The knowledge of key areas and activities of standardization should be included in the education of healthcare IT professionals.

Discussion

Main recommendations

Based on the surveys and previous parts of the study, the following eight main recommendations were made:

1. The standardization relationship between the healthcare IT and the domain-neutral IT must be intensified. *Shared national goals, policies and procedures for IT-related standardization* must be specified. National standardization steering groups are proposed for overall coordination and the healthcare-specific standards.
2. The *continuity* of domain-neutral and healthcare-specific IT standardization must be assured using permanent *funding* from various departments.
3. The primary preference for all domains, including healthcare, must be given to *cross-domain and generic standards*. Healthcare-specific standards should be developed and introduced cautiously and only on areas where they are essential.
4. The participation to the *international standardization* work and the observation of international key developments in standardization must be intensified and resourced. The goal is to identify mature standards which solve current local needs and to avoid contradictions with the international standardization.
5. The participation of healthcare *application vendors and health service providers* in the development, localization and introduction of standards must be supported by funding projects which aim at standards compliance and by developing models to support the balanced participation to the standardization.
6. The national standardization in healthcare IT must primarily support the *goals of the national health project*, especially the interoperable electronic health records. This requires a quick prioritization of the most immediate areas and goals, and the establishment of realistic funding and scheduling for them.
7. The *status, normativeness and mutual relationships* of healthcare IT standards, guidelines and recommendations must be defined unambiguously and accurately.
8. To ensure the interoperability of information systems and to support the introduction of standards, a *support and education network* must be created with adequate expertise to promote these recommendations and to support the steering groups.

In addition to these high-level main recommendations, the report identified 51 detailed goals and 127 recommended actions to support these goals. The *policy recommendations* were related to the organization of the standards-related activities, steering and funding. The *relationship recommendations* focused on improving the international and cross-sectoral linkages in standardization. For the *quality assurance* of standards and guidelines, 20 recommendations were made. Central recommendations were also related to the *improved know-how for the system acquisitions* and to the *establishment of education and support* related to standards. In addition, the support for the *introductions and pilots* involving standards, and *balance in the participation* of standards activities received recommendations. In addition, detailed recommendations were made for many *areas of standardization* and national policies. The most urgent recommendations were related to the core information sets, clinical documents, architecture and security of the national electronic health records.

Current trends of interoperability standardization

Some central trends of standardization are related to the evolution towards advanced eHealth interoperability.

Information systems are increasingly evolving towards networked and service-oriented solutions, which increases the role of standardization. In technical standardization, the aim is to *increase the flexibility* of systems to support different processes and adaptability. On the other hand, accurate *functional and semantic interoperability* is pursued, and *processes and workflows* themselves are increasingly standardized. In particular, *profiles* which constrain the standards are increasingly used to promote plug and play interoperability or automatic adaptability. Such profiles are emerging on the technology level [13], on the functional level [14], on the semantic level [4] and in the field of application of interoperability standards [15, 3]. In addition, emerging support services such as conformance testing and certification are closely related to standardization.

Conclusions

Achieving the benefits of standardization in the eHealth domain requires coordination, the selection and development of standards on many areas, the identification of central actors and close collaboration between them. The different areas require specific expertise and multidisciplinary collaboration. The success of standards is measured only through their utilization on the market. The support for the introductions of standards, the clear scope of standards, quality assurance, and the availability of standards and their support services create a vortex of successful standardization activities. The national participation in international standardization and the evaluation and selection of standards are necessities in this process.

The rapid evolution of IT and complementary standards offer many opportunities. However, generic standards require healthcare-specific profiling and evaluation, and healthcare also has specific standardization areas. In a wider context, standardization and the use of standards promotes competition and open market, and progresses economy as a whole.

The recommendations of this study were published and given to the project board after the report was finalized in 2005. Since then, the Social Insurance Institute of Finland has been selected as the national actor for the development of national healthcare IT services. HL7 CDA (Clinical Document Architecture) R2, DICOM and HL7 version 3 Medical Records have been recommended as some of the key standards of the national EHR in relation to clinical documents, medical imaging and messaging, respectively. In addition, some technical specifications such as X.509 for certificates, http(s) and SOAP for data communications and WS-Security for mediated secure messaging have been recommended. Furthermore, some of the key recommendations related to the steering model of standards-related work are being refined as of March 2007.

Abstract

The Hospital Authority developed the Information Architecture (IA) model in 2002 to support a fast, robust, flexible and accurate electronic patient record (ePR) to meet the high-tempo health care environment in Hong Kong.

With several successful applications in sharing data that were created for the same patients in various systems, the IA model was further developed to extend the longitudinal ePR to include one's fetal data as entered in the mother's record. This paper describes how various IA elements: Section, View, Form, Group, Entity, Content, Document supports the building of a true womb-to-tomb ePR for the HA patients.

The future focus of Information Architecture in the HA will include building a Information Architecture Management System and linking the ePR with other patient records in the community.

Keywords:

Information Architecture, electronic health record, terminology, standards, patient master index

Introduction

Healthcare is a person-centred process with multiple carers providing care to a person at different times at various locations. With the aim to improve a person's health, a nation's health and the world's health, developing a longitudinal electronic health record (EHR) is one of the greatest challenges to the health informatics field.

Electronic health record refers to 'a repository of information regarding the health of a subject of care in computer processable form' [1]. It is essential to ensure the longitudinal EHR is functionally and semantically interoperable such that the systems are able to exchange and further process the received information which is understood with formal defined domain concepts [1,2].

In recent years, various countries started their own initiatives to build health information infrastructure to facilitate a person to access one's health record regardless of where, when and by whom the record is created [3, 4, 5]. The keys to building a 'longitudinal' EHR include a universal unique identifier for the data subject and care provider, the carers and the facilities; terminology standards for recording, storing and reusing information and supporting decision support systems; messaging standards for exchanging information amongst systems; information model such that various standards are able to work together; and security standards to enable the information to be communicated within a consistent security framework [5, 6, 7, 8].

Some common terms to describe the 'longitudinal' record are 'cradle-to-grave', 'womb-to-tomb', or even 'sperm-to-worm' [1]. There is no question that one's health could be related to conditions one had during his/her fetal life. This relationship is so important that the World Health Organisation requests countries to report these prenatal conditions that affect one's health using International Classification of Diseases (ICD) [9].

Yet we find little discussion on how to electronically link the health record of one's fetal life to that created after one's birth. A powerful generic Information Architecture allows us to share data from the record of one's immediate family and utilize this data in subsequent health care. This paper describes how the Hospital Authority (HA) realized the development of a true 'womb-to-tomb' record.

Clinical information systems in the HA

The Hong Kong Patient Master Index (HKPMI)

At HA, all patients are uniquely identified with their Hong Kong Identity Number (HKID), a corporate based patient identifier. To date, the HKPMI has around 6 million unique HKIDs of living Hong Kong residents, which accounts for around 83% of the Hong Kong population. For each admission, outpatient visit or emergency attendance, a separate episode number is created. The episode number serves as a unique identifier to link all clinical information that created in that particular episode. The HKID links all clinical information in various episodes under the same patient.

The Clinical Management System & ePR

The Hospital Authority developed the Clinical Management System (CMS) from 1994. The CMS is an integrated

workstation for doctors to directly enter clinical orders and patient documentation. To create a record in the CMS, there must be an episode in the Hong Kong Patient Master Index (HKPMI).

From 2000, all essential clinical data from all HA hospitals and clinics were consolidated in the ePR repository, building up an enterprise-wide, longitudinal patient record [10]. Currently, the ePR houses 6.3Tb data (not including radiology images) with the records of 7.9 million patients, and garners 300,000 hits per day from clinical users.

The Obstetrics Clinical Information System

The Obstetrics Clinical Information System (ObsCIS) was first implemented in the HA hospital in 1994. The ObsCIS aims to support ongoing patient care and clinical audit. In 2005, out of 57,124 births in Hong Kong, 41,258 (72%) of them were born in HA hospitals, and the antenatal, delivery and postnatal information for all these mothers and newborns are recorded in the ObsCIS.

Information Architecture in the HA

In 2002, HA developed a simple yet generic model, HA's Information Architecture (IA), with the aim to build a fast, robust, flexible electronic patient record (ePR) from data being captured in various systems [11]. The IA framework was developed based on the following principles :

- Simple – easily understood, and implemented
- Generic – able to apply to data captured in any technical environment
- Flexible – support different presentations of the same data
- Concept oriented – ensure the consistency of the meaning of the information

More recently, the model has been refined with groupings of Entities into Forms and Groups to facilitate data capture and management. Under this model (figure 1), medical facts in ePR are described with :

- Sections – the macroscopic structure of ePR
- Views – dynamic presentations that fit according to various requirements
- Forms – source from which Entities are originated from
- Groups – logical grouping of Entities to facilitate data entry and subsequent data reporting and analysis
- Entities – the label that stores data
- Contents – the value that being stored, this could be a code, text data
- Documents – a special type of Content with human readable images

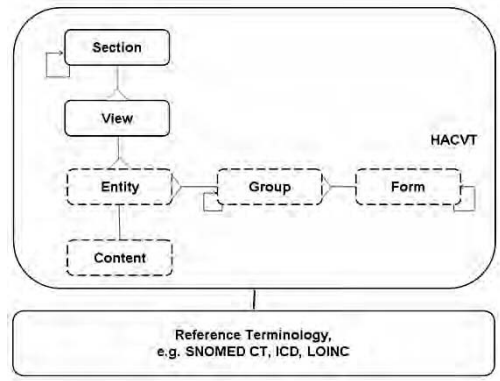

Figure 1 – The Information Architecture Model

Every medical fact has a concept

Central to the IA model is the "concept" attached to Entity, Document and Content. All Entity descriptions are added to the HA Clinical Vocabulary Table (HACVT) [12]. Each HACVT term is uniquely identified with a TermID. Where applicable, these terms will be mapped to reference terminologies, such as, SNOMED CT, or LOINC, ICD 9 CM, or ICD 10 to facilitate subsequent interpretation and data retrieval.

Contents may be codes, numbers, text or even images, and since coded Contents is referenced to the HACVT as well, mapping to the reference terminologies may be required.

Every medical fact has a context

Under the IA, all medical facts are stored in Entities. Entities are related through Groups and Forms. The IA defines relationships between these constructs, insuring that the context of data is preserved. Each Entity is identified with a unique EntityID. Each EntityID, apart from storing Entity description, also includes a set of attributes, such as data format or repetitive indicator.

Every medical fact has a presentation

Sections and Views define how information is organized and presented in ePR. To support flexible data retrieval, the same Group / Entity / Content / Document can be put under different ePR Sections. For example, Psychiatric Nursing Discharge Summary document can be placed under Nursing Section and also the Psychiatric Summary Section.

Although in 2002 other models were already in development, e.g. HL7's Clinical Document Architecture [13], ASTM's standard for the patient record [14], the Good Electronic Health Record [15], HA's IA was able to scale rapidly to the demand of data retrieval on an enterprise-wide scale in a busy clinical environment.

The IA model takes a comprehensive approach in managing information from its generation to how it is used, presented and aggregated. It allows semantic interoperability between the different modules and subsystems of the CMS. IA helps the HA to build a flexible, comprehensive ePR which meets the high volume of data retrieval with

subsecond response whilst still allowing advanced functionality.

The journey begins

The mother-baby relationship table

Since 2003, all newborns born in HA hospitals are admitted and a medical record is created. This allows clinicians to record the newborn's data, e.g. laboratory results, directly in the newborn's own CMS record instead of keeping them in the mother's CMS record as before.

In 2005, it was decided to share the mother's delivery data to the baby's record. The first step is to ensure there is a correct linkage between the mother and the baby in the HKPMI.

The mother's delivery episode number and the newborn's birth episode number are stored in the HA Mother-Baby Relationship Table (M-B table) which is incorporated in the HKPMI. This forms the basis for subsequent sharing of data from a mother's ObsCIS record to the newborn's record.

Data to be shared

The project is governed by the Perinatology Committee with representatives of senior clinicians from all Obstetrics and Paediatrics Department of the HA hospitals. The committee agreed that the following information is shared from the mother's ObsCIS:

- birth datetime
- maturity
- mode of delivery
- duration of membrane rupture
- birth weight
- Apgar score at 1, 5 & 10 minutes
- related diagnoses and procedures

For diagnoses and procedures, only those related to the fetus, the uterus, the membranes, liquor, and umbilical cord are passed to the baby's record. Examples include preterm labour, cord presentation, oligohydromnios, fetal distress, and fetal growth retardation.

Sharing mother's ObsCIS Data to baby's ePR & CMS

Each of the selected ObsCIS information to be shared is assigned with a unique EntityID and referenced to SNOMED CT where applicable. With the same ObsCIS diagnosis / procedure, separate HACVT terms are assigned for the mother's and the baby's records to ensure correct ICD codes are generated in the corresponding records.

The EntityID and TermID, plus the baby's episode number is passed to the ePR repository where the information is separately stored under both the mother's and the baby's episode number. Birth data and related diagnoses and procedures will be retrieved from the ePR repository and stored in the baby's CMS and ePR record.

Doctors can retrieve the baby's birth data while preparing the discharge summary (figure 2).

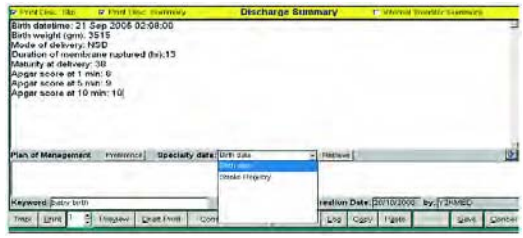

Figure 2 – Retrieving birth data for baby's discharge summary

A Section on Birth Record is created in the baby's ePR to display the baby's birth data (figure 3).

Figure 3 – Birth record in baby's ePR

Subsequent application

In 2006, a Neonatal Form was developed based on the IA and the same data sharing model. The ObsCIS data and mother's antenatal problems are shared to the Neonatal Form via the ePR repository.

The way forward

One of the greatest challenges in the use of the IA is to identify which Entities and which Contents should be referenced to terminologies like SNOMED CT. The CMS includes modules that are developed purely for patient care purpose but also some modules developed to facilitate auditing. Given the diversity, it is neither necessary nor worthwhile to reference all Entities and Contents to a Reference Terminology. Work started with defining Entities and Contents for ancillary services such as laboratory, and radiology – data will most likely contribute to the development of decision support systems – and has proceeded to other areas.

Despite SNOMED CT [16] being the single largest clinical terminology covering quite a number of domains, an internal evaluation of SNOMED CT indicated that it is better developed in areas like findings, but would need improvement in terminologies on others like procedures and allied health. More work, such as using post-coordination, is required to use SNOMED CT to represent concepts for the whole spectrum of healthcare domains. The requirement of post-coordinated terms also creates challenges for future data retrieval and analysis [17].

Given the massive number of Entities and Contents in the HA CMS, the need of a tool to manage these Entities and Content is inevitable. To this end, the Information Architecture Management System (IAMS) is being explored. IAMS aims to provide robust functionalities such as semantic locality and lexical matching to facilitate the management of terminologies. Functions supported

include mapping concepts to classification, managing the terminology lifecycle and managing reference information [18, 19]. In addition, IAMS will also manage relationship between individual IA elements.

Currently, the mother's ObsCIS data are shared to the baby's record at birth. For singleton, it is clear to whom the identified information belongs. More work would be required for linking correct fetal data to records for babies of multiple pregnancy.

Another challenge to be addressed is to protect the mother's privacy. The ObsCIS is adding a 'confidential flag' to indicate the mother particularly requested to keep the information confidential. This flag will also be passed to the baby's record to alert paediatricians to be more careful when discussing the baby's condition with a third party, e.g. baby's father, where applicable.

Conclusion

IA is a relatively simple but comprehensive concept when compared with other development in this area. Emphasizing on context, concept and presentation, the model can be flexibly applied to facilitate the building of a dynamic ePR while retaining the semantics of the data captured.

The HA will complete building a platform to share data with the Department of Health (DH) by March 2007. Discussion has started on sharing the newborn baby's discharge summary to the Maternal & Child Health Centre (MCHC) which is under the DH management. With nearly 90% of babies born in Hong Kong attending the MCHC, and 72% of babies born in HA hospitals, linking the HA and the MCHC baby's record marks another significant step in building a womb-to-tomb record for Hong Kong residents.

Acknowledgments

We would like to thank members of the Obstetric & Gynaecology Coordinating Committee with their contribution to the development of the Obstetrics Clinical Information System. We are grateful to the Perinatology Committee for their support in the design and implementation of linking mother's and the baby's record.

Another HISA – The New Standard: Health Informatics – Service Architecture

Gunnar O. Klein[a], Pier Angelo Sottile[b], Frederik Endsleff[c]

[a] *Dept. of Medcine, Karolinska Institutet, and Cambio Healthcare Systems AB, Stockholm, Sweden*
[b] *GESI, Gestione Sistemi per l'Informatica, Rome, Italy*
[c] *Dept. of Informatics, H:S, Copenhagen, Denmark*

Abstract

In addition to the meaning as Health Informatics Society of Australia, HISA is the acronym used for the new European Standard: Health Informatics – Service Architecture.

This EN 12967 standard has been developed by CEN – the federation of 29 national standards bodies in Europe. This standard defines the essential elements of a Service Oriented Architecture and a methodology for localization particularly useful for large healthcare organizations.

It is based on the Open Distributed Processing (ODP) framework from ISO 10746 and contains the following parts:

Part 1: Enterprise viewpoint

Part 2: Information viewpoint

Part 3: Computational viewpoint

This standard is now also the starting point for the consideration for an International standard in ISO/TC 215.

The basic principles with a set of health specific middleware services as a common platform for various applications for regional health information systems, or large integrated hospital information systems, are well established following a previous prestandard. Examples of large scale deployments in Sweden, Denmark and Italy are described.

Keywords:

medical informatics, hospital information systems, standard, SOA, ODP, HISA, CEN, middleware, data-carrying integration platform

Introduction

Healthcare structure consists of networks of units over a territory characterised by a high degree of heterogeneity and diversity, from organisational, logistic, clinical, technological and cultural perspectives. The structure of individual centres such as hospitals of different sizes and outpatient clinics including primary care is evolving from a vertical, aggregated organisation towards the integration of a set of specialised functional areas. These need to share common information and to operate according to integrated workflows within and between centres of a larger enterprise e.g. a county or a large city.

On the one hand it is necessary to support the specific requirements of each unit or user in the most appropriate and cost-effective way whilst on the other hand it is vital to ensure the consistency and integration of the overall organisation, both at local and territorial level. This integration requirement is not only related to the need for improving clinical treatment of the subject of care but is also demanded by the necessity of to control and optimise the current level of expenditure for health.

It is today common with a large number of different databases and applications, isolated and incompatible, already operational in healthcare organisations to support specific needs of users. Even within the same centre, information systems are frequently fragmented across a number of applications, data and functionalities, isolated and scarcely consistent with each other.

A main need for care delivery organisations is to integrate and to make available the existing information assets, with the interoperability of existing applications, thereby protecting investments made. During integration activities, continuity of service needs to be achieved whilst gradual migration of existing proprietary, monolithic systems towards the new concepts of openness and modularity occurs. The cost-effectiveness of the solutions, especially when projected on the scale of the whole healthcare organisation, represents a crucial aspect to be evaluated carefully.

The goal can be achieved through a unified, open architecture based on a middleware of information services independent from specific applications and capable of integrating common data and business logic. These services shall be made available to diverse, multi-vendor applications through many types of implementations. All aspects (i.e. clinical, organizational and managerial) of the healthcare structure must be supported by the architecture. This must be able therefore to comprise all relevant information and all business workflows, structuring them according to criteria and paradigms independent from specific subdomain aspects, temporary requirements or vendor specific technological solutions.

Standards and technological solutions already exist and will continue being defined for supporting specific requirements, both in terms of *in situ* user operations and with respect to movement of information. The architecture must be able to accommodate such requirements by allowing the specific models to be integrated with the complete information assets of the healthcare organisation and the

communication messages to be "services" extracting or importing data from/to the common information as shown in Figure 1.

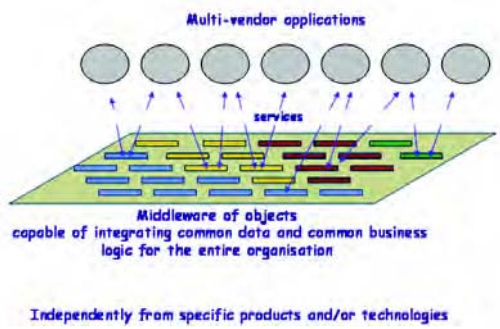

Figure 1 - A Service Oriented Architecture

The purpose of this standard is twofold:

- to identify a methodology to describe healthcare information systems through a language, notation and paradigms suitable to facilitate the planning, design and comparison of systems;
- to identify the fundamental architectural aspects enabling the openness, integration and interoperability of healthcare information systems.

The architecture is therefore intended as a basis both for working with existing systems as well as for the planning and construction of new systems.

Materials and methods

The standards body and process

This standard was developed within CEN/TC 251 (www.centc251.org) which is the technical committee for Health Informatics within the federation of 29 European national standard bodies.

The work in health informatics has been mandated by the European Union and the European Standard is published as a national standard in all of the member countries following the approval based on a weighted vote. In this case only one country was opposing the approval.

This work was developed within Working Group I: Information models by the Task Force HISA led by Gunnar Klein, who was at the time also chairman of CEN/TC 251 and with the two other authors as member of the core group with Frederik Endsleff having a particular responsibility for part 1 and Pier Angelo Sottile for parts 2 and 3.

Experts from the following countries also contributed actively to the development of this standard: Belgium, France, Germany, Hungary, Italy, Norway, Sweden and UK but also as non-European contributors Australia and the USA.

During the extensive formal review process in several stages a total of 112 written submissions where adding to the final version.

Open distributed processing

The standard framework for Open Distributed Processing was first developed by the Object Management Group (OMG) and later approved by ISO/IEC as the International Standard ISO 10746 from 1996.

This standard contains a rich set of specification elements and recommendations for the development of open distributed systems. It has successfully been applied in a large number of different industry sectors including, telecom and banking.

At the time of issuing the first ODP standard, there was no available standard for information modeling. Since then UML (the Unified Modeling Language) has been developed and since it has been adopted as the method of choice for health information modelling by both CEN and ISO and many other organizations, UML was selected as the information modelling language for the new HISA standard.

The ODP framework contains five viewpoints. In the HISA standard we have provided health specific advice and definitions for the three upper levels. The two lower viewpoints, Technology Viewpoint and Engineering Viewpoint are applicable for a concrete development and implementation project but there is no point in providing health specific restrictions in a standard.

Results

Part 1: Enterprise viewpoint

The Enterprise Viewpoint specifies a set of fundamental common requirements at the enterprise level with respect to the organisational purposes, scopes and policies that must be supported by the information and functionalities of the middleware. It also provides guidance on how one individual enterprise (e.g. a regional healthcare authority, a large hospital or any other where this model is applicable) may specify and document additional specific business requirements. This should aim at gradually achieving a complete specification, adequate for all the characteristics of that enterprise.

The strategic paradigm

The specification of the architecture shall start with a very concise, managerial-oriented document (the "Strategic Paradigm") that identifies (at a high level of abstraction) the overall requirements and strategic objectives of the envisaged system. It describes, in natural language:

- the rationale and the scope of the IT system with respect to the overall enterprise;
- the fundamental organisational processes (as defined under terms and definitions) that can be identified in the enterprise and that are relevant for the envisaged system;
- the fundamental constraints and objectives to be satisfied.

The HISA standard gives important guidance for an Enterprise on how to model its detailed requirements. The importance of starting from a model of the care processes

is emphasized and the following model is offered to clarify the different processes.

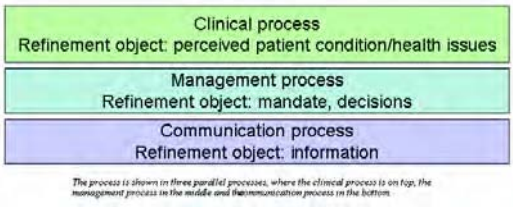

Figure 2 - Subdivision of the care process

The Enterprise Viewpoint deals with the requirement specification and contains *use-cases*, *process descriptions* and models leading to the identification of the overall Service Architecture and the basic clusters of objects. The following are identified:

- Subject of Care Workflow
- Activities management workflow
- Clinical Information Workflow
- Management of authorizations
- Management of resources
- Management of dictionaries and coding
- Interactions with other systems

In the standard, there are detailed use case descriptions specifying common requirements on information management.

It should be emphasized that this standard does not claim to have the description of all possible requirements, only the commonly shared processes of healthcare enterprises.

Part 2: Information viewpoint

The Enterprise Viewpoint of the HISA standard has identified certain processes. The Information Viewpoint is detailing the information structures using UML class diagrams. The information model is specified without any – explicit or implicit- assumption on the physical technologies, tools or solutions to be adopted for its physical implementation in the various target scenarios. The specification is nevertheless formal, complete and non-ambiguous enough to allow implementers to derive an efficient design of the system in the specific technological environment that will be selected for the physical implementation.

This specification does not aim at representing a fixed, complete, specification of all possible data that may be necessary for any requirement of any healthcare enterprise. The information model of the standard only specifies the set of characteristics identified as fundamental and common to all healthcare organisations.

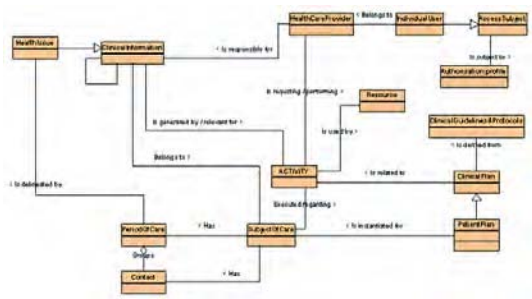

Figure 3 – High level Information Model

HISA Information Objects in each package shall be classified as *operational* or *descriptive*:

- "**Operational**", usually representing the actual (clinical, Organizational, etc.) objects that are continuously generated during (and for) the daily activities. These include the personal and healthcare treatment information on patients, the individual resources used for carrying out the actual activities, etc..
- The operational information objects model the entities involved in the daily activities of the healthcare enterprise in the treatment of subjects of care and in the functioning of the enterprise itself.
- "**Descriptive**", usually Organization-related, specifying the criteria according to which the Organization works and is organized. It includes general classifications of clinical concepts, rules according to which the activities are performed, and more (e.g. the types of activities which are carried out in the radiology department, the diagnostic classification in use in the clinical setting, etc.).

The descriptive information objects model the entities required for the overall knowledge base that is required by the healthcare enterprises to carry out daily activities related to the treatment of subjects of care and in the functioning of the enterprise itself.

For each "operational" information object, therefore, the model foresees one "descriptive" information object, containing the main classification data, the properties, the rules and the default values that are necessary for the management of the live data instantiated in the "operational" object.

The HISA information model is where relevant using existing standards. One example is the European EN 14822: Health Informatics - General Purpose Information Components which is based on the HL7 Reference Information Model.

Part 3: Computational viewpoint

This part of the standard specifies the fundamental characteristics of the computational model to be implemented by a specific architectural layer of the information system (i.e. the middleware) to provide a comprehensive and integrated interface to the common enterprise information and

to support the fundamental business processes of the healthcare organization.

The computational model provides the basis for ensuring consistency between different engineering and technology specifications (including programming languages and communication mechanisms) since they must be consistent with the same computational object model. This consistency allows open inter-working and portability of components in the resulting implementation.

The basic computational objects, corresponding to the information objects, will be equipped with *standard* lower-level **basic** interfaces having the scope of *adding, updating and deleting –in short maintaining-*, *listing*, and *getting one instance* of the main classes described in the information viewpoint. These basic methods allow the access to and the manipulation of each element of the underlying model and secure the openness of the system.

The higher-level computational objects implement more complex business transactions on the objects of the information model, simplifying and ensuring consistency of developments for common fundamental procedures of the organisation.

Examples are:

- Patient/person area, including registering a person, Patient Administration (ADT), merging patient identifiers, period of care, etc.
- Activity management and life cycle, including requests, planning, booking, etc.
- Clinical and EHC record, including terminologies, classifications, problem-orientation, etc.
- Resource management, including standard usages

Examples of use of HISA based architectures

In Europe there are a number of large healthcare organizations that have based their strategic planning on the HISA middleware principles and various technical solutions exist from different vendors and technical generations. Here are a few examples:

UppsalaCounty Council, Sweden

This is one of seven healthcare regions in Sweden that have decided to use the Cambio Spider middleware product. It is used for all its three hospitals and 35 primary care centres in one installation. This HISA implementation is based on a modern Java (J2EE) architecture with choice of Application Server and SQL database.

This system handles healthcare for all the 300 000 inhabitants plus as a regional highly specialised care for a million people. Today there are around 10 000 daily users of the system that includes, the following applications on top of the HISA platform:

- Care Administration
- Resource Planning
- Electronic Health Record
- Medication management including electronic transfer of prescriptions
- Order management for lab, imaging and consultancy services

The same system is also used in the counties of Kronoberg, Jönköping, Östergötland, Västmanland, Kalmar and Värmland in Sweden and also in Odense in Denmark and in the Faroe Islands.

The "Policlinico A.- Gemelli" in Rome "Università Cattolica del Sacro Cuore"

The UCSC information system consists of several applications based on a common architectural approach suitable to ensure the integrity and consistency of the information assets of the organisation, from the clinical, organisational and managerial point of view.

It relies on a healthcare-specific middleware product from GESI (the DHE®, Distributed Healthcare Environment) of services allowing different applications to access the common information heritage and to perform common business processes through a set of services. On top of the DHE, several applications provide specific support to the user activities.

The following figure 4 shows at a high level of abstraction, the overall heterogeneous structure of the healthcare information system of the hospital and the centrality of the HISA-based DHE middleware.

Figure 4 - The Gemelli system in Rome

Copenhagen Hospital Corporation (H:S), Denmark

H:S selected in 2002 the DHE product to implement its HISA strategy for 6 hospitals, in all comprising 4000 beds. The DHE serves as the joint data-carrying Integration Platform, forming the basis and common information heritage for a number of clinical and managerial applications.

Among the applications are the medication module and the master patient index with over 10.000 users, fully rolled out and in integral daily running operation throughout the organisation.

H:S is from 1 January 2007 being merged with a.o. Frederiksborg County and Copenhagen County, into the Capital Region, responsible for regional healthcare of all of the region, including 10 hospitals and 1.6 million inhabitants. The master patient index and the medication module is for this purpose currently undergoing rollout in the Frederiksborg County.

Several further DHE based applications are under current advanced development, such as Reporting, Accounting and the Patient portal, utilising the common information heritage.

Information is exchanged not only with the direct HISA interfaces (provided by the DHE) but also through messaging with other standards (utilising the underlying HISA interfaces) e.g.:

- The Danish national implementations of European standards in Edifact for e.g. laboratory communication and ePrescribing (MedCom).
- Information exchange with other messaging standards such as HL7, XML and Diagnostic Equipment such as for ECG and Imaging

Discussion

HISA is a new standard defining a "Service Architecture" identifying the general principles to secure openness and vendor-independence:

a) information must be separated from specific applications and accessible through services

b) service logic must be independent from technological issues (i.e. multiple technologies and mechanisms must be allowed for accessing the same services)

HISA is also identifying the fundamental elements of a comprehensive information model capable of supporting the whole healthcare organisation and finally the fundamental characteristics of a set of services for managing common information and for performing common business logic

This standard is not an alternative but a complement to other standards for health informatics such as specific messages developed by e.g. HL7 or the general EHR communication standards from CEN and openEHR [4].

Conclusion

After many years of research and standardization activities, there is now a formal standard for a Service Oriented Architeture (SOA) specific for the requirements of health care enterprises based on the general principles of Open Distributing Processing. It is now a European Standard but it has been submitted to ISO and is formally under consideration to become an International Standard.

Abstract

Economies of scale, corporate partnerships and a need to increase the efficiency of Information Technology in the Healthcare sector are leading to the construction of Regional Health Information Organizations (RHIOs) across the United States. RHIOs are normally aligned by service provision given by particular healthcare payers (e.g. Blue Cross-Blue Shield, PacifiCare etc.) in particular geographies. Globalization has created a transient workforce that may require their healthcare provider access their patient data across several sovereign RHIOs. The barrier to enabling RHIO to RHIO collaboration lies in the need to respect the data disclosure policy of each RHIO, to adhere to the geography-specific healthcare legislation and also to not violate the express privacy wishes of the patient(s) involved. In this paper, we propose a data-level control called Sticky Policy Enforcement which allows sharing to occur across RHIOs, while adhering to the concerns mentioned.

Keywords:

privacy, healthcare systems, collaboration

Introduction

Beyond the move to transform the American healthcare landscape by leveraging Information Technology to deliver better care, to reduce medical errors and to improve the quality of life, the existing healthcare topology dictates that computer networks be built that preserve the established business alliances that exist between payers and providers. This motivates the formation of connected information centers called Regional Health Information Organizations (RHIOs). The mandate to create a National Healthcare Information Network (NHIN) in the United States is based on the emerging existence of these RHIOs [1, 2]. A NHIN is a realization of a collaborative network of Healthcare Information Systems.

Formally, a RHIO is an independent regional collective that facilitates the development, implementation and application of secure health information exchange among participating care providers. Each RHIO has independent policies regarding the privacy of health records stored within the RHIO. Figure 1 presents the typical RHIO environment. A limited number of RHIOs exist today in the US and they vary in the ways they approach data sharing. The formation of a RHIO is based on the understanding that all the stakeholders agree to follow a specific set of guidelines.

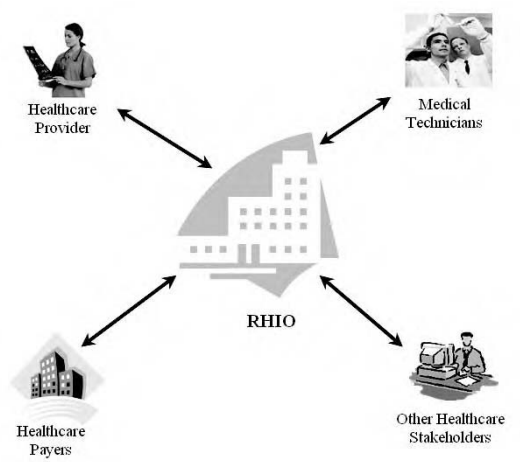

Figure 1 - Regional Health Information Organization (RHIO)

These guidelines detail policies regarding access, dissemination and processing of the patient data in the RHIO. Currently, the mechanism for cross-RHIO information sharing differ so greatly that collaboration across RHIOs to deliver care is still a daunting problem, but critical for the successful adoption of RHIOs.

One of the key challenges is the protection of patient privacy when clinical documents are shared. This challenge is compounded by the facts that there can be no assumption of a central authority; that enforcement may involve multiple privacy policies based on source, destination and the documents involved in the transfer and the fact that data can be forwarded to an entity with additional rights, such as remote update rights.

This paper presents a first step towards addressing these concerns and marches healthcare systems towards achieving inter-RHIO collaboration while adhering to data disclosure constraints (e.g. privacy and security concerns).

The technology is called *Sticky Policy Enforcement* and provides a way to ensure that policy constraints are enforced wherever patient data travels.

In this paper, we will provide a discussion on the related work in the field, highlight the *Sticky Policy* architecture, demonstrate the technology by walking through the enforcement steps and provide concluding remarks.

Related work

The first mention of *Sticky Policies* appeared in computer science literature at the start of the 21st century [3]. It emerged from IBMs work on Enterprise Privacy Authorization Language and was recognized as a concept that is important for privacy preservation in distributed computer systems. The underlying notion behind *Sticky Policy Enforcement* is that the policy applicable to a piece of data travels with it and is enforceable at each point it is used. Though identified over a half a decade ago as a critical problem, application-independent solutions that were technically feasible and scaleable were not realized.

Rivest and Lampsons work [4] embodies the earlier efforts in this space. Their focus was on the establishment of trust for a single disclosure object with a single policy. A data recipient is either granted access to the entire document, or must request authorization from the source. In healthcare environments, this is not sufficient. *Sticky policy* functionality should handle data disclosure to a party with well-defined constraints that allow data release to less privileged parties without requiring the originators involvement. This avoids the potential pitfall of having to contact a (potentially) large number of third parties before making a decision to disclose a specific piece of information.

The work by the Trusted Computing Group (TCG) consortium [5] represents another, more popular, approach to establishing the trust in single object, single policy environments. The general concern with the traditional approaches is that they require targeted application development and are not application and data agnostic, which is a mandatory requirement for situations with a complex web of pre-existing infrastructure, which are likely to be from differing vendors and running different, even proprietary, systems. Additionally, an ideal approach to *Sticky Policy Enforcement* should account for the fact that data changes occur frequently. It is not clear how approaches like that of the TCG would handle this without incurring a severe performance penalty.

System description

The goal of our system is to enable distributed privacy policy enforcement. The difficulty in achieving this lies in the fact that there is no single entity with *a priori* access to all the policy constraints applicable to a document in a given state of the system. Our solution to this problem involves identifying the applicable privacy policy constraints for a document(s) to be shared and sticking them together, forming a single entity of transfer.

In taking the approach of packaging policy with data, we maintain centralized decision making in a distributed enforcement. As only policy constraints that apply to the disclosed data are transferred, the communication impact is relatively small and the system does not require prior agreement among all medical organizations, states and patients.

Hippocratic database technology

Our solution approach to the distributed privacy policy enforcement problem leverages the Hippocratic Database (HDB) Active Enforcement (AE) technology [6], which provides cell-level, policy-based disclosure management functionality, such that databases only return data that is compliant with company policies, applicable legislation, and customer preferences. The AE component ensures that enterprise applications accessing a database adhere to fine-grained data disclosure policies. These policies, which may be security policies, privacy policies or data management policies, are distilled from the companys own policy, legal and regulatory requirements, customer preferences, and opt-in and opt-out choices. The component automatically rewrites user requests (i.e. queries) and returns only data that is consistent with these policies, allowing applications to enforce disclosure policies on arbitrary data elements at query execution time. A detailed description of HDB AE can be found in [7]. A quick overview of its operation is that, for a centralized or federated data system, HDB AE allows the definition of fine-grained disclosure policy, the creation of user preferences, the resolution of conflicts between preferences and policy and the enforcement of all the applicable constraints in an architecture that is application and database agnostic.

HDB Active Enforcement technology was chosen as our platform because: (i) it offers a general platform for handling and codifying privacy policy and preference information; (ii) its enforcement mechanism is transparent to enterprise applications (integration currently assumes a database interface such as ODBC or JDBC); (iii) it is agnostic to underlying database technology; (iv) it allows policy changes without any modifications to the applications in use; and (v) in the typical case, it improves query processing speed.

Sticky privacy policy

The format of our *Sticky Policy* package (Figure 2) consists of three parts: Data, Policy and Audit information. The Data segment contains the health documents requested. The Policy segment embodies the policy constraints applicable to the documents to be made available. The semantics of the policy entries are:

1. Requestor: The entity requesting access to part(s) of clinical document(s) from the source. The values for this entry could be taken from the roles mentioned in CDA standard.
2. Recipient: The entity that will be the final consumer of the data. The domain of possible values is similar to the set used for a requestor.
3. Purpose: The purpose for which the document(s) is being requested.
4. Retention: Time period until which access to the data is allowed. This could be computed based on various organizational policies.

5. Copy-forward: The condition specifying whether the recipient is entitled to forward the requested document(s) to a third party after copying. The set of possible values are:

Copy forward	
Yes w/notification	*May copy and forward the data with a notification to the sender*
Yes w/o notification	*May copy and forward the data without any notification*
No	*May not forward at all*
Ask	*Must ask the sender on forward*

6. Append/Modify: The Boolean condition specifying whether the recipient can append/modify the document.

Append/Modify	
Yes w/notification	*May append/modify with a notification*
Yes w/o notification	*May append/modify without any notification*
No	*May not append/modify at all*
Ask	*Must ask on append/ modify attempt*

The Audit section of the sticky policy consists of information including the source, requestor, a timestamp and digital signature to verify the authenticity of the sticky policy.

Figure 2 - Format of sticky privacy policy

Data

×	Clinical Document n
Policy	
×	Requestor
×	Recipient
×	Purpose
×	Retention
×	Copy forward
×	Append Notification
Audit	
×	From
×	To
×	Timestamp
×	Verifiable Signature

The source and requestor information is used by the auditor to track the data while the timestamp is used to determine the causal ordering. The digital signature serves two purposes: 1) to maintain the integrity of the healthcare documents, i.e. guaranteeing that the document(s) are not tampered with, and, 2) to ensure the non-repudiation of the sticky policy.

Architecture & model

In solving the distributed policy enforcement problem, we assume a trust model where authenticated users are honest-but-curious. Thus, our attack model focuses on the user who inspects the data they receive and attempts to gather data that they are not entitled to, and does not address malicious users who attempt to gain access to data they have not received even if it violates the policies.

Figure 3 illustrates the conceptual architecture of our system and showcases the creation and management of sticky policies.

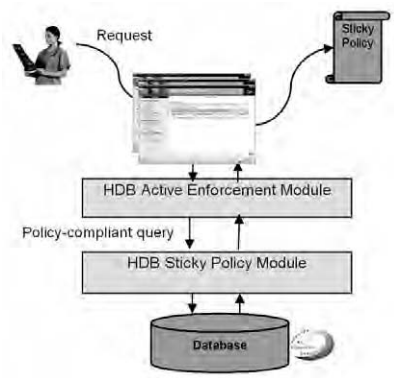

Figure 3 - Sticky policy enforcement architecture

Our enforcement model consists of two approaches:

Proactive enforcement involves prevention of unauthorized disclosure before it occurs by blocking operations or suppressing results that may lead to a privacy violation.

Reactive enforcement involves detection of the violation through audits. This is based on an optimistic assumption that the environment is non-malicious.

These approaches differ in their points of execution. Proactive enforcement eliminates violations before they occur, which has limited use in scenarios when *a priori* knowledge of all the possible access situations is not possible. For example, in an emergency situation, violations should be allowed as long as they are auditable and necessary for the delivery of care. Reactive enforcement achieves this by tracking all the access information and assuming the existence of a trusted auditor system. The auditor must be able to access data from the source and recipient including any intermediaries between those parties. For the US healthcare environment, this could be the responsibility of the Department of Health and Human Services or its delegates. In the case of a violation, the system presumes the node to be guilty and demands records to certify innocence.

For distributed environments, proactive and reactive enforcement can be achieved through either a centralized or a federated approach leveraging a set of cooperating enforcers.

In our design, we perform proactive enforcement through HDB Active Enforcement technology. In the case of reactive enforcement, a centralized approach employs a single auditor which is trusted and authorized to investigate all aspects of a suspected policy violation. In a decentralized model, a set of cooperating auditors can be employed with each team responsible for a specific set of nodes, data or both.

Beyond the issues of proactive and reactive enforcement, there is a question of where the enforcement occurs. We consider two possible locations: at the source and at the recipient. Enforcement at the source is simpler because it relies on the sources controls. Enforcement at the recipient places trust in all recipients. However, some enforcement can only occur at the recipient. For example, restricting the recipient from forwarding the result on to others is not something the source can enforce. Our approach is to attempt to perform all enforcement at the source and only rely on enforcement at the recipient when no alternative exists.

Scenario

Initially, a request for clinical documents is placed through an application interface, which issues a query or a set of queries. On receiving the query, the proactive enforcement module rewrites the query to account for all applicable disclosure policies. In a traditional HDB-enabled system, the rewritten query would continue directly to the data systems native query execution engine. However, for our system, the rewritten query is redirected to the sticky policy module where the query is further modified to create a sticky policy result set. A digital signature is computed on the source using a User-Defined Function (UDF) and included in the sticky policy. The final sticky policy is then transferred to the recipient in its entirety. Figure 4 provides a sample healthcare sticky policy.

For this prototype, we chose to use XML as the data format for representing the sticky policy for multiple reasons. The interoperability among various EMR, HER and PHR systems used in the healthcare industry has been limited based on the proprietary interfaces and standards [8]. Although, XML processing as in the case of any text processing involves a lot of overhead, it offers the much needed features of platform independence and simplicity demanded by the healthcare industry. When the XML processing overhead becomes unbearable, specialized hardware and software can be used to mitigate this concern.

For the purposes of this work, we assumed an agreement on vocabulary among interoperating parties. We also assume that proactive enforcement is achieved by leveraging HDB Active Enforcement. On the recipient, the AE component accepts the received sticky policy, assigns a unique id to the policy and stores an unaltered copy of policy for the purposes of auditing. The policy elements are then de-coupled and the corresponding data and policy constraints are extracted. The policy rules are then entered into the HDB metadata tables. The document(s) or their part(s) are then stored in a database and links are created from the entries in the HDB metadata

Reactive enforcement is achieved by traversing the sticky policy audit logs to find a violation or to prove innocence. An audit begins with the suspicion of a privacy violation. We presume that any party with access to the data but without a sticky policy is guilty. In essence, the sticky policy is a certificate of innocence. This is similar to not having a license demonstrating legal ownership of a software product.

The auditor searches the database for the data item for which enforcement is presumed as violated. Once identified, the auditor checks the HDB metadata, and identifies the relevant policy and archive entries. If the ability to identify these entities does not exist (i.e. there is no policy or the archive entry is missing), then a violation has occurred. The auditor then tries to verify the signature on the sticky policy stored in the archive table. Again if the signature is not valid, a violation has occurred.

Figure 4 - Sample sticky policy for healthcare RHIO sharing

To - Alice/ Admin Role/ Arizona Care

Timestamp - Nov 19 2006

Signature - ...

If everything has been successful so far, the auditor checks to make sure the sticky policy and data content agree. The auditor compares the policy in the policy table to its counterpart in the sticky policy and similarly compares the data in the sticky policy with that in the database. The auditor also verifies that the HDB metadata tables cover all the data included in the sticky policy. Even if everything checked so far is OK, the audit is not stopped.

It is possible for an enforcement breach to have occurred before the current node even received the sticky policy. The auditor then traverses through the sticky policy to identify the node that forwarded the sticky policy. The auditor continues the audit up the chain to the originators

until he reaches the bounds of his jurisdiction or the first sender.

Performance discussion

We ran experiments to evaluate the overhead cost of sticky policy generation and sticky policy consumption. In the interest of terseness, we will just provide the results here. Our experimental platform used a synthetically generated dataset based on the Clinical Document Architecture [9]. All experiments were run using IBM DB2 UDB 8.2. The operating system was Microsoft Windows XP with Service Pack 2. The hardware consisted of a PC with Pentium-4 2.4GHz processor and a 60GB disk. The buffer pool was set to 1 MB. All other DB2 default settings were used.

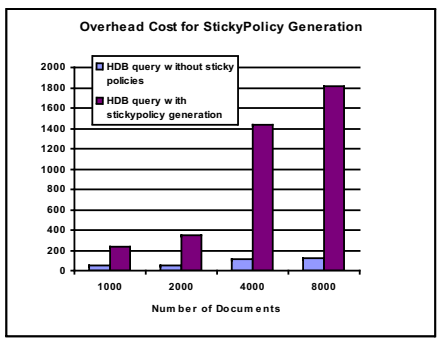

Figure 5 - Overhead cost for sticky policy generation

We examined document sharing for sets of 1000, 2000, 4000 and 8000 documents, which is well over the current limits for healthcare document sharing. It was observed that the overall cost introduced by sticky policy generation over the privacy preserving query processing in HDB is acceptable (Figure 5) considering that the generation is done using XML.

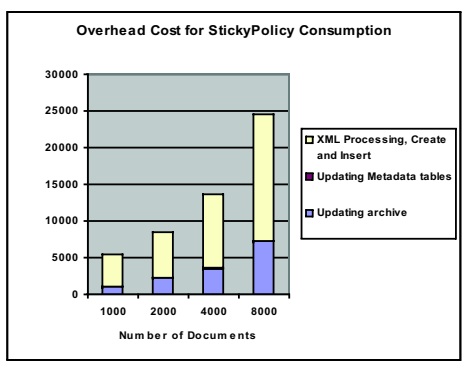

Figure 6 - Overhead Cost for Sticky Policy Consumption

For policy consumption, the time elapsed in updating the metadata tables and the archive is less than 30% of the overall policy consumption cost (Figure 6). As pointed earlier, XML hardware appliances may be used to reduce the overall consumption cost.

Future work

Our future efforts will focus on 1) further deployment and enhancement of the current *Sticky Policy* functionality, and 2) innovating new approaches to enable *Sticky Policy Enforcement* in distributed systems with a central repository. On the first task, we plan to start by including technology that increases the transmission security strength. i.e. removing the assumption that the channel is inherently secure and encrypting the shared documents before transfer. Then we will remove the assumption of an honest-but-curious user and consider hostile environments; touching on the difficulties in considering Byzantine failures or collusion among several participants. For the second task, we will assume a system of shared policies and construct mechanisms to provide privacy guarantees when data is transferred.

Conclusions

The construction of RHIOs and the sharing of information between them is an important pre-requisite for the successful creation and deployment of a National Healthcare Information Network (NHIN). Very little attention has been placed on technology to enable this RHIO to RHIO collaboration in a privacy preserving manner, till now. In this paper, we present *Sticky Policy Enforcement* technology, which provides mechanisms to perform proactive and reactive enforcement when sharing clinical documents between RHIOs.

Pulling Back the Covers: Technical Lessons of a Real-World Health Information Exchange

Atif Zafar, M.D.[a,b], Brian E. Dixon, M.P.A.[a]

[a]*Regenstrief Institute, Inc., Indiana*
[b]*School of Medicine, Indiana University, Indiana*

Abstract

Several nations and local communities are striving to achieve widespread, secure exchange of clinical data between various health care providers and public health organizations. Most of the literature on health information exchange focuses on the financial, political, and privacy aspects of these initiatives. Perhaps just as important are the technical and organizational factors that have influenced development of data exchange methods and results.

One mature network in the Midwestern United States has had success in establishing consistent, secure exchange of clinical data for more than ten years. Presented here are the technical lessons learned and design decisions made from this initiative with the hope that they can be used by others striving to connect disparate clinical information systems for the improvement of health care quality and safety.

Keywords:

computerized medical records systems,
computer communication networks, equipment reuse

Introduction

Everything in health care ultimately revolves around the accessibility and effective use of clinical data. When physicians, nurses, and other health care professionals have the information they need when they need it, they serve patients better, in terms of both the quality and the safety of the care they provide. Making these data available electronically, then, appears to make good sense.

Electronic clinical data abound. The problem is that they are often inaccessible to providers, because health care organizations tend to house their clinical data in distinct, isolated repositories. Many providers and policy makers now recognize that the sharing of data among hospitals, doctors, and other health care organizations in a given city, state, or region often referred to as health information exchange (HIE) can make health care safer, more efficient, and more effective [1].

The Indiana Network for Patient Care (INPC)

Indianapolis has pioneered an extremely successful HIE initiative, the Indiana Network for Patient Care (INPC), launched in 1993 under the leadership of the Regenstrief Institute. Initially, the INPC provided data from one hospital to providers in emergency departments at three other hospitals. By 2005, a more mature network, with a membership comprising 95 percent of all hospital and emergency care in Indianapolis, expanded to include providers in other parts of the state. By the end of 2006, the INPC contained more than six million distinct patient registration records, 850 million discrete observations, 17 million text reports, 50 million radiology images, and 40 million orders.

A number of factors have contributed to the INPCs success, including political and legal dynamics, which have been addressed in other publications [2][3][4]. Here we outline the reasons for the technical design decisions and functionality of the INPC, highlighting the technological and organizational factors that have contributed to the networks growth, ease of use, and sustainability.

Technological factors

Regenstrief has examined, deployed, refined, and evaluated a variety of operating systems, programming languages, software applications, and database management systems over its thirty-year history. The philosophical approach has been to *select a technology, stick to it, and make it work*. This means we rarely make radical changes (e.g., redesign a program written in one language using another language) unless there is a clear need (e.g., the new language is far superior to the old one). For example, early use of the Web (prior to 1995) for results aggregation brought many challenges. To enable asynchronous communication between clients and servers, we developed customized tools that possessed modern asynchronous JavaScript and XML (AJAX) functionality. Only recently have we begun to redesign our tools to utilize current AJAX frameworks.

Although sometimes slow to change, *our organization is not afraid to experiment*. We have worked with state-of-the-art image-compression technologies, such as JPEG

2000 and Wavelets, and motion video (MPEG) for display of radiology images and cardiac echo movies, respectively, in Web browsers. We have also experimented with voice-recognition and voice-annotation for clinical notes and display of laboratory results on mobile devices in wireless settings. Currently, we are experimenting with nomadic computing technologies so that clinicians can have an access-anywhere system for clinical data.

The INPC is composed of many moving parts, some of which are legacies while others are more modern. It is not the formula of a certain operating system with a specific database management system that has produced success for the INPC. Rather, the technical success of the INPC may be attributed to its adherence to these philosophies and the principle that, *when possible, one should build upon existing infrastructures rather than inventing or implementing new ones*. Below we discuss this principle in the context of the INPCs security, speed, flexibility, and reusability.

Security

Secure exchange of information between the INPC and participants operates using point-to-point connections. In the past, the INPC has employed T1 lines (data pipes as weve referred to them in other publications). We are now phasing out T1 lines in favor of virtual private networks (VPNs).

INPC security policy dictates the use of up-to-date encryption methods and good password hygiene and RSA keys. Currently the INPC relies on 128-bit SSL encryption to protect data on the rare occasion we use the public Internet to exchange information. Passwords must be changed at specified intervals, require a certain combination of letters and numbers, have a minimum length, and cannot be reused by the same individual.

The INPC also requires users to sign a confidentiality agreement and devices to be equipped with time-limit controls to prohibit unauthorized access. However, users do not log in directly to the INPC. User authentication is done via providers. First, users login to a provider portal or local area network (LAN), then they access INPC applications through a gateway created between the provider and the INPC network. The INPC relies on providers to implement access and time-limit controls on devices and ensure that users have signed a confidentiality agreement, which is required of them anyway to access the providers electronic resources.

Federated data sharing model

At its core, the INPC is a series of federated vaults, sometimes referred to as edge proxies or silos, storing data from the various participating institutions. Each institution has its own privileged silo where only data from that institution resides. The architecture of each silo closely resembles that of the Regenstrief Medical Record System (RMRS), a well known electronic medical record system [5]. A simplified data model of the RMRS is presented in Figure 1.

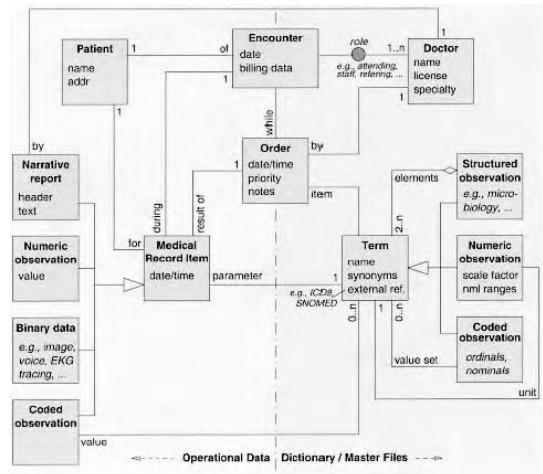

Fig. 1. Simplified data model for Regenstrief EMR.

Figure 1 - Simplified data model for the Regenstrief Medical Record System (RMRS)

Each silo represents mirrored data from one participating institution. Patient registry data, such as name, medical record number, and date of birth, and clinical data, like laboratory results, immunizations, and free-text notes recorded by the doctor during an encounter (e.g., clinical visit), are stored in the silos.

Silos can be created technically using a variety of methods. Hierarchical databases using large flat files running on clustered VMS nodes have been employed in the past. More modern relational databases can also be used to develop silos. Each silo can function as a separate database, or indices can partition data stored in a table on separate physical disks.

The specific technologies employed to create silos are not as important as the concept. Creating federated vaults gives participants peace of mind that their data will be segregated and secure. Yet data in federated vaults can exist within a single network access storage (NAS) unit, reducing latency when retrieving data during a clinical encounter. To date, the centralized, federated model developed by Regenstrief has yielded better performance (speed) when compared to decentralized federated networks used by other HIE initiatives.

A centralized, federated model also simplifies the process of data standardization ensuring identical blood urea nitrogen (BUN) results from various laboratories are interpreted the same way. The burden of reconciling various tests is shifted from individual provider organizations to Regenstrief. We can employ a single data model and dictionary and resolve errors as they arrive at the central hub for processing. Troubleshooting and mapping data elements to the standardized model requires overhead approximately 1-3 FTEs for the volume of messages we process. However, the costs and occasional painstaking mapping efforts are justified, because *we value the quality of the data stored in the INPC*. Our methods ensure that the

data retrieved from the INPC is reliable and standardized, which builds trust amongst network users and makes retrieval and delivery methods efficient.

Standards

Since its inception, the INPC has strived to provide optimal access to relevant clinical data at the point of care. To that end, the INPC has invested significant time and resources into the development and use of health information technology (health IT) standards (e.g., HL7, LOINC, CPT, etc.). These standards permit disparate systems to share data among one another, making them *interoperable*. They also permit the INPC to quickly add new types of data by reducing the time required to create customized interfaces for information delivery to providers.

Standards also enable data reusability, the ability to store a single concept and use it multiple times in a variety of applications. For example, a physician may order an HIV 1 AB (LOINC #7917-8) to indicate the presence of HIV in a patient. Once the result is reported to the INPC from the lab, three separate actions can be taken using the same HL7 message and LOINC code. First, the result would be stored in the institutional silo corresponding to the provider identified in the message. Second, the result could be delivered electronically to the physician using a clinical messaging application. Finally, the result could be reported to one or more public health agencies.

The example demonstrates that a single element, a standardized clinical message, can be used by three very different components of the INPC to store and exchange clinical information. Standards are employed so that the provider, physician, and health department interpret the result in the same way (e.g., all three receive a message indicating a positive value for LOINC #7917-8). This reuse of the same data is efficient, flexible, and cost-effective.

At the time of inception for the INPC, standards were *immature* and *limited*. We had to *invent* standardized methods for transmitting and mapping data between networked provider organizations. One such invention, the LOINC standard, was created because SNOMED and other existing terminologies lacked breadth for laboratory and some clinical concepts. We hope that other organizations can benefit from early experiments by us and other organizations. We believe that *field tested standards*, such as HL7 2.x and LOINC, can help others create interconnected systems in less than half the time it has taken us to develop the INPC.

Although we are experimenting with HL7 Version 3, current INPC members continue to transmit data using HL7 2.x. We encourage continued development and refinement of standards, and we will support them as they mature and become adopted by INPC participants.

Applications

An important lesson learned from building an **aggregated**, **standardized** data repository is that *data can then be reused for many applications*. For example, the same dataset that is reported out to clinicians using a clinical messaging application, we call ours DOCS4DOCS, can be sent to the State Health Department for communicable disease reporting. Similarly, data received from private practices could be aggregated and presented to an ER physician for delivering emergency care. These compelling applications allow INPC *stakeholders* to get some value-added by joining the collaborative, with an understanding that *their data* will only be used according to the agreed upon terms within the data-sharing contract.

Component-based architecture

The INPC employs a number of component technologies to process much of the data that travel across the network. Technologies like *interface engines*, *message processors*, and a *global patient and provider index* perform specific tasks that are generic enough to be re-used from application to application. Thus each component can be optimized for its task and easily modified to include a newly interfaced system. This creates a network in which components are not only interoperable but also reusable.

The idea of developing and reusing components is not unique to Regenstrief or the INPC. The object-oriented paradigm has influenced software development practices, with conventional modular techniques abandoned in favor of component-based approaches [6]. This is especially true in the open source software movement [7].

Regenstrief has embodied the philosophy of component-based development into the INPC, which has enabled the network to remain flexible. Expansion over the last thirteen years has involved the addition of new participants (e.g., hospitals, laboratories), new applications that use the data for a variety of tasks, and new forms of data (e.g., we added pathology reports in 2003 and dictated notes in 2005). With each new addition, the network has required slight modification. Development time is shorter, because components can be reconfigured and redeployed faster than monolithic programs. New components can be developed more quickly, because insertion into the network does not require recompilation or reconfiguration of other components.

Organizational factors

Designing, constructing, and operation of a working technical infrastructure for interoperable exchange do not guarantee success. In addition to its technical infrastructure successes, the INPC has also benefited from a number of organizational factors that have shaped its development over the last 13 years.

Incremental evolution

Incremental change has played a significant role in the INPCs long-term success. What began as an experiment to connect emergency rooms together slowly evolved into a large network that provides clinical information to emergency rooms, hospital staff in other departments, and ambulatory providers. This growth was guided by steady leadership that focused consistently on the INPC vision rather than on trends in the budding HIE industry.

Some HIE projects can and will evolve more quickly than the INPC. However, leaders of such projects should temper expansion with a clear vision for their network and agreement from all their partners.

Human resources

Technology is not the single most critical factor for successful HIE. To succeed in the development of a broad clinical data exchange, the INPC employed many capable people to manage and support the technology of the network. A knowledgeable staff is necessary on both ends of the network, at each participating organization as well as at the data exchange entity. Technical difficulties and bugs are inevitable, so capable humans are needed to troubleshoot errors, resolve data issues, and continue to move the vision of the exchange forward. And as the INPC has grown, so too has its need for more staff members to effectively monitor all of its members relations and data connections.

For example, we recently had a lab send us an HL7 message using unexpected units (up/mL). The INPC exception processor detected the anomaly (unrecognized units), which resulted in 26,000 records being dumped into an exception queue for analysis. Turns out the lab system had an embedded typo (the units should have been ug/mL), and the problem was resolved after a phone call and a few emails.

A more common problem we face is reporting of units in any other field, usually the notes field, except the appropriate HL7 units field (OBX-6). This is a problem common to all the labs from which we receive data, and it is a recurring problem for newly created tests.

Exceptions require human intervention as subtle differences between common clinical concepts are difficult for computers to resolve, despite several attempts in the past [8][9].Given the need for regular human intervention, we employ 2-3 FTEs to constantly monitor and troubleshoot the more than 150 message streams from the major hospital systems in Indianapolis, regional referral laboratories, specialty providers, several rural providers throughout the state of Indiana. We predict the need to add trained personnel in the future as the INPC continues to grow.

Our human resources also drive innovation. For years we have benefited from the talents of National Library of Medicine (NLM) informatics fellows typically post-doctoral physicians. These individuals have been key players in designing, creating, testing, and evaluating innovative components of the INPC infrastructure, including add-on programs such as CHICA™ and PHESS™ that extend the INPC beyond clinical messaging. Many of these fellows have stayed on as faculty at Regenstrief and the Indiana University School of Medicine, continuing to enhance the INPC and mentoring new fellows.

Sustainability

The ability of senior leadership to repeatedly make a clear, evidence-based business case for the INPC has contributed significantly to its sustainability. Initial funding for the INPC came from the NLMs high-performance computing and communication initiative. Subsequent funding has come from the NLM, the Agency for Healthcare Research and Quality (AHRQ), the Health Resources and Services Administration (HRSA), the National Cancer Institute (NCI), the Indiana Genomics Initiative, and the Indiana Twenty-First-Century Fund [2]. Each grant supporting a portion of the INPCs development enabled Regenstrief to measure clinical, financial, and community outcomes. These data provided support to the INPCs business case, which allowed the network to secure additional funding for expansion of existing services and development of new ones.

In addition, the networks interoperable, flexible design supports a variety of clinical and research activities. Applications such as CareWeb™, DOCS4DOCS, the Shared Pathology Information Network (SPIN) anonymous query tool, and the Public Health Emergency Surveillance System (PHESS™) for syndromic surveillance build on the INPCs core infrastructure. However, each creates a unique service for all or specific network members. An innovative, legally separate organization, the Indiana Health Information Exchange (IHIE), has also capitalized on the INPC infrastructure, creating a highly reliable, customer-oriented organization to support care delivery organizations using Regenstrief technology. By vertically expanding the INPC in this way, senior leadership has successfully created new resource opportunities for the INPC to grow and improve.

Conclusion

Reliable, up-to-date clinical data at the point of care remain the key to improving both the quality and safety of health care. Successful exchange of clinical data occurs only when all participating providers and organizations share not only data, but an understanding of what those data mean. Incremental change and growth are key to the success of data exchange networks. Over time, effective networks tend to expand the types of data they carry, as well as the applications for those data. Standards and reusable components help HIEs to maximize their efficiency through shorter development time and lower costs creating opportunities for integration with new systems and organizations. If other exchanges are as successful as the INPC, valuable improvements in care will be achieved in many communities.

Acknowledgments

This work was produced under Agency for Healthcare Research and Quality contract no. 290-04-0016. The authors thank staff at Regenstrief Institute, Inc. and the Indiana Health Information Exchange (IHIE) for their contributions to this work and tireless pursuit of health information exchange to improve the quality, safety, and efficiency of health care.

Abstract

There is a significant increase in the use of medical images in clinical medicine, disease research, and education. While the literature lists several successful systems for content-based image retrieval and image management methods, they have been unable to make significant inroads in routine medical informatics. This can be attributed to the following: (i) the challenging nature of medical images, (ii) need for specialized methods specific to each image type and detail, (iii) lack of advances in image indexing methods, and (iv) lack of a uniform data and resource exchange framework between complementary systems. Most systems tend to focus on varying degrees of the first two items, making them very versatile in a small sampling of the variety of medical images but unable to share their strengths. This paper proposes to overcome these shortcomings by defining a data and resource exchange framework using open standards and software to develop geographically distributed toolkits. As proof-of-concept, we describe the coupling of two complementary geographically separated systems: the IRMA system at Aachen University of Technology in Germany, and the SPIRS system at the U. S. National Library of Medicine in the United States of America.

Keywords:

medical informatics applications, image information storage and retrieval, Internet services

Introduction

There has been an explosive growth in the acquisition of medical images for clinical diagnosis, and use in medical research and education [1]. Hospitals have been adopting technology such as Picture Archiving and Communication Systems (PACS) and Hospital Information Systems (HIS) to assist in the digital collection, organization, and storage of patient data. The goal of these systems is to make patient data more accessible; in reality, the amount of data that is entered and stored in these systems have created new challenges in effective information indexing and retrieval. Retrieval of image information from these systems is done using limited text keywords in special fields (e.g., unique patient identifier, fields in the image header). These keywords, however, do not capture the richness of features depicted in the image itself. It would be beneficial if the images could be retrieved by their visual content to help improve research, education, or medical practice. Content-Based Image Retrieval (CBIR) has received significant attention in the literature as a promising technique to ease the management of large image collections in a variety of domains [2-4]. Recently there has been an increasing interest in applying it to medical image repositories [5]. Rather than limiting queries to textual keywords, users can also query by example image or image feature (e.g., color, texture, or shape computed from a region of interest) to find similar images of the same modality, anatomical region, and disease along with the matching associated text records.

While the literature lists several successful systems for content-based image retrieval and image management methods [2, 5], they have not made significant inroads in routine medical informatics. In addition, although many large imaging databases exist, such as the National Cancer Imaging Archive (NCIA) or the Lung Imaging Database Consortium (LIDC) created under the aegis of the Cancer Imaging Program[1] at the U.S. National Cancer Institute (NCI), these efforts have concentrated on data collection and transmission but have left development of applications to the research community. Lack of CBIR adoption has been attributed partly to the difficulty of integrating current implementations with existing healthcare systems [6]. The following reasons may further explain this anomaly: (i) challenging nature of medical images, (ii) need for specialized methods specific to each image type and detail, (iii) lack of effective image indexing methods, and (iv) lack of a uniform data and resource exchange framework between complementary systems. Most systems tend to focus on varying degrees of first two items, making them very versatile in a small sampling of the variety of medical images, but unable to share their resources or strengths. This requires each project to redevelop what may exist as an advanced implementation, but inaccessible. The lack of suitable image indexing methods is a problem for large image collections. Image comparisons performed linearly are inefficient and too slow for practical use. This paper proposes to overcome these shortcomings by defining a data and resource exchange framework using open stan-

1 http://imaging.cancer.gov (Last accessed: March 27, 2007)

dards and software to enable such specialized systems to act as geographically distributed toolkits. The approach enables communication between two or more geographically separated complementary systems with possibly different architectures and developed on different platforms, and specialized for different image modalities and characteristics. The resulting system provides the user with a rich functionality operating within a familiar interface on the Web-browser, making it portable and independent of location and underlying user operating systems. Figure 1 illustrates this concept.

In this figure, each circle represents a CBIR system specializing in particular image types, pathologies, or CBIR techniques. Using a standard open protocol any system could act as a client using the services available elsewhere to provide the user with a rich medical image informatics resource.

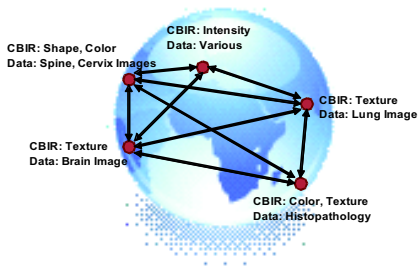

Figure 1 - Concept: Geographically distributed framework of complementary CBIR systems

As proof-of-concept, we describe the coupling of two leading, complementary geographically separated image informatics CBIR systems: The Image Retrieval in Medical Applications (IRMA) project at the Aachen University of Technology (RWTH) [7, 8] and the Spine Pathology & Image Retrieval System (SPIRS) project at the U.S. National Library of Medicine (NLM) [9-11]. IRMA and SPIRS retrieve images based on different approaches: Traditionally, IRMA has focused on image retrieval by computing overall (or global) image characteristics such as color, intensity, and texture. In particular, the image distortion model was developed and proven as a robust distance measure for differences on smaller sub-regions in the image [12]. Such an approach permits queries on a varied image collection and helps identify similar images, e.g., all chest X-rays in the A-P view. The IRMA system lacks the ability to find particular pathology that may be localized in specific regions within the image. In contrast, SPIRS can retrieve images that exhibit pathology that may be localized to a particular region under the assumption that the query to a large image collection containing images of only one type, e.g., vertebral pathology expressed in spine x-ray images in the sagittal plane. SPIRS lacks the ability to select pertinent images from a large varied image collection typical in a hospital PACS system, for example. We believe that combining the strengths of these two complementary technologies of whole image and local feature-based retrieval is unique and valuable for research into the retrieval of images in large repositories that are similar in type as well as pathology.

Background

IRMA project

The IRMA project[2] aims to develop and implement high-level methods for CBIR with prototypical application to medico-diagnostic tasks on radiological image archives. Stated goals include support for semantic and formalized queries to the medical image database with support for inter- and intra-individual variance and diseases. Example tasks are the staging of a patient's therapy or the retrieval of images with similar diagnostic findings in large electronic archives. Formal content-based queries also take into account the technical conditions of the examination and the image acquisition modalities. The system classifies radiological images in a general way without restriction to a certain diagnostic problem or question. Pattern recognition and structural analysis methods describe the image content in a feature-based, formal and generalized way. The *mean* image description enables a fast and reliable image comparison and retrieval. The project also includes an automatic classification and indexing process for insertion of new data into the system without manual interaction.

The IRMA project has several interfaces and can be characterized by its features: (i) Automated classification of radiographs based on global features with respect to imaging modality, direction, body region examined and biological system under investigation; (ii) Identification of image features that are relevant for medical diagnosis; these features are derived from a priori classified and registered images; and (iii) Image retrieval on similarity to an a priori selected feature set based on the visual similarity of certain image structures. Current image data consists of radiographs, with future plans to include medical images from other modalities. An IRMA retrieval interface supporting query refinement is shown in Figure 2.

SPIRS project

SPIRS[3] provides a Web-based interface for performing image retrieval from a database of digitized spine x-rays using the morphological shape of the vertebral body. Its framework enables interaction with and retrieval of relevant information from large databases of image and patient data using rich hybrid image and text query methods.

A query editor enables users to pose queries by sketching a unique shape, or selecting or modifying an existing shape from the database. It aims to capture query semantics through support of advanced mechanisms like multiple partial shape matching. Additional text fields enable users to supplement visual queries with other relevant data (e.g., anthropometric data, quantitative imaging parameters, patient demographics). These hybrid text-image queries may be annotated with pertinent pathologies by selecting and weighting local features to indicate importance. Query results appear in a customizable window that displays the top matching results and related patient data. SPIRS provides a working proof-of-concept that is capable of accommodating large amounts of imaging data expected in the near future.

Figure 3 - SPIRS interface with (a) crop and (b) detail view

At NLM, the focus of CBIR research has been to develop systems capable of performing a range of queries on large medical multimedia databases comprising various biomedical images and patient health data. Such a database in current use contains digitized spine x-rays and associated person metadata that comes from a large nationwide survey, the Second National Health and Nutrition Examination Survey (NHANES II). NHANES is conducted regularly by the National Center for Health Statistics in the United States. The goals of NHANES include estimating prevalence of selected diseases, monitoring disease trends, and studying the relationship between nutrition and health. The NHANES II collection is considered very valuable to radiologists, bone morphometrists, researchers in osteo-arthritis, and medical educators. Domain experts reviewed a sample of the data and identified 23 key biomedical features that were exhibited in the x-rays. Of these, anterior osteophytes, subluxation/spondylolisthesis, and disc space narrowing were determined to be frequently occurring and reliably detectable. Each of these key features may be identified by examining the boundary shape of the vertebra. SPIRS may be used to determine what features (e.g., protrusion on the anterior edge of the cervical vertebra) are consistently associated with a certain symptom (e.g., neck discomfort) or whether a certain feature is a precursor to more serious illnesses (e.g., arthritis). Pathology or medical condition may also be documented in the text of the patient record as a survey response or in the medical diagnoses. The SPIRS Web-interface is shown in Figure 3. In addition to the Web-interface, SPIRS also offers a service to its core shape similarity algorithms and data. Although SPIRS focuses on shape-based queries its framework is extensible to adopt features particular to other biomedical image and data collections, e.g., its core architecture is being extended to include color, texture, and spatial location in uterine cervix images from the National Cancer Institute at the NIH [11]

SPIRS-IRMA multilevel distributed CBIR

Medical CBIR systems can be classified by the type of numerical features used to characterize the images: (i) **global** approaches extract a single feature vector from the entire image, (ii) **local** approaches assign the feature vector to distinct regions of interest, and (iii) **structural** approaches additionally cope with spatial and temporal relations between the image objects of interest. In this context the IRMA system is a global feature system with particular structural aspects of some image regions that are also computed. In contrast, SPIRS takes a more local approach to image similarity with some structural knowledge available from the vertebral image labels. In this sense, SPIRS-IRMA jointly may be considered a multilevel distributed CBIR system [11, 13].

In this joint system, IRMA serves as the front-end for the end user, while SPIRS provides specific shape similarity algorithms and supplies formatted responses to structured queries. In this proof-of-concept system, extensive data interchange was minimized through data mirroring. It is conceivable, however, that the data could also be securely shared in a purely service oriented setup. Screenshots from the combined SPIRS-IRMA system are shown in Figure 4.

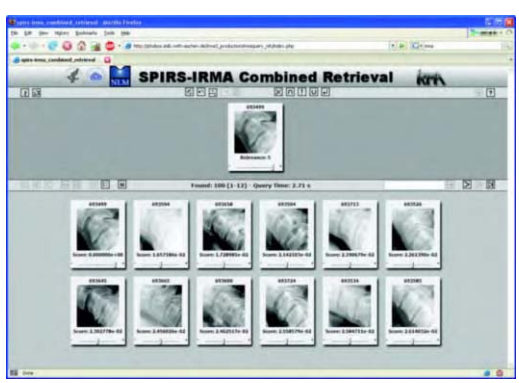

Figure 4 - SPIRS-IRMA interface

3 http://archive.nlm.nih.gov/spirs (Last accessed: March 27, 2007)

The system has plans for development in several phases. SPIRS-IRMA is utilizing only limited services provided by SPIRS with near term goals to use all available features. Future phases will also include permit users to upload their own images, as in the current IRMA system, and segmented or sketched boundary outlines of interest. Next steps include multi-resolution shape queries and support for query logging and relevance feedback.

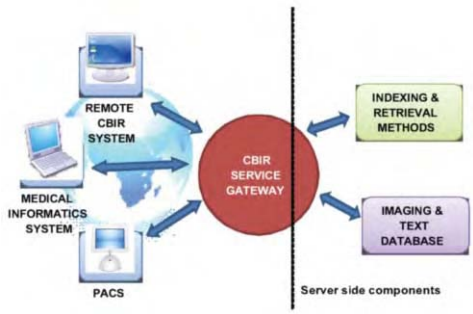

Figure 5 - The distributed architecture of SPIRS.

Data and resource exchange framework

CBIR systems sharing their data and computational resources need to be developed with a distributed architecture as shown in Figure 5. Each CBIR system would require the following components: (i) a gateway that acts as a mediator between client and server-side components, (ii) the indexing and retrieval server, which performs the feature representation and similarity matching, (iii) the databases containing images and associated text data, and (iv) an open communication standard for sharing of data and commands between the systems. Key components are described using the protocol developed for the SPIRS-IRMA system.

Gateway

The gateway is the entry point for all service requests. It can be implemented in any standard Web interface. In case of the SPIRS-IRMA collaboration, SPIRS has the service gateway implemented as a Java servlet. The gateway acts as a mediator between client requests and server-side components. It manages multiple simultaneous connections (users) as separate sessions and queues requests to the core CBIR engine. It translates query components that require information from the MySQL text database into SQL queries. The gateway is also responsible for formatting responses from server-side components and sending them to the client.

Server-side components

The core CBIR algorithms that operate on image feature data and text databases comprise the server-side components. While these algorithms rarely need any modification, their implementation is of particular importance. Typically, monolithic CBIR systems have indexing and similarity retrieval components closely wedded to the query and result visualization user interfaces. It is necessary to decouple these core algorithms from their user interfaces and implement them such that the local interfaces also use the gateway for all system communication. SPIRS indexing and retrieval algorithms use a variety of shape similarity metrics embedded within feature indexing techniques for efficient retrieval essential for Web use [11]. All text data is stored in a MySQL database and is accessible via both the gateway and the CBIR algorithms. In this initial prototype both systems hold all images and shape contours to minimize data exchange. Future plans include allowance for secure image and feature data exchange.

Communication protocol and data exchange format

A distributed computational framework relies extensively on a robust communications protocol and data exchange format. In case of SPIRS-IRMA, the systems are loosely-coupled over the Internet making it possible to use open communication standards. XML documents styled to a developed DTD are used for data exchange. The entire transaction is divided into three primary events, viz., *querystatus*, *query*, and *queryresult*. Each element in the XML file is designed for a particular event. For example, the <*querystatus*> element is used to determine if a desired service is available and to obtain a list of currently available services.

The <*query*> element is used to make shape queries where each query contains: (i) the query vertebra contour (boundary data points), (ii) partial shape indices and weights (if any) (iii) requested matching method (iv) maximum number of responses requested, and (v) range of similarity result scores. SPIRS responds with the <*queryresult*> element populated with: (i) matching image - vertebra tuples, and (ii) similarity scores. The design of the SPIRS-IRMA collaboration, the DTD, and sample XML data, are discussed in [13].

Discussion

The field of medical informatics has been unable to take advantage of image retrieval methods and systems in spite of their acknowledged importance in the face of growing use of image data in medical practice, research, and education. Image management and pathologically sensitive image content-based retrieval systems are thus increasingly necessary. The challenging nature of images and lack of comprehensive systems have hindered their acceptance. While it is difficult to develop a single comprehensive system, it may be possible to take advantage of the growing research interest and several successful systems with techniques developed for specific image collections. In addition to supporting rich segmentation, validation, indexing, query, retrieval, and visualization methods, inclusion of open interfaces using standard communication protocol, such as that described above, to the projects can enrich individual systems. The proposed approach has the following advantages:

- Simplicity: The simple communication interface allows for rapid development of methods for individual systems by expanding the available resources reachable through open communication standards.

- Extensibility and Flexibility: By separating the user interface from the core image informatics algorithms, the proposed approach allows systems offering services to continue development of other techniques and add them as they mature. It is no longer necessary to rebuild entire applications. In unusual cases, the protocol allows removal of some services advertising their unavailability.
- Security: Separating the core algorithms enables selective additional data security, user authentication, and encryption of the communication component (the gateway), where appropriate. The flexibility also allows sharing of just the methods.

We have demonstrated some of these features through the SPIRS-IRMA collaboration. In the IRMA system, it is possible for a user to find images from their database similar to an uploaded image. The query is limited to this extent, however. It requires manual viewing of each resulting image to identify those with pathology similar to that in the query example. While the SPIRS system allows shape queries with multiple parts highlighted, which indicates their relative importance, and includes text fields for further refined responses, it is limited to the spine x-ray database. When completed, users familiar with the IRMA interface can extend their searches beyond finding similar x-rays to include localized searches. Goals include enabling image segmentation services for user-supplied images. The resulting system is a multi-level, pathologically sensitive, geographically distributed system.

Conclusions and future work

In addition to formalizing the implementation of all aspects of the SPIRS-IRMA system, we plan to develop and publish a formal specification to enable sharing of image informatics resources among various systems. As a test, we will expand this framework to the CBIR system under development for uterine cervix images that uses color, texture, and spatial location information in generating an image description.

In this article, we have proposed a resource sharing strategy for increasing the impact of traditionally limited medical CBIR systems on medical informatics, and possible applications to clinical medicine, medical research, and education. We propose the use of open standards and a distributed framework that is simple to implement, extensible, flexible, and secure for the development of CBIR systems. We demonstrate its impact through a prototype SPIRS-IRMA combined retrieval system.

Utilizing SELinux to Mandate Ultra-secure Access Control of Medical Records

Peter R Croll, Matt Henricksen, Bill Caelli and Vicky Liu

Information Security Institute, Queensland University of Technology, Brisbane, Australia

Abstract

Ongoing concerns have been raised over the effectiveness of information technology products and systems in maintaining privacy protection for sensitive data. The aim is to ensure that sensitive health information can be adequately protected yet still be accessible only to those that "need-to-know". To achieve this and ensure sustainability over the longer term, it is advocated that an alternative, stable and secure system architecture is required. This paper considers the adoption of a model targeted at health information that provides much higher degrees of protection. A purpose built demonstrator that was developed based on enterprise-level systems software products is detailed. The long term aim is to provide a viable solution by utilizing contemporary, commercially supported operating system and allied software. The advantages and limitations in its application with a medical database are discussed. The future needs in terms of research, software development and changes in organizational policy for healthcare providers, are outlined.

Keywords:
information security, health information systems, operating systems, access control

Introduction

Advances in storage and communication technologies have made large repositories of data available even when they are maintained on separate systems and geographically distributed. The access to such data sets is often subject to varying degrees of legal, social and ethical constraints. Further, the data sets may not be available for open scientific research due to the sensitive and private nature of the information they contain. For example, individual personal health records offer significant value for medical and related research but such information cannot be readily accessed in a manner suitable for such research. The reasons include the need to abide by national privacy legislation, the reluctance to change to electronic record format due to security fears and the requirement to maintain end-user trust in the overall healthcare information system. Even when access rights have been granted - for example the data has been sanitized by having all personal identification removed - there are still legitimate concerns over the degree of privacy that contemporary IT applications will provide. The present reality is that IT applications operate on commodity level computer operating systems that do not - and cannot - provide the required level of assurance needed for scientific research to be undertaken on sensitive data. They were never designed for this purpose.

Information security mechanisms do exist to ensure sensitive information is protected and only accessible on a "need-to-know" and approval basis. It is imperative that both adversaries, such as external system "hackers" and technical/operations personnel with in-house knowledge be denied inappropriate access. The security mechanism known as Mandatory Access Control (MAC) is described below and can be used, as adapted, to enforce the necessary security and privacy processes required for handling sensitive health data. Such mechanisms have been studied and understood for over 30 years, mainly in defence related systems. However, they have not been evident in contemporary commodity level operating system or allied application level environments.

In particular, the ICT industry's move towards development of application systems based on so-called "Service Oriented Architectures (SOA)" and "Web Services" software environments presents new security challenges in the healthcare environment. Security standards, even for these high level service structures are often based on "interpreter" sub-systems such as XML, etc., and Internet/World-Wide-Web "browser" packages; they are complex and are only in the early stages of development and deployment. Moreover, all of these structures critically depend upon the overall security and dependability of the underlying "middleware", operating system and computer hardware systems. An application cannot be any more secure than the underlying systems upon which it depends. The same holds true for contemporary computer grid technologies, e.g., the Globus [1]. In other words, trying to adequately secure the shared "virtual machine" environments that grid technologies currently exploit is next to impossible (i.e., far too challenging for the foreseeable future).

The primary aim of this project is to build a "Concept Technology Demonstrator", based upon advanced cryptographic and information research and technologies (e.g., Cryptocards[1] and Starlight InfoSec technology[2]) in order

1 "Cryptographic plug-in cards", Eracom (Safenet) Australia.
2 "Starlight InfoSec Technology", Defence Science and Technology Organisation (DSTO), Australia.

to provide ultra-secure and sanitized access to the protected data sets.

The non-sustainability of current approaches

There is a strong vested business interest by mainstream suppliers of computer operating systems and similar middleware products to perpetuate the belief that computer applications can be *"made secure from within"*, irrespective of other software or even hardware components. In other words, the correct use of their technology will ensure a sufficiently secure operating environment upon which application programs can run safely. Unfortunately, any such assumption is flawed since in reality they represent a "fortress built upon sand" [2].

Current base operating systems in the commercial arena are based on what is designated as "Discretionary Access Control" or DAC. Essentially this design allows the "owner" of any object in a system to, at their discretion (from where the term DAC comes) pass on their access rights to any other person or entity in the overall information system's environment. In particular, DAC really does not acknowledge the essential difference between a computer "user", a person, and the individual "processes" in the system that act on his/her behalf. Moreover, the DAC structure assumes that the user is completely familiar with and trusts any program or related software system which he chooses to execute in the computer. In the current environment these assumptions, while possibly valid in the era of large mainframe computer systems with large "in-house" software development and support organisations prior to the development of global "packaged" software industry, are simply no longer true. The DAC approach, moreover, assumes that users formulate their own "discretionary" policy, a situation that is no longer valid as overall information systems become subject to overriding legal, societal and enterprise policy requirements.

The applications will not be secure unless the underlying operating system and hardware have been specifically developed with security in mind. A system that is built to utilize a MAC mechanism will provide levels of security relating to all aspects of the computing system, i.e., *"enforce an administrative set policy over all subjects and objects in a system, basing decisions on labels containing a variety of security-relevant information"* [3].

Practical implementations of MAC

There are many implementations of MAC based systems, but one of the most popular is called SELinux (Security-Enhanced Linux) [4]. It was designed and engineered by the National Security Agency, an intelligence-gathering organization belonging to the government of the United States. Released in 2000 as a patch to the Linux operating system, SELinux quickly gathered popularity within the Linux community due to its structural simplicity and the impeccable credentials of its designers. It now exists as an open-source module transparently integrated into the Linux OS kernel. Optimistically, the casual user may receive security support from SELinux without even noticing that the module is active, due to generic security configurations created by some of the recently arisen SELinux support groups.

SELinux shares two fundamental properties with many MAC systems. Firstly, the super-user concept of DAC systems (i.e., "root" or "Administrator") is banished, so that all users of the system are controlled by the same configuration policy. The policy is written by a security administrator. If an attacker can acquire the privileges of the security administrator, then the policy can be changed to suit his or her ends. But unlike the super-user, who controls any aspect of the system, the security administrator exists only to secure the machine, and not to make use of it.

Secondly, like some other MAC systems, SELinux is based upon the concept of "type enforcement", in which all the objects in an operating system (be they files, network sockets or processes) are labelled and classified as "domains" or "types". The system configuration determines how domains with label *x* are able to access types with label *y*. Typically the access rights will be described, in a broad sense, as "domain *x* can read type *y*", "domain *x* can write to type *y*", "domain *x* can execute type *y*", combinations of these, or "domain *x* cannot interact with type *y* in any way". This last option is the implicit default, so only positive relationships between domains and types need to be configured.

Nevertheless, the flexibility provided by SELinux tends to be its undoing, at least from the perspective of the casual user. Because there are many domains and types within even a single-user system, and because each possible positive interaction needs to be considered, configuration of access rights is a laborious and error-prone process. Add to this the fact that each system is guaranteed to be different to the one on which the prepackaged configuration was prepared, and a nightmare scenario in which SELinux denies essential accesses - such as allowing the system's Graphical User Interface to start - becomes a common one [5].

There are well-known strategies that can help to reduce configuration complexities. One of the most popular of these is Role-Based Access Control (RBAC), which intersperses a "role *r*" into the relationship between domain and type, such that, for example, if "role *r* can read type *y*" and "if domain *x* is a member of role *r*", then "x can read y". Since there are a small number of roles relative to the number of domains and types, then the number of rules relating roles to types and domains to roles should be much fewer than the number of rules that relate domains directly to types. SELinux supports a primitive version of RBAC, yet a typical SELinux configuration file still runs to about 50,000 lines.

The RedHat company sells RedHat Linux Enterprise and sponsors the "Fedora Core" open-source software activity, both of which sport an extension of SELinux that includes "strict mode" and "targeted mode" structures. Strict mode is no different to the "vanilla" version of SELinux, but targeted mode protects only a subset of domains and types, usually those which have interaction with the external world via network sockets, etc. (that is, those objects which are most likely to be attacked by hackers). The

remaining objects within the system are labelled "unconfined" and can "run amok" with only the discretionary access controls regulating their behaviour. RedHat ships SELinux in the default mode of "targeted", so that basic protection is afforded to the system without the mechanism becoming invasive, in turn preventing the user from being productive, and swamping RedHat support with basic administrative support requests. The flipside to this is that RedHat does not offer support to issues arising from the strict mode of SELinux. As will be seen later, this has a substantial impact on the use of SELinux to protect medical or other application data.

Protecting medical application data

The primary intention of SELinux is to protect objects embedded within the operating system, with security of application data being an afterthought. SELinux in effect partitions the operating system space into a set of "sandboxes", protected areas between which communication is tightly regulated. The mechanism is generic, and consequently, the security administrator can create an additional series of sandboxes at the application level to protect medical and other kinds of data. For example, the administrator may configure a web-browsing sandbox that permits a web browser such as Internet Explorer or Mozilla Firefox to access the internet. In addition, the administrator may also configure a medical-related sandbox in which a medical application is permitted to access medical records. However, unless explicitly permitted, the web browser does not have access to the medical records. Neither does the medical application have the same level of exposure outside the network as the web browser. The security administrator can create arbitrary levels of complexity in the application layer by constructing sandboxes for different applications, yet the enforcement mechanism of SELinux treats them all equally and prevents unauthorized accesses. Whereas if a hacker attacked a DAC system through the network interface, and managed to acquire super-user permissions, in an SELinux scenario, the hacker would control only a single sandbox, and would need to launch additional exploits, each of which became increasingly infeasible with distance from the network interface.

An important caveat is that the "targeted" mode of Red Hat Enterprise Linux and Fedora Core does not permit application-level sandboxes, because all application process run in the unconfined domain. Any system supporting application level security is compelled to run in strict mode, which in turn means that it is likely not to be fully supported by its commercial vendor.

Building an SELinux proxy

Application data tends to be much more dynamic and flexible than operating-system level data. There may be many users of an application level database, whereas the number of owners of operating system processes tends to be very small. By default, SELinux is configured for four users, including system, staff, sys-admin and ordinary users. Adding new users involves recompiling and reloading the configuration policy, as does adding new rules for interactions between domains and types. As operating-system level relationships tend to be very static, for example, changing only when new software is installed, this is not especially disadvantageous for the normal use cases for SELinux but is not well suited for creating rapidly changing sandboxes.

Our solution to this problem, which also avoids the problem of creating additional complex interactions between application and operating system level objects, is to create a proxy. The proxy runs at the application level and is secured in its own sandbox by SELinux, preventing unwanted interactions with other processes. The proxy regulates access by application-level process to protected data, using its own set of configuration files. In one sense, this solution can be viewed as nested SELinux, whereby the proxy represents a micro-instance of SELinux that deals only with application data. Operating system level processes see only a monolithic object (the proxy) representing application processes, meaning that the number of configuration rules between the two layers is linear rather than multiplicative.

The proxy deals with the added levels of interaction complexity at the application layer by using an enhanced version of RBAC, in which role permissions are inherited throughout a hierarchy. By collating roles into hierarchy, and associating the lowest member of each hierarchy with each type, this obviates the need to associate every role with every type. As an example, a vertical slice of a role hierarchy may consist of "Doctor is a subset of role Clinician" and "Surgeon is a subset of role Doctor". Configuring the policy with "any user in the role of Clinician has access to type *y*" automatically covers the rules for "any user in the role of Doctor has access to type *y*" and "any user in the role of Surgeon has access to type *y*" by virtue of their membership of the family. Portions of the hierarchy can be overridden: configuring "any user in the role of Surgeon does not have access to type *y"* does not cause a contradiction but allows only Clinicians and Doctors access to type *y.*

An option in this research was to build the extended RBAC functionality natively into SELinux for which the source code is freely available. However, the benefits to operating-system level objects, which are not ordered hierarchically, are unlikely to outweigh the disadvantage in branching the SELinux source code, consequently reducing the successful uptake of this solution.

The mechanism by which the proxy works is very simple, and abstractly mirrors the SELinux mechanism. A client interacts with the proxy via a pair of Client and Server messages. For each client message received, the proxy sends exactly one server message.

The client authenticates itself to the proxy using a client message with type CREDENTIALS and with a payload containing the user, role and password that describe the client. Until the next such message is received, the proxy caches the credentials. This mimics the SELinux mechanism, which authenticates a user via a password before transitioning the user into the requested role. The proxy

generally responds to credential messages by sending a dummy OK response.

The credentials are evaluated whenever the client requests access, either a read or a write, to a record in the proxy database. The proxy passes the credentials, along with the record identifier and the policy to the security filter. The security filter assesses the credentials, decides whether the record can be accessed in the way intended and passes this decision to the proxy. In the case of a read request, the proxy relays the appropriate record back to the client. If the client has requested a write, then the material passed in the payload of the REQUEST_WRITE_FILE message is appended or overwritten to the record.

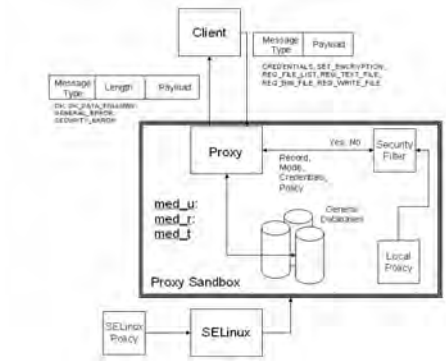

Figure 1 - Architecture of the SELinux proxy

Whereas SELinux can protect data to the granularity of the file, the proxy has arbitrary granularity, as determined by tags exchanged between the proxy and its client. The client may wish to retrieve a single word from a database, or an entire collection of files. Our mechanism allows this with as little as a single configuration, although for more complex cases, the number of configuration rules will increase linearly in the number of database items.

There are some cases when records must be accessible even in the absence of legitimate credentials. For example, if the authorized viewer of a patient's case file is not present, but the patient requires emergency treatment, then the availability of the information is more important than its privacy. So the proxy is programmed to respond to a special role of "Emergency", in which case it moves into auditing mode, until a new set of credentials with a differing role is provided. In auditing mode, all records can be retrieved and modified, but each action is recorded and flagged for review by the security administrator. Appropriate punishment for abusing this mode can be metered out at a social level. Our prototype does not handle differential records, whereby the deltas between subsequent versions of records are stored, although this would be advantageous for malicious or accidental modification of records in auditing mode.

It is not essential for the proxy and the client to maintain an encrypted channel, since access control on the channel can be maintained by SELinux. For ease of configuration, all communication can be encrypted using commonly available algorithms such as the Advanced Encryption Standard. Our research did not consider key management issues between the client and the proxy, although the usual public key establishment protocols, such as Diffie-Hellman can be used.

To prove the effectiveness of the proxy, we developed a simple prototype of the proxy and a client, as shown in Figure 2. Auditing data for the client is shown in Figure 3. We used the proxy and client to demonstrate the security advantages of SELinux over DAC-based systems such as Windows XP. In DAC-based systems, it was relatively easy to use hacking tools such as rainbow tables [6] to break weak Windows system administrator passwords, and modify the proxy and client code to allow unauthorized and unaudited accesses. As the proxy was housed in its own sandbox under SELinux, traditional hacking tools did not provide an avenue for breaking into or changing the proxy. The issue remains that this security is present only in the unsupported "strict" mode of SELinux which is still too complex to deploy in commercial situations.

Although the proxy significantly simplifies configuration of application data, it does not address problems at the operating-system level that need to be resolved. Further research in this area needs to focus on simplifying generic SELinux configuration, to allow realistic deployment of "strict" SELinux, which supports protection of application data. This is indeed happening, as witnessed by the development of modular policy logic in Fedora Core 5, which allows the configuration to be developed and loaded in blocks relating to the processes or daemons being protected. The efficacy of this strategy has yet to be solidly determined.

Figure 2 – The Proxy Client

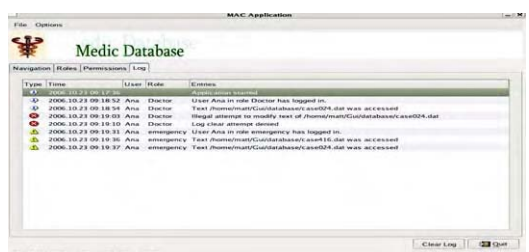

Figure 3 – Auditing data for the proxy client

Conclusions

Sufficient evidence is emerging that the security requirements and obligations for the protection of sensitive health data cannot be sustained using contemporary data access control and protection mechanisms in current commercial, commodity computer systems. *"Mandatory Access Control"* or MAC, incorporated into basic operating systems and allied supporting software structures, provides an alternative, strict, security policy driven approach far superior to industry standard DAC mechanisms. MAC can strengthen protection from unauthorised access to sensitive health related information from both outside and inside an organization. This provides enhanced privacy protection from staff, including knowledgeable ICT professional staff members, gaining access to such sensitive data for which they are not authorised (i.e., view, modify, copy, transmit, delete, etc.). It further provides enhanced 'boundary' security from outside intrusion whereby adversaries, such as hackers and spyware operatives, are unable to gain full control of an information system. In the MAC case it can be demonstrated that damage can be limited to violation of an individual user's account [7].

This research has found that a MAC based medical data system, although viable, still presents some key research and practical deployment challenges. In particular, the "strict" operational mode offered by SELinux may be seen as being too rigid for deploying Role-Base Access Control or RBAC structures with the required levels of flexibility needed in practical healthcare situations. Without this flexibility, system reconfiguration may be required each time a user is added or removed. This is infeasible in practice and is already the subject of a number of active research projects. It was shown with the demonstrator described in this paper that a compromise can be derived that provides an application level proxy to facilitate a secure, role-based access interface. A balance has to be struck between strict access control security and the degree of flexibility for dynamic modification of any system in the "real world". Any approach taken should be determined from a privacy impact oriented risk assessment process. For example, such an assessment might readily determine a need for emergency over-ride capability to enable at least wide read-only access to medical/health data. Such a facility would, however, have to be subjected to new audit and control requirements as well as to limitations potentially related to time periods and the location of users. In this regard an implementation that can support dynamic reconfiguration in a manageable and understandable manner may be essential. Earlier MAC systems were simply not designed for this environment where the security policy may need to be dynamic, not just in detail but also in structure.

Future needs in terms of research also involve a better understanding of the complementarity of SELinux's concept of "type enforcement" versus more traditional security structures based on hierarchical "Multi-level Secure" or MLS schemes. In the health information area it needs to be determined whether or not such hierarchical security schemes have a place or not and, if so, to what level are modifications of the basic concepts involved necessary. Likewise, the concept of "compartmentalization", reflected in the SELinux type enforcement system, needs to be assessed in relation to its suitability for all levels of information services needed in a nationwide health information structure. At the same time, application software development needs to become aware of the new parameters afforded by the MAC facilities and determine to what level such applications may or may not make use of the security mechanisms and services offered, i.e., to determine the distinction between what may be labelled as "security aware" versus "security ignorant" applications. Moreover, the integration of existing software systems into this environment must be understood, requiring further research into appropriate techniques for system integration in higher security environments. In turn, this places new demands on education and training as ICT professionals need to develop the skills needed to understand, utilise and manage this new environment. This indicates that necessary or desirable changes in organizational policy and management structures for healthcare providers may be also needed. At present, full guidance to policy makers and operational management in relation to deployment of newer MAC based overall information systems do not appear to exist. This leads to the need for further research and experimental system development in the area to enable study of the economic, cultural, social and legal responses required.

Acknowledgments

This research was supported under the Australian Research Council's Special Initiative on e-Research funding scheme (project number SR0567386). The authors would like thank RedHat (Asia Pacific) Ltd. and the E-Health Research Centre (a joint CSIRO and Queensland Health initiative) who have been highly supportive.

Abstract

The French ministry of Health is setting up the Personal Medical Record (PMR). This innovative tool has long been expected by French Health Authorities, Associations of Patients, other Health's associations, those defending Individual Liberties and the French National Data Protection Authority. The PMR will lead to improvements in many areas such as Diagnosis (Research and monitoring) Healthcare (Management of emergencies, urgent situations, Temporal health monitoring and evaluation), Therapy (Cohorts of patients for Clinical trials and epidemiological studies). The PMR will foster safe healthcare management, clinical research and epidemiological studies. Nevertheless, it raises many important questions regarding duplicates and the quality, precision and coherence of the linkage with other health data coming from different sources. The currently planned identifying process raises many questions with regard to its ability to deal with potential duplicates and to perform data linkage with other health data sources. Through this article, using the electronic health records, we develop and propose an identification process to improve the French PMR. Our proposed unique patient identifier will guarantee the security, confidentiality and privacy of the personal data, and will prove to be particularly useful for health planning, health policies and research as well as clinical and epidemiological studies. Finally, it will certainly be interoperable with other European health information systems. We propose here an alternative identification procedure that would allow France to broaden the scope of its PMR project by making it possible to contribute to public health research and policy while increasing interoperability with European health information systems and preserving the confidentiality of the data.

Keywords:

electronic health records, unique patient identifier, security

Introduction

In the majority of industrialized countries, at the heart of many of the concerns relating to electronic processing of health information lies the problem of patient identification. In August 2004, the French government decided by law to initiate a national project concerning Electronic Health Records called the "Dossier Médical Personnel", the Personal Medical Record (PMR) [1]. It intends to promote health care coordination, enhance the communication of health information and reduce iatrogenic accidents. The most important aim of this article is to show and present the principles of the French unique patient identifier created relative to the PMR. However, it will also explain and show its major disadvantage, which is its interoperability characteristic. For example, this current patient identifier seems to be incompatible with the identifier of the European health card [2]. This paper will thus demonstrate, in its first section that the French health identification number does not ensure interoperability at the European level. The second section proposes an alternative identification process that would allow France to improve the quality, security, precision and coherence of its PMR project. The developed and proposed health identifier will be extremely useful for health planners, those dealing with health policies, public health research and clinical and epidemiological studies, and this, at national, regional and international level.

Materials and methods

The issues and criteria of a unique patient identifier

The identification of the patient in a health-care structure and particularly in the framework of the electronic healthcare record of a care network is a major issue [3]:

- Patient care continuity requires secure, precise, coherent and reliable patient identification through all of the health information systems.

- The reduction and management of identification-related error is one of the major constraints necessary to maintain and improve the quality of care;
- A reliable unique format for patient identification is required in order to design and implement an interoperable health information system focused on the patient.

In the context of the "Principle and Process of Patient Identification" project, the French Group for the Modernization of Hospital Information Systems (GMSIH) [4] inventoried the principles and the architecture of identification systems by specifying two aspects of the problem:

1. "Identification" will specify which information will be used to uniquely identify a patient. Multiple identifiers can be proposed for the same patient in different applications.
2. "Merging" identification areas, requiring the implementation of specific methods (intra-health structures and among health structures).

This group also inventoried the international patient identification experience of ten countries (Germany, Australia, Canada, Denmark, Finland, Luxembourg, the United States, New Zealand, The Netherlands and the United Kingdom) considered by the GMSIH as representative of best practices in the areas of socialized health care, electronic health care information systems or patient identification.

The American Society for Testing and Materials (ASTM), a standards development organization accredited by the American National Standards Institute, identified 30 criteria that were published in the *Standard Guide for Properties of a Universal Healthcare Identifier* [5]. The most recent standard on Health Care Client Identification we know is from Australian Standard® AS 5017-2006 published in June 2006 [6]. This standard includes data elements that jointly comprise a unique identifier for health care clients. It is explained that the combination of the client identifier and the health care establishment that assigned the identifier is one way to indicate unique identification. The logical structure for these data elements has shown that, there may be multiple identifiers collected for any one individual. Together, the data elements that makeup one complete Health Care Client Identifier are

a) Health Care Client Identifier Designation b) Health Care Client Identifier Geographic Area c) Health Care Client Identifier Issuer d) Health Care Client Identifier Type.

Most health care clients have more than one identifier. The most commonly used identifier should be collected as the Primary Client Identifier (the first listed client identifier). This identifier is generally that assigned by the organization as the means of uniquely identifying the client. Often, there are other identifiers also related to the client, and these should be collected and recorded as Other Client Identifiers (listed second or subsequently in the identifier list). There can only be one Primary Client Identifier, but there may be many Other Client Identifiers collected for any one application. Examples of Health Care Client Identifiers include 1)Person Identifier 2) Medical Record Number (MRN) 3) Local Client Identifier 4) Health (care client) Identification Number 5)Unit Record (UR) Number 6) Enterprise Identifier 7) Area Identifier 8) State/Territory Health Identifier 9) Unique Identifier (UID) 10) Unique Health Identifier (UHID) 11) National Health Identifier (NHI).

The five most important criteria and characteristics (Table 1) of the Health Care Client Identifier (HCCI) Designation are adapted from the AS5017-2006 and provided here as a guide to assigning a unique identifier [6].

Table 1 - criteria and characteristics of the Health Care Client Identifier (HCCI)

Atomic (the HCCI Designation should be a single data item. It should not contain sub-elements that have meaning outside the context of the entire HCCI Designation. Nor should the HCCI Designation consist of multiple items that must be taken together to constitute an identifier).
Content-free (the HCCI Designation should not depend on possibly changing or possibly unknown information pertaining to the health care client. Including content in the HCCI Designation will make it impossible to assign the 'correct' identifier if that information is not known. It also leads to invalid situations if the information changes: for example, what happens to an identifier based on sex if the health care client has a sex change procedure).
Longevity (an HCCI system should be designed to function for the foreseeable future. It should not contain known limitations that will force the system to be restructured or revised radically).
Permanent (once assigned, an HCCI Designation should remain with the health care client. It should never be reassigned to another client, even after the health care client's death).
Unambiguous (whether represented in automated or handwritten form, an HCCI Designation should minimize the risk of misinterpretation. Where using alphanumeric identifiers, be aware of possible confusion with the number '0' with the letter 'O' and the number '1' with the letter 'I')
Unique (a valid HCCI Designation should identify one and only one health care client. A health care client should have only one primary HCCI Designation)

These criteria are designed to support four basic functions of a universal health care identifier:

1. Positive identification of patients when clinical care is rendered,
2. Automated linkage of various computer-based records on the same patient for the creation of lifelong electronic health care files,
3. Provision of a mechanism to support data security for the protection of privileged clinical information (does not attempt to address all safety concerns, however)
4. Use of technology for patient record handling to keep health care operating costs at a minimum.

The founding principles of the French Health Identification Number

In September 2005, the French government defined the founding principles of the Health Identification Number (INS in France) of the personal medical file (PMR). This number must be:

- **unique**: to ensure that two people cannot have the same INS, thus avoiding erroneous attribution of a diagnosis. An identifier is therefore associated with a person whose identity can be validated.
- **content-free:** the number reveals no information about the holder (sex, age, place of birth…).
- **public:** the number can be legally used by all health care professionals authorized by the patient. It can be stored in the health care professional's information system. The number is therefore not secret.
- **permanent:** will remain the same for the life of the patient and, possibly, beyond.
- **irreversible:** impossible to determine the identifier by calculating backwards from the social security number. However, if lost, the same number can be recreated.

First proposal for the creation of the INS in the PMR

To meet the "uniqueness" condition, the French patient identification working group recommended that the identifier be associated with the social security number. The solution proposed by this working group involves the creation of a Health Identification Number (INS in France) for each patient managed at the patient's request by an independent organization known as a "trusted authority". The role of the "trusted authority", which may not be a host, is to guarantee that the identifier is not and will not be duplicated. The trusted authority will also be in charge of the secure access, the respect of confidentiality and the integrity of all the identification workflows.

To preserve the anonymity of the identifier, the trusted authority creates the INS through the following process:

- The patient chooses an approved host and advises the PMR office using a request form and the host using a membership form.
- By contacting the National Health Insurance organization the PMR office confirms the requester's affiliation and that it is a first-time request
- The trusted authority creates the INS using the request form number that it transmits along with patient attributes to the host.
- The host then informs the trusted authority that the patient's INS is operational

The use of the request form number and not the social security number to generate the INS is designed to guarantee that the number is content-free and the INS creation process mathematically irreversible, i.e. no mathematical operation would permit backward calculation from the INS to lead to the social security number. The guarantee of INS anonymity would rely on the absence of a table of correspondence *directly* linking INS and the social security number. Detection of collisions and duplicates would occur by way of the request form number. Nonetheless, the relationship between the social security number and INS would be indirectly maintained at both sides. One and only one request form number would be associated with each social security number and one and only one INS would be associated with each request form number. The trusted authority would not require knowledge of the social security number to prevent collisions; they would need only to ensure that the INS had been assigned to no other request form number. Similarly, by checking that each form number is given to only one INS, they would prevent duplicates provided that no duplicate form number existed further up the chain.

The trusted authority would send the INS to the host along with other patient identifiers, such as first and last name and date of birth, but never the social security number. The host would thus possess only those identifiers that could not be used to reconstitute the social security number.

Criticism of this method of generation

The principal criticism [7] addresses the second main function, as defined in the ASTM *Standard Guide for Properties of a Universal Healthcare Identifier* [5]: Automated linkage of various computer-based records on the same patient for the creation of lifelong electronic health care files.

Thus, the fact that the proposed system leads to an institutional disconnect between the INS as a central health system identifier and the social security number. The main reason cited to justify this disconnect is the desire to prevent the creation of a population table of correspondence between the social security number and the INS. This argument is, however, open to criticism insofar as all health professionals and in particular large institutions whose patient databases cover a large proportion of the population of a region must have access to the correspondence between the social security number and the INS.

If the link between the Social Security Number (SSN) and the INS is broken, relating PMR data with other patient data for research purposes becomes impossible. For example, relating PMR with other sources is necessary not only to complete their data but also to ensure multi-source validation in conformity with the recommendations of the report of the academy of sciences regarding epidemiology. If research using PMR data is not possible in the short term because of the time necessary to create databases that are sufficiently structured, exhaustive and validated, it can be expected that the data will be of use in less than a decade, if an acceptable identifier is adopted. That's why, like our British colleagues who complain that overzealous interpretation of UL laws stifles epidemiological research [8-11], we think that the current French identifier may cause particular difficulties regarding epidemiological and clinical research.

Moreover, it must be possible to reconstitute the INS, which represents the true signature of a patient, whatever the nationality or the country of origin starting from features of identification that are always available. These methodological principles must guarantee the secure and perennial identification of all the patients. These principles must apply whatever the future use of the information. Indeed, the technical and methodological choices must be able to follow evolutions in the legislation, which may be modified according to the evolution of mentalities and cultures.

Our proposal

It would be perfectly possible to preserve the confidentiality due to the patient and desired by patient associations by setting up anonymous procedures [12-14] such as those adopted by the Institut de Veille Sanitaire (Health Surveillance Institute) on the recommendation of the French National Commission for Data protection and the Liberties (CNIL), in the context of the follow-up procedures for the 30 diseases subject to mandatory reporting (including AIDS).

Unlike encryption methods that must be reversible to allow the legitimate recipient to decode the message, unidirectional hashing techniques are irreversible. Hashing produces a perfectly anonymous code (it is not possible to retrace the patient's identity) that is always the same for a given individual so that patient data can be linked. There are many medical applications, which include the creation of national databases (such as those relating to the national follow-up of infected subjects - approximately 100,000 patients – an excellent example of what can be put to the service of epidemiological research, with complete patient approval) as well as regional and inter-regional databases in many areas (cancer, perinatality, genetic diseases). This system has also allowed (based on the hash-coding of the Social Security Number (SSN), the gender and the date of birth), standardized hospital discharge abstracts to be linked, classified into French Diagnosis Related Groups at the French national level and linked to the data of the national medical insurance information system. An anonymous procedure based on hash coding is also used for chaining patient files in Switzerland [15].

In the case of the PMR the situation is not, in fact, more complex because several requirements must similarly be met in a similar way:

- demands of the CNIL, patient and healthcare professional associations regarding confidentiality of personal information contained in the PMR, and respect of the law of August 13, 2004 concerning the use of data,
- needs in public health or for individuals to have access to these data, particularly when the patient has given express consent.

Ideally, hashing the social security number would help meeting these requirements (Figure 1).

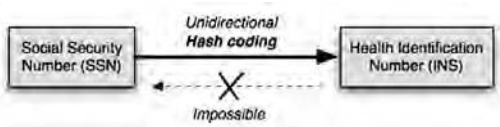

Figure 1 - Hash coding

Regarding confidentiality, insofar as the social security number could not be reconstituted using the INS, the link between them would be broken. Another advantage of using hash-coding is to meet the criterion of being focused (created and maintained solely for supporting health care cf. Table 1). As a consequence, using different keys for hash-coding will allow the creation of distinct identifiers according to different purposes (health administration, diagnosis and healthcare, epidemiological research). The same solutions also derived through an irreversible encryption of the unique Social Security Number (SSN) have been proposed in Belgium [16] and New Zealand.

Regarding data access for public health research, the use of the Social Security Number (SSN), after hash-coding, would thereby allow the linkage of the main national databases. However this solution raises many questions. Firstly, in France, foreigners do not a have a complete social security number. For instance, the last characters, corresponding to the country of birth, are not systematically filled. Moreover, as the date of birth in some foreign countries is not known precisely, two different patients may have the same date and the same country of birth, resulting in collisions, and linkage errors. Secondly, as the Social Security Number (SSN), has a different structure according the country, it can not be a solution for a unique patient identifier, interoperable at the European level.

One solution would be to add personal patient characteristics such as family name, first name, date of birth (separately hashed) to the social security number, which would help to conform to the recommendations of the International Association of Medical Information Technology and where possible to ensure interoperability of this identifier with a European identifier [17]. In fact, in the national medical insurance information system like in the standardized discharge abstracts, gender and date of birth have already been associated with the social security number, in the same identification field, before hash-coding, resulting in a single code. We could thus propose to build the INS through the simultaneous hash-coding of gender and date of birth associated with the social security number.

However, due to a simple error in the field for gender, linkage of data from the same patient can be definitively refused. It is important to note that this field is highly unreliable (numerous data entry errors have been observed in hospital settings). In addition, with regard to the quality of the linkage this variable is undiscriminating insofar as the probability of two people being the same gender is close to 50% and it does not discriminate for twins. It would therefore be preferable to replace this variable with one that is more sensitive, such as the first and last name of the beneficiary. As a consequence, our first proposal is to separately hash the social security number (removing the last digits), the date of birth and the last and first names, then merge this into a single signature of patient identity (Figure 2).

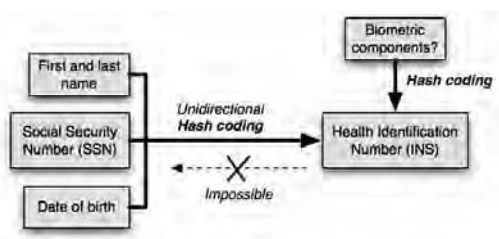

Figure 2 - Extended identifier for European interoperability

We could also propose, if possible to add biometric components (separately hashed). Biometric technologies are sometimes proposed in solving the problem of associating patients with their medical data, as they do not require the patient to bring any documents or remember information. Though this technology represents a real progress both in the identification and in the authentication of the patient, it raises many questions [18]. First, the accuracy and reliability of each biometric technology (for instance: finger print, iris scan, retinal scan and DNA) are not optimal in all circumstances. For example, fingers are frequently injured. Though retina scans and DNA analyses are the most accurate (with the exception of twins for DNA) they are also quite intrusive, which render even more difficult the possibility of combining these technologies, as proposed in some commercialized biometric systems. Moreover, the costs of the biometric solutions have to be considered. But the main problem lies in their acceptation by ethical organizations such as patients associations, national committees on ethics, human rights associations and national committees for data protection. In order to render this solution compatible with the current national procedures, it would be preferable to add the biometric component (separately hashed) to the hashed social security number, in order to ensure (at the European level) the interoperability of this identifier with national ones.

Conclusion

Our proposal for a French Health Identification Number will make it possible to uniquely identify and link a patient to his specific medical data. By hashing the social security number it will be possible to link the information of the personal medical file to other national health information sources, with the aim to complete or validate Personal Medical Data (PMR) or conduct epidemiological research. Adding personal patient characteristics such as first and second names and date of birth and/or biometric identifiers (separately hashed, then merged) to the hashed social security number would also contribute to the establishment of European public health statistics by matching healthcare data of the patients' records with other administrative data (mortality, social information …). This data linkage would thus meet the requirements of anonymous data of the European directive on data protection. This proposal could also be used in the discussions about the creation of European health care identifier. Of course, even if anonymised, the use of biometric components would require, the authorization of the National commissions for data protection.

Clearinghouse: A Teleradiology Platform Emphasizing Security of Data and Communication

Michael Spitzer, Lars Brinkmann, Frank Ueckert

Department of Medical Informatics and Biomathematics, University Hospital, University of Muenster, Germany

Abstract

The Clearinghouse application platform is a web based solution for secure digital exchange of radiological images and other clinical documents among authorized researchers and physicians. It implements a sophisticated security and role model to protect privacy and to minimize the risk of eavesdropping of patient data. The Clearinghouse serves as a centralized platform for distributed, distantly located medical research and health care. It is based on Open-Source software, thus ensuring continued support, maintenance, security and last but not least continuity of the platform. The use of the Clearinghouse minimizes turnaround times by superseding comparably slow and insecure conventional communication methods otherwise used for the exchange of radiological images and clinical documents, such as standard mail and courier services. Furthermore, it alleviates the integration of distantly located expert knowledge into diagnostic routines, culminating in an increased health care quality regardless of location of patients or physicians.

Keywords:

telemedicine, teleradiology, radiology information systems, PACS, remote consultation, computer security, information storage and retrieval.

Introduction

In medicine and radiology applications the efficiency and contribution to health care quality of collaborations of distantly located participants is primarily dictated by the efficiency of the communication methods used. Travel times of several days for international mail are not unusual, and may be too lengthy to deliver advantages for a patient's treatment. Furthermore, important original documents may be lost irrecoverably during delivery. In case of e.g. rare diseases the probability not to find expert knowledge on-site is comparably high, and local physicians without a strong background in such diseases are forced to *(i)* send these patients to specialists or *(ii)* to rely on conventional mail to communicate diagnostic findings and subsequent treatment with colleagues.

The Clearinghouse application as an approach for a teleradiology platform aims to improve the speed and latency in communication of medical imaging and other clinical documents, while at the same time providing a maximum of flexibility, data security and privacy.

The integration of the Clearinghouse platform into the daily radiological routine enables effortless communication and collaboration with national and international experts. In reverse, patients in rural regions without ready access to specialists may benefit from expert opinions, improving the quality of their therapy. Due to the nature of e.g. rare diseases, and the fact that diagnosis, research and treatment are geographically separated in most of these cases, the Clearinghouse is especially suited to centrally organize and distribute relevant data. Exchange of data and knowledge in internationally relevant studies is intensified, while communication costs and turn-around times are lowered.

Materials and methods

Traditional workflow

The traditional workflow for exchanging clinical documents in general and radiological images in particular, involves mainly delivery by either patients themselves or by standard mail and courier services. Patients may be sent by their physicians to radiologists for taking radiological images, which in turn are sent back either via mail or are given to the patients to hand them over personally to their physician. If no other parties are involved in diagnosis and treatment based on such documents, this practice may be feasible, depending on the geographic distance of physician and radiologist.

Once multiple, probably distantly located, parties are involved in diagnosis and thus require access to existing or newly acquired documents of a patient, these documents have to be sent out (preferably as copies) to all participants by mail, courier services or as fax. Taken that none of these services are trusted with original documents the risk of irrecoverable loss of data is minimized, however the risk of eavesdropping of private and possibly compromising data still remains. This risk may be diminished by using e.g. sealed envelopes which in turn increase cost and expenditure, yet this measure does not eliminate disclosure of private data by accidental loss.

This traditional, decentralized workflow of exchanging patient data and documents bears several unratable risks of

data loss or delay in schedule which may negatively influence a patient's diagnosis and treatment.

The Clearinghouse platform

The Clearinghouse platform addresses these risks and shortcomings by unifying and optimizing access to a patient's data, documents and clinical history. It poses a centralized web application, amalgamating the contributions of geographically separated institutions to a patient's file and subsequent treatment. It features a sophisticated security concept and role model, both of which are described in the following paragraphs. On the client's side, no additional software needs to be installed apart from a web browser and Java, all other components (cf. section *Clearinghouse features*) are provided online and instantaneously by the server.

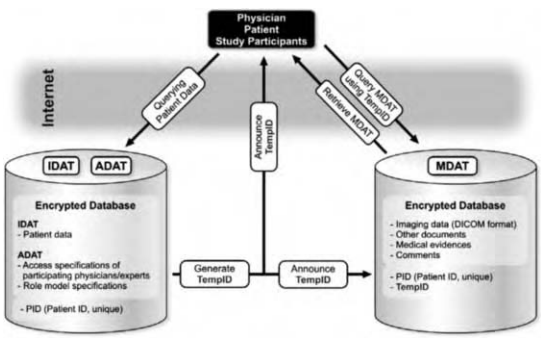

Figure 1 - Abstraction of the Clearinghouse security concept and communication flow

Data Security Concept

The security concept of the Clearinghouse platform (cf. Figure 1) is derived from a generic data security concept developed by the Telematic Platform for Medical Research Networks (TMF), Germany [1], and has been specifically tailored to meet the requirements of a web-based platform for digital image exchange. It implements a strict physical and logical separation of patient identification data (IDAT) such as name, gender and age, and medical treatment data (MDAT) such as digital images, clinical documents, medical evidences and diagnoses. In the case of DICOM objects, the header data is made pseudonymous by replacing data identifying patients in corresponding header fields with a so-called picture ID. It is generated by the MDAT component of the system and will not be propagated to other system components, except to clients (i.e. treating physicians) who are legally entitled to obtain knowledge of both data classes (IDAT and MDAT).

Each data class is stored on a separate database server featuring encrypted storage space. Each server is maintained by a separate system administrator and is located in the demilitarized zone of separate data centers, behind a firewall. Thus no persons except legitimate treating physicians (or in general, users with appropriate data access rights) are able to merge patient and treatment data. Furthermore, should one server be compromised, no association to the other data class is possible, thus protecting privacy of patients ([2], [3]). All internal and external communication is encrypted to prevent eavesdropping and possible "man in the middle" attacks (cf. Figure 2). Both data classes (IDAT and MDAT) are transmitted separately to the client using encryption and merged in the client's web browser only.

Queries on treatment data of specific patients are internally carried out using temporary IDs (TempID, cf. Figure 1). The TempID is generated by the IDAT server and propagated to the client *and* the MDAT server. The client then automatically queries the MDAT server for the corresponding patient's data using the TempID. The latter is invalidated upon completion of the transaction or after a specific idle period has passed. This procedure ensures that no transaction may be carried out twice by e.g. interception by unauthorized parties, and eliminates the possibility of malicious transactions not explicitly requested by authorized persons.

The Clearinghouse platform is implemented using inexpensive Open-Source software and is strongly based on the LAMP concept (**L**inux, **A**pache, **M**ySQL, **P**HP).

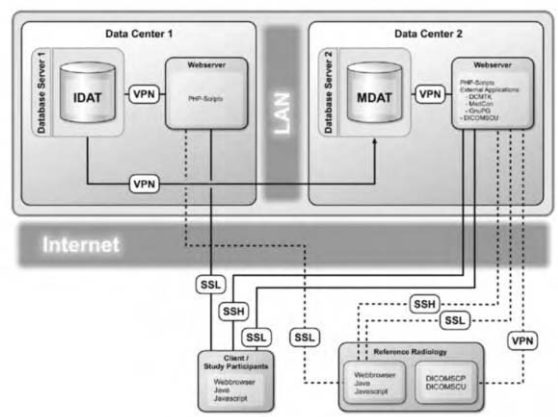

Figure 2 - Scheme of the Clearinghouse IT infrastructure

Infrastructure

The infrastructure of the central Clearinghouse teleradiology system (cf. Figure 2) resembles the theoretical data security concept as described in the previous section. The strict physical separation of the IDAT and MDAT data classes is realized by housing corresponding components in separate data centers, including system administration tasks carried out by different persons. Two web servers are used to deliver encrypted IDAT or MDAT content to the client's web browser. Communication to and among system components (i.e. database servers and web servers) is carried out exclusively via secured lines, e.g. using a virtual private net (VPN) for the Clearinghouse system components or SSL encryption for communication with clients. Reference centers, e.g. reference radiologies, may be integrated via VPN or using SSL/TLS encryption of the DICOM network protocol ([4], [5]).

Workflow

The Clearinghouse platform transforms the traditional decentralized workflow into a centralized one. The web application forms a central venue for all participants and data corresponding to clinical documents. On the one hand, the platform is suitable for mutual exchange of documents between several physicians and experts, to confer clinical diagnoses with high efficiency and low latency. On the other hand, it is also suitable as a central platform for patient and data acquisition within the scope of a clinical trial or study. Here, participating physicians, institutions and clinics contribute patients and corresponding relevant documents to a specific study, with the study center having access (probably pseudonymous only, depending on study treaties) to all contributed data.

Multiple studies may coexist within the same platform instance, without the need to have separate servers for each particular study. The security concept, including the role model, ensures that no data is exchanged between studies. Access to a study and patients or documents therein is granted by either the study manager and/or the person who contributes a specific patient. Read and modification rights may be granted to other users (e.g. of the corresponding study), while the right to delete objects, documents or patients is exclusively granted to the person who contributed the specific patient to the Clearinghouse platform. The study center always has read access to all contributed data and documents, as described above.

The Clearinghouse allows dispatching DICOM objects to previously specified, trusted Reference Radiologies by implementation of the DICOM STORESCP protocol. This way, reference diagnoses, which are then included in the corresponding patient's file, may be obtained when needed.

Figure 3 - The Java upload applet of the Clearinghouse teleradiology platform for upload of complete DICOM CDs

Clearinghouse features

The Clearinghouse teleradiology platform is specifically suited to handle, besides generic bitmap graphics formats, digital medical images encapsulated in the DICOM format. The DICOM format has become the most important format for the generation, storage and communication of digital medical images. This standard includes a comprehensive description of data organization within the DICOM container, as well as protocols for the networked communication of DICOM objects (e.g. STORESCP). The Clearinghouse supports the whole DICOM workflow by integration of Open-Source software and libraries (Offis DICOM toolkit [6], XMedCon [7]).

Apart from DICOM objects containing a single image the Clearinghouse is also able to handle multislice DICOM objects as generated by e.g. systems employed in cardiology diagnoses and treatment (e.g. heart catheter movies). Conversion of image objects into other formats (e.g. MPEG movies for multislice DICOM objects) is possible in almost any arbitrary way. Furthermore, up- and download of virtually any generic non-graphic file formats like PDF, Microsoft Office or Open Office documents etc. is possible.

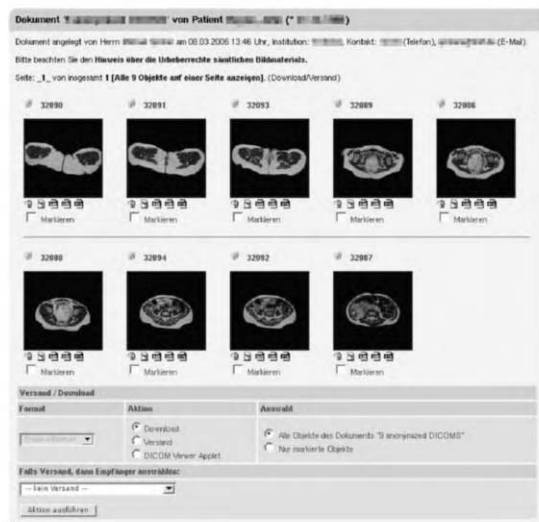

Figure 4 - Thumbnail overview of image objects contained in a specific document (some data garbled for privacy reasons)

The Clearinghouse enables straightforward upload of complete DICOM CD-ROMs by a sophisticated, operating system independent Java applet (cf. Figure 3). The applet is executed within the web browser of the user and automatically scans CD-ROMs for DICOM data. Once identified, these data are compressed, then transmitted to the platform via encrypted communication and stored within a previously defined document of the corresponding patient's record.

For each patient a virtually unlimited number of documents may be created, and each document may comprise any number of objects. Primarily, a document is presented as a thumbnail overview of all image objects therein (cf. Figure 4), automatically sorted according to the header data (e.g. based on study ID and/or slice number). By clicking on an object a detail view is entered, with (in case of a DICOM object) a listing of all available header data (cf. Figure 5).

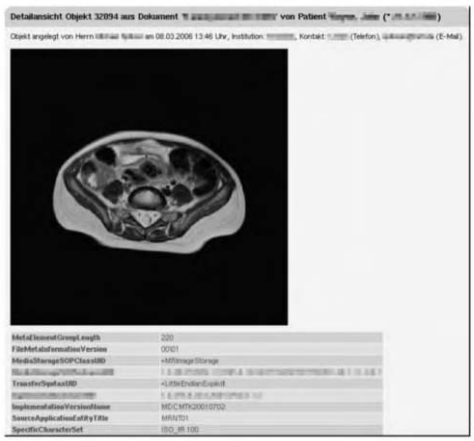

Figure 5 - Detail view of a DICOM image object including header data (some data garbled for privacy reasons)

To allow users the quick visualization of selected DICOM objects, the Radscaper [8] DICOM viewer (cf. Figure 6) was integrated into the Clearinghouse. As for the DICOM upload applet, the Radscaper viewer is written in Java and thus is operating system independent. This built-in DICOM viewer functionality relieves users to install standalone DICOM viewers on the client's workstations, and allows for portable and more detailed analyses of DICOM objects. The Radscaper applet features several tools e.g. for adjusting window center and width, zoom, image rotation and measurement functionalities. A cinematic mode allows advancing through multiple slices with adjustable speed.

Results

Advantages

By focusing on the exchange and annotation of digital image data the Clearinghouse platform improves the otherwise slow traditional transfer of medical images via standard mail. Both the risk of data loss and the response time are significantly decreased since

- geographical distances are transformed into virtual "technical" distances,
- the centralized structure guarantees for immediate access to any document as well as for reliable backup,
- IDAT and MDAT are securely stored in physically separate databases (cf. section *Data Security concept*),
- the sophisticated role-based user model enables to define access to documents with fine granularity.

Figure 6 - The Radscaper Java DICOM viewer applet of the Clearinghouse teleradiology platform

In summary, the Clearinghouse telemedicine approach has the potential to improve diagnosis and treatment while data security and privacy are improved at the same time.

The cost-saving employment of the Clearinghouse platform is one of its major advantages. Due to consistent use of Open Source software the costs for installation, maintenance and support are comparably low. Furthermore, the platform constitutes an easily extensible and maintainable basis for future research projects.

Comparison to other teleradiology solutions

There are several solutions for teleradiological platforms, some following a similar architecture with a central web server communicated with by clients using a web browser [16], other implement a special Java-based solution for execution at the client's workstation [17] or use the DICOM-e-mail facilities of the DICOM standard [18]. The latter approach allows for simple participation in such teleradiology networks by use of a standard Email application. However, collaborative features such as instant access for multiple users are not available except by sending mails to several recipients simultaneously. Furthermore, utilization as an electronic patient record is not feasible since other document types would have to be encapsulated in a DICOM container first. The Java-based solution described in [17] features a security concept comparable to the Clearinghouse in terms of encrypted communication, yet supposedly without the strict separation of IDAT and MDAT data classes, missing in [16] as well. Additionally, the solution in [17] features teleconferencing abilities and an interface to existing PACS applications, a topic that has not been tackled yet in practice by the Clearinghouse system. Main advantages of the Clearinghouse platform over the aforementioned solutions are:

- no installation of specific standalone client software necessary, thus updates of the central system software are immediately available and usable by all clients,
- inexpensive setup and administration due to the use of Open-Source software and a centralized infrastructure,
- integration of reference centers by DICOMSCU/-SCP,

- immediate availability of uploaded documents and digital images for all legitimate users,
- a security concept based on the generic concept of the Telematic Platform for Medical Research Networks (TMF), Germany. The concept is commonly accepted among local institutions and fully complies with at least German legal requirements.

Current employment

The Clearinghouse platform has already been proven to be beneficial for e.g. studies and participating institutions by facilitating secure, instantaneous and geographically independent access to data and documents via the Internet. It is already successfully tested and used routinely within the scope of the Ewing study [9], the Nephroblastome and AML study [10], the competence network of pediatric oncology and hematology ([11], [12]), the Network for Ichthyosis and Related Keratinization disorders ([13], [14]) as well as the network for Epidermolysis bullosa [15].

Future development

The current development and research is based on already implemented functionalities of the Clearinghouse. It concentrates on the further development and full implementation of the data security concept as described in this document. Further projects involve the extension of DICOM integration and functionalities and embedding of a WYSIWYG editor for elementary online editing of documents, as well as internationalization and translation of the platform.

Acknowledgments

The project is partially funded by the German Federal Ministry of Education and Research within the scope of the Competence Network for Paediatric Haematology and Oncology GPOH/KPOH (code 01GI0413), the Network for Ichthyoses and Related Keratinization disorders NIRK (code 01GM0606), and the German beneficence for child cancer (Deutsche Kinderkrebsstiftung).

K-Box: Automatic Structuring and Exchange of Medical Documents Based on the Clinical Documentation Architecture (CDA)

Minh H. Doan, Paul-Ludwig Lott, Marek Václavík, Prof. Dr. Frank Ueckert

Department of Medical Informatics and Biomathematics, University Hospital, University of Muenster, Germany

Abstract

Sustainable health systems should understand information as a resource which also has to be managed efficiently. Today's electronic documentation is only the mandatory first step to automatic information exchange between hospitals, physician offices, pharmacies and other participants. The K-Box is a modular system which allows different monolithic information systems to be connected and integrated by using the clinical document architecture (CDA) as the standard document exchange format. A prototype K-Box has been implemented and a trial run is scheduled. The workflow selected for the trial produces discharge summaries in CDA format.

Keywords:

information systems, systems integration,
public health informatics

Introduction

Defining historical medical attendance records as an instance of *information* in the context of health system, today's hospitals and other healthcare organizations should understand *information* as a resource beside other resources. Furthermore, we assume that within this context information will become one of the most expensive resources in the future. Missing information would mean additional or double tests in some cases and cause extra costs as the consequence. Therefore, the development of sustainable health systems also has to pay attention to *save* the resource information by endeavoring after its *reuse*.

Today, in German hospitals medical data are processed and handled by hospital information systems (HIS') which also include electronic patient records (EPRs) [1]. Also, most of the medical offices in Germany usual use computer-aided patient management systems to save medical data related to constituent patients. Regarding the German health system we can notice, therefore, that the evolutional step from paper supported documentation to electronic documentation is mostly done.

Even though the documentation is done electronically, there is a big gap in electronic *communication* between German healthcare organizations because the electronic documentation was not forced to follow a nationwide or international standard. As a result, there is no integration or direct communication between different information systems in different organizations possible [2]. Some organizations joined together and implemented electronic communication between their systems. But the majority is still exporting their medical information by using word processing software to write a report. The importing party then has to copy the data from the written down report and paste it into their information system manually.

Regarding building sustainable health systems, we are sure that the ability to automatic information exchange between the system elements would enhance the property "sustainability" of the system itself. The *K-Box* described in this paper is such a software system which allows different medical information systems to be connected and exchange structured information.

The idea behind the K-Box is to have handy servers ("boxes") at hospitals, physician offices, pharmacies and other participants, which are connected to local information systems to provide them a unique communication and data exchange capability. At this phase of the project we focus on clinical document exchange between physicians such as exchange of discharge summaries. The "K" in the name of the project is representing "Kommunikation" as the German word of communication. But actually, beside the communication subsystem the K-Box also comprise another subsystem which we call the *structuring* subsystem. The structuring subsystem is able to convert every document it receives in a CDA (Clinical Document Architecture) document by using machine-learning supported methods. Based on the generated CDA particular information entities then can be extracted and imported directly into foreign systems.

The K-Box architecture is modular. Each K-Box installation can be extended with the support of new document formats or communication interfaces by adding pluggable components ("Plugins") to the running system.

Materials and methods

Component-Based Software Engineering

The K-Box development follows the paradigm of Component-Based Software Engineering (CBSE). That means that we focus on software components in all phases of development. Furthermore, all components have their own

development cycle, and are released independently from each other.

The term of *software component* is not new to the software engineering domain. It was first used in 1968 by Doug McIlroy at the NATO software engineering conference in Garmisch where the discipline Software Engineering itself was born. In his article McIlroy's described his vision - based on the model of mass production in the industry - about mass development of software by combining *reusable* components instead of programming blocks of similar functionality from zero every time [3]. The term reusability is often used in the context of Object-oriented Programming (OOP). From this background CBSE is often confused with OOP. In fact, reusability is the main motivation of both paradigms. However, we distinguish between white-box reusability and black-box reusability: White-box reusability means that we reuse written source code and add modifications to it to solve a similar but not the same problem. On the other side black-box reusability means that we reuse independent software components in binary format to solve, intra-domain, independent, and repeating sub-problems [4]. It is the art of CBSE to design components that are not too specific to a context to make them widely reusable but also not too abstract. In other words, OOP makes use of white-box reusability and CBSE makes use of black-box reusability.

OOP and CBSE are no competitive paradigms. On the opposite, it is wise to combine both techniques in an advantageous way. In our project, we use OOP to develop the components themselves and follow CBSE to design the component hosting core-system. The OOP language used at the K-Box project is Java.

Information extraction

To process incoming messages, a typical commercial EAI system relies on explicit structure definitions. It expects a description written in a vendor specific meta-language. This approach reaches its limits when the explicit message structure is unknown (e.g. undocumented legacy systems) or too complex to be expressed this way. Integration engineers usually apply workarounds to solve this situation: they "reconstruct" the message structure by generalizing available examples or they content themselves with a functional definition: "How do I extract a certain data element?" Learning the structure "by example" can also be performed automatically or semi-automatically, by means of information extraction (IE) and machine learning. IE with text data (*text extraction*) has been widely applied in the medicine domain for biomedical data mining. (e.g. [5])

The task of text extraction comprises populating data slots in a given target format with information pieces from the input text. *Text classification* means analysing a text part and assigning it with a discriminating attribute (*tagging*), like "relevant" versus "irrelevant" or "regular mail" versus "spam". The choice of the appropriate text extraction method depends on the *structuredness* of the text. Extracting information from an *unstructured* text (words, sentences, paragraphs) requires linguistic analysis (*natural language processing, NLP*) to maintain a certain level of *text reasoning*. A s*emi-structured* text contains additional information (e. g. presentation mark-up), enabling non-NLP techniques to reach comparable or even better results. Non-NLP methods are typically based on sets of extraction rules (*wrappers*), often modelled as finite-state automata [6]. Both approaches can utilize machine learning, i.e. to adapt the extraction process according to the received feedback.

We apply adaptive text extraction to discharge summaries, trying to turn them from an unstructured form (binary Word-File) to a structured XML-document conforming to Clinical Document Architecture (CDA). CDA is a document standard based on the HL7 v3 Reference Information Model. In Germany, the SCIPHOX-specification (CDA Release 1) developed into the "Electronic Medical Report" (eArztbrief), derived from "CDA Release 2".

Results

Architecture of the K-Box

The K-Box architecture conforms to the layered model for message-based integration systems, as described by Keller [7]. Four functional layers can be distinguished: An adaptor layer which supports various communication protocols, an internal transport layer which is responsible for intra-component-communication, a format transformation layer which converts a document to a new format, and a workflow layer which routes documents though the K-Box.

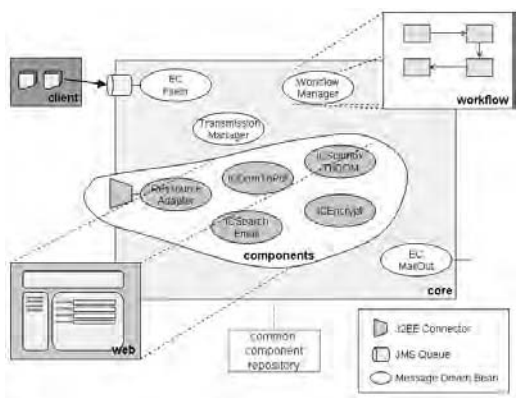

Figure 1 - Modules of the K-Box architecture

The entry point for a document into the K-Box is an inbound adaptor. Inbound adapters are components of the communication subsystem. They are responsible for the receipt of documents through different communication protocols, e. g. FTP, SCP, or SMB/NetBIOS. After a document is received the inbound adapter creates a new transaction within the K-Box. Each transaction is related to an internal document envelope (IDE) which contains the document itself as an attachment and further meta information in the header part of the IDE. The body part of the IDE is reserved for the CDA. Subsequently, the document is routed through the K-Box following the information

from a predefined workflow. After the document is finally converted the result will be sent by an outbound adaptor.

From the software design point of view, K-Box has been conceived as a component-based software system, which adds new functionality dynamically. The development of the component infrastructure takes place in the project module we call the *core*. Beside the core we declared four further project modules, namely: *components, web, workflow* and *client* (figure 1).

kbox.core is a J2EE application containing the essential *SessionBeans*, a *WorkflowManager* and a *TransmissionManager* for tracking and logging. It also includes the generic *AbstractIC* and *AbstractEC* classes, designed as abstract *MessageDrivenBeans* (MDB). Each MDB is bound to a JMS-Queue (*Java Message Service*). The queues enable asynchronous message exchange between the components. The internal message type used in the K-Box is a SOAP message with attachments, a protocol related to the Web Services technology.

Within the core we develop **kbox.components** for external connectivity (resource adaptors - *J2EE Connector Architecture*) and message transformation.

The **kbox.web** GUI allows K-Box administrators to manage and configure the K-Box core. It also provides a uniform view of the components and their properties.

kbox.workflow is a stand-alone Java application for graphical design of workflow objects. The constructed workflow object can be saved locally or uploaded to the connected K-Box core by employing the remote WorkflowManager.

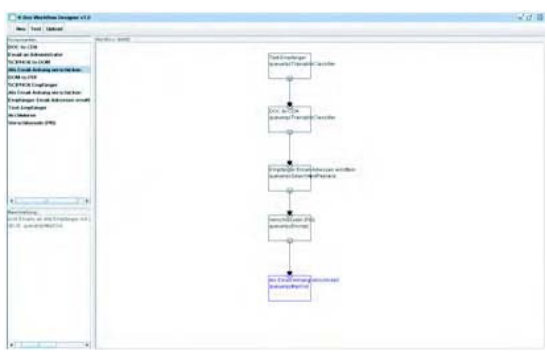

Figure 2 - Screenshot of the graphical workflow designer

kbox.client serves as an alternative K-Box adaptor, meant for external systems without a J2EE resource adaptor. kbox.client is a generic, extendable JMS client, capable of sending byte stream messages to a specific EC in a configured K-Box.

Information extraction from unstructured and semi-structured documents

Discharge summaries in an unstructured form are unsuitable for further automatic processing. Provided there are enough document examples available, machine learning can be applied. One of K-Box's transformation components extracts CDA body information using text classification. CDA section captions (Level 2) such as "Diagnosis" or "Therapy" are being assigned to a particular text-block. For higher domain independence the method considers only unstructured (free)

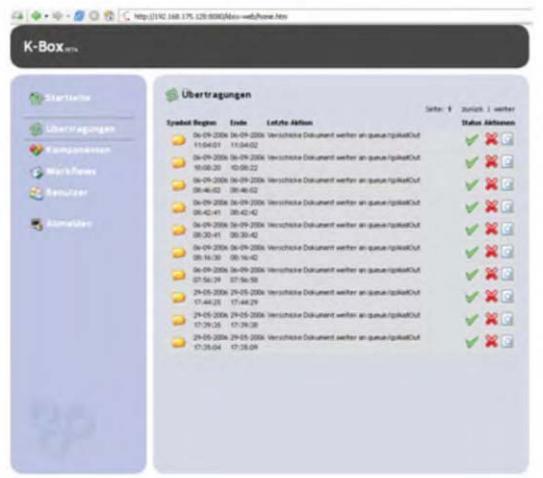

Figure 3 - Screenshot of kbox.web

formatting information. For this method to be effective, the system has to be trained with typical data. During the training process the user marks up a few documents manually and tells the system to which categories the document contents should be mapped.

Document transformation consists of three steps: plain text extraction, text-block classification and classified block processing. In the first step control characters, tags and proprietary mark-up are removed from the document by a learning algorithm comparable to those used in today's email-spam-filters. The normalized document is then passed to the second step where it is divided into distinct text blocks. Each block is then automatically assigned with a certain content-category (e.g. „Diagnosis"), thus adding semantic information to the document. After classifying all blocks, the document can be transformed to the destination format, using the semantic information from the previous step. Further, some more tightly focussed post-processing can be applied according to the content category. For example, a text-block classified as "Diagnosis" is likely to contain ICD-codes. These can be extracted automatically and converted to a highly structured, CDA Level 3 compliant document. The classification is based on NGRAM-Analysis, an adaptive classification algorithm which already proved to be effective in other areas of information extraction. [8]

Discussion

The K-Box is an integration tool with the focus on automatic structuring of unstructured medical documents. While commercial EAI-products are naturally developing into powerful and universal integration suites, a simple interface engine presents in many use cases a more transparent and manageable solution. Compared to other

branches, healthcare seems to adapt new IT trends rather reluctantly [9]. Replacing "interface engines" with more complex, business-process oriented EAI-tools is still at the beginning [10]. Straightforward and lightweight solutions might be particularly appreciated in smaller enterprises, with minimalist equipment and limited budget, such as medical practices. This is one of our target groups.

The component-based design should increase acceptance of K-Box among potential developers. The final component specification must find a reasonable trade-off between flexibility and complexity. A component repository should serve as a platform for component exchange inside the user community. The basic prerequisite is a complete development framework which is the objective of our current development.

Information extraction from websites [11], often wrapper-oriented and combined with machine learning [6], has been widely explored and exploited. However, there have been significantly fewer attempts to utilize these methods in the Enterprise Application Integration [12] or specifically in messaging systems. The goal of our approach is to minimize the need for explicit message structure descriptions or formal transformation-rules. At present we are exploring methods for precise and domain-independent extraction of CDA header data. Incorporating domain specific information might increase the quality of the extraction, but has to be added in a flexible, replaceable way.

The K-Box supports protocols and data formats that are usually used in healthcare. Such an emerging standard for inter-sectoral communication is the CDA. This format has been chosen for the nationwide health telematics platform in Germany. By means of the freetext-to-CDA transformation the K-Box provides the link between an isolated standard-unaware information system and the centralized infrastructure.

To receive a field test experience with the architecture, a prototype of the K-Box has been deployed in one of the departments at the University Hospital of Muenster. The implemented workflow transmits CDA discharge summaries to external recipients via encrypted emails. A trial run is the next step.

Using Distributional Analysis to Semantically Classify UMLS Concepts

Jung-Wei Fan[a], Hua Xu[a], Carol Friedman[a]

[a] *Department of Biomedical Informatics, Columbia University, USA*

Abstract

The UMLS is a widely used and comprehensive knowledge source in the biomedical domain. It specifies biomedical concepts and their semantic categories, and therefore is valuable for Natural Language Processing (NLP) and other knowledge-based systems. However, the UMLS semantic classification is not always accurate, which adversely affects performance of these systems. Therefore, it is desirable to automatically validate, or, when necessary, to semantically reclassify UMLS concepts. We applied a distributional similarity method based on syntactic dependencies and -skew divergence to classify concepts in the T033 Finding class in order to determine which ones were biologic functions or disorders. A gold standard of 100 randomly sampled concepts was created that was based on a majority annotation of three experts. Precision of 0.54 and recall of 0.654 was achieved by the top prediction; precision of 0.64 and recall of 0.769 was achieved by the top 2 predictions. Error analysis revealed problems in the current method, and provided insight into future improvements.

Keywords:

semantic classification, UMLS, distributional similarity, natural language processing

Introduction

Ontological knowledge bases are important for developing Natural Language Processing (NLP) and other knowledge-based applications because they provide well-defined specifications of the concepts, semantic classification, conceptual normalization, and indicate relevant semantic relations between the concepts. The specifications help define the meaning and semantic category of each concept unambiguously whereas normalization helps unify synonymous surface terms to enhance retrieval. For example, blood platelets and thrombocytes should be normalized into a single concept. The relations defined in the ontology can be used in semantic parsing or pattern recognition as well in logical inference. For example, a semantic parsing rule that uses a broad semantic class, would be satisfied for concepts that are children of the broad class. The parent/child relations can also be useful in question answering systems by providing knowledge of hierarchical relation and use of inheritance. More specifically, information about malignant melanoma can be implied from texts containing its descendents, such as necrotic melanoma or choroidal melanoma, diffuse.

There are many such structured knowledge bases in the biomedical domain, e.g. the SNOMED-CT [1], MeSH [2], and Gene Ontology [3]. The most comprehensive integration of these resources is the Unified Medical Language System (UMLS) [4], which includes 139 source vocabularies in the current release (2007AA). Each concept in the UMLS has a unique identifier, called CUI, which is assigned one or more semantic types in the Semantic Network (SN) [5]. The SN also contains relations defined between the semantic types, and at the concept level, there are also various relations inherited from the source vocabularies. The semantic classification of a CUI, when appropriate, is very valuable for NLP applications. Textual patterns can be recognized on the basis of UMLS relations and the semantic types of UMLS concepts identified in text, or developers can define their own application-dependent relations based on UMLS semantic types. For example, the template [(*Food*) **interacts with** (*Pharmacologic Substance*)] can be used to screen potential food-drug interactions in text. The SN has been used to determine relations between the concepts extracted through specified semantic patterns [6] and used as semantic filters in literature-based knowledge discovery [7]. In this paper we focus on semantic classification within the UMLS because it is a comprehensive system in the biomedical domain with continuous maintenance and a large user population.

Although the SN semantic types are a valuable resource, there are issues about their granularity and correctness. For example, the current release assigns C0021494 Injections, Intravenous to T169 Functional Concept, but it seems that it would be more appropriate if it were assigned T061 Thera peutic or Preventive Procedure or a broader class *procedure* for general NLP purposes. Research has been performed to coarsen the granularity of the SN, which involves combining SN types [8] [9] [10], and to audit SN errors [11] [12]. However, the above coarsening approaches only aggregate existing types into broader classes without considering the validity of SN assignments themselves, and the auditing approaches work by finding contradictions derived from the existing semantic type assignments. The drawback of relying on existing assignments is that inappropriate assignments are retained along with the high-level reorganization. For example, through inheritance Injections, Intravenous would still not be con-

sidered a procedure-related class by the above methods. On the other hand, we cannot assume that all concepts in the Functional Concept class belong to *procedure*, since the SN type also includes concepts such as Solar system, Poisonous effects, and Hairy.

We have observed that some SN types are more problematic than others because they are high level, vague, or heterogeneous. We consider that a SN class is vague when it includes many CUIs that are very semantically heterogeneous or inappropriate for that class. For example, T033 Finding contains many concepts of the disorder sense (e.g. Nasal cartilage loss and Hemianopsia), but also contains many different types of concepts that are not clinically relevant, such as Spiritual state alteration, or that are not well-defined, such as Wanted, which requires additional context to determine the correct meaning. For example, the online Free Dictionary has over nine definitions for wanted (http://www.thefreedic tionary.com/wanted) with examples including context for clarity. This causes some applications, such as [6], to avoid using the concepts in these classes, but then relevant concepts are also dropped. For example, Progressive renal failure and Acute inflammation are in T033, and would be missed by applications using only well-defined classes, such as T047 Disease or Syndrome. Therefore, it is important to develop an automated method for reclassifying UMLS concepts, particularly those that are assigned vague SN types, into more appropriate semantic classes.

In the biomedical domain, Sibanda et al. showed that syntactic features are especially useful for determining the semantic categories of terms and clauses in discharge summaries, using Support Vector Machine classifiers [13]. Pedersen et al. used window-based contextual distributions from the Mayo Clinic Corpus of Clinic Notes to measure the semantic similarity between SNOMED-CT concepts, and reported high correlation with human experts [14]. Weeds et al. used distributional similarity based on syntactic dependencies and a nearest neighbor voting process to classify terms into semantic types of the GENIA ontology and achieved good accuracy [15]. In a previous paper [16] we showed that it was feasible to apply a distributional similarity approach to classify UMLS concepts. The distributional approach is based on Harris sublanguage theory: terms are syntactically dependent on other terms with unequal likelihoods especially in specialized domains [17], so that terms can be characterized and classified through the distribution of their syntactic dependencies. For example, the adjective psychogenic is more likely to be an adjective of a noun that is a disorder and unlikely to modify a noun that is a microorganism. We used Lees -skew divergence [18] as the measure of distributional similarity:

$$S(\mathrm{P}(C|t), \mathrm{P}(C|t_2))$$

$$= D(\mathrm{P}(C|t_2) \| \quad \mathrm{P}(C|t_1) + (1\text{-}) \quad \mathrm{P}(C|t_2)) \qquad (1)$$

where 0 1, t_1, t_2 are two terms, C is the union of the syntactic dependencies of t_1, t_2 , $\mathrm{P}(C|t_1)$, $\mathrm{P}(C|t_2)$ are the corresponding distributions, and D is KL divergence. We generalized the approach to one that measures similarity of concepts instead of individual terms. This is accomplished by forming each concepts distribution with the syntactic dependencies of all its synonymous terms in a training corpus. When reclassifying concepts of well-defined SN types into seven broader classes, we achieved a precision of 0.802 for the top prediction and 0.884 when considering the top two predictions. An advantage of the corpus-based approach is that it is automated and therefore high-throughput. In addition, it is based on real language usage and thus tends to be more reproducible than experts using their own judgments, which may vary from person to person and thus consistency would be more difficult to achieve. Consistency using multiple experts could be obtained but would necessitate a costly process involving consensus.

In this paper we focus on evaluating the classification of CUIs for the SN type T033 Finding because it includes many important concepts associated with disorders and functional information, e.g. some disorder-related adjectives like Hypertensive are only covered by T033. Our approach differs from the related work in that we used a typical distributional similarity measure, -skew divergence, based on more abundant types of syntactic dependencies obtained from a huge shallow-parsed corpus to reclassify/audit UMLS concepts. It also differs from other UMLS concept classification methods because our approach automatically proposes the most appropriate semantic class for a CUI, regardless of the SN type(s) that were originally assigned.

Materials and methods

The distributional classification method can be outlined as follows, and is elaborated on below: 1) determining clinically relevant semantic classes for building distributional profiles, 2) obtaining a training corpus, 3) extracting syntactic dependencies from the corpus for CUIs in the relevant classes, 4) using the syntactic dependencies to build distributional profiles for the classes, 5) using syntactic dependencies to build distributional profiles for the test CUIs, and 6) using -skew divergence to compute the distributional similarities between the CUI and class profiles for classification.

Based on previous work [16] we grouped subsets of the SN types (2006AC) into seven clinically relevant broad classes: *biologic function*, *anatomy* (above the molecular level), *disorder*, *gene or protein*, *microorganism*, *procedure*, and *substance*. For example, Laboratory Procedure, Diagnostic Procedure, and Therapeutic or Preventive Procedure were grouped to form the *procedure* class. Vague types, such as Finding, Functional Concepts, and Health Care Activity were excluded from forming the seven classes. We obtained a corpus of 199K MetaMap-processed abstracts fr[1]om the 2005 MEDLINE/PubMed Baseline Repository (MBR) database [20]. Perl scripts

1 MetaMap is a program that performs part of speech tagging, shallow parsing, and statistical methods to map terms in free text to the UMLS concepts. See [19].

were created to extract the part-of-speech (POS) tags, identify the phrase types, and trace the mapped CUIs to the original extractions from the machine-readable format of the requested corpus. For example, the machine-readable output of a sentence containing the concept Hemianopsia would be processed as shown in Figure 1 (simplified for clarity). Then we used a set of context-searching rules to extract syntactic dependencies for each concept. For example, in Figure 1 the syntactic dependency {associated noun: notch} can be obtained for Hemianopsia from the sentence The macular notch in hemianopsia was studied because the attached prepositional phrase in hemianopsia modifies notch. We aggregated the syntactic dependencies of all the CUIs in each class to build the distributional profile for that class. For a CUI to be classified, the syntactic dependencies of that CUI were used to build its distributional profile. Classification was performed by computing the distributional similarities between the test CUI and each of the seven classes, and the class with highest similarity score was selected.

Figure 1 - A sentence with POS tags, phrase types, and CUI mappings reconstructed from MetaMap output. Notations: S- sentence, P- phrase and phrase type, W- word and POS, asterisk marks the head noun, E- mapped term, concept term, and CUI

We semantically classified CUIs in T033 to determine the concepts in that type that were *biologic function* or *disorder*, but not other types because those two classes constituted the two most clinically important concepts in that class. There are a total of 55,445 concepts in T033 (2006AC), and 848 of them occurred in the 199K training corpus. We tested our method under feature-sufficient condition (10 syntactic dependencies) to ensure that we would have the appropriate number of features, since it would be possible to obtain more syntactic dependencies by expanding the training corpus. As we were also interested in studying if concepts that rarely occur in a large body of literature were of less value for clinical applications, we qualitatively evaluated some T033 concepts of varying frequencies in the training corpus.

To evaluate recall of our method in classifying T033 concepts into *biologic function* or *disorder*, we randomly sampled 50 CUIs from the set of CUIs that had 10 syntactic dependencies. For evaluating the precision, we randomly sampled 50 CUIs from the set that were classified as *biologic function* or *disorder*. Recall and precision by the top prediction and the top 2 predictions were both calculated, where the latter means the correct class was within the highest 2 classes in terms of the similarities ranking. The gold standard was generated by taking the majority judgments of three medical experts. They were given both the recall and precision test sets. For each set, the testing CUI and corresponding strings in the UMLS were displayed, and the experts were asked to annotate each concept as *biologic function*, *disorder*, or *neither of the two classes*. Kappa statistics [21] for the inter-annotator agreement were calculated. We also performed an error analysis on the recall and precision set respectively.

Results

Exemplary concepts of varying frequencies in the corpus are displayed in Table 1; we found that frequency does not reflect the usefulness of concepts, because concepts that seemed useful or not useful were distributed similarly over different frequencies. There were 365 CUIs (for evaluating recall) with 10 syntactic dependencies extracted from the corpus, and 238 of them (for evaluating precision) were classified as *biologic function* or *disorder*. There were 26 of the 50 sampled CUIs in the recall set annotated as *biologic function or disorder*, and they served as the denominator in evaluating recall. The recall and precision of our classifier is shown in Table 2. The Kappa statistics of all the three annotators on the recall set was 0.421, and was 0.462 on the precision set.

Table 1 - Concepts with different frequencies in the corpus

Frequency	Examples
0 or 1	Abdominal swelling, Gingival bleeding, Partial deafness, Abnormal or prolonged prothrombin time, Birth Place, Vegetarian
5 and < 10	Panting, Hypoesthesia, Hyperlactatemia, Diaphragmatic paralysis, Vegan, Vagabond
10	Albuminuria, Sudden death, Fever, Cardiomegaly, Hematuria, HIV positive, Nervousness, Problem, Unemployment, Divorced

Table 2 - Recall and Precision of the classifier

	Recall	Precision
By top prediction	0.654	0.54
By top 2 predictions	0.769	0.64

We performed an error analysis based on the results by the top predictions. The errors in the precision set could be

grouped into two types: 1) irrelevant concepts were classified as *biologic function* or *disorder*, 2) *biologic function* and *disorder* concepts were confused with each other. The first group had errors for concepts such as Wanted, Optimistic, and Spells. Some examples of errors in the second group are: Low birth weights as *biologic function*, Normal vision as *disorder*, and Hyperalgia as *biologic function*. Errors in the recall set could also be grouped into two types: 1) errors due to confusing *biologic function* with *disorder*, 2) concepts belonging to the two classes but classified otherwise. In the first category, Stress was classified as *biologic function*, as were Low birth weights and Unresponsiveness. In the second group Does move and Assisted were both classified as *procedure*, while the gold standard had them as *biologic function* and *disorder* respectively.

Discussion

From Table 1 we determined that some frequent concepts may be too general to be informative (e.g. Problem), suggesting the need to filter out some very general and uninformative concepts even before performing classification. In contrast, lengthy terms like Abnormal or prolonged prothrombin time are less likely to occur, which is consistent with the estimation by [22] that only about 10% of the UMLS strings could be found in MEDLINE. The Kappa statistics over the three annotators indicated only moderate degree of agreement, which manifests the difficulty of the task. However, noticing that one annotator often checked *neither of the two classes* when the other two agreed on *biologic function or disorder*, we considered the gold standard generated by voting to be adequate overall but future evaluations should be performed using more experts. The recall and precision by the top 2 predictions show that the similarity function did rank the correct class higher out of the seven, but the performance was not satisfactory. We hypothesize that the T033 set, with more heterogeneous, high-level, and ambiguous concepts, poses a harder task for automatic classification than the other well-defined semantic types we tested (e.g. Disease or Syndrome and Organism Function).

We summarize and provide examples of the main classification errors in Table 3. The first category contained concepts that are very general English terms, and that do not have a well-defined meaning without additional context. For example, Wanted was classified by our method as a *biologic function*; we believe this term alone is much too vague to be assigned as a concept. Another example was Spells, which is also very ambiguous, and thus, all three annotators marked it as being *neither of the two classes*. When examining the corpus, we found it was classified by our method as *disorder* because frequently the term Spells occurred in contexts such as apneic spells, cyanotic spells, or spells of respiratory distress. It is likely that the annotators would agree on the *disorder* sense, if given the corresponding contexts. Literally, Spells could also mean the *biologic function* of being able to spell. The second category characterized behavioral/affective observations and also included many general English terms. Some examples of differences between our method and the gold standard are Apprehension and Patient noncompliance, which were classified as *disorder*, whereas Optimistic and Well-being were classified as *biological function*; however, in the gold standard these are *neither of the two classes*. The above examples show that our method is very sensitive, but not specific enough to rule out imprecise classifications. The third error category occurred when there was a combination of a modifier (usually a qualitative adjective, such as *low or normal*) and a clinical attribute, such as *weight* or *blood pressure*. These errors could result from the limited coverage of our classes. For example, there was not a class for findings specified as normal. It is also possible that the distributional approach *per se* is not adequate to differentiate that type of nuance, and lexical features from the concept strings may need to be introduced. Concepts in the fourth error category were misclassified based on contextual distributions but could have been classified more appropriately using morphologic information. For example, the suffixes *-algia* and *-opsia* frequently occur with disorders. Thus, from the results, it appears that, other features in addition to contexts, should be used for semantic classification because syntactic dependencies are not adequate in certain situations.

There were also borderline cases where one of the annotators agreed with our classification. For example, we classified Resting state as *biologic function* and Atypia as *disorder*, and each agreed with one annotator. There were some ambiguous cases, which stemmed from the strings associated with the concept. For example, the concept Sweating, included the two strings Sweats, function and Sweating symptom NOS from the source vocabularies. The UMLS did not sharply differentiate the two different senses. However, our method obtained the latter sense, while the annotators agreed on the former.

Table 3 - Categories of the classification errors

Category	Examples
1 Common English term	Does move, Spells, Wanted
2 Behavioral/ affective observation	Apprehension, Patient noncompliance, Optimistic, Well-being
3 Modifier + clinical attribute	Low birth weights, Blood pressure normal, Normal vision
4 Disorder by morphology	Hyperalgia, Hyperosmolarity, Hemianopsia

In summary, we believe that most of the errors resulted from three main limitations of our current approach: 1) the specificity issue associated with the first two categories of error indicates the lack of a global cutoff value and/or a

negative class distributional profile, thus resulting in many false positives, 2) the third error category suggests that the coverage of our existing classes is not adequate to appropriately accommodate some concepts such as neutral clinical findings, 3) errors in the third and fourth error categories show that using only the contextual syntactic dependencies could miss morphological and lexical cues that are essential to precise semantic classification, especially for concepts that are equivocal for multiple classes when given only the contexts. For example, in previous work we observed that *biologic function* and *disorder* were easily confused by our method, contributing to one third of the misclassifications because many pathologic functions were classified as normal biologic function. We believe this issue was exacerbated when the method was applied to T033 because it contained many poorly defined concepts.

Although the performance of our automated method was lower than expected, we believe automatic classification is possible and highly desirable, and will explore adding additional features to our method as well as developing complementary methods and performing more extensive evaluation. More specifically, future work will focus on 1) filtering out concepts that are too general to be useful before and/or during the classification, 2) reconsidering the formation of the classes and possibly incorporating more classes, and 3) reducing the classification errors that occur between *biologic function* and *disorder*. After the implementation refinements, we would also like to reclassify concepts under other types such as T169 Functional Concept. For example, we have observed that some T169 concepts such as intramuscular injection were appropriately classified as *procedure* by our method.

Conclusion

We used a distributional similarity approach to classify the concepts of the UMLS T033 Finding class into *biologic function* or *disorder*. The precision and recall were 0.54 and 0.654 by the top prediction, and 0.64 and 0.769 by the top 2 predictions. The error analysis indicated this task was intrinsically difficult when using only a distributional similarity measure and also helped identify the main factors hampering performance. We conclude that there is room to improve the method and it is definitely worth exploring further.

A Reappraisal of Sentence and Token Splitting for Life Sciences Documents

Katrin Tomanek, Joachim Wermter, Udo Hahn

Jena University Language and Information Engineering (JULIE) Lab, Friedrich-Schiller-Universität Jena, Germany

Abstract

Natural language processing of real-world documents requires several low-level tasks such as splitting a piece of text into its constituent sentences, and splitting each sentence into its constituent tokens to be performed by some preprocessor (prior to linguistic analysis). While this task is often considered as unsophisticated clerical work, in the life sciences domain it poses enormous problems due to complex naming conventions. In this paper, we first introduce an annotation framework for sentence and token splitting underlying a newly constructed sentence- and token-tagged biomedical text corpus. This corpus serves as a training environment and test bed for machine-learning based sentence and token splitters using Conditional Random Fields (CRFs). Our evaluation experiments reveal that CRFs with a rich feature set substantially increase sentence and token detection performance.

Keywords:

biomedical text mining, natural language processing, linguistics, text processing.

Introduction

Natural language processing systems expect their input to be properly delimited into consecutive sentences and sentences to be properly segmented into their basic tokens. Real-world documents lack such fine structure and, typically, some simple heuristic pre-processor performs these analysis steps. In the newspaper domain, manually defined patterns for sentence splitting rely on the fact that, e.g., a period is a sentence boundary, if it is followed by an uppercase letter and not part of a known abbreviation ("e.g.", "Dr.", etc.). Tokenization is often performed by splitting at a closed set of special characters (especially punctuation symbols, quotation marks, parentheses, brackets, etc.). While such rules may be adequate for the newspaper domain, they are underspecified for the biomedical domain, in which complex naming conventions lead, in particular, to quite unsatisfactory tokenization results when few and simple hand-written rules are applied. Here, both sentence and token boundary symbols are much more ambiguous because they often appear within entity names (organism, protein, cell names, etc.) and their abbreviations, as well as within (chemical) formulae, bibliographic references. If these challenges are not met, in an analysis pipeline for text mining each error occurring in the course of these preprocessing steps will unavoidably be propagated upwards in the pipeline. As a consequence, text mining modules, such as (named) entity recognition and relation detection, fed by erroneous segmentation results will inevitably suffer in terms of performance.

Rather than adding further complexity to manually maintained rule sets, supervised machine learning (ML) is becoming more and more the method of choice for many demanding natural language processing (NLP) tasks. From a given set of training examples a statistical model is learned automatically which is then used to assign labels to unseen data. Those approaches are to a large extent data-driven, i.e., by exchanging the training material they can be ported to other domains and languages, possibly without further changes. This constitutes a clear advantage over rule-based approaches which require a lot of manual tweaking and tuning, especially when more complex rules have to be supplied [1]. Furthermore, supervised ML approaches have been shown to outperform rule-based ones on several NLP tasks, including sentence boundary detection and tokenization, both in performance and breadth of coverage [2]. Therefore, we redesigned the entire pre-processing cycle and developed a new approach to sentence and token splitting based on Conditional Random Fields (CRFs), a sequential machine learning technique.

For sentence and token boundary detection, two annotated biomedical text corpora are available which may hold adequate training data for a supervised ML approach, *viz.* the GENIA corpus [3] and the PennBioIE corpus [4]. Whereas determining the sentence boundaries in a text corpus may be seen as a comparatively easy task, deciding on token boundaries is not as straightforward as it might appear at first sight. In particular, in biomedical language such as found in PubMed abstracts (or in full articles), crucial semantic units, such as entity names or even references to biological processes, can be contained within larger string units and hence are not simply delimited by white spaces. Thus, a closer look at both corpora reveals that only PennBioIE addresses the problem of semantically motivated word token boundary annotation at all, whereas GENIA annotates tokens around the same closed set of special characters used for English newspaper language [5].

In this paper, we report first on the compilation and annotation of the JULIE corpus which provides sentence and word token boundary information in a semantically moti-

vated and linguistically feasible way. The JULIE corpus is composed of documents from a large variety of biomedical subdomains and entity types with critical word token issues. We then report on an ML-based tool suite for sentence and word token boundary detection, the JULIE Tools. We evaluate both the corpus and the tools against GENIA and PennBioIE and against another ML-based tool suite, the OpenNLP Tools.[1]

Background

To train ML-based tools for sentence and/or token boundary detection, high-quality annotated text data resources are needed. In particular, several ambiguous non-alphanumeric character symbols may denote sentence or word token boundaries (or not) and, furthermore, these symbols may (or may not) be part of names for biomedical entities, such as protein, cell, or organism names etc. In the following, we outline the annotation guidelines considered for the compilation of the JULIE corpus which we annotated with sentence and token boundary information.

Sentence boundary annotation

For sentence boundary annotation, it is first necessary to determine potential sentence boundary symbols (*SBS*). For biomedical language texts, such as those from the PubMed literature database,[2] we defined the "classical" sentence boundary symbols (".", "!", "?", ":") and also two PubMed-specific ones (")", "]"). In particular, for periods (".") and colons (":"), we encountered many cases where they did not denote an SBS:

- General abbreviations ("e.g.", "i.e.", "et al.", "ref.", "*viz.*", "Dr.", "vs.", etc.);
- Numbers (0.05, 1.2, .4);
- Entity names, e.g., organism names ("E. coli", "F. oxysporum", "f. sp. Lycopersicim", "P. decumbens"). Classifying these symbols as SBS would break up organism names which are essential for disambiguating protein names and mapping them into their database entry (e.g., UniProt). Obviously, simply stating a rule that marks an SBS after every period if the following word starts with a capital letter would break up the organism entity "f. sp. Lycopersicim". Moreover, it would also fail to recognize an SBS in cases where the beginning of the following sentence starts with a lower-case letter, as is the case with many protein names (e.g. "p53", "tac", etc.);
- Author and journal names in literature citations which are contained in many Pubmed abstracts (e.g., "Am. J. Physiol.", "J. Biol. Chem.", "L. Hoffmann", "Schindler L.");
- Other alphanumeric strings, such as EC numbers, chromosome locations, database identifiers ("EC1.7.3.3", "LEN.PK113-78");
- Colons followed by enumerations ("Several cytokines interact with each other: IL-2, IL-5, and IL-18.").

Token boundary annotation

For the annotation of word tokens in biomedical text (or any other domain), it is essential to determine which word tokens denote semantic units (i.e., entities) of interest and thus should be recognized as such (e.g., by named entity recognizers). In biomedical text, there are various symbols which may (or may not) denote word token boundary symbols, such as "-", "+", "/", " ' ", "=", "%" "(", ")", etc., and thus are very ambiguous with respect to their status as token boundary symbols (*TBS*). The most important cases are:

- Parentheses must usually be split from regular words, but, e.g., in chemical terminology they are part of the name, such as in "Ca(2+)" or "(S,S)-Tartate". The same holds for enumeration list items such as "1)", "(2)", "a)", "b)", etc.;
- Plus ("+") symbols and hyphens may denote relevant semantic information, such as indicating the presentation (+) of an antigen on a cell or the absence (-) thereof: "CD34(+) T-cells", "CD83+ dendritic cells", "CD11c(++) B-lymphocytes", "CD8alpha(-) DCs". Here, it can be seen that biomedical language expresses complex biological processes by means of a single character symbol. In such cases, of course, these symbols should be tokens on their own;
- Hyphens often concatenate entity names (such as protein names) with other words ("IL-2-specific",[3] "CD28-dependent", etc.) or even with other entity names, such as cell names, as in "CD43-DC". Lacking recognition of these entities as word tokens would prevent entity recognizers from detecting them at all;
- Similar observations can be made with respect to slashes ("/") which often separate two (or more) entity references ("IL-2/CD34", "HA-1/2", etc.);
- Hyphens (and slashes) may also denote the knock-out status of a certain gene with respect to an organism, such as in "flt3L-/- mice".

One could argue that such problems might be overcome by simply splitting (i.e., marking a sentence or token boundary symbol) at every potential split symbol (i.e., at every parenthesis, hyphen, period, colon, etc.). This strategy would split a protein name such as "IL-2" into [IL], [–], and [2]. However, modules further up in a typical text mining pipeline (part-of-speech taggers, phrase chunkers, syntactic parsers, etc.) would not be able to perform adequately on such broken data because their linguistic representations (either rule-based or derived from training data) could not deal with such fragments.

Materials and methods

JULIE Corpus

Currently, only one biomedical text corpus, *viz.* PennBioIE [4], addresses both sentence boundary and tokenization annotation issues at all, although insuffi-

1 http://opennlp.sourceforge.net

2 http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?DB=pubmed

3 Here, only the second hyphen should be split because the first one is actually part of the protein name "IL-2".

ciently. Furthermore, it is limited to two highly specialized biomedical subdomains, *viz*. the CYP450 enzyme and oncology, focusing on few organism types (human and mouse). No manual token annotation was done on the second well-known annotated biomedical corpus, GENIA [3], whose domain scope is also rather limited (transcription factors in human blood cells). Hence, by using different sets of MeSH terms,[4] we assembled a PubMed text corpus both for sentence and for word token annotation which covered a more varied set of biological subdomains, including gene expression and regulation, stem cell biology/transplanta-tion and immunology. We refer to this as the *Subdomain Corpus*. Additionally, by using the MeSH thesaurus, we also assembled subcorpora with respect to biomedical entity types which are known to pose severe problems for sentence and token boundary detection, *viz*. organisms, chemicals, cell types and cell components. We refer to this as the *Entity Corpus*.

The Subdomain and Entity Corpora for sentence boundary information were automatically preprocessed with the OpenNLP Sentence Splitter trained on the PennBioIE corpus [6]. Then the annotations were manually inspected and, if necessary, corrected by a computational linguist (the second author of this paper) and a biologist. In addition, we have added the sentence annotations from GENIA and PennBioIE. Altogether, the **JULIE Sentence Corpus** contains 62,400 sentences. A similar procedure was performed for token annotation. Due to the more complex task, only the Subdomain Corpus was annotated with word token boundary information. Furthermore, we corrected the token annotation in the PennBioIE corpus when it did not conform to our guidelines. The **JULIE Token Corpus** contains both the annotated Subdomain Corpus and the corrected PennBioIE data, summing up to around 35,900 sentences. Both corpora (sentence and token) are here referred to as the **JULIE Corpus**.

ML-based JULIE tools

Our tools for sentence splitting and tokenization are based on supervised machine learning, i.e., from a given set of training examples a statistical model is learned. Such a model can be used to predict labels for unseen data. Here, we employ Conditional Random Fields (CRF), a *sequential* learning approach which assigns a label sequence to an observation sequence [7]. This approach fits well the inherent sequential structure of natural language text. As an implementation of CRFs, we employed the machine learning toolkit MALLET.[5] In the following, the sentence and the token splitter (referred to as **JULIE Tools**[6]) are explained in detail. As a general rule, we tried to optimize our tools not only in terms of accuracy, but also with respect to the kind of errors made, *viz*. false positive (FP) and false negative (FN) errors. As for the sentence splitter, we prefer FNs over FPs. As many consecutive NLP components work on the sentence-level the costs of erroneously splitting a sentence is higher than not splitting. For the tokenizer we favor FPs over FNs because in many consecutive processing steps tokens are considered as atomic units; and if these are too coarse information is lost.

JULIE Sentence Boundary Detector (JSBD)

The input text is broken down into a sequence of (observation) units by splitting at all white space positions. For each such unit our sentence splitter has to decide whether it is at the end of the sentence or not (binary classification). Thus, the following piece of text from a PubMed abstract would be split into the following units (with the actual SBS after "T-cells"):

> … [on] [IL-2-activated] [CD34(+)] [cytotoxic] [T-cells.] [p3hr-1,] [the] [Burkitt's] [lymphoma] [cell] [line,] [was]

Each unit is represented by the following features:

- the unit itself (lexical feature) and its size in characters;
- sentence boundary symbols (SBS):[7] whether unit ends with SBS, whether unit contains SBS;
- brief word class: capital letters are replaced by "A", lowercase letters by "a" etc. and then identical consecutive letters are collapsed (e.g. *IL2* → *AA0* → *A0)*;
- orthographical features: based on regular expressions (e.g. *HasDash, AllCaps, InitalCap, hasParenthesis*, ...);
- abbreviations: whether the unit is contained in the list of known abbreviations, whether the unit conforms to abbreviation classes (*"[A-Z].", "([A-Za-z].)+*", "*[a-z]+.*");
- local context: features of neighboring units in window [-1,1] copied.

JSBD also employs a rule-based post-processing routine to avoid that a sentence is split within opened parentheses or brackets. This is a useful extension, as scientific papers and abstracts often contain complex bibliographic references within parenthetical or bracket-like expressions. Such a reference should be considered as one sentence. However, within these parenthesized sentences there are often many SBSs, especially periods, which could also be considered as sentence boundaries. Preliminary experiments showed that this processing routine, though it does not improve the overall performance, shifts the FP/FN ratio favorably, i.e., false positives are avoided (clearly at the cost of some more false negatives).

JULIE Token Boundary Detector (JTBD)

For the tokenizer we have defined a set of critical token boundary symbols[8] (TBS) where it should check for possible token boundaries. It should be noted that periods, exclamation and question marks are not considered as TBS because these SBS symbols have been disambiguated by the sentence splitter before. This is in line with the paradigm of running NLP tools in a (sequential) pipeline, where each tool is designated to one NLP task and there is a (natural) order to the tools due to input/output dependen-

4 http://www.nlm.nih.gov/mesh/meshhome.html
5 http://mallet.cs.umass.edu/
6 The tools can be downloaded from http://www.julielab.de
7 Sentence boundary symbols are, e.g., period, question and exclamation mark, etc.
8 Token boundary symbols: { } , + – ( ) [ ] ; = / < > % &

cies. Thus, tokenization is typically performed after sentence splitting.

At all white space positions and at each TBS we split the sentence into single units, the TBS itself is treated as a separate unit. Our example piece of text from above would thus contain the following units (for each sentence fragment):

[on] [IL] [–] [2] [–] [activated] [CD34] [(] [+] [)] [cytotoxic] [T] [–] [cells] SBS [p3hr] [–] [,] [the] [Burkitt] [’] [s] [lymphoma] [cell] [line] [,] [was]

For each such unit, JTBD decides whether or not this unit is the end of a token. A token thus consists of a sequence of *n* units where the last unit was labeled as token end but the other *n-1* units not.

Furthermore, we assign each unit its so-called super-unit: therefore we also split the sentence into larger strings at each white space as we did for sentence splitting. Such a string is considered a super-unit for a unit if it covers this unit in the sentence. In our example sentence fragments, we would have the following super-units:

[on] [IL-2-activated] [CD34(+)] [cytotoxic] [T-cells] SBS [p3hr-1] [,] [the] [Burkitt’s] [lymphoma] [cell] [line,] [was]

The super-units are needed as context information when building the features. Each unit is then represented by the following features:

- the unit itself, the super-unit itself (lexical feature);
- whether the unit had white space to the right in original sentence;
- whether the unit is a TBS;
- features equivalent to the sentence splitter: size, brief word class, abbreviation class, local context, rich orthographical features of the unit;
- bracket information: whether the super-unit contains brackets (*hasOpeningBracketOnly, isInBrackets, hasClosingBracketOnly,...*);
- whether the super-unit is an enumeration (“(1)”), whether the super-unit has genitive (“enzyme's”), whether the super-unit has plural in brackets (“enzyme(s)”);
- other orthographical features of the super-unit with focus on hyphens, arrows, +/– symbols which are often contained in biomedical texts, and structure of chemical names

Experimental results and discussion

Sentence splitting and tokenization performance is typically evaluated in terms of the accuracy (A), i.e., the number of correct decisions divided by the total number of decisions being made. Here, the total number of decisions equals the number of units. In our evaluation, we focus on two question, *viz.* (1) how well are the different corpora suited for training and (2) whether the JULIE Tools perform better than another well-known ML-based NLP tool suite, the OpenNLP Tools, whose general applicability to the biomedical domain has already been shown [6]. Among other NLP tools, OpenNLP also provides a sentence splitter and a tokenizer, both based on conditional maximum entropy models [8], also known as logistic regression. Compared to the rich feature sets of the JULIE Tools, the OpenNLP counterparts have substantially fewer features (mainly lexical ones) coupled with a non-sequential learning algorithm.

Sentence splitter evaluation

To address the first question, we trained the JULIE sentence boundary detector on both the GENIA (18,529 sentences with approximately 486,000 word tokens) and the original PennBioIE (23,277 sentences with approximately 590,000 word tokens) corpora. The models learned from this training material were then evaluated against the JULIE Subdomain and Entity Corpora. We did not evaluate against the complete JULIE Sentence Corpus because it comprises both the GENIA and the PennBioIE corpus. The results are depicted in Table 1. There are only very small differences in the accuracy of the two models (accuracy about A=99.6). In addition, we also trained and cross-validated JSBD on the complete JULIE Sentence Corpus which yields an accuracy of A=99.8. Here, we encounter a small improvement over the last three experiments. Table 1 also shows the performance of OpenNLP's sentence splitter on the complete JULIE Sentence Corpus (10-fold cross-validation). In this setting, JSBD performed notably[9] better than OpenNLP's sentence splitter (A=99.8 vs. A=98.7).

Table 1 - Sentence splitting performance: evaluated on different tools and different corpora

tool	training material	evaluation material	accuracy
JSBD	GENIA	JULIE Subdomain + Entity Corpus	99.58 (FP=30%)
JSBD	PennBioIE	JULIE Subdomain + Entity Corpus	99.62 (FP=27%)
JSBD	10-fold cross validation on JULIE Sentence Corpus		99.8 (FP=30%)
OpenNLP	10-fold cross validation on JULIE Sentence Corpus		98.7 (FP=48%)

This can be explained by the rich feature set in our sentence splitter and the fact that we consider sentence splitting as a sequential learning problem. Also, our sentence splitter produces fewer false positives (FP) than OpenNLP's sentence splitter (FP=30% vs. 48%), which is more favorable for this task.

Tokenizer evaluation

We trained JTBD on GENIA and PennBioIE, and evaluated the models on the JULIE Token Corpus to determine how well these corpora are suited for training (see Table 2). As GENIA is only tokenized using newspaper language patterns, it is not so well suited for training; only an accu-

9 On such a level of accuracy, a 1-percentage-point difference is notable because this affects mostly critical cases (organism names etc.).

racy of about A=71.5% is reached. PENNBIOIE is more apt because its word token annotation is more semantically motivated. A 10-fold cross-validation of JTBD on the complete JULIE Token Corpus showed that the performance is thus improved by approximately 1 percentage point. Table 2 also indicates that in comparison with the 10-fold cross-validation of OpenNLP's tokenizer on the complete JULIE Token Corpus (A=95.0), both JTBD's machine learning algorithm (sequential learning) and its rich linguistic feature representation (super-units/units) are superior (A=96.7). Looking at the tokenization decisions, the OpenNLP tokenizer runs into particular problems with hyphens which either get split not at all or in a rather inconsistent way. Thus, an expression like "IL-2-activated" is sometimes tokenized as [IL-2][–activated], [IL][–2][–activated], or not at all. Similar errors occur with expressions such as "CD34(+)".

From the above experiments we conclude, that for sentence splitting the respective corpus used for training is not that critical because sentence annotations are not very controversial within different biomedical subdomains. Tokenization, however, is a much more complex task with respect to the relevant biomedical semantic units to be annotated. Still, performance of tokenization can be improved significantly by employing a tool with a linguistically adequate representation and a rich feature set. In both cases, the extension of an annotation corpus by a set of critical (and rare) subdomain and entity cases, as is done in the complete JULIE Corpus, boosts performance.

Table 2 - Tokenizer performance: evaluated on different tools and different corpora

tool	training material	evaluation material	accuracy
JTBD	GENIA	JULIE Token Corpus	71.5 (FP=3%)
JTBD	PENNBIOIE	JULIE Token Corpus	95.9 (FP=25%)
JTBD	10-fold crossvalidation on JULIE Token Corpus		96.7 (FP=45%)
Open NLP	10-fold crossvalidation on JULIE Token Corpus		95.0 (FP=47%)

Conclusion

We introduced a sentence splitter and a tokenizer based on sequential machine learning methods and rich feature sets as well as novel corpora for the biomedical domain to train these tools. These corpora are an extension and a correction of the PENNBIOIE corpus: an extension because we added training material so that this corpus covers a more complete section of the biomedical domain and is not specialized to a subdomain; a correction because we removed some inconsistencies, annotation errors, and extended the semantic motivation of word token annotation. Our evaluation experiments run on these corpora indicate that forboth the sentence splitting and the tokenization task, a substantial improvement in performance could be achieved. Compared to a maximum entropy approach with poor feature sets (OpenNLP), these results suggest a ML approach based on CRFs for such NLP preprocessing tasks. In the future, we will optimize our tools in terms of feature representation as well as extend the JULIE Token Corpus to include more critical entity types.

Abstract

Cross-language document retrieval systems require support by some kind of multilingual thesaurus for semantically indexing documents in different languages. The peculiarities of the medical sublanguage, together with the subjectivism of lexicographers' choices, complicates the thesaurus construction process. It furthermore requires a high degree of communication and interaction between the lexicographers involved. In order to detect errors, a systematic procedure is therefore necessary. We here describe a method which supports the maintenance of the multilingual medical subword repository of the MorphoSaurus system which assigns language-independent semantic identifiers to medical texts. Based on the assumption that the distribution of these semantic identifiers should be similar whenever comparing closely related texts in different languages, our approach identifies those semantic identifiers that vary most in distribution comparing language pairs. The revision of these identifiers and the lexical items related to them revealed multiple errors which were subsequently classified and fixed by the lexicographers. The overall quality improvement of the thesaurus was finally measured using the OHSUMED IR benchmark, resulting in a significant improvement of the retrieval quality for one of the languages tested.

Keywords:

controlled vocabulary, information storage and retrieval, quality control.

Introduction

The medical language presents several challenges to information engineering due to its specialized terminology and the large amount of texts found in literature databases, on the Web, and in medical record systems. Furthermore there exists a considerable mismatch between the language of medical science, the jargon used by health professionals, and the language used by laypersons such as patients and their relatives. Multilingualism is another important issue here, because even though the global tendency is to use English as the primary language of research, the local idioms are still used for patient-related everyday documentation and communication. Furthermore, medical language is extremely dynamic with novel terms, names, and acronyms being constantly created and English terminology increasingly permeating non-English medical documents.

In light of this scenario, document retrieval systems necessitate domain-specific thesauri [1]. We understand by multilingual thesaurus some organized repository of linguistic symbols that are mapped to language independent, concept-like descriptors tailored to the needs of a certain domain. Furthermore, a thesaurus usually provides additional semantic relations between these descriptors [2]. According to [3], the main rationale for the use of a thesaurus is the supply of a controlled reference vocabulary to represent the contents of documents and thus abstracting away from linguistic variation, for the sake of ameliorating and simplifying document retrieval.

In contrast to automatically generated word indices, such as the ones maintained by current Web search engines, thesauri are generally constructed manually, in a labor intensive process that requires the grouping of synonyms and translations into semantic classes, the addition of semantic relations between classes and the resolution of lexical ambiguities. It is therefore self-evident that such a scenario, which normally involves a group of domain experts, requires some measures for error detection and quality assessment.

The objective of this work is to demonstrate how a quality control mechanism can be implemented for the maintenance of the *MorphoSaurus* dictionary, a multilingual thesaurus tailored to support document retrieval in clinical medicine [4]. To this end, we exploit test samples of multilingual corpora exhibiting a high degree of content similarity, in order to discover weaknesses in the thesaurus content by comparing the distribution patterns of MorphoSaurus descriptors in these samples.

Materials and methods

Subwords and semantic indexing paradigm

The construction of a thesaurus starts with the identification of the most informative terms (i.e., words and phrases) for the domain under scrutiny [5]. The main difference between MorphoSaurus and virtually any other thesaurus is that the inclusion of lexical entries into the repository is

guided, as much as possible, by criteria of semantic atomicity. The main corollary of this decision has been the definition of a new kind of lexical item, the so-called *subword* entry. Subwords are defined as self-contained, semantically minimal units [6], since we assume that neither fully inflected nor automatically stemmed words constitute the appropriate granularity level for lexicalized content description. In the medical sublanguage we observe particularly complex words such as *"pseudo|hypo|para|thyroid|ism"*, *"append|ectomy"*, or *"tooth|ache"*. Such words are constituted, in our model, by two or more subwords (in here, e.g., *"pseudo-", "-ectomy", "tooth"*). In the MorphoSaurus system, subwords are listed as lexicon entries together with their attributes such as language and subword type (i.e., stem, prefix, suffix, invariant). Each entry is assigned to exactly one identifier representing a group of synonyms and translations. These concept-like semantic descriptors are named *MorphoSaurus identifiers* (*MIDs*).

The MorphoSaurus engine indexes texts by mapping every word to a subword sequence, which is then checked for morphological plausibility, using a finite-state automaton. Thus, invalid segmentations such as ones without stems or ones beginning with a suffix are rejected. Finally, each meaning-bearing subword is replaced by its corresponding semantic identifier (MID). This in turn constitutes the interlingual output representation of the system. For example, *#physioterap* is the MID of the meaning of the subwords *krankengymnast*^{GE}, *physiotherap*^{EN}, *fisioterap*^{PT} or *fysioterap*^{SW}, extracted from text words such as "krankengymnastisch", "physiotherapist", or "fisioterapia".

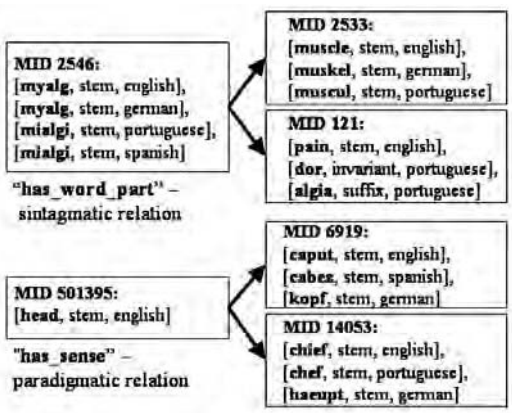

Figure 1 - Paradigmatic and syntagmatic relations: "has_sense" and "has_word_part" respectively

MorphoSaurus provides two different kinds of semantic relations between MIDs (cf. Figure 1):

- *has_sense*: This paradigmatic relation links ambiguous MIDs to their respective senses, e.g., the MID *#head* is linked to the MIDs *#caput* and *#boss* by *has_sense*.
- *has_word_part*: This syntagmatic relation links an MID having a composed meaning to its parts, e.g., the MID *#myalg={"myalg-", "mialg-",...}* to both *#muscle={myo-, muscle, mio, muscul, ...}* and *#pain={pain,-algy, -algi, -algia, dor, schmerz,... }*. The reason for this is the need to deal with composed meanings even in cases where a compound word cannot be properly dissected.

There are principally three approaches to treat ambiguous MIDs:

i. Substitute each ambiguous MID by the sequence of the MIDs representing its non-ambiguous senses.
ii. Substitute the ambiguous MIDs by exactly one MID which represents its most likely sense, computed from the MID frequency distribution.
iii. Substitute the ambiguous MIDs by exactly one MID representing its most likely sense, according to its context, using a corpus-derived co-occurrence matrix.

Whereas (iii.) has already experimentally tested [7], it has not yet been integrated into the MorphoSaurus system. For information retrieval purposes we use solution (i.), aware of the decrease in precision it may bring about.

The MorphoSaurus subword lexicon currently contains 90,550 entries, with 22,561 for English, 23,976 for German, 14,984 for Portuguese, 10,936 for Spanish, 7,812 for French, and 10,281 for Swedish. All of these entries are related in the thesaurus by 21,432 equivalence classes Fig. 2 depicts the process of semantic indexing, performed by the MorphoSaurus system.

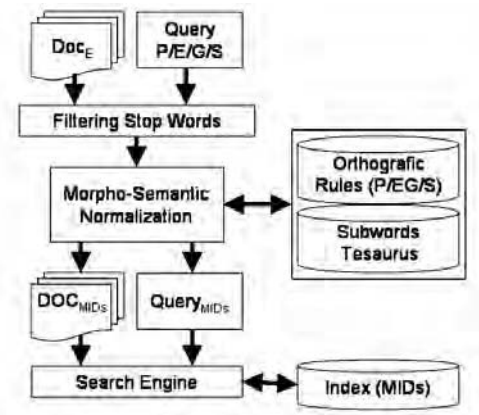

Figure 2 - Morpho-semantic normalization scheme

Pragmatics of thesaurus maintenance

An important advantage of constraining a dictionary to subword entries is the achievement of a high coverage with much less lexicon entries than in conventional lexicons. Nevertheless, the principal problems in the management of such a resource, as mentioned above, also exist with MorphoSaurus and require a principled solution. Although the lexicographers' work is based on written guidelines, many situations still require common-sense decisions which tend to produce more or less arbitrary results. Here, a particular difficulty of a subword thesaurus turns out to be that not only decisions about the semantic

relations between entries but also the proper delimitation of subwords have to be decided by the lexicographers.

Corpus-based error detection approach

We developed the following methodology to support the detection of weaknesses in the thesaurus. According to the current workflow, the lexicographers are already using a moderated mailing list in order to facilitate the communication of errors and to support consensus decisions of difficult modeling issues. However, we observed that this process is guided rather by serendipity than by systematic contemplations, although good responses can be found to any sort of posting. Our objective has been to improve this process by an automated detection of errors in the content of the thesaurus.

Our methodology is based on the hypothesis that in closely related corpora [8, 9] (i.e., texts that deal with the same subject-matter in different languages), the statistical distribution of semantic identifiers exhibits a high degree of similarity. In consequence, any exception to this expected conformity is likely to indicate some kind of fault in the indexing process, or a weakness in the semantic relations between entries in the lexicon.

General proposal

Our proposal aims at triggering the lexicographic activities with a ranked list of potential problems generated by the comparison of the "semantic extract" of comparable corpora, i.e., the MIDs extracted from them. In addition, we monitor this work via the repeated execution of a summative quality metric which uses an information retrieval benchmark that has already been applied in previous studies [10]. This benchmark measures the general appropriateness of a thesaurus to support medical text retrieval.

Multilingual related medical corpora

In order to create frequency distributions between the MIDs, generated from related multilingual corpora from different languages, we used the Merck Sharp & Dohme (MSD) manual of clinical medicine, a reference handbook of clinical medicine, available for the languages English (EN), Spanish (SP), Portuguese (PT), and German (GE), and freely available from the website http://www.merck.com. These corpora were submitted to the MorphoSaurus indexer and a frequency table was generated for each language.

Scoring of descriptors

For each MID in each language pair, an S value is calculated based on MID frequency distributions, using both relevance (S_a) and imbalance (S_d) measures:

$$S = \frac{2S_d - s_a}{3} \quad (1)$$

$$S_d = \left| \frac{f_1 - f_2}{f_1 + f_2} \right| \quad (2)$$

$$S_a = \frac{f_1 + f_2}{(f_{x1} + f_2)\max} \quad (3)$$

with f_1 being the MID frequencies in a normalized corpus of one language and f_2 the frequencies in another language; S_d scores the degree of imbalance between the MID occurrences between either language, and S_a relates the frequency of the MID under scrutiny with the frequency of the MID with the highest frequency in both corpora. Thus the S values range between zero and one. The overall score is therefore predominantly influenced by the degree of imbalance, but also gives an additional boost to highly frequent MIDs.

Redefinition of workflow

Guided by the sequence of problematic MIDs in the generated frequency lists, the lexicographers then started revising the thesaurus and the modifications were put down in a computer-based journal containing the following information in a semi-structured form: MID, problem description, problem class, solution, and rationale for modification.

Progress assessment

There are two different ways to assess the progress achieved in the thesaurus cleansing:

- Formative Evaluation: MID frequency lists are periodically generated, expecting a decrease of indices;
- Summative Evaluation: performance of a multilingual document retrieval system is measured, using the MorphoSaurus approach for indexing both documents and queries.

We subscribed to the second approach which is expected to yield stronger conclusions for the usefulness of the proposed error detection methodology.

According to [11], we use precision and recall as performance parameters in an IR system. Precision is defined as the proportion of relevant documents among all retrieved documents and recall as the rate of all relevant documents which could be retrieved. In IR systems which return all documents and produce a ranked output it is possible to measure precision at different recall points, thus yielding a precision / recall diagram. By interpolation it is then possible to compute precision values at defined recall points. As an overall assessment parameter, we computed the *eleven point average* value (*AvgP11*), defined as the arithmetic mean of the precision values at eleven recall points 0.0, 0.1, …, 0.9, 1.0.

For the precision / recall benchmark we used the OHSUMED collection, a subset of Medline abstracts, manually classified with regard to their relevance to a given set of authentic user queries [12]. In order to use this resource for benchmarking in a cross-language retrieval system, all queries had previously been translated to Portuguese, Spanish, German, and Swedish.

Table 1 - A sample of MID frequencies and related parameters. Top of the list for the language pair English / Portuguese

MID	Meaning	EqClass	f_1	F_2	S
#people	People	500783	6352	0	0.7155
#from	From	060077	4676	0	0.7026
#icas	icas	023555	0	3022	0.6899

During the correction period (three months), ten thesaurus backups were produced. Each of these backups was used for a complete IR experiment with the OHSUMED corpus. Each of these experiments in turn produced an AvgP11 benchmark value for each of the four languages.

To get a better visibility of the performance, we plot the average of Avg11P of all experiments in Fig. 2.

Results

Experiences with the correction process

During the process of problem analysis and correction it became clear that most of the highly scored MIDs spotted real problems which could be solved. Table 1 shows three rather extreme examples of imbalance between Portuguese and English, due to missing MIDs in one of the two languages. For example, the preposition *"from"* belongs to a MID which is marked for indexing, but its Portuguese analogue *"de"* is marked as a stop word and is therefore ignored for indexing.

Table 2 - Problems identified during the MID corrections

Reason for MID high score	Frequency Portuguese / English	Frequency German / English	Frequency Spanish / English
Ambiguities	0.23	0.38	0.14
Missing or dispensable MID	0.49	0.18	0.53
Same Sense in Different MIDs	0.06	0.12	0.19
One MID with Different Senses	0.04	0.05	0.06
No problem	0.11	0.10	0.04
Unclassified	0.07	0.17	0.04

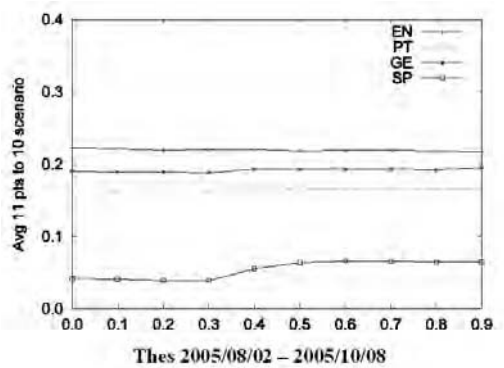
Table 2 depicts the most frequent problems:

- The ambiguity is mainly due to ambiguous lexemes (and, the according MIDs) in one language but not in another. In some cases the ambiguous MID was found not to be mapped to the unambiguous ones and was therefore used for indexing, since the normal procedure consisting of the substitution of an ambiguous MID by the MIDs that represent its non-ambiguous senses, did not take place. This is a problem that can easily be corrected by including the missing *has_sense* links.
- Missing or dispensable MIDs were common in borderline cases where a lexical entry had a very unspecific sense resulting in the fact that an entry was given a semantic identifier in one language but not in another one. An example is the preposition *"from"* (see discussion above and Table 1). The solution is to create a consensus about what should be considered as stop (sub)words, i.e., lexicon entries excluded from indexing.
- The same sense was found in different MIDs (which generally did not contain lexemes of all languages). This problem could be solved by merging different MIDs.
- Different senses were found in the same MID, and at least one of them was also present in another MID (generally with a focus on a different language). The solution consisted in splitting the non-uniform MID and redistributing its entries.

Surprisingly, other problems occurred only with quite low frequency. For instance, problems of string delimitation rarely had an impact on the MID distribution. Instead they seem to raise the overall noise level. So we conclude that other approaches may be better suited for detecting this kind of problem.

Summative evaluation measures

Fig. 2 demonstrates the evolution of the changes undertaken, using the IR benchmark described above. The AvgP11 values were calculated at 10 points within an evaluation period of nine weeks. During this time, about hundred hours were invested by experienced lexicographers who had already been working in the MorphoSaurus project before.



Thes 2005/08/02 – 2005/10/08

Figure 2 - Average of eleven point average value (AvgP11) evolution

For none of the languages under scrutiny there was a monotonous increase in performance. Comparing the first with the last AvgP11 value, there is a relatively insignificant growth of the values for Portuguese and German, namely by 1.8% and 2.6% respectively. This improvement seemed to be principally due to the addition of relations between MIDs and the rearrangement of MIDs. We even found an IR performance decrease of 1.9% in the case of English. We could argue that this value, just as the increase for German and Portuguese, lies within the range of normal variation, especially considering that the benchmark does not measure the whole information space but exactly the IR performance of a sample of 106 queries. Certainly, the more consolidated a resource, the less likely simple modifications will make it better. In contrast, the increment in performance of the Spanish benchmark amounted to a factor of 53% which cannot be attributed to chance. We interpret this finding as a good support for the hypothesis that the right problem selection – as done by our error detection approach – increases the performance in very short time.

The different degrees of maturity between the language-specific subsets of the thesaurus also became obvious when comparing the values from Table 2. The main difference is the relatively low rate of missing or unnecessary MIDs for German / English, a fact which may be derived from the maturity of the German part of the thesaurus on the one hand, but also from a more concordant treatment of stop words in this language pair.

Another interesting fact was that 10% of the MID disparities could not be attached to any thesaurus error. We interpret this as a consequence of lexical ambiguities occurring in one language but not in the other. So it frequently happens that one ambiguous MID (representing ambiguous terms in the same language) expands to one MID that is very common in the domain, and another one that is uncommon. As we disambiguate trough employing the expected frequency (cf. ii. in the second section) one or more readings will be ignored. For instance, if the English noun *"head"* corresponds a bit more likely to the sense of *"caput"* than to the one of *"boss"*, the latter sense will simply be ignored, which in turn may cause a disparity of the MID corresponding to the sense of *"boss"*, compared to other languages.

Conclusion

In this paper we presented an approach for data-driven error detection in the maintenance process of a multilingual thesaurus in the medical domain. The usefulness of the method could be demonstrated by the fact that most problems detected corresponded to real errors which could be fixed by the lexicographers. This showed the heuristic value of this approach in the process of continuous quality assurance and formative evaluation of the resource.

For the summative evaluation of our error-detection approach we used an IR benchmark during a nine-week period of thesaurus maintenance work. Whereas no significant increase in the benchmark parameter could be observed for those three languages which already exhibited a good quality after years of maintenance (i.e., German, English, Portuguese), there was a considerable increase for a fourth language, Spanish. This language, which had been added only much later, had therefore not received such a high level of attention due to the lack of Spanish language skills among the lexicographers.

Hence we can recommend the methodology especially for streamlining the lexicographers' efforts, particularly in the case of yet unconsolidated portions of a thesaurus. In addition to what we applied during this experiment we suggest the following elements to be included into a workflow for thesaurus quality assurance:

- For each language pair MID frequency, lists ordered by imbalance should be generated periodically, with a period covering one day to one week, according to the intensity of lexicon maintenance effort;
- An overall indicator for MID imbalance for each language pair should be generated and recorded over time;
- For each MID edited, the imbalance score S should be recorded over time;
- Alerts should be generated for every MID which exhibits an increase in imbalance above a given tolerance interval;
- IR benchmarks should be generated on a weekly basis and AvgP11 values monitored over time. Alerts could be generated in case of strong decrease in value, or cumulated decrease, considering both sequences of measurement for one language, or single-point measurement for all languages.

Abstract

Medical language, as many technical languages, is rich with morphologically complex words, many of which take their roots in Greek and Latin—in which case they are called neoclassical compounds. Morphosemantic analysis can help generate definitions of such words. This paper reports work on the adaptation of a morphosemantic analyzer dedicated to French (DériF) to analyze English medical neoclassical compounds. It presents the principles of this transposition and its current performance. The analyzer was tested on a set of 1,299 compounds extracted from the WHO-ART terminology. 859 could be decomposed and defined, 675 of which successfully. An advantage of this process is that complex linguistic analyses designed for French could be successfully transferred to the analysis of English medical neoclassical compounds. Moreover, the resulting system can produce more complete analyses of English medical compounds than existing ones, including a hierarchical decomposition and semantic gloss of each word.

Keywords:

natural language processing, morphosemantic analysis, word definition, neoclassical compounds

Introduction

Medical language, as many technical languages, is rich with morphologically complex words, many of which take their roots in Greek and Latin. These so-called neoclassical compounds are present in many areas of the medical vocabulary, including anatomy (*gastrointestinal*), diseases (*encephalitis, cardiomyopathy*), and procedures (*gastrectomy*). Segmenting morphologically complex words into their components is the task of morphological analysis. When this analysis is complemented by semantic interpretation, the process is called morphosemantic analysis. Complex words are often "compositional," in the sense that the meaning of a complex word is often a combination of that of its parts.

Morphosemantic analysis can therefore help processes interested in semantics, such as the detection of similar terms or the generation of definitions. This was for instance the aim of [1], where Morfessor, a tool for unsupervised learning of morphological segmentation [2], was used to contribute mappings between WHO-ART and SNOMED terms. Early work on medical morphosemantic analysis focused on specific components such as *–itis* [3] or *–osis* [4], then on larger sets of neoclassical compounds [5]. Lovis [6] introduced the notion of morphosemantemes, *i.e.*, units that cannot be further decomposed without losing their original meanings. The Morphosaurus system [7,8] segments complex words using a similar notion called subword. The UMLS Specialist Lexicon [9], with its "Lexical tools," handles derived words, *i.e.*, complex words built through the addition of prefixes or suffixes. It provides tables of neoclassical roots, but no analyzer to automatically decompose compound words. DériF [10] morphosemantically analyses complex words. In contrast to [8] or [6], it computes a hierarchical decomposition of complex words. Moreover, it produces a semantic definition of these words, which it can link to other words through a set of semantic relations including synonymy and hyponymy. In contrast to the Specialist tools or to [11], DériF handles both derived and compound words. Designed initially for French complex words, then extended to the medical domain, its potential for cross-linguistic application was showed in [12]. Its transposition to English would fill a gap in the set of tools currently available to process complex English medical words.

This paper reports work on the adaptation of DériF to English medical complex words. It focuses on neoclassical compounds and is based on the hypothesis that this type of words is similarly formed in related European languages (here French and English). Our goal is to have DériF analyse English words and present its results in English.

We first describe the morphosemantic analyzer and our test set of words. We explain the modifications performed on this tool and the evaluation conducted. We then expose the results, discuss the method and conclude with some perspectives.

Selected for best paper award.

Material and methods

The principle on which this work is based is morphosemantic analysis, that is morphological analysis associated to a semantic interpretation of words. In other words, we want to obtain a decomposition and a description of the meaning of a complex word based on the meanings of its parts. A complex word may be formed through any combination of the following word formation rules:

- derivation, which adds an affix (prefix or suffix) to a base word, *e.g., pain/painful*;
- compounding, which joins two (or more) components together, those components being either neo-classical roots called Combining Forms (CFs) or modern-language words, *e.g., thermoregulation, arthritis*.

For this work we chose to analyze neo-classical compounds (formed from CFs). However, a compound may also undergo derivation, so that mixed-formation words must also be addressed. Therefore we included not only "pure" compounds, but also those neo-classical compounds that were prefixed or suffixed (*e.g., haemorrhagic*).

Our main hypothesis for the transposition from French to English is that a same linguistic analysis can be applied to neo-classical compounds of several languages. We assume that they are formed in a similar way and that the components involved are the same, the major differences being orthographic (such as *-algia/-algie*).

Material

We started from the French version of the DériF ("Derivation in French") morphosemantic analyzer. DériF was designed both for general language and more specialized vocabularies such as medical language. It performs an analysis purely based on linguistic methods and implements a number of decomposition rules and semantic interpretation templates. It also uses resources which include a lexicon of word lemmas tagged with their parts-of-speech and a table of CFs. The system goes further than simple decomposition and interpretation steps by predicting lexically related words. Another of its distinctive features is that it yields a structured decomposition of words and not simply a linear segmentation, so that we know which part is the head of the word.

As input the system expects a list of words tagged with their parts-of-speech and lemmatized (in their base form & no plural). It outputs the following elements:

1. a structured decomposition of the word into its meaningful parts;
2. a definition ("gloss") of the word in natural language;
3. a semantic category, inspired by the main MeSH tree descriptors (anatomy, organism, disease, etc.);
4. a set of potentially lexically related words. The relation identified can be an equivalence relation (*eql*), a hyponymy relation (*isa*) or a see-also relation (*see*).

For instance, the French word *acrodynie* (English *acrodynia*) is analyzed in the following way (*N* stands for *noun*, *N** is assigned to a noun CF):

acrodynie/N ==>
(1) [[acr N*] [odyn N*] ie N]
(2) douleur (de—lié(e) à) articulation *(pain of—linked to joint)*
(3) maladie *(disease)*
(4) eql:acr/algie, eql:apex/algie, see:acr/ite, see:apex/ite

It has been pointed out [12] that the method could be extended to other languages. Indeed the rules for generating lexically related words (item 4.) do not rely on any language-specific features so that this part of the system is fully language-independent. The morphosemantic parser however needs to be adapted to the language.

To test the transposition of DériF to English, we prepared a list of test words. These words were taken from the WHO-ART terminology, which describes Adverse Drug Reactions (ADRs), since one of the intended applications of this work is to contribute to the pharmacovigilance domain by grouping terms describing similar ADRs. We selected the English terms of this terminology; since DériF works on single words and not on multi-word units, we split them into single words; and since we adapted DériF to analyze neo-classical compounds, we only retained those types of words. The selection was done both automatically by removing all words of 4 characters or less (these words are practically never morphologically complex), and manually by reviewing the list to look for neoclassical compounds (the work was done by a language engineer, LD). This gave us a list of 1,299 words to be decomposed out of a total of 3,476 words. These words were lemmatized and tagged with their parts-of-speech using the Treetagger[1] part-of-speech tagger. We used a lexicon of tagged words from the UMLS Specialist lexicon[2] to help TreeTagger deal with unknown words.

Methods

Adapting the Morphosemantic Analyzer

The method of morphological analysis that we want to transpose to English is schematized in figure 1.

1 http://www.ims.uni-stuttgart.de/projekte/corplex/TreeTagger/DecisionTreeTagger.html (last access 26/03/07)
2 http://www.nlm.nih.gov/pubs/factsheets/umlslex.html (last access 26/03/07)

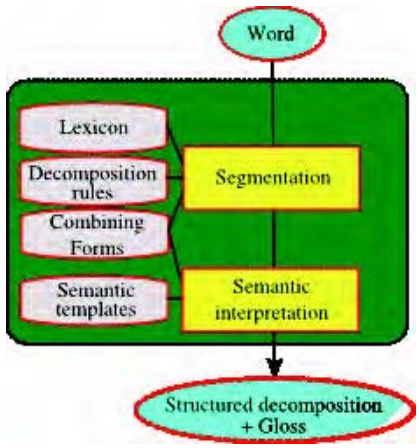

Figure 1 - Morphosemantic parsing

Language-specific material is located in:

1. *the lexicon* of tagged word lemmas which is used by the system to test whether a component exists and to retrieve its part-of-speech;
2. *the table of Combining Forms(CFs)*: each CF is associated with a modern-language word which describes its meaning, a semantic type, a part-of-speech, and a set of CFs related through relations *eql, isa, see*;
3. *the decomposition rules*: these rules are triggered in a certain order according to the part-of-speech of the word and to the affix identified (if any). They identify the head of the word and its other components, relying on the table of CFs and lexicon. Each rule may have a set of exceptions. Orthographic normalization is also performed on the components;
4. *the semantic templates*: they provide template glosses of a complex word based on the relation between its head and its other components.

We address each of these in turn.

(1) We replaced the French lexicon by an English lexicon derived from the UMLS Specialist lexicon.

(2) Our hypothesis is that CFs are mainly the same in English and French save for a few minor orthographic differences. We handled these by making small modifications to the French CFs (*e.g.*, removing accents as in *blépharo – blepharo*) to obtain the English equivalents. Semantic types assigned to the CFs might have been left with French labels since they are conceptual labels, but we considered that English names would be more consistent and translated them; this was done very easily since they were few. In the same line, we provided modern-English names for the CFs. They were obtained from two lists of CFs, one taken from the UMLS Specialist lexicon, the other one extracted from the Dorlands medical dictionary, where CFs were paired with modern-English words.[3] We automatically matched them to our English CFs and reviewed the results. Those roots that could not be matched were dealt with manually. The set of related CFs was also replaced by their English equivalents (obtained from the orthographic modifications mentioned above). The parts-of-speech were kept as is. An extract of the resulting table can be seen in table 1. The lexical relations between the CFs are labeled as follows: <- for an hyponymy relation, ~ for a see-also relation and no sign for an equivalence relation.

(3) Intervention at the rule level remained limited since we assumed that neo-classical compounds were formed in a similar way in French and English. So this mainly involved adapting the exceptions, the orthographic normalizations performed and the affixes (*e.g.,* French suffix *–ique* becomes *–ic*).

(4) Finally, we translated the semantic templates so that they could generate English glosses. For instance, the following template is now associated with the *–ia* suffix, the *hyper-* prefix and Y/X as nouns:
Affection of **X** *linked to the excess of* **Y**
where **X** and **Y** will be substituted with modern-language equivalents of CFs or with simplex words from the lexicon, as in *hypercalcemia*, which is analyzed into *Affection of blood linked to the excess of calcium*.

Table 1 - Table of Combining Forms (excerpt)

CF	English	Type	Relations
algia	pain	disease	odyn, algo, ~itis
blephar	eyelid	anatomy	palpebr, <- ocul, ~coro
ectomy	surgical excision	act	~tomy, ~stomy
gastr	stomach	anatomy	stomac, gaster, ~hepat, ~entero, <-abdomin, ~pancreat

Evaluation

We ran the updated DériF on the 1,299 complex words extracted from WHO-ART. The expected output for each word is a hierarchical decomposition into the word components, a definition in natural language, a semantic type and a set of related words, which we evaluated for coverage and validity. We define coverage as the proportion of words the system was able to analyze. An analysis was considered valid if its decomposition and definition were correct; in this evaluation, we did not take into account the semantic type nor the set of potentially related words. At this point we computed two standard measures of evaluation in natural language processing: precision and recall. Precision is the ratio of correct analyses over the total number of analyses. Recall is the ratio of correct analyses

3 http://www.merckmedicus.com/pp/us/hcp/thcp_dorlands_content.jsp?pg=/ppdocs/us/common/dorlands/dorland/dmd-a-b-000.htm (last access 26/03/07)

over the total number of analyses that should have been produced. The validity of the answers was determined by a language engineer when reviewing manually the output.

Results

In the present state of its transposition, DériF was able to analyze 859 out of the 1,299 words in our list (see table 2), thus obtaining 66% coverage. Example word analyses are given in table 3. They illustrate that both pure neoclassical compounds (*[[arthr N*] [algia N*] N]*) and derived words built on a classical base (*[a+ [dactyl N*] +y N]*) are analyzed.

Table 2 - Coverage

Total nb of words	Decomposed words	Coverage
1,299	859	66%

We identified several causes of non-decomposition:

- Certain suffixation rules are not currently implemented in the system (in both French and English versions). This is the case for *–ation* and *–ism* suffixes so that words like *lacrimation* and *hermaphroditism* are not decomposed;
- Some components are listed neither in the table of CFs nor in the lexicon; e.g. as *campt-* is not in the table of CFs, the word *camptodactyly* has not been decomposed;
- Errors at the preprocessing level (mistagged words), *e.g., corporal/N* was tagged as a noun while being an adjective in our context.

Table 4 - Precision/recall figures

Nb of correct results	Precision	Recall
675	78.5%	52%

We measured a precision of 78.5% (see table 4) which is fairly good. Combined to a moderate coverage, this yields a 52% recall. Incorrect results were mainly due to:

- Wrong structuring of the decomposition. An example can be seen in table 3 with the word *meningoencephalitis*. Its correct decomposition should be:
  [**[** [mening N*] [encephal N*] **]** [itis N*] N]
  -itis should be the head of the conjunction of *mening-* and *encephal-,* which would give a definition such as "*inflammation related to head and meninges.*"
- Unsatisfactory definition (often due to the fact that the meaning of the word was not sufficiently reflected by the meaning of its parts). See for instance the analysis of the word *acanthosis* in table 3. The decomposition is right but its meaning has evolved too much and cannot be derived from that of its parts. This word should not be considered a complex one.
- Mistagged words that could not be correctly analyzed. This is the case of *alveolar* (last row of table 3), which was treated as a noun derived from an adjective (*alveolar* as an adjective is correctly analyzed by DériF).

Discussion

The precision of the adapted system is good, especially for a first implementation. Recall is lower but should rapidly grow when increasing the size of the table of CFs and the lexicon.

The present state of the system already shows that this language-dependent system could be adapted to another, related language for the task of analyzing medical compounds. The advantage of doing so is that we did not have to start from scratch and implement a new system. Indeed, a certain amount of manual work is still necessary, such as preparing the table of CFs and adapting the semantic templates; but there is a stable basis on which to work, so that we believe that this solution is overall less time-consuming. An additional advantage is that in the process, we can

Table 3 - Example word analyses generated by the updated DériF

Word/POS	Decomposition	Definition	Type	Related words
Correct analyses				
arthralgia/N	[[arthr N*] [algia N*] N]	pain (of -- linked to) joint	disease	eql:arthr/algesia see:arthr/itis
adactyly/N	[a+ [dactyl N*] +y N]	Affection characterized by the absence of digit	disease	_
gastroesophageal /ADJ	[[gastr N*] [oesophag N*] al ADJ]	Related to oesophagus and stomach	anatomy	eql:stomac/oesophag isa:abdomin/oesophag
Errors				
meningoencephalitis/N	[[mening N*] **[** [encephal N*] [itis N*] N**]** N]	(Part of -- Specific type of) encephalitis related to meninges	_	_
acanthosis/N	[[acanth N*] [osis N*] N]	(Part of -- Specific type of) disease related to prickle	disease	_
alveolar/N	[[alveolar A] N]	Entity being alveolar	_	_

transfer to English linguistic analyses which were initially designed for French. For instance, Namer [13] proposed an analysis of pathology nouns of the form Pref-(Y)X-ie, for instance *hypercalciurie*, which she showed could also apply to German, Spanish, Italian, and English. In the present work, the implementation of this analysis in the French DériF is directly transferred to its English version.

Using a linguistics-based morphosemantic analyzer such as DériF has a number of advantages. The system performs both morphological decomposition and semantic interpretation while other methods remain at the level of morphological segmentation [8] or add semantics after using a tool for decomposition [1]. We also provide a hierarchical decomposition as opposed to a linear one [1,6,8]. In [1] the method was also applied to the WHO-ART terminology, so that we could compare results. The same word list was submitted to the Morfessor segmenter in exactly the same conditions as in [1], and obtained a coverage of 93.7%, but a precision of 53.2% (25% less than DériF) and a recall of 49.9% (slightly less than DériF). This means that about the same number of words was correctly analyzed (recall), but DériF was much more to the point by proposing significantly less incorrect analyses. By relying on a statistical segmenter, the method in [1] has the advantage of being language-independent; however, its implementation also uses a table of morphemes, so transposition to another language is not immediate either. Besides, statistical segmentation also brings certain types of errors that could be avoided with linguistic rules as implemented in DériF, *e.g.*, *chemosis* segmented as *c+hem+osis*. Moreover, as pointed out above, DériF outputs more complete information than Morfessor (simple linear segmentation).

This work also suggests the perspective of a system that could work with several languages. We transposed the system from French to English, but a possible next step would be to be able to use it for translation: i.e. producing an English definition of a French word (or vice-versa). This would require a multilingual table of CFs (as suggested in [12] and prepared here for French+English), multilingual semantic templates (as obtained from the present work for these two languages), and translations of simplex words involved in compounds. Such a system could contribute for instance to cross-language information retrieval, with the same principles as [14]. Another potential next step would be to test the adaptation method on other related languages.

Conclusion

In this work, we successfully transposed a linguistics-based morphosemantic analyzer from French to English in order to provide definitions for English neoclassical medical words. This verifies our hypothesis that neoclassical compounds from different languages can be analyzed in a similar way, as can be expected in the medical vocabularies of languages in the Romance (*e.g.*, French) and Germanic (*e.g.*, English) families. This can be seen as a first step towards a multilingual system.

Future work includes improvement of the system as well as using the results for a specific application such as pharmacovigilance. The decompositions and definitions generated can be used to measure proximity between WHO-ART terms and group similar terms, but without necessarily relying on SNOMED as done in [1]. Grouping similar terms describing Adverse Drug Reactions would allow better signal detection in pharmacovigilance.

Abstract

Radiology reports are written primarily in natural language. Automated extraction of malignant findings from narrative reports is an important technique for clinical support or alert generation for physicians. This paper proposes a method for automatically extracting malignant findings from narrative radiological reports written in Japanese. First, sentences are parsed and a medical attribute of each phrase is determined. Next, sub-trees related to radiological findings are extracted from a dependency tree using medical attributes. Finally, the malignant findings in each sub tree are extracted with their positive or negative assertions, each of which is determined by the multiplication of pos/neg signs along a path in a sub-tree. The recall and precision for the extraction of malignant findings with their positive or negative assertions were 76% and 91% respectively. The experimental results showed the validity of the proposed method for extracting malignant findings with correct assertions.

Keywords:

information extraction, radiology report, radiological findings, syntactic analysis, natural language processing

Introduction

Radiological reports contain a great deal of information about a patient's medical condition, and malignant findings such as "*carcinoma*" are especially important. As such, for a physician who orders an examination, automated extraction of such malignant findings is an important technique for clinical support or for alert generation from the viewpoint of medical safety control.

However, simple methods such as extracting only malignant keywords from each sentence do not work well. For example, if a malignant keyword "*cancer*" is found in a sentence in a patient's record (e.g., post operation), it may not be relevant to a current malignant finding and should not be extracted. Furthermore, if the phrase "*suspect for metastasis*" is found in a sentence, "*metastasis*" should **not** be extracted as "positive study" for cases in which the entire sentence is: "*There was* ***no nodular lesion suspect for metastasis."***

Note that an approach that attaches greater importance to recall than to precision and that depends on later screening burdens the users and is impractical. Thus, an effective alert system requires high precision.

Several studies have examined information extraction (IE) from narrative reports [1][2][3][4][5][6]. However, few studies have examined IE from narrative reports written in Japanese [7][8]. The previous approach for extracting findings from Japanese radiological reports [7] is based on pattern matching using assertions at the end of sentences. However, this approach does not consider dependency relationships between non-contiguous terms so that plural findings cannot be extracted from one sentence with their correct assertions. As a result, the previous approach achieved very high precision but the recall was no more than approximately 50%.

In the present paper, we propose an improved method for extracting malignant findings from narrative reports written in Japanese, using both medical attributes and syntactic information (in other words, "dependency structure"). The Japanese dependency structure is usually defined in terms of the relationship between phrasal units called *bunsetsu* segments (hereafter "phrase"), each of which consists of a content word and a function word. In addition, each content word or function word consists of morphemes and the process of recognizing plural morphemes as one phrase is called "chunking".

The dependency structure is necessary not only for extracting plural findings from one sentence, but also for determining positive or negative attributes of long and complex assertions (e.g., double negation). However, as is often mentioned in the previous studies [4], there are many difficulties in parsing radiology reports because of ungrammatical writing. The existing Japanese syntactic parser based on newspapers does not work well. Most errors occur in excessive "chunking" caused by shorthand and telegraphic writing style. Therefore, in the proposed method, the system performs the correction of excessive chunking of parser output. The system then determines the positive or negative attribute of each malignant finding using [+]/[-] signs in a sub-tree of the entire dependency tree. An outline of the proposed system is shown in Figure 1.

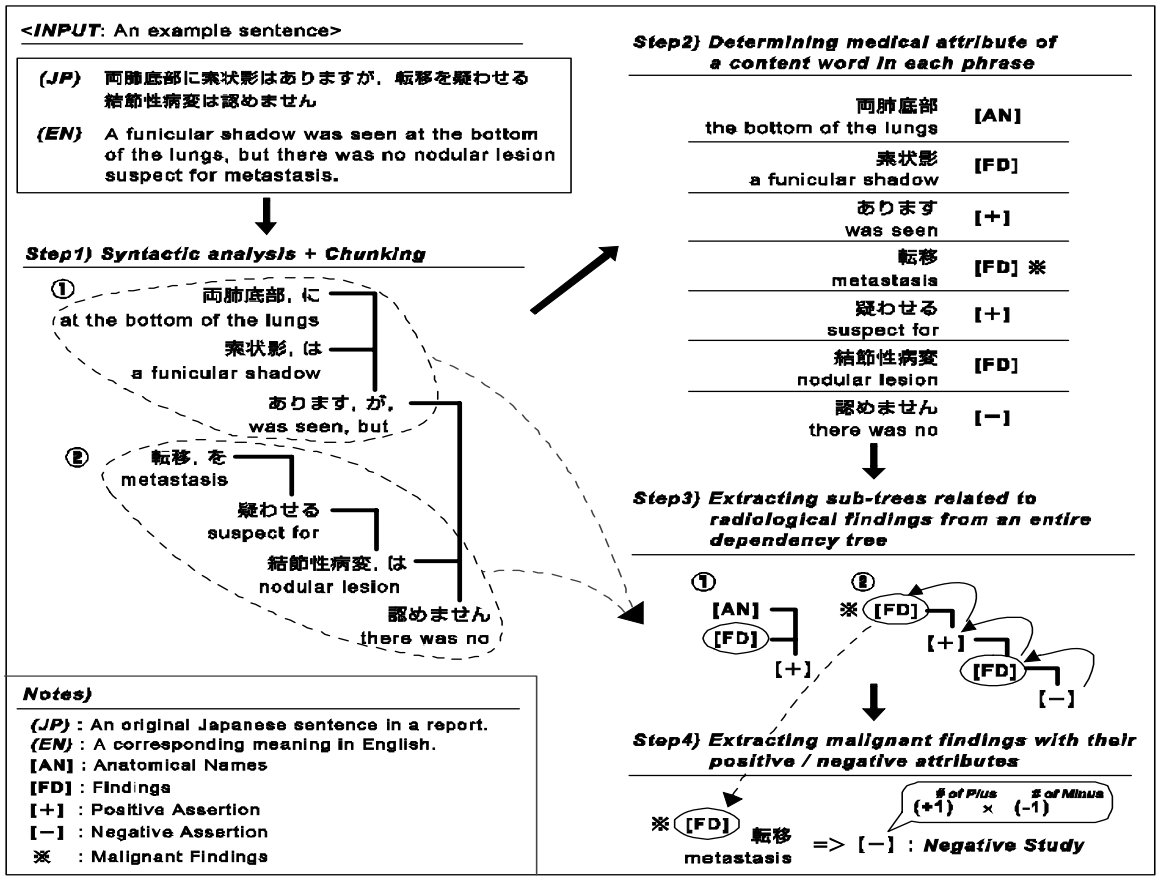

Figure 1 - Overview of the proposed method

Materials and methods

Materials

We used 22,496 CT and MRI reports stored in the Department of Radiology of the University of Tokyo Hospital from February 1, 2005 through August 31, 2005.

Radiology reports usually consist of various sections such as “Exam”, “Comparative Study”, “Patient Status”, “Recommendation”, “Findings”, and “Additional Information”. First, the sentence classification process was performed using a rule-based classifier described in a previous paper [7] (Recall = 99.1%, Precision = 98.8%). Then, sentences that include “keywords expressing malignant findings (Table1)” were randomly selected from the “Findings” category. We prepared 10,000 sentences for use in developing the rules of the proposed system and another 100 sentences for the evaluation set.

These typical malignant keywords (Table1) were selected by medical specialists for trial, and their future extension is discussed later herein.

Medical attributes

In order to determine a medical attribute of a content word in each phrase (in Step 2), a medical dictionary was constructed using four resources, as shown in Table 2.

We unified these four resources, while omitting some duplicate records, and then defined their medical attributes as shown in Table 3. Terms that have “Finding” attributes are (1) entries in ICD-10, where the first character of the ICD-10 code is ***‘R’*** (i.e., “Finding” category) in resource (D1) and (2) findings defined in resource (D4).

Table 1 - Keywords expressing malignant findings

[Straightforward words expressing malignant findings]
malignant, malignancy, cancer, carcinoma, recurrence, recurrent, melanoma, metastasis, glioma, lymphoma, leukemia, sarcoma, blastoma, cytoma, (and their corresponding words in Japanese)
[Abbreviations of malignant findings]
HCC, AML, CML

Table 2 – Unified medical dictionaries to determine medical attributes

Dic.	Resource	# of words
(D1)	'Standard Disease Names in Japan corresponding to ICD-10 for electronic medical record'*	34,634
(D2)	'Thesaurus for Medical and Health related Terms version 5'†	172,782
(D3)	Japanese Medical Terms in 'UMLS2005AA'‡	54,274
(D4)	Terms for radiology region collected from past radiological reports	2,773

* http://www.dis.h.u-tokyo.ac.jp/byomei/
† http://www.jamas.gr.jp/thesaurus.htm
‡ http://www.nlm.gov/research/umls/

Table 3 – Medical attributes

Attributes	# of Subtypes	# of Words	Examples
Anatomical Name	2	9,043	'liver', 'lung',..
Disease	1	75,051	'osteosarcoma',
Finding	3	4,994	'carcinoma',..
Examination	3	19,426	'CT', 'MRI',..
Modifier	8	777	'right','upper',.
*General	5	106,140	'protein',..

[Notes]:

Each attribute may have subtypes.
(ex) Modifier – 'for Temporal Coordinates'
Modifier – 'for Anatomical Names'

*"General" attributes were not used for selecting subtrees related to radiological findings.

Methods

Step 1) Syntactic analysis and chunking

First, syntactic analysis and chunking are performed. We used the general Japanese parser KNP [9] and added only 137 ***Sahen-nouns*** and 55 ***Na-adjectives*** into the KNP dictionary, both of which function not only as nouns or adjectives but also as predicates, and are especially important in avoiding parsing errors in Japanese syntactic analysis. KNP performs a chunking process using case particles, so that compound nouns or phrases that are unique to medical terminology can be detected as one chunk with high accuracy, even if these terms are not included in the dictionary of the parser.

Step 2) Determining the medical attribute of the content words in each phrase

Next, a content word in each phrase is detected, and morphological analysis is performed for each content word, using Japanese Tokenizer, JUMAN [10] in which the unified medical dictionary mentioned earlier is added to the default dictionary. As in the previous morphology-based approach like [11], we used the attributes of the morphemes in a content word in order to determine the medical attribute of the content word. This is basically performed by the Head-Final rule (i.e., the last morpheme decides the attribute of the content word), but the attributes of the previous morphemes or the sub-types of the attributes are used when the last is a continuation of a modifier (see Figure 2).

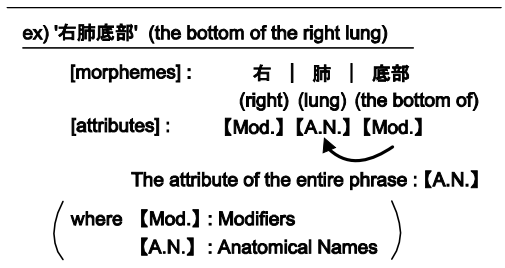

Figure 2 – Determining medical attributes

In addition, the system also detects positive or negative assertions about the existence of findings. We manually composed a list of 258 words (Table 4) with declined and conjugated endings, which should be recognized as positive or negative assertions, respectively, based on the frequency in the rule set.

Table 4 – Positive forms of negative assertions

Attributes	# of Terms	Examples (in English)
[+] (pos.)	165	'is seen', 'is found',…
[-] (neg.)	93	'is not seen', 'is notfound',…

The system then corrects excessive chunking caused by a lack of case particles. If the positive or negative assertions in the above list are at the end of the phrase (such assertion should be separated as another phrase), then the phrase with excessive chunking is separated into two phrases.

Step 3) Extracting sub-trees relating to radiological findings from the entire dependency tree

Next, searching from the end of the dependency tree, all subtrees that begin with the [+] or [-] assertion are recursively extracted (see Figure 1) by the following rules:

1. Each sub-tree must consist of only [+], [-], [Disease], [Finding], [Anatomical Name], and [Examination].
2. If a dependency tree is terminated with [Disease] or [Finding] (i.e., a shortage of an assertion), then [+] node is added as the top node of the sub-tree.
3. An edge between two [+/-] signs (direct dependency between two assertions) is separated.

For example, in Figure 1, the system extracts two sub-trees from the input sentence.

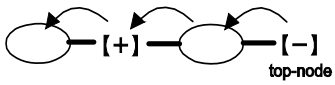
Step 4) Extracting malignant findings using their positive/negative attributes

In the last step, for each phrase that includes a malignant keyword in a sub-tree, the system determines whether it should be extracted. We consider only [Disease] or [Finding] phrases that include malignant keywords as candidates, so that malignant keywords in [Examination]

or [Patient Status] phrases are excluded. The positive or negative attribute of the existence of each malignant finding is then determined by multiplication of positive or negative signs along the path from the top node to each node (phrase) in the sub-tree, as defined below.

$$\text{Pos/Neg Sign} = (+1)^{\#\text{ of Plus}} \times (-1)^{\#\text{ of Minus}} \quad (1)$$

# of Plus or **# of Minus** is counted along the path from the top-node to each node (phrase) in the subtree (see Figure1).



For example, in Figure 1, "metastasis" should be extracted with "Negative attribute" because there are [-] and [+] in the path from the top-node to "metastasis" in the sub-tree.

Experiments

Experimental set-up

In order to evaluate the performance of the proposed method, we used the evaluation set (100 sentences) mentioned earlier. All phrases that include a malignant keyword were manually annotated with 'Positive study (+)', 'Negative study (-)', or 'Not an object to be extracted (N)' (gold standard). For example, if a phrase including a malignant keyword is not related to current malignant findings (e.g., 'past patient status' or 'examination'), then the phrase is annotated with '(N)'.

Our intent is to extract malignant findings that have (+) or (-) attributes. Therefore, we label such findings ***"(OBJ)".***

***"(OBJ*) = A phrase of [Disease Name] or [Findings]**

that includes a malignant keyword"

The system output was judged as to whether ***(OBJ)s*** were properly extracted using their positive or negative attributes. The evaluation set includes 97 pairs of ***(OBJ)*** and ***(Positive/Negative Sign)*** as the gold standard. In the evaluation, we used (BASE1) and (BASE2) as baselines and compared them with the proposed method (PROP).

Table 5 – Comparison of methods

(BASE1)	Extracting ***(OBJ)*** as ***Positive***
(BASE2)	***(OBJ)* + *Pos/Neg sign*** of the phrase upon which the ***OBJ*** is directly dependent
(PROP)	***(OBJ)* + *Pos/Neg sign*** determined by multiplication of [+][-] signs along the path in a sub-tree (defined in Equation (1))

Results

The results are shown in Table 6. The recall and precision of (PROP) are much better than the baselines. The precision of the proposed method is greater than 90%, whereas the recall rate is not so high. Some pairs could not be extracted because the system cannot detect the beginning of a sub-tree owing to the insufficiency of rules to detect certain assertions, such as ***"doutei dekinai*** (cannot identify)". On the other hand, badly extracted pairs were caused by errors in determining the **[+] / [-]** sign. For example, from sentences such as ***"Syuyou ha / ohkisa ni / tyohen / arimasen.*** (The tumor did not change in size.)", the system extracted "***syuyou*** (A tumor)" with the **[-]** sign, which was caused by the word ***"arimsen*** **[-]** (not)" (i.e., ***"syuyou"*** directly depends on ***"arimasen"***). In this case, the system recognized the negation as being in regard to the existence of a tumor, whereas, in fact, the negation was regarding a "change in size".

Table 6 - Results

Methods	Extracted Pairs	Correctly Extracted	Recall	Precision
(BAS1)	97	47	48.5%	48.5%
(BAS2)	74	58	60.0%	78.3%
(PRO)	81	74	76.2%	91.4%

Discussion

Both (PROP) and (BASE2) use dependency information. However, there is significant improvement in both recall and precision. Improvement in recall shows that the proposed method can extract a finding that does not directly depend on assertion, while an improvement in precision shows that the proposed method works well for a finding that changes its pos/neg attribute through plural assertions, such as "metastasis" in Figure 1.

In order to achieve a higher recall rate, further development of the rules to detect various patterns of assertions is necessary. In particular, it is important to deal with assertions that consist of more than one phrase, such as ***"~ wo / hiteisuru koto ha / konnan de aru*** (It can not be denied that ~)". In addition, we should construct a system to process English sentences (which occasionally appear in Japanese radiological reports) so as to deal with both Japanese and English sentences. Although the present study focuses on Japanese sentences, the proposed method for determining pos/neg signs along a path in a dependency tree is essentially language independent.

There is no tagged corpus of Japanese radiological reports, so that we cannot perform machine learning methods at the present time. We are currently constructing a large tagged corpus to carry out an evaluation on a larger scale and to make comparison with machine-learning methods in the near future. The proposed method will also be effective for supporting the construction of such a tagged corpus.

In the present study, we used approximately 30 keywords expressing malignant findings for the trial. Those keywords are not sufficient, to be sure. However, in the future, determining the malignancy of each [Disease Name] or [Findings] should be performed using hierarchical information of controlled vocabulary, such as ICD-10 or SNOMED-CT, that is, malignancy can be determined using attributes of hypernyms or top-node in the hierarchy. To extend malignant keywords by constructing such a module is an important future task, but the essentials of the proposed method will not be affected by the changes.

Related work

Many studies, such as MedLEE [1][3] and so on [2][4][5][6], are being conducted to extract findings from narrative reports, however there have been few studies concerning the extraction of information from Japanese radiological reports [7][8]. Above all, previous studies about Japanese narrative reports did not use syntactic information efficiently because of ungrammatical writing of narrative reports, which differs from 'standard' sentences such as newspapers.

The proposed method is novel because it (1) enables the efficient use of syntactical information by correcting excessive chunking caused by lack of case particles and (2) calculates the sign (positive or negative) of each malignant finding, which is determined based on medical attributes, by focusing on a path in a sub-tree.

Conclusion

In the present study, we proposed a new method for extracting malignant findings using their positive or negative attributes, through the multiplication of [+][-] signs in sub-trees related to radiological findings. Experimental results showed the validity of the proposed method for correctly determining the positive or negative attribute of each malignant finding.

Acknowledgments

The authors would like to thank Dr. Tomohiko Masumoto in the University of Tokyo Hospital for providing the corpus of radiological reports.

[b] *National Library of Medicine, National Institutes of Health, United States*

Abstract

The National Library of Medicine has developed a tool to identify medical concepts from the Unified Medical Language System in free text. This tool – MetaMap (and its java version MMTx) has been used extensively for biomedical text mining applications. We have developed a module for MetaMap which has a high performance in terms of processing speed. We evaluated our module independently against MetaMap for the task of identifying UMLS concepts in free text clinical radiology reports. A set of 1000 sentences from neuro-radiology reports were collected and processed using our technique and the MMTx Program. An evaluation showed that our technique was able to identify 91% of the concepts found by MMTx in 14% of the time taken by MMTx. An error analysis showed that the missing concepts were largely those which were not direct lexical matches but inferential matches of multiple concepts. Our method also identified multi-phrase concepts which MMTx failed to identify. We suggest that this module be implemented as an option in MMTx for real-time text mining applications where single concepts found in the UMLS need to be identified.

Keywords:

MetaMap, natural language processing, text mining, UMLS

Introduction

The recent past has seen a phenomenal growth in the amount of textual information generated in various areas of biomedicine such as clinical reports associated with electronic medical records and scholarly publications [1],[2]. There have been repeated calls for the development of text mining and natural language processing tools to extract information from the biomedical literature [3]. To cater to such needs, the National Library of Medicine (NLM) has developed several open-source text processing tools for the biomedical domain. The *MetaMap Program* is a tool developed at the NLM to map free text to concepts in the Unified Medical Language System Metathesaurus (UMLS) [4]. *MetaMap* and its java version *MMTx*, henceforth referred synonymously as MM, have been extensively used for a wide variety of biomedical text mining applications. We have developed a technique for fast and accurate mining of whole UMLS concepts. This is one of the applications for which MM has been used extensively, but for which MM is considered to be slow [5]. We report the details of this system and suggest that it be implemented as an optional module in future releases of the MM toolkit.

Background

In order to get an understanding of the various scenarios in which MM is being applied, we conducted a literature review to identify all reports of MM usage in the past three years. We identified 8, 13 and 9 articles within the proceedings of MEDINFO 2004, AMIA 2005 and AMIA 2006 respectively, all of which directly used MM for their respective tasks. We ignored the articles which made secondary use of MM via other NLM applications like *SemRep*. We also did not analyze journal articles since conference publications often get extended to journal articles.

Recent uses of MetaMap

Recently, MM has been used for several different applications both within and outside the NLM. Whalen et al. used MM to identify UMLS concepts for use in medical textbook summarization [5]. Mary et al. report the usage of MM for identifying genes and proteins in scientific articles related to molecular biology [6]. Chapman et al. used MM to index emergency department reports by UMLS terms related to respiratory findings [7]. Hsieh et al. tried to identify UMLS terms used by patients in email messages using MM [8]. Kim et al. indexed descriptive clinical text from a web-based repository of dermatology cases to MeSH terms using MM[9]. Bernhardt et al. identified diagnoses and causes of death and mapped them to MeSH terms using MM [10]. Lacson et al. identified nouns and replaced then with the UMLS semantic labels through MM [11]. Wedgwood used MM to map medical terms to the UMLS as a module within a medical question answering system [12]. Gay et al. indexed the title and abstracts of biomedical articles using MM [13]. Niu et al. identified UMLS semantic categories for analyzing polarity information in medical text [14]. Kahn et al. annotated radiology images with patient demographics and UMLS concepts generated using MM for a digital searchable library [15]. Mirhaji et al. used MM to identify single UMLS concepts found in chief complaint data [16]. Silfen et al. processed biomedical publications using MM to identify UMLS con-

cepts [17]. Peace et al. used MM to index concepts in nursing procedure manuals [18]. Meystre et al. customized the target dataset of MM adapted to 80 targeted medical problems and used it to identify a predefined list of problems [19].

Baud et al. used MM to analyze the variability of Medical terms [20]. Leroy et al. tried to disambiguate word senses using UMLS concepts identified by MM and their semantic types[21]. Hagerty et al. processed clinical guidelines using MM [22]. Tringali et al. used MM to process gastrointestinal endoscopy reports [23]. Meng et al. identified anatomy-related concepts from surgical reports with MM [24]. Coonan coded clinical narratives to UMLS concepts using MM [25]. Yetisgen-Yildiz et al. used MM as a phrase chunking tool [26]. Zhou et al. identified UMLS concepts in documents related to five health domains using MM [27]. Crowley et al. used MM as a coding module of an intelligent tutoring system [28]. Lieberman et al. used MM to extract concepts from chief complains entered into an ambulatory medical electronic medical record [29]. Wang et al. report the use of MM as an identification tool for medical terms which are later manually labeled for an information retrieval system [30]. Ogren et al. tried to annotate corpora using UMLS semantic types using MM [31]. Patel et al. attempted to mine cross terminology links in the UMLS and used MM to process their dataset [32]. Hagerty et al. used MM to identify UMLS concepts and associated concepts for encoding clinical text in a markup language [33]. Ruiz used MM to first identify English concepts and then translate them to French [34].

Need for a new module

Our examination indicated that 15 [5-19] of the 30 mentioned reports used MM primarily to identify whole concepts in the UMLS. This task does not require some of the sophisticated processing modules present in MM which are computationally complex and hence time consuming. By making a reasonable assumption that this set of articles accurately reflects the distribution of MM usage in the medical informatics community, we safely conclude that around 50% of MM applications only seek whole UMLS concepts and not multiple concept mappings. A method bypassing the time-consuming modules of MM would be very suitable for these applications. Our experiment was a step toward this goal.

Materials and methods

Our methodology consisted of four stages – 1) Identifying the data to be processed our method and by MM, 2) Processing the data by our method, 3) Processing the data with MMTx and, 4) A comparative evaluation of the two methods. The details of the individual stages follow:

Data Collection

Collection of the sentences to be indexed to the UMLS was the first stage in our experiment. We followed the steps outlined below to collect sentences.

Step 1: A set of one thousand radiology reports related to the neuro-radiology domain were collected from the existing hospital database at our institution.

Step 2: Section boundary detection was performed on the reports to break up a report into individual sections such as HEADER, HISTORY, FINDINGS, CONCLUSIONS etc. Next, sentence boundary detection was performed on the sections. Both of these modules have been previously tested, with recall and precision accuracies of over 99% within the domain of radiology [35].

Step 3: A lexical analyzer processed each sentence performing tokenization, part-of-speech tagging, semantic class tagging and word-sense disambiguation. Our lexicon categorizes tokens into twenty syntactic categories and over eight hundred semantic categories.

Step 4: We identified a list of the primary semantic classes which occur in radiology reports, such as anatomy, findings, procedures, equipment etc. Using a high-recall sentence-level parser, all target sentences were conservatively identified while sentences that obviously have no instances of our target semantic types were rejected. To illustrate, the presence of the semantic type `phys-obj.anatomy` (e.g. brain) in a sentence would automatically result in the sentence being accepted as containing a possible UMLS concept. This step is necessary so that we do not try to find UMLS concepts in sentences which might not have any. Thus, we chose to process the sentences that are highly likely to contain UMLS concepts.

Step 5: From the target set of sentences, we randomly sampled 1000 sentences for processing by our technique and by MM.

Identifying UMLS concepts

We previously prepared a normalized word index of the entire UMLS concepts tagged as English concepts and serialized the index in a database. This index is similar to the index used by MM, GSpell and other such tools developed at the NLM. Each sentence was preprocessed using the 'LuiNorm' stemming tool developed at the NLM to generate a sentence normalized at the word level [36]. We identified a list of and word types words types such as conjunctions which, when normalized are likely to give false positive errors. These words were intentionally not normalized.

Each normalized sentence was processed by our module to identify all UMLS concepts by referring to the index. The method used to identify the concepts is the longest substring matching algorithm developed by Aho and Corasick. Details of this algorithm can be found in the original publication [37]. The algorithm finds a list of longest substrings according to the parse order (left to right in this case) given a lengthy string. Thus, this method will only identify a list of lexically matching concepts but not attempt to find any partial matches, combinatorial matches, etc. The output of this module for an example sentence is shown below.

Sentence:
The liver is enlarged.

UMLS Substrings:
1. C0023884 (Liver)
2. C0442800 (Enlarged)

Using our method, all the 1000 sentences were processed and the UMLS concepts were stored in a list.

MMTx processing

We used the MM API to process the same corpus. The MM methods were used to parse the sentences into phrases, process these phrases to obtain the best final mappings, and then arrange the final mappings into a single output set. In cases where MM found multiple equally-scoring mappings, the procedure merged the common mappings, and then arranged the dissimilar candidates as a pipe-delimited list. For example, the phrase "right thalamus" returns the two "tied" final mappings shown below:

First Candidate:
1. C0205090 (Right)
2. C0039729 (Thalamic structure)

Second Candidate:
1. C0205090 (Right)
2. C1269896 (Entire thalamus)

The result was rearranged and output as two concepts where the second concept was one of two possible concepts:

1. C0205090 (Right)
2. C0039729 | C1269896 (Thalamic structure OR Entire thalamus)

Evaluation

The list of mappings produced by MM was compared to the mapping list generated by our method. A match on either token for the 'thalamus' was considered a correct hit. In addition to gathering mapping data, the times taken to process the sentences and obtain final mappings by both methods were logged. The average time taken by MM to process each sentence was 1.03 seconds whereas our module had an average processing time of 0.14 seconds.

Results

The total number of concepts identified by MM was 6859. The total number of concepts identified by our method was 6513. Of the 6513 concepts, 173 concepts were large phrases (which MM had broken down into two or more concepts). 457 terms were erroneously mapped to wrong concepts in the UMLS which account for false positives. Considering the large phrases as accounting for two concepts each and subtracting the false positives, we arrive at 6229 valid UMLS concepts identified by our method. Since our current objective is to provide a faster, equivalent system to MM, we assume that all the concepts identified by MM are correct mappings. Thus we arrive at an accuracy score of 91%. However it is important to know that MM itself has a lot of false positive issues which have been reported by several people [24]. Table 1 summarizes the results.

Discussion

Error analysis

False positives occur for to several reasons. First, the UMLS Metathesaurus contains several concepts which are orthographically identical but have different concept unique identifiers (CUIs). When such concepts are encountered, our system adopts an adhoc method of choosing one of the multiple mappings. An example of such a false positive would be the verb am mapped to the concept am (ante-meridiem).

Other types of false positives occur due to the natural ambiguity introduced when words are stemmed. Multiple words when normalized to the same stem increases the ambiguity. Replacing the stemmed word index by a regular word index can result in an increase in precision but a possible drop in recall. To illustrate, plural forms of words would still map to the same concept when normalized but would not when indexed directly. These types of errors could be potentially reduced by using a regular word index in addition to a normalized word index.

Table 1 – Results of Evaluation

	MMTX	**Normalized Lexical Lookup**
No. of Concepts Identified	6859	6513
Large Phrases		+173
False Positives		-457
Total	6859	6229

Multiple phrasal concepts

Since we do not use a shallow parser to chunk sentences into phrases, we are able to identify concepts spanning across multiple phrases. An example of this is the phrase `liver` and spleen which exists as a concept in the UMLS (C0545797) but is not recognized by MM as a single concept returning the individual concepts liver (C0023884) and spleen (C0037993). Our method is able to return the whole concept liver and spleen. While it can be argued that failure to separate the coordinated concepts is an undesirable feature, we would like to stress that our system is also not intended to correct errors present in the UMLS. A retrieval system is only as good as the content it is retrieving. Though our method is intended to be as close to MM output, it is independent of, and can be used with any lexicon other than the UMLS. The system only needs a list of concepts with corresponding unique identifiers and can perform efficient lookup. Thus, as concepts are removed from or added to each new release of the UMLS, we don't have to make changes to our system.

Methodology differences

Our technique differs from the MM approach in several ways:

1. MM tokenizes a sentence into terms and phrases whereas our method only tokenizes sentences into words.
2. To identify phrases, MM requires the services of a part-of-speech (POS) tagger to first tag the words or terms, and a shallow parser to use the tags to mark phrase boundaries and phrase head assignments. Our system bypasses the POS tagging and shallow parsing component.
3. To identify terms, MM performs a lexical lookup within the sentence to find the longest spanning terms from the SPECIALIST Lexicon. Our method does a longest spanning match to a normalized word index of the UMLS, bypassing the term tokenization and lexical lookup into the SPECIALIST Lexicon. One of the benefits to this approach is the potential of retrieving multi-phrase concepts as demonstrated previously.
4. MM has several modules to find a) matches to the terms within phrases, b) generate spelling and inflectional variants, synonyms, derivations, acronyms, abbreviations and expansions of the words in the phrase, and a recursive combination of these, to make the match. Our system does not have any of these modules.
5. MM categorizes the retrieved matches as partial matches, over matches, and matches with gaps to the phrase. This categorization requires an alignment mapping technique that is at the heart of MM. This is a technique that is computationally expensive. By default, MM filters out over-matches and matches made with concept gaps, to reduce the noise caused by such matches. Our system does not have this alignment mapping technique.
6. MM includes a ranking mechanism to evaluate the quality of the matches. It ranks 'exact' and 'near exact' matches higher, and 'partial matches' with matches made on the basis of some form of lexical variation, lower. Our method does not include a ranking of the matches returned but returns a fixed list of concepts identified in a sentence.

Our method does not return matches made with gaps, but could return partial matches. Because of these differences, it is likely that our method will do a better job than MM at quickly finding exact and normalized exact matches within a sentence. However, since our method lacks the variant generation and ranking capabilities, it is likely to miss matches based on non-inflectional lexical variation or because of word order differences. Our method will do a better job retrieving multi-phrase concepts. It is an open question whether phrase spanning concepts occur more often in a target corpus than concepts that could only be matched via non-inflectional variation, and whether the added precision is worth the extra computational costs. These issues may be highly dependent on specific domains.

Scope for improvement and future work

Previous internal studies at the NLM have shown that over 95% of the time taken by MM in processing a sentence is due to the alignment mapping algorithm. Since we avoid the alignment mapping module, the shallow parser and the part-of-speech tagger, theoretically our method should perform much faster than its current performance. We took no particular effort in optimizing our implementation of the Aho-Corasick algorithm. Our aim was to show that for specific applications, it is possible to achieve results similar to that of MM using simpler modules and by avoiding the computationally complex modules. Thus, an efficient implementation has a possibility to be a lot faster than our current system. Additionally, there are methods other than the Aho-Corasick algorithm which could be used for finding the largest substrings. The performance of those methods for this particular application needs to be explored. Finally, a more extensive evaluation of MM versus our method needs to be conducted to arrive at conventional precision, recall and f-score measures.

Conclusion

A module for MetaMap is proposed with focus on high processing speed suitable for real-time applications. This module uses components already being used in MetaMap with minor changes. This module is likely to have multiple useful applications in medical informatics.

Abstract

In order to make more informed healthcare decisions, consumers need information systems that deliver accurate and reliable information about their illnesses and potential treatments. Reports of randomized clinical trials (RCTs) provide reliable medical evidence about the efficacy of treatments. Current methods to access, search for, and retrieve RCTs are keyword-based, time-consuming, and suffer from poor precision. Personalized semantic search and medical evidence summarization aim to solve this problem. The performance of these approaches may improve if they have access to study subject descriptors (e.g. age, gender, and ethnicity), trial sizes, and diseases/symptoms studied.

We have developed a novel method to automatically extract such subject demographic information from RCT abstracts. We used text classification augmented with a Hidden Markov Model to identify sentences containing subject demographics, and subsequently these sentences were parsed using Natural Language Processing techniques to extract relevant information. Our results show accuracy levels of 82.5%, 92.5%, and 92.0% for extraction of subject descriptors, trial sizes, and diseases/symptoms descriptors respectively.

Keywords:

randomized clinical trial, information extraction, subject demographics, semantics. statistical NLP, text analysis

Introduction

To undertake informed medical decision-making, healthcare consumers must have access to accurate and reliable medical information, particularly about illnesses and their treatments [1]. Randomized Clinical Trial papers are a reliable source of information about treatments, their efficacies, and potential adverse consequences. Although generally intended for a professional medical audience, healthcare consumers routinely discover this information using online keyword-based search methods such as Google and PubMed [2]. These methods can overload the user with irrelevant information.

Personalized semantic search and text summarization are two approaches that aim to improve the precision of the search results. In the healthcare setting, these approaches entail extracting structured and machine-understandable information from documents [3].

The PICO framework [4] is designed to provide personalized medical evidence from RCT papers. It represents structured information from RCT papers and patient records related to problem, population, intervention, comparison, and outcome. The structured information extracted from the patient records serves as query context, and is matched with the structured information captured from the RCT paper. However, the PICO framework only provides a model of the clinical information-seeking process; no operational methods are provided in the framework to actually extract structured information.

RCT Bank [5], a well-known medical summarization approach, has focused on modeling information that is to be extracted from RCT papers. This model includes concepts that encode trial information such as the trial protocol, execution, and results summary. Currently, this information is manually extracted from RCT papers, and is archived in the RCT Bank. The number of RCT papers archived, however, is low, primarily because the curation process is manual.

Approaches such as RCT Bank and PICO require methods to automatically extract trial information from RCT papers, in order to assess the relevance of a trial report to a particular query. For example, the *number of participants* may be indicative of the quality of the trial; *subject descriptors* such as gender and age of the participants as well as *diseases/symptoms* can be used to stratify trials into subgroups of interest. These items of information should improve search precision, while providing a measure of the quality of these trials. In this paper, we present a novel method to extract subject demographic information from RCT abstracts.

Prior work on an automated approach for extracting subject demographics from abstracts used manually crafted pattern-matching rules [6]. The accuracy of this approach was 80% for extracting subject descriptors. Noisy perfor-

* Authors contributed equally to this work.

mance may be a source of error in subsequent steps of the search and retrieval process, so improvements in precision/recall would be valuable. Moreover, this approach only retrieves the sentences that contain the demographic information, and not the itemized information such as age and number of trial participants.

Materials and methods

To improve performance, we developed a method to automatically extract subject demographic information from RCT abstracts. We used text classification augmented with a Hidden Markov Model to identify sentences containing subject demographics (step 1 of our Methods), and subsequently parsed these sentences using Natural Language Processing techniques to extract relevant information (step 2 of our Methods).

Step 1: Identifying sentences containing subject demographics

Most abstracts from articles reporting the results of RCTs are conceptually organized into five sections (Background, Objective, Methods, Results, Conclusions). Subject demographic information is more likely to be contained in the Methods section[1]. Only 28% of all RCT abstracts, however, are explicitly structured into these five sections. In order to automatically label sentences in an abstract as belonging to the Methods section, we combined text classification with a Hidden Markov Model [7]. 3,896 structured RCT abstracts that contained Methods sections, published in 2005, were de-labeled and parsed into 46,370 sentences using a sentence parser that we developed. Each sentence was a labeled input to a multi-class (Background, Objective, Methods, Results, Conclusions) text classifier. These sentences were used for model training. We then used this trained classifier to label 4018 sentences from 250 unstructured abstracts of RCTs with these five labels.

The Methods section not only contains sentences that describe subject demographics, but also contains additional sentences that describe information such as trial design, settings, interventions, and outcome measures. Only 4% of all RCT abstracts, however, are explicitly structured into these subsections, thus making the task of identifying the subject demographic sentences difficult. In order to identify the specific sentences that contain subject demographics, we used a Maximum Entropy two-class (Subject-Demographics, Other) text classifier. 14,774 structured RCT abstracts were selected. These abstracts are all those that contained subsections explicitly labeled as Participants, within the Methods section; the sentences in these Participants sections contain the demographic information. Unigrams and bigrams that appeared in these sentences and that appeared in non-Participant sentences from the Methods section were used as features for model training. We then used this trained classifier to label the 982 predicted Methods sentences from the 250 unstructured abstracts described above with these two labels.

Step 1 was a necessary part of our method, because patients are described throughout the abstracts, however the relevant information that we desired to extract typically appears in 1 or 2 sentences within the Methods section of abstracts. Solely using presence of anchor words such as "patient", "participant", etc., to identify informative sentences, would have resulted in a high number of false positive sentences.

Step 2: Extracting subject descriptors, number of trial participants, and diseases/symptoms and their descriptors from sentences labeled as subject demographic related

Using the sentences that were classified in Step 1 as subject demographic related, we extracted three specific types of information: (1) *subject descriptors* (such as "men", "healthy", "elderly"), (2) *number of participants* (or all subgroups, when total number is not available), and (3) *diseases/symptoms* and their *descriptors*.

(1) Extracting subject descriptors:

For each subject demographic related sentence, we extracted *subject descriptors* such as "men", "diabetic", "healthy", and "elderly". These words mainly appear before/after anchor words such as "patients", "participants", or "subjects" in a sentence (e.g. "we studied 300 elderly diabetic patients"). For each sentence, these anchor words were extracted and tagged as [PATIENT] using a closed set of words approach. The set included 37 words, and is available at http://www.stanford.edu/~xurong/medinfo2007.

In order to extract the descriptors that modify the word tagged [PATIENT], we used the parse tree of the sentence that was generated by the Stanford parser [8]. The Stanford parser is an unlexicalized natural language parser developed by Klein et al. at Stanford University. It was trained on a non-medical document collection (Wall Street Journal), but has been successfully used in the biomedical domain [9]. From the word tagged as [PATIENT] in the parse tree, the unary chain was traversed to extract siblings of the [PATIENT] word. *Subject descriptors* are located in the preceding part (left-sibling) and the following part (right-sibling) of the [PATIENT] word. For example, in the parse tree shown in figure 1, the left sibling phrase of the word "patient" (which is tagged [PATIENT]) contains the subject descriptor "severely brain-injured", and the right sibling phrase is "with first-episode psychosis".

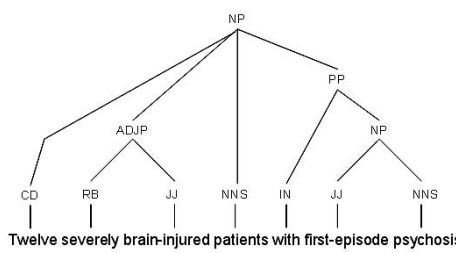

Figure 1 - Parse tree of an example subject demographics related sentence.

1 1000 randomly selected structured abstracts were manually annotated to determine sentences that contained subject demographics. 931 out of 1000 had subject demographics in the Method section.

(2) Extracting number of trial participants:

For each subject demographic related sentence, we extracted the number of trial participants. Each sentence was tagged with the Stanford parser, and words identified as "CD" (the lexical tag for numbers) were tagged as [NUMBER]. This process was augmented with a closed set of words approach, as the parser missed some words. For each sentence, these identified words were also tagged as [NUMBER]. Most sentences contain multiple numbers; however only one is to be extracted as the number of trial participants (e.g. "40 participants above age 50 who suffered from diabetes for over 2 years participated in the trial"). To identify the one ("40 participants") that contains number of trial participants, initially, [NUMBER] words such as "age 50" and "2 years" that do not pertain to the number of trial participants were filtered out using rules such as [age][NUMBER] or [NUMBER][years].

However, the filtering process, in some cases, leaves more than one word that is tagged as [NUMBER]. From this set of words, identifying the exact [NUMBER] word(s) that contain number of trial participants is non-trivial. For example: in the sentence "300 patients included 100 men and 100 children who suffered from diabetes", there are three numbers (300, 100, 100) left by the filtering processing; the correct number of trial participants is 300.

To address this complex sentence structure, (i) we manually created a grammar based on a subset of subject-demographic related sentences, (ii) this grammar was used to extract grammatical sentence structures from the rest of subject demographic related sentences, and (iii) subsequently the number of trial participants was extracted from the grammatical sentence structure identified in step ii, either directly in the case of only one [NUMBER], or by summing several numbers (in a post-processing stage) if several subgroups were identified. Each of these steps is described in detail in the following text:

(Step i) Our grammar includes 39 rules which encapsulate the different ways by which authors describe subject demographics. The lexicon of the grammar comprised of the tags [NUMBER], [PATIENTS], [INCLUDE], and several classes of words such as "are", "in". Readers can view grammar on the web at http://www.stanford.edu/~xurong/medinfo2007.

(Step ii) We extracted the grammatical sentence structures, such as "S→ [NUMBER] [PATIENT] [INCLUDE] [NUMBER] [PATIENT]", from each sentence. For example, the sentence "200 participants included 70 men" has the above-mentioned grammatical structure. To correctly extract the grammatical structure, each sentence was first transformed by replacing words with the tags in our lexicon such as [NUMBER], [PATIENT], and [INCLUDE], and omitting all others. Then, a modified Cocke-Younger-Kasami (CYK) backtracking algorithm was used to determine the longest span beginning at the sentence start, which still contains a complete sentence structure based on our grammar. For example, the sentence "The study observed 300 men who underwent over 6 operations each" is converted to "[NUMBER] [PATIENT] [NUMBER]" (corresponding to "300 men 6"), and is then traversed to extract the longest span containing a full sentence according to our grammar, which in this case is S→ [NUMBER] [PATIENT] (our grammar does not contain the rule S→ [NUMBER] [PATIENT] [NUMBER]). Thus, "300 men" is extracted, and the number of trial participants is correctly identified as 300. In this way we are able to identify which number within a sentence actually represents the number of trial participants. The significant benefit of our approach over traditional CYK based methods [10] is that not only can our approach extract grammatical structure from the whole sentences but it can also extract structure from embedded sentences within the sentence. This benefit is particularly advantageous for our problem as most of the subject-demographic related sentences have a left embedded sentence, which has number of trial participants. In the previous example, this entails extraction of "200 participants" which was the left embedded sentence that corresponds to the structure S→ [NUMBER] [PATIENT] in our grammar. The traditional CYK algorithm in this case will fail since it extracts the structure from the whole sentence, and the structure extracted for the example does not have a corresponding structure in our grammar.

(Step iii) We extracted the number of trial participants from the grammatical sentence structure identified in step ii; this was either done directly in the case of only one [NUMBER], or by summing several numbers if subgroups were identified

(3) Extracting diseases/symptoms and their descriptors:

For each subject demographic related sentence, we extracted the *diseases/symptoms* (e.g."diabetes", "rhinosinusitis") and their *descriptors* (e.g. "severe", "acute"). We extracted these using UMLS MetaMap [11], and extracted descriptors of these *diseases/symptoms* by traversing the parse tree.

UMLS MetaMap, a tool developed by the National Library of Medicine, semantically processes an input sentence by (i) parsing the sentence and then (ii) identifying the sentence phrases within it which map to a semantic type such as disease, syndrome, or symptom. MetaMap performs step (ii) by mapping the parsed sentence phrases onto concepts in the UMLS Metathesaurus, a metathesaurus of all clinically related terms (e.g. "rhinosinusitis" is mapped to the semantic type "Disease or Syndrome"). Each subject demographic related sentence was inputted into UMLS MetaMap. Sentence phrases that were mapped to the semantic type "Disease or Syndrome" or "Sign or Symptom" contain the diseases/symptoms.

In addition to identifying names of *diseases/symptoms* it is also important to extract *descriptors* of these *diseases/symptoms* not identified by UMLS Metamap. For example, in the sentence phrase "acute juvenile diabetes" MetaMap correctly identifies "juvenile diabetes" as *diseases/symptoms*, but misses the *descriptor* "acute". To extract these descriptors from the subject demographic related sentence, we generated a parse tree for that sentence. In this parse tree, the modifiers preceding the sentence phrases identified by MetaMap as *diseases/symptoms* contain the descriptors.

Results

Step 1: Identifying sentences containing subject demographics

For the task of identifying the Methods section of unstructured RCT abstracts, our five-class text classifier augmented with a Hidden Markov Model achieved an F1 measure of 91.5% on the test data. The F1 measure is a combined measure of precision and recall.

F1=(2*precision*recall)/(precision+recall)

For the task of identifying the subject demographic related sentences in the predicted Methods section of 250 unstructured abstracts, we used a two-class text classifier on the 14,774 structured RCT abstracts that contained a Participants subsection. The classifier was first trained using 60% of the 14,774 abstracts, while the remaining 40% were used to test the classifier, which achieved an F1 score of 92%. However, when testing the classifier on the predicted 982 Methods sentences from the 250 unstructured abstracts without Participants subsections, the F1 score was only 77%. We postulate that the low F1 score is due to a difference in writing style used by authors when writing a structured abstract that has an explicit Participants subsection versus one without one. To test this hypothesis, we retrained the two-class classifier on the Methods sentences from 1000 unstructured abstracts that were manually tagged either as 'Subject-Demographics' (for participant-related sentences) or 'Other'. The results of this test (F1 score = 91%) show a significant improvement over the previous results.

Step 2: Extracting subject descriptors, number of trial participants, and diseases/symptoms and their descriptors from sentences labeled as subject demographic related

Using the sentences that were classified in Step 1 as subject demographic related, we extracted three types of information.

(1) Extracting subject descriptors:

Using the method previously described in the Methods section, we extracted *subject descriptors* from each sentence. The accuracy of identification of the correct *subject descriptors* in 250 unstructured abstracts was 82.5%. In this paper, accuracy equals the percent of correctly tagged entities.

(2) Extracting number of trial participants:

Using the method previously described in the Methods section, we extracted the *number of trial participants* from 50 unstructured abstracts. The accuracy of identification of the correct *number of trial participants* in the test data was 92.5%.

(3) Extracting diseases/symptoms and their descriptors:

For each subject demographic related sentence, we used UMLS MetaMap to extract *diseases/symptoms* (accuracy = 51.0%). *Descriptors* for these *diseases/symptoms* were then extracted by traversing the parse tree (accuracy = 92.0%).

Table 1 - Accuracy measures for information extractions steps

Information Extracted	Accuracy (%)
Subject Descriptors	82.5
Number of Trial Participants	92.5
Diseases/Symptoms	51.0
Descriptors of Diseases/Symptoms	92.0

Discussion

In this paper we describe a novel method to automatically extract from RCT abstracts three types of subject demographic information: (1) *subject descriptors*, (2) *number of participants*, and (3) *diseases/symptoms* and their *descriptors*. The accuracy measures for extracting these three types of information appear in Table 1.

Our good performance relies on two novel elements used in our methods. First, we extracted the subject demographic information from the sentences in the abstract that are most likely to have that information, namely, specific sentences found within the methods section. Previous approaches examined the entire abstract and thus did not take advantage of the inherent structure within the RCT abstract. Second, we used a handcrafted grammar to extract the subject demographic information from the relevant sentences. We developed this grammar by analyzing unstructured abstracts in order to capture the diversity of ways to describe subject demographic information. This grammar-based approach is advantageous over existing approaches that use handcrafted rules, and thus are not robust to varying writing styles.

The performance of our method is not perfect, and in the following section we analyze, for each step, limitations of our methods and propose solutions that may be useful in overcoming these limitations.

Limitations in identification of subject demographics related sentences

We trained the multi-class text classifier used for classifying sentences into five sections using structured abstracts. This classifier had an accuracy of 91% when tested on unstructured abstracts. We may further improve this accuracy by training the classifier using unstructured abstracts, instead of structured, which were chosen to avoid the time-consuming process of manual tagging of unstructured abstracts.

Limitations in extraction of subject descriptors

For each subject demographic related sentence, we identified anchor [PATIENT] words and then the parse tree of that sentence was used to extract descriptors that modify the [PATIENT] words. This approach works well for sentences that have a simple structure (Accuracy =82.5%). However, this approach tends not to perform well in cases where authors tend to describe subjects using a complex sentence structure. For example, for the sentence "Forty

ASA physical status I, II, and III patients presenting for primary total hip replacement" our method extracts "III patients" as subject descriptors. This is because the comma before "and III patients" causes the parser to separate this phrase as a new noun phrase.

These parse tree errors are not surprising, because the Stanford parser used to generate the tree was trained using a non-medical text corpus. To improve the parse tree, this parser could be retrained using a relevant medical corpus, but no good corpus exists for RCTs.

Limitations in extraction of number of trial participants

For each subject demographic related sentence, we tagged words in that sentence with tags in our lexicon. All the words that were not tagged were deleted. We then used our handcrafted grammar to extract *number of trial participants* from the tagged words.

Our approach for extracting number of trial participants works very well for sentences that have the numbers in close proximity to the word tagged as PATIENT] (accuracy = 92.5%). However, our grammar tends not to perform well in cases where the numbers are not in close proximity. For example, for the sentence, "We checked 20 patients and found that 6 of the patients had …", would be tagged as "[NUMBER] [PATIENT] and [NUMBER] [PATIENT]". Since our grammar has the rule "S→ [NUMBER] [PATIENT] and [NUMBER] [PATIENT]" because this rule often allows us to identify two subgroups (e.g. "40 men and 30 women"), the grammar in this case interprets the sentence as including two subgroups of 20 patients and 6 patients, which of course is wrong, and simply results from the fact that we have the word "and" in the sentence, followed by a number and the word "patients" with words interspersed between them, that are removed due to the sentence transformation algorithm. We may avoid this problem if we can encode heuristics such as: "if there is a distance of over 10 words between the 2 numbers, we truncate the tagged sentence before the second number." However, we may then lose correct information, such as cases where two true subgroups are separated by many words.

Limitations in extraction of diseases/symptoms and their descriptors

For extraction of *diseases/symptoms*, we used UMLS MetaMap, which has some limitations. For example, MetaMap did not recognize some diseases. For those cases in which it did extract the *diseases/symptoms*, we extracted *descriptors* for these *diseases/symptoms* with high accuracy by traversing the parse tree generated using the Stanford parser. However, this parser was trained on the Wall Street Journal corpus, which does not focus on diseases and symptoms. Therefore, if the parser encounters a word that is not present in the training corpus, it will not know the correct part of speech (POS) and thus will give equal probability to all POS tags. In many cases, the parser may incorrectly tag *diseases/symptoms* as verbs. The subsequent parse will then be entirely wrong. The accuracy of this step may be further improved by training the parser using a medical corpus.

Conclusion

By focusing on specific sentences in the abstract, and subsequently using a grammar we developed, we obtained high performance in automatic extraction of subject demographics from RCT abstracts. This extracted information can be used to build systems that deliver accurate (*subject descriptors* and *diseases/symptoms* can be used to stratify trials into subgroups of interest) and reliable (*number of participants* may be indicative of the quality of the trial) information for informed medical decision-making. It should be possible to extend our method to obtain broader types of information, such as outcomes from individual RCTs, and to use the automatically extracted data for labor-intensive projects like meta-analyses.

Coupling Ontology Driven Semantic Representation with Multilingual Natural Language Generation for Tuning International Terminologies

Anne-Marie Rassinoux[a], Robert H. Baud[a], Jean-Marie Rodrigues[b], Christian Lovis[a], Antoine Geissbühler[a]

[a] *University Hospitals of Geneva, Service of Medical Informatics, Switzerland*
[b] *University of Saint Etienne, France*

Abstract

Objectives: *The importance of clinical communication between providers, consumers and others, as well as the requisite for computer interoperability, strengthens the need for sharing common accepted terminologies. Under the directives of the World Health Organization (WHO), an approach is currently being conducted in Australia to adopt a standardized terminology for medical procedures that is intended to become an international reference.*

Method: *In order to achieve such a standard, a collaborative approach is adopted, in line with the successful experiment conducted for the development of the new French coding system CCAM. Different coding centres are involved in setting up a semantic representation of each term using a formal ontological structure expressed through a logic-based representation language. From this language-independent representation, multilingual natural language generation (NLG) is performed to produce noun phrases in various languages that are further compared for consistency with the original terms.*

Results: *Outcomes are presented for the assessment of the International Classification of Health Interventions (ICHI) and its translation into Portuguese. The initial results clearly emphasize the feasibility and cost-effectiveness of the proposed method for handling both a different classification and an additional language.*

Conclusion: *NLG tools, based on ontology driven semantic representation, facilitate the discovery of ambiguous and inconsistent terms, and, as such, should be promoted for establishing coherent international terminologies.*

Keywords:

natural language generation, standardized terminology, ontology, medical procedures or interventions

Introduction

Today, one of the major challenges in clinical terminology standards is the ability to build consistent terminological systems that fit the needs of specific healthcare systems while being reusable in different countries. They should provide the basis for communication between human actors and simultaneously be computer understandable, in order to insure interoperability between systems. By definition, a clinical terminology is a set of terms, expressed in a specific language, and organized within a universe of discourse in order to reflect specific entities in clinical reality. A model that organizes these entities into a taxonomy, provides formal definitions for them and clarifies their distinctive properties is called an ontology. A terminology can then be seen as a bridge from ontology to linguistic information and as such, is strongly language-dependent. Specific purposes and links between terminologies, ontologies and natural languages must be clearly understood in order to avoid confusion [1, 2].

Sharing terminologies at regional, national and international levels requires standardization processes at two levels: information technology level and information content level. The first level concerns the choice of a language-independent modeling structure able to represent entities and relationships expressed in terms, in a way that is tractable (that is to say allowing navigation, parsing and interpretation) by a machine-based system. Formal ontological representations expressed through a logic-based language have proven to be adequate for this task [1]. Concrete implementations have come to light in recent years with the GALEN model [1] that consists of around 52,000 entities and 800 relationships, SNOMED CT [1] that describes over 366,000 entities with unique meanings that are depicted by a set of terms (descriptions), or the FMA ontology [1] that contains approximately 75,000 classes and 168 relationship types for expressing biomedical knowledge. The second level deals with what must be expressed in such a modeling structure and requires tools for disambiguating and validating the overall content. For this task, natural language generation (NLG) tools have proved their efficiency as they allow the semantic meaning of terms to be assessed both at the level of the internal representation and at the level of the natural language (NL) expressions [1, 2, 3].

The main objective of this paper is to show that the abovementioned dual approach is feasible and cost effective for the development of an international terminology for procedures. First, a description of the interest in several countries and for the World Health Organization (WHO) [1] to have an international classification for procedures

and interventions is given. Then, the flexibility of this method to add representations of new terms into the ontological structure of GALEN, and to further generate them into an additional language, is emphasized. The disambiguation and refining processes of both the intermediate representation and the initial terms are performed by comparing the generated terms with the original ones. Finally, critical points for establishing the basis of an international terminology are highlighted.

Classification of interventions: state of the art

The first International Classification of Procedures in Medicine (ICPM) was published in 1978. But, contrary to the international Classification of Diseases (ICD-9) that is used almost worldwide, ICPM was never accepted by many nations that were compelled to develop their own incompatible standards for coding procedures and interventions. The most significant work was conducted in Australia with the development of the Australian Classification of Health Interventions (ACHI) [11], in Canada with the Canadian Classification of Health Interventions (CCI) [12], in the USA with the ICD-10 Procedure Coding System (ICD-10-PCS) [13], and in France with the new French procedures classification called CCAM (a French acronym for Classification Commune des Actes Médicaux) [14].

International evaluations of these local classifications, as well as comparisons with their national adaptation of ICD (such as ICD-10-AM in Australia or ICD-10-CA in Canada), are difficult to carry out without the existence of a common accepted structure upon which agreement on standards can rely. Recent initiatives from the National Centre for Classification in Health (NCCH) – Australia, conjointly with the World Health Organization Family of International Classifications (WHO-FIC), tend to fill in this gap by proposing an international reference coding system for procedures. It is based on the existing reduced Australian International Classification of Health Interventions (ICHI), that is derived from both ACHI and ICD-10-AM classifications. Moreover, it is intended to be used by countries that do not, as yet, have their own classification of interventions.

The decision to generate this new terminology in the additional Portuguese language is not fortuitous as no widespread classification for procedures exists in Portuguese speaking countries. This paper presents the tuning and assessment of this new terminology, by first describing its language-independent representation using the GALEN methodology and then focusing on the efforts needed to adapt the NLG tools, developed in Geneva as part of the GALEN project [15], for the handling of the Portuguese language.

GALEN CCAM developments and ICHI

Following the interest of WHO and in several countries for the GALEN CCAM developments, a similar approach was adopted to assess the meaning of terms described in ICHI. Indeed, the GALEN project affords, in a language-independent manner, a high level ontology that organizes concepts and relationships in a multiple inheritance hierarchy, together with formal subsumption and multi-level sanctioning to constrain composition of sensible concepts. This common reference model for medical concepts (the so-called CORE Model) is expressed in a formal language (the so-called GRAIL formalism for GALEN Representation and Integration Language) [16]. This project thus evolved between 1996-1999 toward the GALEN-IN-USE project whose aim was to assist national coding centers in the collaborative construction and maintenance of surgical procedures classifications. In particular, the University of Saint Etienne Medical Informatics Centre (France) has applied this methodology for ensuring the quality and coherence of the new French coding system for surgical procedures called CCAM [17]. Such a methodology produces a structured, language-independent representation for each original term. This is realized by the various national coding centers that are in charge of producing semi-automatically an intermediate representation (so-called a dissection) which was subsequently nearly-automatically expended into a GRAIL expression. For the needs of the NLG tools [15], this GRAIL expression is automatically transformed into a conceptual graph (CG) [18] using Definite Clause Grammar (DCG). These semantic graphs, depicting entities or concepts linked by relationships, allow formal operations [19] to be performed in order to contract or expand parts of the graph.

The 15 chapters of the new French CCAM classification, each containing about 500 French rubrics, were successfully represented in the GALEN model, enlarged for this task with around 700 new entities. In order to disambiguate and refine the final linguistic labels of these rubrics, a generation from these semantic representations, in French, but also in English for comparisons, was systematically performed. The validating process of these generated terms against the initial ones has prompted their authors to reformulate 20% of the initial rubrics. Errors were mainly due to ambiguities in the source terms which were never detected before computer representation was performed [15, 17].

The flexibility of both the ontological representation of GALEN and the generation process to disambiguate and refine the terms, justifies its adoption by WHO for checking the ability and appropriateness of the existing reduced Australian ICHI coding system to become the international reference coding system for procedures [20]. ICHI contains approximately 1,400 procedure codes in its tabular list, as well as inclusion terms (i.e., additional procedural terms categorized to the code and giving examples of terms) that are distributed into 20 chapters. It is structured with a principal axis of anatomical site and a secondary axis of procedure type, and embraces surgical and non surgical interventions. A detailed example of the GALEN methodology is shown in Figure 1 for the handling of the procedure code 1361, belonging to chapter XV of ICHI. The first three steps afford the clarity of meaning, as information is described in a non-ambiguous way, as well as the specificity as only information relevant for interpretation and sharing is expressed. Several GRAIL expressions are produced when the input ICHI procedure code contains

more than one procedure or anatomical localization. This is the case for the ICHI code 1360 "*Application, insertion or removal procedures of head*" or the ICHI code 1364 "*Excision procedures on maxilla, mandible or temporo-mandibular joint*" whose conceptual representation results in three distinct graphs. Each conceptual graph constitutes a reliable starting point for the fourth step dealing with multilingual generation.

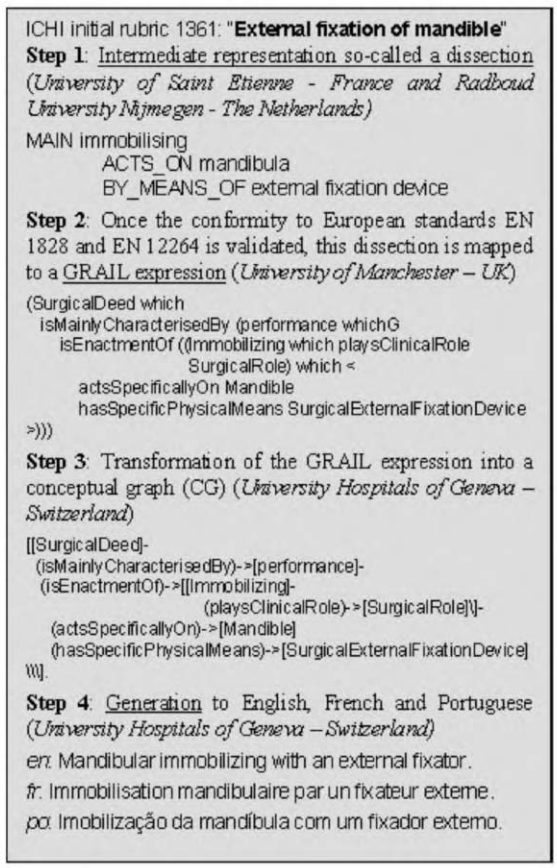

Figure 1 - GALEN methodology applied on ICHI code 1361

Portuguese generation of ICHI procedure codes

A large-scale experiment of generating natural language phrases for surgical procedures modeled in GRAIL has already been achieved within the framework of the French CCAM classification [17]. Target languages for generation were French, English, and to a minor extent Italian. The decision to generate ICHI in the additional Portuguese language was a good opportunity to scale the flexibility and adaptability of the NLG tools to cope with a new language.

The generator, developed as part of the GALEN project, mainly consists of a two-phase process. The first one is concerned with the transformation operations (i.e., expansion and/or contraction of both concept's and relationship's definitions) on the input graph. The second one is concerned with the linguistic realization and consists of selecting the syntactic structures and words that are allowable in the target language, in order to express relationships and concepts respectively. The first phase has two main goals: 1) to simplify the input graph by concealing the specific modeling styles (such as masking the concepts "*SurgicalDeed*" and "*performance*" in Figure 1); 2) to take into account the desired language style which, in this terminological context, is to produce phrases "as detailed as necessary but as concise as possible" thus preferring concise over verbose generations. Moreover, the management of these operations agrees with the linguistic realization phase as replacing an adjacent portion of graph by an explicit entity, is only performed when corresponding words exist in the target language to name this latter. Therefore, adapting the NLG tools, based on the ontological GALEN model, to an additional language, consists of adding a linguistic layer to the two main semantic components of the model, namely the typology of concepts, and the semantic rules that govern the sensible combinations of these concepts. The first linguistic task relates to the language annotation process for concepts, resulting in the creation of dictionaries. The second linguistic task concerns the annotation process for semantic rules. This consists of clarifying syntactic structures that are commonly used in a given language to support the expression of the relationships occurring between conceptual entities. In addition, grammatical rules, that define how the language entities are actually put together, must be specified such as subject/verb or adjective/noun agreements, style, capitalization, punctuation and so on.

The modular representation of data in our system, which results in a clear separation between linguistic knowledge and conceptual knowledge, greatly facilitates the handling of a new language by taking advantage of what was already made in other languages. In the present work, the linguistic features of Portuguese have been added in strong analogy with those existing for French. Indeed, French and Portuguese are two Romance languages (sometimes referred to as Romanic), as they descend from Latin, the language of the Roman Empire. As a result, they share many similar linguistic features. In particular, they have lost the inflection system of nouns to indicate cases (subject, object and so on), they have relatively rigid SVO[1] sentence structure, and they make extensive use of prepositions. Therefore, the same concepts for which an annotation was needed to generate French (likewise English) terms were also annotated for Portuguese. Moreover, all the annotations of the GALEN sensible statements were systematically modified by recopying, for Portuguese, the syntactic structures already defined for French. Finally, function words (or grammatical words) as well as general word usages were added for Portuguese by pointing out those existing for French. For instance, the

1 In linguistic typology, agent-verb-object (AVO), commonly called subject-verb-object (SVO), is a sentence structure where the agent comes first, the verb second, and the object third.

following three rules that describe the definite articles in French:

```
fct_wrd(cl_grammatical,fr,le,det(art_def,mas,sing),_).
fct_wrd(cl_grammatical,fr,la,det(art_def,fem,sing),_).
fct_wrd(cl_grammatical,fr,les,det(art_def,no,plur),_).
```

were translated for Portuguese into the following four rules:

```
fct_wrd(cl_grammatical,po,o,det(art_def,mas,sing),_).
fct_wrd(cl_grammatical,po,a,det(art_def,fem,sing),_).
fct_wrd(cl_grammatical,po,os,det(art_def,mas,plur),_).
fct_wrd(cl_grammatical,po,as,det(art_def,fem,plur),_).
```

In the same way, the convention saying that in French the adjective is generally positioned after the noun is also reutilized for Portuguese.

The obvious effect of this systematic approach is the similarity of the syntactic structures generated in each language. The example shown in Figure 1 corroborates this observation as an adjectival (adj) then a noun-complement (cpl) structures are specified in this order (corresponding to the usage weight given to the structure) in French (fr), English (en) and Portuguese (po), to support the expression of the relationship "*actsSpecificallyOn*", in the mentioned context. In particular, the following more general sensible co-occurrence pattern is applied:

```
stat_annot(22.1,cl_GeneralisedProcess,
                rel_actsOn, cl_BodyStructure,
    [en([adj,cpl,nprem]), fr([adj,cpl]), po([adj,cpl]), it([adj,cpl])],
                                    [en([adj,partPerf(affected,by)]),
fr([adj,partPerf('affecté',par)]),
    po([adj]), it([adj,partPerf(trattato,da)])]).
```

It is worth noting that the relation "*actsOn*" subsumes the relation "*actsSpecificallyOn*". Moreover, the second part of the aforementioned pattern describes the syntactic structures for the realization of the relation "*isActedOnBy*", which is the reverse relation of "*actsOn*". The fact that a noun complement, rather than an adjectival structure, is generated in Portuguese for expressing the localization in the ICHI code 1361, is due to the small coverage of the Portuguese dictionary, where only the noun "*mandíbula*" is defined as annotation for the concept "*Mandible*".

This approach by analogy must nevertheless be carefully checked. On the one hand, the fact that it is based on reusable French rules endangers the generation results that could become a French kind of Portuguese. In order to avoid this outcome, a review process of the generated terms by a Portuguese speaking person is systematically performed, thus leading to the subsequent refinement of the statement annotations, in order to accurately take into account the regular Portuguese language style. On the other hand, producing similar generated terms in different languages strengthens the congruence between generated terms and eases the quality assessment of the resulting terms. Indeed, the generated phrase can be compared, not only with the initial rubric, but also with the terms generated in similar languages.

Results

In order to rapidly evaluate the feasibility and quality of the Portuguese generation on the Australian ICHI coding system, an experiment of applying the GALEN methodology for ICHI was conducted on chapter XV that includes procedures on the musculoskeletal system. This chapter contains around 200 rubrics whose codes are extended from 1360 to 1579. Generating these procedure codes in Portuguese has required an extension of the GALEN model with 6 new concepts, as well as the creation of a Portuguese dictionary of 220 words corresponding to the annotation of 193 distinct GALEN concepts. All the sensible statements (126 in all) were extended to the Portuguese language. Finally around 70 grammatical rules, specified for French, were adjusted. One man-week was necessary to perform the dissections of the 200 initial rubrics and around the same time period was required to adapt the NLG tools for Portuguese.

The initial results for Portuguese generation are outstanding. Future progress would cover the treatment of compound words [9], as well as the growth of the Portuguese dictionary by adding more lexical variants for the annotation of concepts. The review process of the generated terms, against the original ones, pointed out inconsistencies amounting to 20% in the ICHI-Chapter XV source terms. A relevant example, discussed in [21], highlights the incompatible usage of the word "arthroplasty" in three ICHI procedure codes: 1489 (*Arthroplasty of hip*), 1518 (*Arthroplasty of knee)*, and 1519 (*Arthroplasty of knee with bone graft to femur or tibia)*. Indeed, this same word is used to denote either a limited or a complete plastic joint repair. In order to correct these inconsistencies, an improvement of the ICHI structure, using the benefits of the CCAM architecture, is recommended [22].

Discussion and conclusion

Performing comparisons of data between different countries and services, in particular for statistical reporting or cost analysis, implies sharing a common accepted terminology. It should be recognized that, to be an international standard, a terminology should rely on a sound ontology that serves as a formal basis for multiple natural languages.

The GALEN model has proved to be suitable for the computerization of clinical terminologies. Indeed, it supports accepted specifications including among others, conceptual definitions, sensible rules, and basic as well as composite entities that establish a referent language, upon which understanding and exchange of information between different parties can be performed. The total development effort for maintenance and validation is then reduced by sharing such an internal language-independent representation of entities that constitutes a common platform between various WHO member states.

Coupling such a model with NLG tools, constitutes an interesting approach that presents attractive benefits. First, the generation of nonsensical terms is prevented as the semantic representation from which the generation is trig-

gered, is defined unambiguously. The review process of the generated terms, against the original ones, serves to identify and repair inconsistencies and ambiguities both at the level of the original classification and at the level of the derived dissections. Second, this approach automates, and therefore greatly speeds up, the translation of the original classification into various languages, as the internal representation of the original rubrics is made once and serves as a basis for generating terms for all target languages. Similarities between languages are also strongly utilized and this accelerates the adaptation of the NLG tools to new Romanic languages. The fact that the generation is restricted to noun phrases also simplifies the linguistic approach while fitting precisely the terms' structure used to express health classifications. In reality, concise terms are often preferred to wordy ones. Finally, this approach avoids local cross-lingual maintenance and validation of standardized terminology, as comparable national versions of such a terminology can be generated for each country.

In the coming years, NLG tools based on ontology driven semantic structure should become the standard multilingual means to rapidly deliver, in many different countries, consistent national versions of any standardized health terminology.

Acknowledgments

We wish to thank Stefan Schultz for his Portuguese language expertise in reviewing part of the term generation performed on chapter XV of ICHI.

Biomedical Knowledge Discovery with Topological Constraints Modeling in Bayesian Networks: A Preliminary Report

Guoliang Li, Tze-Yun Leong

School of Computing, National University of Singapore*, Singapore*

Abstract

Serving as exploratory data analysis tools, Bayesian networks (BNs) can be automatically learned from data to compactly model direct dependency relationships among the variables in a domain. A major challenge in BN learning is to effectively represent and incorporate domain knowledge in the learning process to improve its efficiency and accuracy. In this paper, we examine two types of domain knowledge representation in BNs: matrix and rule. We develop a set of consistency checking mechanisms for the representations and describe their applications in BN learning. Empirical results from the canonical Asia network example show that topological constraints, especially those imposed on the undirected links in the corresponding completed partially directed acyclic graph (CPDAG) of the learned BN, are particularly useful. Preliminary experiments on a real-life coronary artery disease dataset show that both efficiency and accuracy can be improved with the proposed methodology. The bootstrap approach adopted in the BN learning process with topological constraints also highlights the set of the learned links with high significance, which can in turn prompt further exploration of the actual relationships involved.

Keywords:

Bayesian networks, domain knowledge, bootstrap approach, coronary artery disease

Introduction

Serving as exploratory data analysis tools, Bayesian networks (BNs) support modeling direct dependency relationships among various domain variables, which may lead to understanding or discovering the causal knowledge involved. In the last two decades, many promising methods have been proposed to learn BNs from data (1, 2). One of the main problems with the existing methods is that some links in the learned BNs are inconsistent with the domain knowledge.

Many authors have tried to combine domain knowledge in the BN learning process. Cooper and Herskovits required the complete causal ordering of the variables in the domain (1). Heckerman, Geiger and Chickering used a prior network for BN structure learning (2). These methods work well theoretically when the required systematic domain knowledge is available. In practice, however, only partial domain knowledge is available in most cases. For instance, certain variables are known as roots or leaves, or there are known links among some variables. BN learning with such partial domain knowledge is supported in packages like LibB, TETRAD and BN PowerConstructor[1].

Experience has shown that partial domain knowledge can be very helpful in improving both the efficiency and accuracy of the learned BN structures. However, systematic analyses and discussions on incorporating partial domain knowledge into BN structure learning are lacking; explicit effects and influences of different kinds of topological constraints are unknown, especially in biomedical domains. In this paper, we examine the representation of partial domain knowledge, its usage in BN structure learning and its effect on the accuracy of the learned BN structures. We base our discussions on both a canonical BN example and a case study on a real heart disease data. We hope our discussion on and examination of a set of relevant topological constraints can lead to active causal pattern discovery with experiments.

We propose two ways to represent partial domain knowledge as topological constraints in BNs: in rule format and in matrix format. The rules for partial domain knowledge are easier to derive from the domain experts. These rules can then be compiled into a matrix format, which would facilitate consistency checking in the topological constraints.

We combine the specified domain knowledge with the score-based greedy search method for BN structure learning. Experiments on the canonical Asia network example show that the topological constraints can increase the accuracy of the structure of the learned BNs, especially for the constraint sets with the undirected links in the corresponding completed partially directed acyclic graph (CPDAG) of the BN.

Experiments on a case study in coronary artery disease (CAD) show that both efficiency and accuracy of BN learning can be improved with the proposed methodology. The significance of the identified direct dependency relationship among variables is estimated with the bootstrap approach. The direct links in the learned BN with topolog-

ical constraints are statistically significant, which can in turn be used as new hypothesis for further analysis.

Materials and methods

Bayesian networks

Bayesian networks (BNs) are directed acyclic graphs (DAGs). The nodes in a BN represent the variables in the target domain. The links between nodes represent probabilistic dependencies among different variables. The node at the head of a link is called a *child*, and the node at the tail of a link is called a *parent*. Together, the graphical representation models the qualitative information in a domain – which domain variables are probabilistically dependent to each other. The quantitative information of a BN is represented as the conditional probability distribution inside each node, which represents the probability of the variable under each configuration of its parent variables. Combining the qualitative and quantitative parts, a BN can define a factorized joint probability of variables $X_1, \ldots, X_n$ in the domain:

$$p(X_1,...,X_n) = \prod_i p(X_i \mid Pa(X_i))$$

where $Pa(X_i)$ means the parents of variable X_i in the BN.

Bayesian network construction and learning

Bayesian networks can be constructed entirely from domain knowledge elicited from domain experts (3, 4). However, in many domains, only partial domain knowledge is available, which is not enough to support full BN construction. Even if there is sufficient domain knowledge, the elicitation process is usually time-consuming, especially for eliciting the numerous conditional probabilities. There are many recent research efforts to build BNs from data (see (5) and references therein). Although there are good applications in BN learning, the learning process remains computationally costly. It is also common in practice to observe that some links in the learned BNs contradict the domain knowledge. For example, in the medical domain, the variable "Age" is usually believed as one not affected by other variables. It should be a root node in a BN, but may not be so in a BN learned without taking into account of this "common sense" domain knowledge (see Figure 2 in our experiment). In order to address this problem in general, we need to properly capture the available domain knowledge in the BN learning process.

Representing domain knowledge as topological constraints in Bayesian networks

In any domain, we may have certain prior knowledge, which could come from scientific laws, common sense, expert opinions, accumulated personal experiences, etc (6). Such domain knowledge can be combined in the BN learning process to establish better structures (1, 2). Usually such domain knowledge is qualitative, but the extent of the influence between two related variables is not certain. A class of useful and important domain relationships are related to the topological structures of the BNs, and can be represented as topological constraints in the BNs. Table 1 summarizes the known topological constraints in rule format, some of which have been applied in BN learning package TETRAD, LibB, and BN PowerConstructor. These rules are easy to elicit from domain experts. However, if there are conflicts and/or cycles in the elicited domain knowledge, it is difficult to detect them in the rule representation.

To facilitate consistency checking, we propose to compile the rules of topological domain knowledge into matrix format: one matrix for the known links, one matrix for the forbidden links, and one matrix for the partial ordering, one vector for the maximum number of parents, and one vector for the maximum number of children, as summarized in Table 2. The first ten rules in Table 1 suggest the known links, forbidden links and partial orderings in Table 2. The last two suggest the limits on the number of parents and children.

Table 1 - Summary of the domain knowledge in rule format

Type of domian knowledge	Meaning
Roots	Nodes without parents. Such variables influence other variables, but are not influenced by any other variable
Leaves	Nodes without children. Such variables are influenced by other variables, but do not affect other variables.
Known links	The links are fixed before learning.
Forbidden links	Definitely there are no such links.
Partial ordering	Some variables are before some other variables in the ordering.
(Conditional) independence	Some variables are conditional independent.
Known parents	The parents of some variables are known.
Known children	The children of some variables are known.
Possible parents	The parents of some variables are restricted to a subset of variables.
Possible children	The children of some variables are restricted to a subset of variables.
Maximum number of parents	The numbers of parents of variables can be different and limited.
Maximum number of children	The numbers of children of variables can be different and limited.

Table 2 - Summary of domain knowledge in matrix format

Names of components	Meaning
Matrix_k	Matrix for knowledge links
Matrix_f	Matrix for forbidden links
Matrix_p	Matrix for partial ordering
V_maxParents	Vector for the maximum parents
V_maxChildren	Vector for the maximum children

Checking the consistency of the topological constraints

After the compilation, we need to check the consistency in the specified domain knowledge before we apply it in the BN structure learning process. The following are the five main steps in consistency checking.

1) Check whether there are cycles in the known links. There should be no cycles in the valid BN topology.

2) Check whether there are overlapping links in the known links and the forbidden links. There should be no overlapping in valid BN topology.

3) Check whether there are cycles when combining the known links and the partial orderings. If there are cycles, it means that certain paths of the known links conflict the known partial orderings.

4) Check the number of the maximum parents of each variable. The sums of the parents of the known links to each node represent the number of the known parents.

5) Check the number of the maximum children of each variable. The sums of the children of the known links from each node represent the number of the known children.

If there are inconsistencies in the topological domain knowledge, report them. Currently we do not resolve the inconsistencies computationally, and leave the work to the domain experts or further experiments.

Greedy search algorithm with topological constraints

In this work, we adopt a score-based approach with a greedy search method and the Bayesian Information Criterion (BIC) score to learn the BNs. The learning process starts from a randomly-generated BN, and continues moving to the best neighbors in the structure space until there is no improvement in the BIC score.

In the learning process, we check whether the candidate BN structures are satisfied with the topological domain knowledge. If yes, we will keep the candidates; we reject them otherwise. This helps to narrow the structure space and speed up the learning process. Figure 1 shows the pseudo code of a greedy search algorithm for BN structure learning.

Compared with the general greedy search, there are two main changes in the process. First, the initial DAG generated should be consistent with the domain knowledge. Second, an additional step filters out neighbors of the current DAG which are not consistent with the topological constraints. This step is to guarantee that the selected neighbors are consistent with the topological domain knowledge. The process of the filtering is similar to domain knowledge consistency checking.

Generate an initial DAG consistent with the topological constraints as the current DAG
Done = false
While ~Done
Generate all the possible neighbors of the current DAG
Filter out the neighbors which are not consistent with the topological constraints
Evaluate the remaining neighbor DAGs
If the best score of the remaining neighbor DAGs is better than that of the current DAG
Set the DAG with the best score as the current DAG
Else
Done = true

Figure 1 - BN learning with topological domain knowledge

Estimation of edge significance with bootstrap approach

We are also interested in the confidence level of the learned links: do these links appear in the learned BNs by chance or with statistical significance? We adopt the bootstrap approach to examine the confidence of the links in the learned model. A bootstrap approach is a statistical method to re-use the original samples. It draws the same number of samples from the original samples with replacement as a new sample set, and builds a model with the same method to analyze the original data. Such experiments repeat many times (500 in our experiments). The results from multiple experiments show the significance of the conclusions from the original samples alone. In our work, the confidence level of the learned links is the percentage of the links appeared in the repeated experiments. If a link appears with a high percentage in the bootstrap experiments, it means that the strength of the direct dependency relationship between two variables is not spurious or accidental but actually indicating strong correlations. Friedman *et al* (7) first applied the bootstrap approach to assess the significance of the edges in the learned BNs.

Results

In this section, we describe experiments on testing the effect of the topological constrains on the BN structure learning process. Since we filter out the DAGs inconsistent with the topological constraints, the learned BN will be consistent with the domain knowledge. Another effect is the change in running time when topological constraints are included. The third effect is the correctness of the learned BN structure

with different topological constraints, when compared with the original structure. Our experiments are based on a benchmark BN Asia network. We have also applied our method on a real heart disease data set without known BN structure. All the implementations are under Matlab with the support of Bayes Net Toolbox (BNT)[2]. The learned BNs are visualized with Genie[3].

Time for consistency checking

We have implemented the consistency checking in both rule format and matrix format. For comparison purpose, we randomly generated 100 topological constraint sets for BNs with different numbers of nodes from 10 to 100. The time for consistency checking in matrix format includes the time to compile the topological constraints from rule format to matrix format. On average, the consistency checking in matrix format is about 8.3 times faster than that in rule format. A possible reason is that, in the matrix format, consistency checking is done by matrix operation; but in the rule format, we need to enumerate all the possible situations for consistency checking, which would take more time.

Effects of topological constraints on Asia network

The canonical Asia network example(8) is an eight-variable BN that models the situation for determining the likelihood of a person having a disease, given his visiting history and smoking habit. In the first experiment, we applied the learning algorithm on the randomly sampled data sets from Asia Network. 1000 cases were sampled for each randomly-sampled data set, which were combined with each individual constraint set to learn a BN. There are 61 different constraint sets in this experiment, each with a single constraint (1 without constraints, 2 with one root, 2 with one leaf, and 56 with 1 links, known or forbidden). 100 different data sets were randomly-sampled. The program ran 36 hours and 6100 (=100*61) BNs were learned in total.

The results showed that the single constraint, which led to the maximum number of average correct links in the learned BNs, is a link from node "visit to Asia" to node "Tuberculosis". This link is distribution-indistinguishable. Establishing this link can lead to more correct links in the learned structure. The second most useful constraint is a link from node "lung cancer" to node "Tuberculosis or Lung Cancer". This constraint is a link in a v-structure. The third most useful constraint is a leaf node "Dyspnea". These results suggested that we need to pay more attention to certain types of topological constraints in practice.

We also experimented with multiple constraints in one constraint set. We randomly selected links in the original BN as known links or forbidden links in the constraint sets with one to seven links selected. There were 43 constraint sets in total. There were 1000 randomly-sampled cases in each data set, and 93 different data sets were sampled. Each data set was combined with every individual constraint set to learn a BN. Altogether 3999 (=93*43) BNs were learned for multiple constraints, and 453 of them were found to be the same as the original one. Combined with the results from the single constraints, where almost no learned BNs were exactly the same as the original ones, this means that more topological constraints are more likely to lead to the correct BNs. This coincides with our belief that the more the links we know, the easier the remaining links can be learned.

Heart disease data

We performed a case study on a data set collected from a Singapore hospital for coronary artery disease (CAD) study. It contains 2,949 cases of human subjects. 1,462 of the subjects were diagnosed to have coronary artery disease at the time of data collection; and the rest were healthy at the time of recruitment. The values of CAD in this work were based on the presence of at least 50% narrowing in at least one of the major coronary arteries by angiography. In the data set, aside from CAD, another ten patient profile factors were selected for our experiments. They are the subject's 1) age, 2) sex, 3) race, 4) current body mass index (CBMI), 5) smoking habit, 6) absent of hypertension or not, 7) absent diabetics or not, 8) family CAD history (FCAD), 9) family hypertension history (FHY), and 10) family diabetic history (FDM). In these ten variables, eight factors are discrete variables and two other variables, Age and CBMI, are continuous variables. These two continuous variables were discretized separately. Refer to (9) for more detailed data summary.

BNs learned with and without topological domain knowledge

The BNs learned without and with topological domain knowledge are shown in Figure 2 and 3. In Figure 2, the variables "Age", "Race" and "Sex" have parents, which is conflicting with common sense as these variables are not affected by other variables in this case. This motivated us to combine topological domain knowledge in the BN learning process.

In our work, we applied two types of topological domain knowledge. First, variables "Race", "Age" and "Sex" are specified as roots in BNs, since we know from common sense that the probability distributions of these three variables are not dependent on other patient profile information. Second, variables "FHY", "FDM" and "FCAD" precede all other variables in partial ordering, since family health history precedes the patient profile in time. However, these three family health history variables may depend on each other. The BN learned with such topological domain knowledge is shown in Figure 3. As compared to the BN in Figure 2, the BN structure in Figure 3 is more meaningful as judged by commonsense.

3 Genie: http://genie.sis.pitt.edu/

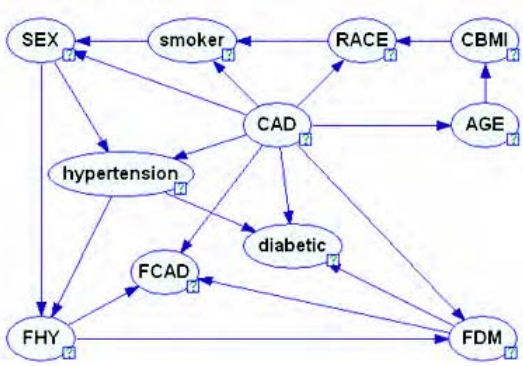

Figure 2 - BN learned without domain knowledge

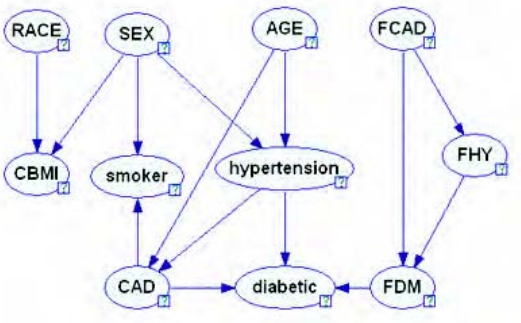

Figure 3 - BN learned with domain knowledge

Effects of domain knowledge on heart disease data

To verify the significance of the links in the learned BNs, we applied the bootstrap approach. We sampled data from the original data with replacement, and two BNs were learned from each sampled data set – one without topological domain knowledge and one with such knowledge.

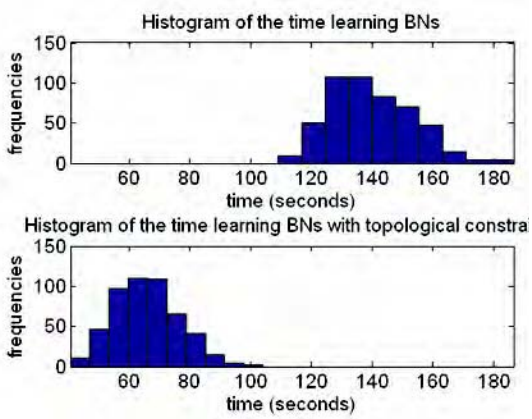

Figure 4 - Histograms of the times learning BNs with/ without domain knowledge

Figure 4 shows the histograms of the running time of the BN learning processes with and without topological constraints. As indicated, the running times with topological constraints are much shorter than those without constraints. The average running time with topological constraints is 65.9 seconds. Compared with the average running time without topological constraints (140.1 seconds), the speed-up is more than two times. However, we notice that the speed-up of the learning process is dependent on the available domain knowledge. In our example, there are 11 variables and 110 possible links (two directions for 55 pairs of variables). The available domain knowledge in our example is that three variables are roots and three variables are not affected by the other 8 variables. Based on such constraints, 54 links were forbidden. The BN structure space with the constraints was much smaller, which led to the speed-up in the BN structure learning process. If the known domain knowledge is small compared to the whole possible topological constraints, the speed-up may not be so significant.

Table 3 shows the significant pairs of variables in the learned BNs with the bootstrap approach. The results showed that almost all the links in the learned BNs were quite significant and appeared more than 60% of times in the 500 bootstrap experiments. The top pair of variables in the learned BNs with bootstrap approach and domain knowledge is Sex-Smoker, which appeared surprisingly 100% in the 500 bootstrap experiments. This pair of variables is deemed to be related based on the current domain understanding. Other evaluation methods such as chi-square and mutual information, however, did not rank it highly (data not shown here for space limit). Other highly ranked pairs of variables in Table 3 appeared in the learned BN with topological domain knowledge (Figure 3). It means that the links in the learned BN with domain knowledge are statistically significant.

Table 3 - Top occurring links in BN learning with bootstrap and topological constraints

Order	Variable 1	Variable 2	Occurrences (%)
1	SEX	smoker	500 (100%)
2	AGE	CAD	482 (96.4%)
3	CAD	smoker	469 (93.8%)
4	CAD	diabetic	453 (90.6%)
5	CAD	hypertensi on	408 (81.6%)

Note: The percentage in the Occurrences column means the percent of the links appearing in the 500 learned BNs from bootstrap approach.

Discussion and conclusion

Identifying the possible direct dependency relationships among variables is an important task in exploratory data analysis. BNs are a good tool for this purpose. There are

several advantages in BN-based data analysis: 1) easy to combine prior knowledge, 2) easy to interpret and 3) easy to deal with missing and noise data. In this paper, we have proposed two canonical formats to represent domain relationships as topological constraints in the BN learning process. In addition to improving the efficiency of the BN learning process, the experiments show the links in the learned BNs with domain knowledge are potentially more meaningful. Results from bootstrap approach show that the learned links are statistically significant. Our case study in CAD risk analysis with the learned BN allowed us to discover some interesting patterns, which have prompted further analysis.

We want to emphasize that the purpose of the analysis with BNs and domain knowledge is to identify the properties in the data with high probabilities and consistent with common sense, which can be used as new hypotheses for further analysis. The purpose of using BN and topological domain knowledge is not to replace the other traditional data analysis methods for hypothesis testing.

Our on-going work is to extend the proposed method based on more extensive experiments with more data. We have collected the genotype single nucleotide polymorphism (SNP) data for the subjects in the heart disease data set. We will incorporate the genotype data with the patient profile for further analysis. For future work, we also plan to verify patterns found by our method with new biological or clinical experiments.

Acknowledgments

We thank Dr Chew Kiat HENG for sharing with us the Heart Disease data set in this work.

Automatic Infection Detection System

Abstract

An infected person may be contagious already before the first symptoms appear. This person can, in the period of disease evolution, infect several associated citizens before consulting a general practitioner (GP). Early detection of contagion is therefore important to prevent spreading of diseases. The Automatic Infection Detection (AID) System faces this problem through investigating the hypothesis that the blood glucose (BG) level increases when a person is infected. The first objective of the prototyped version of the AID system was to identify possible BG elevations in the incubation time that could be related to the spread of infectious diseases. To do this, we monitored two groups of people, with and without diabetes mellitus. The AID system analyzed the results and we were able to detect two cases of infection during the study period. The time of detection occurred simultaneous or near the time of onset of symptoms. The detection did not occur earlier for a number of reasons. The most likely one is that the evolution process of an infectious disease is both complicated and involves the immune system and several organs in the body. The investigation with regard to isolating the key relations is therefore considered as a very complex study. Nevertheless, the AID system managed to detect the infection much earlier than what is possible with today's early warning systems for infectious diseases.

Keywords:

health intelligence, automatic infection detection, disease surveillance

Introduction

Disease outbreaks like SARS in March 2003 and the deliberate spread of *B.anthracis* in the US in 2001 have drawn attention to the need for tools to detect and monitor disease outbreaks. In august 2005, WHO provided the following assessment of the threat of an avian influenza pandemic [1]:

1. The risk of a pandemic is great.
2. The risk will persist.
3. Evolution of the threat cannot be predicted.
4. The early warning system is weak.
5. Preventive intervention is possible, but untested.
6. Reduction of morbidity and mortality during a pandemic will be impeded by inadequate medical supplies.

Early detection of contagion is important to prevent spreading of diseases. By the time the health authorities is able to identify a disease outbreak by reports, it may be too late to prevent large epidemic or pandemic outbreaks. It is therefore important that the authority receives timely and adequate indication of ongoing infectious disease activity. An important goal is therefore to reduce the time from infection, to the time when the authorities get information about infectious disease activity as much as possible.

An infection is in traditional medicine first established in accordance with a diagnosis on the day of consultation. This leaves an unexplored time gap back to the time of intrusion. We have therefore explored new approaches in order to reveal diseases at an earlier stage, e.g. syndromic surveillance. In the future management of chronic diseases, transfer of vital sensor data from patients to the public health care system is likely to become commonplace. Systems for automatic transfer of sensor data are now at the prototype stage [2], and that Electronic Health Record (EHR) systems will include improved functionality to capture sensor data is also likely.

This has aimed our curiosity in direction of how to detect infections outside clinical settings. One way of facing this goal is to use self monitoring equipment to measure indicator data. The starting point of this project has therefore been to exploit secondary use of blood glucose (BG) measurements performed daily by diabetics. These measurements are then analyzed to see if they can be used to reveal and detect infections.

We believe that it may be possible to detect an infection close to the time of contagion (pathogenic intrusion), and escalating trough the incubation time. The project was therefore designed to investigate if BG measurements are suitable as an infection indicator in public health care surveillance. This leads to the following problem definition: *Is it likely that a person's BG- level, given an infection (independent of type), would change sufficiently and early enough that monitoring of these changes can be used as a reliable indicator of an infectious disease?*

Materials and methods

This paper describes the development of the prototyped AID system for detecting infectious diseases, discusses the results from the captured clinical BG measurement data

and evaluates the experiment. The work is based on an experimental approach. An important part of the work has been input from a clinical study of nine participants, of this; two people with and seven people without diabetes mellitus. The group monitored their BG level over a period of up to 6 weeks. The results from the clinical study were used for testing of the AID system prototype. Each participant was instructed to perform measurement according to a time definition before or after a meal. One part of the group was instructed to perform measurements before the main meals and up to four times a day. The other group was instructed to measure within a time interval after each main meal, also up to four times a day.

The measured data is provided by use of a blood glucose meter; FreeStyle Mini from Abbott. The data is transferred to a Microsoft SQL Server 2005 database for EHR simulation purposes. The captured sensor data was then analyzed in a two-step detection algorithm. The first step is a moving average algorithm that main objective is to smooth out large fluctuations, especially with regard to BG measurement. Then, both the original BG measurement and the moving average data are analyzed in the detection algorithm against the clinical defined Cut-Off value. The number of measurements per participant in the study ranges from 44 to above 120 measurements. Those with diabetes provided a larger number of measurements, and from a longer period. These measurements permitted us to test run and tune the detection algorithm against BG cases with real-time quantity of fluctuations. The corresponding feedback from the participants made it possible to tune the algorithm to make detections of incidents of real infections.

The number of participant in this experiment is too low to fulfill the statistical power demands. The experiment provide useful information in order to indicate trends and reveal important signals that could be followed up in future work. However, the reader needs to be aware that the results from the experiment are preliminary.

AID system background

Current medical knowledge states that the BG values increases during an infection [3]. Based on this knowledge, we wanted to investigate whether BG measurements were suited as an indicator of infections and able to be used to predict and detect a disease outbreak at an early stage. Continuous analyses of daily blood glucose measurements may enable early detection of infections on a person level. On a population level, this may in turn enable us to prevent large outbreaks of infectious diseases, such as different strains of influenza, cholera, plague, smallpox and anthrax.

When the analyzed data indicating infections exceed a predetermined threshold of incidents, the health care authorities would be able to initiate early investigation at an early stage in order to begin treatment, prevent the disease to spread, and to prepare for vaccination etc. We have not identified other studies that use BG measurements for infectious disease surveillance purposes. There are few studies [4] linking use of point of care testing or near patient testing (NPT) [5], to outcomes [6]. Some studies have been performed on inpatients, (both diabetics and non-diabetics) with particular focus on glycemic control and its possible impact on hospital outcomes. The result shows that patients with hyperglycemia have had an increased risk of both postoperative infections and in hospital mortality [7]. The C-reactive protein (CRP) is the most commonly used marker to establish a diagnosis of infectious diseases. CRP is normally used as an infection parameter or inflammatory marker primarily to establish bacterial infections, but to a certain extent also as a marker of viral infections.

The University of Tromsø and the Norwegian Centre for Telemedicine have previous collaborated on projects investigating the use of BG measurements in different medical settings [2]. This co-operation evolved gradually into this new idea and the desire to investigate the usefulness of BG measurements, performed several times a day by diabetic patients, in order to investigate a secondary utility value. Systems that support rapid and automatic transfer of NPT outcomes are evolving. Data from NPT equipment that is used in hospital settings and integrated in practice and bedside treatment of patients is likely seldom or never transferred and reused outside the treatment of the current/local patient. Systems that automatically transmit results of NPT information to EHRs are also evolving. This development creates a need for systems able to interpret the data.

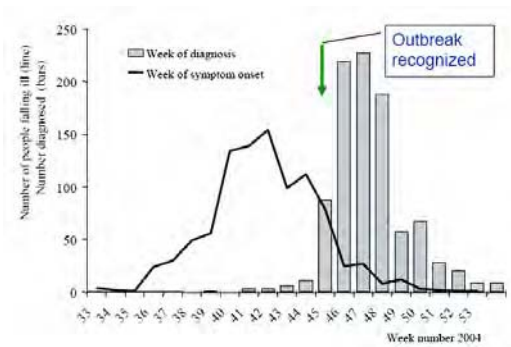

Figure 1 - Characteristic of Giardiasis disease propagation in Bergen 2004 (Graphics by Chief Physician P. Aavitsland, The Norwegian Institute for Public Health)

Figure 1 shows the Giardiasis outbreak in Bergen in 2004 where the health authorities first became aware of the scope of the disease at a time when the disease outbreak was decreasing.

Our intention is to capture self-measurements from diabetes NPT settings (that primarily is used to provide the patient with information to take necessary self-treatment actions), and to exploit and make secondary use of these measurements in disease and public health surveillance. A synergistic effect of real time analyzed NPT outcome would provide general practitioners, outpatient clinics, and public health authorities with real-time information, which may change clinical practice, and improve the ability to

quickly determine whether to take proper actions. Normal intervention in the capture of NPT-results has previously been insufficiently recorded in EHRs. Our intended use omits this previous potential loss [8] of valuable measurements which may improve health surveillance efficiency. We believe that our approach may provide solutions to some of the challenges that exist in public health. It expands the methods for and potentially the ability to detect infectious diseases and to take timely actions that could limit the scope of disease propagation.

Additionally, occurrences of bioterrorism [9] has also increased the need and focus on anti-bioterrorism and precautions towards defeating malicious use of biological warfare agents. Infectious diseases due to deliberate terror actions are no longer a question of if, but of when and where [9]. We should, when faced with such a threat, even if it at best may be of limited effect, immediately start to optimize our safety and increase preparedness.

Results and discussion

At the Norwegian Centre for Telemedicine in co-operation with the University of Tromsø, we have constructed an AID - Automatic Infection Detection system, which is a prototype system for detection of infection through monitoring blood glucose values collected from people with diabetes using a communication enabled blood glucose meter. The blood glucose meter may communicate wirelessly with a mobile phone that transfer the BG measurements to a remote system where the analysis may be performed, as described in [2].

The basis for the proposed detection system is the hypothesis that the BG level elevates when a person gets an infection [10]. The International Diabetes Federation estimates that there are currently some 194 million people around the world with diabetes [11]. Monitoring and control of blood glucose levels is critical in the management of Type 1 and Type 2 diabetes, and the patients measure their blood glucose levels up to several times a day to minimize long-term complications [12, 13]. If values from all diabetes patients in a region were instantly accessible, it would provide a foundation for extended data analysis. Extreme accumulations of infection indications in a specific geographical area could be spotted, and the public health authorities could monitor and act on such signals.

We were able to detect two cases of real infections from data provided by the nine participatns in the investigation. The detection algorithm detected all cases above the predefined Cut Off value. The time of detection occurred in parallel with the patient symptoms, i.e. the onset date. Both cases of infection detections were made from the diabetic's participant measurements. As a result of feedback from the patients we were able to check and verify that our AID system was able to detect infections even from more complex BG fluctuations. The ability of detecting an infection in a person with adequate insulin regulation is assumed to be less complicated than for patients that are not well regulated.

Figure 2 illustrates the outcome of an analysis on population level. The left table summarizes participating individuals / sensors (column 3), the corresponding number of total measurements and indications from participants in the zip code areas 9011, 9037 and 9100 on the December 27th 2005. This provides information about indications of infections. The number of indications is in this case negligible. However, we believe, given the occurrence of a serious outbreak, that the number of indications of infections would increase dramatically. When a zip code area holds an adequate number of reporting sensors representative to the population of that specific area, and when the number of indications exceeds a given threshold, this information may be a signal for the health authorities to take proper action.

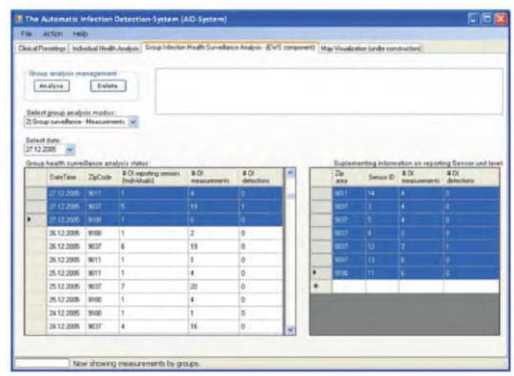

Figure 2 - Group infection health surveillance analysis

The right side shows each sensor device's recorded measurements and indications. This information provides the authorities with additional information to support decision. E.g. if a known diabetes patient that normally performs an average of 6-8 measurements each day suddenly measure a noticeable number of measurements (e.g.12 times) with a corresponding high level of detections this would support the suspicion of an infection

In our study we did not see any significant changes in the period before onset. It is advantageous to perform new experiments, and/or collaborate with hospitals in collecting continuous blood glucose values, e.g., from NPT settings. The experience and empiricism in use of BG as an infection indicator is now in the very beginning. Our preliminary results hopefully will encourage others to follow up with studies, experiments and evaluation on the topic.

Our algorithm also detected six false positives. The false detections occurred due to unregulated diabetic conditions. The false positive rate we experienced is a challenge that could potentially reduce the value of our detection system. However, because the system is based on using a mobile phone as a gateway, the mobile phone may also be used to collect additional data about the patient. We therefore recommend that the diabetic patient is sent a SMS with a question like "Are you feeling well?" or something similar, to get additional data from the patient. The diabetic patient should then provide a "yes" or "no" answer, using

SMS. This communication could form the basis for a system that can aid the diabetic patient both when the blood glucose values are too high, like when the patient has an infection, or too low, like when the patient experiences hypoglycemia. Such use of the mobile phone could strengthen the evidence for a real infection as well as aiding the patient in potentially very dangerous situations.

What may also strengthen prediction performance is including additional infectious indicators such as temperature, blood pressure, heart beat, pedometer /accelerometer or the outcome of measurements from bioinformatics equipment e.g. CRP etc. Additional registration of the patient's physical activity integrated with the patient's mobile phone could also contribute to a better prediction. E.g. if a person BG-value and temperature rise at the same time as activity drops it could support the suspicion of illness and even an infection. A confounding element is whether highly affected patients would measure their BG value or answer SMS messages. This happened to one of the non diabetic patients that became ill during the study but was unable to measure the BG value during the disease episode. Other confounding elements may be the occurrence of a simultaneous outbreak of less dangerous diseases as normal influenza.

However, we believe that data from patients with diabetes could provide early warnings of an outbreak in a population. This would give the public health authorities the opportunity to take action to limit an outbreak and its consequences for all the inhabitants in the affected area. Typical actions may be advice, vaccination and even isolation in serious cases.

Using blood glucose as an indicator of infection

There is a differece between inflammatory markers and infection markers (also called indicators). Inflammatory markers cover a more broad area including physical injuries, while indicators imply that the infection is solely caused by a pathogenic agent. Infection indicators are measurable parameters able to give certain health information of a specific condition present during an infection. One such indicator may be blood glucose. There might be a connection between different types of infectious diseases and which impact each specific disease causes in elevation of BG, and further research is needed to see if the investigation of if elevated BG condition is similar among different infectious diseases.

Type 1 diabetes patients measure their BG level several times a day in order to regulate their BG, while diabetes type 2 patients have a lower frequency in order to maintain well regulated. BG measurements is performed several times to adjust injection of insulin [14]. Different types of measurement equipment exists ranging from devices which only require a small droplet of blood (e.g. FreeStyle Mini) to continuous glucose monitoring (CGM) by subcutaneous test devices e.g. FreeStyle Navigator [15] and non-invasive devices as the GlucoWatch [16] provided by Animas Technologies, LLC.

The AID system made one detection of a confirmed real case of infection for the individual using sensor unit 13 (see. Figure 3). Vaccination of the individual using sensor unit 13 took place at the 21.Oct. 2005.

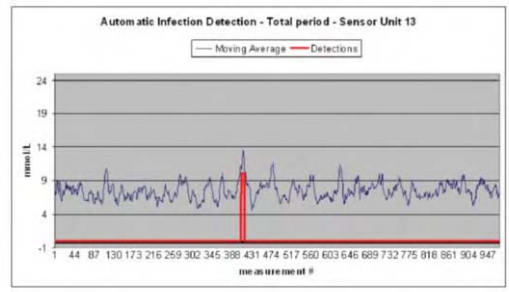

Figure 3 - Analyzed data from Sensor Unit 13 (diabetes)

Figure 3 shows The Automatic Infection Detection system for analysis of patients' sensor data. The sensor data consists of physiological parameters, in this case monitored blood glucose data. The red line detection peak correspond with the clinical defined cut-off threshold value: 10,2 mmol/l.

The system analyses and evaluates each patients BG data, and potential abnormal BG increases are detected. The evaluation seeks to eliminate random variations. In addition, the values must be higher than a predefined cut-off value before they are indicated as an infection.

Conclusion

Use of BG data holds a potential to act as an indicator of infections in health care surveillance. Use of BG as an indicator of infections seems to be suitable. BG measurement from sensor patients provide a continuous stream of data and the frequency in measurements per day opens up for further development and secondary usage of sensor data from patients and NPT measurements.

Exploiting secondary use of BG measurements to perform public heath surveillance might lower the total social- and medical economic costs of pandemics. Remote monitoring increase the health care efficiency, but maybe most important are the patient's quality of life. Our approach aims to only collect physiological data, which means that personal integrity and ethnical issue also could be safeguarded.

Our approach, seems to provide detection of infection very early.

Our main recommendation, with regard to facing timely detection and impending usage of BG measurements, is to include and correlate measured BG values against other non-invasive health indicators, such as temperature, heart rate, blood pressure and activity instruments (movement sensors, step counters, etc). We also recommend future research to perform investigations with use of non-invasive devices or subcutaneous continuous glucose monitoring (CGM) type devices. A subcutaneous CGM device like Abbott's Freestyle Navigator could provide even more realistic real-time data. Due to the possibility of developing a stronger algorithm this approach may

increase the detection reliability. In this technological area, many different solutions already exist. The challenge seems to be in part to merge all non-invasive sensors into one small wearable unit that wirelessly transfers health data via the mobile phone or internet network access node (e-house technology) into the public health services.

Independently of which way to obtain indicator data, it is important to note that there will always be some disease activity present. Before a surveillance system could make use of BG values or other suitable infection indicator data, data must be collected and be representative of the population. By expanding the number of patients providing sensor data it would be possible to cover each geographic area. Outbreaks can be discovered very early and it is possible to take proper action.

Risk Stratification for LDL Cholesterol using Induction Technique

Seung Hee Ho[a], Hyun Young Park[b], Yang Soo Jang[b], Sun Ha Jee[c]

[a] *Department of Health Informatics, Graduate School of Public Health, Yonsei University, Korea*
[b] *Cardiovascular Genome Center, Yonsei University Medical Center, Seoul, Korea*
[c] *Department of Epidemiology and Health Promotion, Graduate School of Public Health, Yonsei University, Korea*

Abstract

We identified the combined patterns of LDL cholesterol risk factors including biometric, environmental and genetic factors using induction technique. In this hospital based cardiovascular genome study of Korean men and women, we found that CART (classification and regression tree) was a better method to predict LDL cholesterol compared to the regression method. The CART had a better prediction ability than the multiple regression for male and female, respectively. We also identified combined patterns of LDL cholesterol risk factors and segment specific information for LDL cholesterol management using induction rules. The CART method provided more detailed results according to each segmentation and subgroup. In addition, we demonstrated how the CART algorithm could be used in risk assessment and target segmentation of LDL cholesterol management.

Keywords:

risk stratification, LDL cholesterol, induction technique, genetic polymorphism

Introduction

Because low-density lipoprotein (LDL) cholesterol is multi-factorial in origin, it is important to consider all risk factors simultaneously, including biometric, environmental, and genetic factors, when estimating an individual's LDL cholesterol risk. The relationship between gene polymorphism and LDL cholesterol has been studied by many groups [1-6]. Most past LDL cholesterol studies have focused on describing individual patient characteristics and genetic polymorphisms separately using statistical methods. Therefore, the relative importance of risk factors could not be compared together and their relative statistical significance could not be established.

With the intention of overcoming limitations of past studies, we attempted to discover the combined patterns of LDL cholesterol risk factors including biometric, environmental and genetic, using an induction technique as a data mining approach. Data mining, which is also known as knowledge discovery in databases, is a process of non-trivial extraction of implicit, previously unknown and potentially useful information from databases [7].

This study presents a classification and regression tree (CART) algorithm as an induction technique to discover the knowledge to predict LDL cholesterol risk by biometric, environmental and genetic factors. We examined the risk factors for LDL cholesterol using multiple regression and the CART algorithm, then analyzed the relationship among biometric, environmental and genetic factors for LDL cholesterol using the CART algorithm. In addition, we compared multiple regression and the CART algorithm results, and presented the practical use of rule induction for the management of LDL cholesterol.

Materials and methods

Research model

We analyzed the simultaneous relationship among biometric, environmental and genetic factors for LDL cholesterol using the CART algorithm (Figure 1).

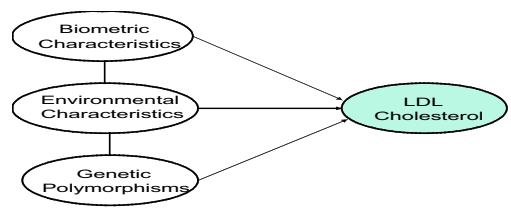

Figure 1- Framework of the analysis

Subjects

This study analyzed data from a hospital-based cardiovascular genome center in Korea. Blood samples were collected from patients from January 2001 to January 2004. In this study, 242 males and 295 females were selected. Subjects presenting with cardiac problems or receiving treatment that would affect serum lipoprotein and carbohydrate metabolism were excluded from the study.

Measurements of risk factors

This study analyzed data from a hospital-based cardiovascular genome center in

- Biometric and Environmental Characteristics
  Body mass index (BMI) was calculated as weight in kilograms divided by height in meters squared. The

concentration of LDL cholesterol was calculated using the Friedewald equation [8]. Environmental parameters including smoking, alcohol consumption and exercise, were obtained via one to one interview type questionnaire.

- Genetic Polymorphisms Testing
  Genomic DNA was isolated from whole blood using a Genomic PUREGENE® DNA Isolation Kit (Gentra Systems, Inc., MN, USA). Genotyping was performed using a polymerase chain reaction (PCR)-based method, and negative controls without DNA template were included for each reaction.

Decision tree induction: CART algorithm

Decision Trees are powerful and popular tools for classification and prediction capabilities. The attractiveness of tree-based methods in contrast to neural networks, is largely based on the concept that decision trees represent rules [9]. The CART algorithm is one of the most popular methods of building decision tree. Since its publication by Briemen [10] and associates in 1984, it has been a staple algorithm of machine-learning experiments. The CART tree is constructed by splitting data into subsets using all predictor variables to create two child nodes repeatedly, beginning with the entire data set. The best predictor is chosen using a variety of measures to reduce impurity or diversity.

Results

The effect of biometric, environmental and genetic factors on LDL cholesterol by multiple regression analysis

The effects of the independent variables to LDL cholesterol were tested (Table 1). In males, the overall model was significant (F=1.781, p = 0.032) and 12.5 percent of the variance of LDL cholesterol level is explained by independent variables (R^2=0.125). Biometric and environmental factors had significant influence on LDL cholesterol in one variable, drinking status. Drinking status was significantly related to LDL cholesterol (beta= -13.635, t-value= -2.169 , p<0.031). Three genetic polymorphisms had significant influence on LDL cholesterol, TAQ1B, I405V, and M235T.

In females, the overall model was significant (F=1.798, p = 0.028) and 10.3 percent of the variance in LDL cholesterol is explained by independent variables (R^2=0.103). Biometric and environmental factors had no significant influence on LDL cholesterol, but two genetic polymorphisms had significant influence on LDL cholesterol, APOE and APOA5(-1131T>C).

Decision tree and rules for the prediction of LDL cholesterol

We used the CART algorithm to build a decision tree for predicting the LDL cholesterol, and identified the risk factors that play important roles in explaining LDL cholesterol for the two groups, male (Figure 2) and female (Figure 3). The decision tree shows the risk factors that were significantly different between the two nodes based on t-test at 5% level.

Table 1 - Determinants of LDL cholesterol by multiple regression analysis

Covariate		Male			Female		
		beta	t-value	P-value	beta	t-value	P-value

Fitness *P*-value		0.032			0.028		
R square		0.125			0.103		

In males, the mean LDL cholesterol for all subjects was 130.51 mg/dl. The first split was based on age, with younger subjects (54.5 years old) having the higher LDL cholesterol (134.99 mg/dl) than that (119.70 mg/dl) of older subjects (>54.5 years old). This indicated that age was the most important determining factor for LDL cholesterol.

Differences were observed between the two subtrees. Older subjects (>54.5 years old) are subsequently split by drinking status. Younger subjects (54.5 years old) are subsequently split by age again, with tracts having an age between 31.5 and 54.5 years old in one node and an age less than 31.5 years old in the other. Subjects between 31.5 and 54.5 years of age had higher LDL cholesterol (138.04 mg/dl) than (112.04 mg/dl) subjects less than 31.5 years of age.

I: Improvement (reduction of the within-node variance)
M.L: Mean of LDL cholesterol

Decision trees are charts that illustrate decision rules. Decision rules provide specific information about risk factors based on the rule of induction. As shown in Figure 2, the decision tree has 20 leaf nodes and 11 terminal nodes. Figure 3 demonstrates a decision tree having 18 leaf nodes and 10 terminal nodes. Each terminal node depicted in the

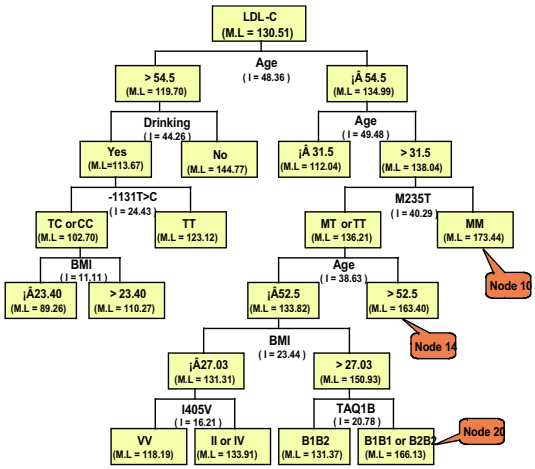

Figure 2- Male CART algorithm decision tree

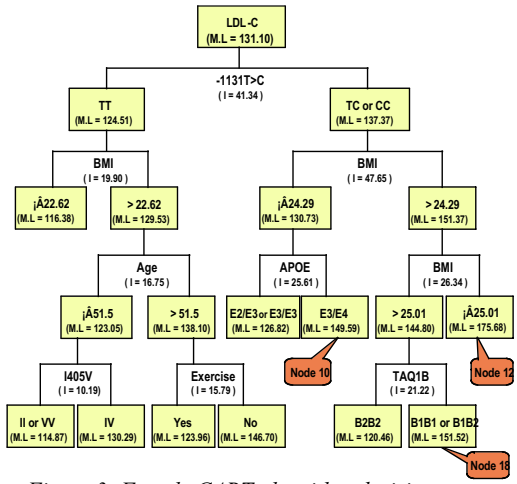

Figure 3- Female CART algorithm decision tree

decision tree can be expressed in terms of an 'if-then' rule, as follows:

For male, /* Node 10 */
If [(31.5 < Age ≤ 54.5) and (AGT-M235T genotype = MM)],
then the mean of LDL cholesterol = 173.44 mg/dl

Risk assessment and target segmentation for the management of LDL cholesterol

The gains chart produced by the decision tree can be used for as risk stratification for LDL cholesterol management. There are two parts to the gains chart, node-by-node statistics and cumulative statistics (Table 2). In regards to the target variable LDL cholesterol, which is continuous, gain charts provide node statistics relative to the mean of the target variable.

For the male group, the first node in the table, node 10, indicates the mean LDL cholesterol is 173.44 mg/dl for 7 subjects. For node 10 in males, the index score is 132.89%, indicating that the mean LDL cholesterol for this node is about 1.32 times higher than the overall sample.

Cumulative statistics demonstrate that cases with elevated LDL cholesterol can be derived by procuring the best segments of the sample. In males, if only the best node, (node 10), is reviewed, cases with LDL cholesterol means 1.32 times higher than the overall sample are reached by targeting only 3.06 % of the sample. If the next best node is included, (node 20), then cases with a 1.29 times higher LDL cholesterol mean than the overall sample are returned, from only 6.99 % of the sample.

Table 2 - Male risk stratification for LDL cholesterol by gains chart

Node	Node-by-node				Cumulative			
	Node(n)	Node(%)	Gain	Index (%)	Node (n)	Node(%)	Gain	Index (%)
10	7	3.06	173.44	132.89	7	3.06	173.44	132.89
20	9	3.93	166.13	127.29	16	6.99	169.33	129.74
14	11	4.80	163.40	125.20	27	11.79	166.91	127.89
4	13	5.68	144.77	110.92	40	17.47	159.72	122.37
18	91	39.74	133.91	102.60	131	57.21	141.79	108.64
19	7	3.06	131.37	100.66	138	60.26	141.26	108.23
8	29	12.66	123.12	94.33	167	72.93	138.11	105.82
17	18	7.86	118.19	90.56	185	80.79	136.17	104.33
5	19	8.30	112.04	85.85	204	89.08	133.92	102.61
12	16	6.99	110.27	84.49	220	96.07	132.20	101.29
11	9	3.93	89.26	68.39	229	100.00	130.51	100.00

* Node (n) : Number of cases for the node Node (%) : Percentage of the total sample cases falling into the node
Gain : Mean of LDL cholesterol for the node Index (%) : Ratio of the gain score for the node to the gain score for the total sample

Comparative assessment of multiple regression and CART

A comparison of performance for the two models is shown in Table 3. The CART algorithm performed better prediction (24.53%, 20.66%) than multiple regression(12.5%, 10.3%) for male and female groups, respectively. In the CART algorithm, error estimate is calculated as the within-node variance about the mean of the node. The total variance equals the within-node variance plus the between-node variance.

The within-node variance of this model for the male group is 975.144, while the total variance is 1292.14. The proportion of variance due to error is 975.144 / 1292.14 = 0.7547. Thus, the proportion of variance explained by the model is 100% - 75.47% = 24.53%. The within-node variance of this model for the female group is 863.255, while the total variance is 1088.03. The proportion of variance due to error is 863.255 / 1088.03 = 0.7934. Thus, the proportion of variance explained by the model is 100% - 79.34 % = 20.66%

Table 3 - Performance Comparison of Multiple Regression and the CART Algorithm

Model	Fitness	Male	Female
Multiple Regression	F statistics P-value R^2	1.781 0.032 0.125	1.798 0.028 0.103
CART	Total variance Within-node variance Proportion of variance explained by model	1292.140 975.144 24.53 %	1088.030 863.255 20.66 %

Discussion and conclusion

In this hospital-based cardiovascular genome study of Korean men and women, we found that CART is a better method to discover the knowledge to predict LDL cholesterol by biometric, environmental, and genetic factors compared with the regression method. Based on the CART method, we found that genetic polymorphisms APOA5, M235T, CETP(I405V), and CETP(TAQ1B) for male and APOA5, APOE, CETP(I405V), and CETP(TAQ1B) for female, were associated with LDL cholesterol. The genetic polymorphisms combined with other risk factors generated the rules for the prediction of LDL cholesterol.

Although genetic factors have been extensively investigated as risk factors for CVD, the results are still debatable [1-6,11]. In this present study, overall results displayed association of risk factors with LDL cholesterol which were very similar in both the CART and regression methods. However, the CART method provided more detailed results according to each segmentation and subgroup.

This study examined characteristics of the CART algorithm to demonstrate how they can be used to predict LDL cholesterol risk and provide management information from a patient database. The CART algorithm provided cumulative statistics demonstrating how efficient high LDL cholesterol cases were obtained by taking the best segments of the sample. The gains chart also provided valuable information about which segments to target and which to avoid. In addition, we presented rules that provided an occurrence relationship among the risk factors. Such information, which could not be obtained from multiple regression, can be used in examining the effects of individual risk factors on a specific segment of the target population.

There were several limitations in this study. One limitation is its reliance on data from a single hospital, and thus was biased in terms of the affluence of the subject group. In order to generalize data from a larger sample, partitioning data into training and testing set or cross validation is a pre-requisite or requirement. Sufficient validation for the generalization of our findings was not performed.

Future analyses will include an improvement to the CART algorithm. Furthermore, cost-effectiveness information will be incorporated into a data mining algorithm for each of the risk factors in order to estimate budgets for providing LDL cholesterol management services to the specific target population. This model provides a comprehensive analytic framework to construct the optimal design of clinical guidelines and healthcare policy for the prevention and management of LDL cholesterol.

Abstract

This work is part of an ongoing effort to examine and improve clinical workflows in radiology. Classical workflow analysis is time consuming and expensive. Here we present a purely data-driven approach using data mining techniques to detect causes for poor data quality and areas with poor workflow performance. Data has been taken from a operational RIS system. We defined a set of four key indicators for both data quality and workflow performance. Using several mining techniques such as cluster analysis and correlation tests we were able to detect interesting effects regarding data quality and an abnormality in the workflow for some organizational units of the examined radiology departments. We conclude that data-driven data mining approaches may act as a valuable tool to support workflow analysis and can narrow down the problem space for a manual on-site workflow analysis. This can save time and effort and leads to less strain for clinicians and workflow analysts during interviews.

Keywords:

data mining, data quality, workflow, radiology

Introduction

Improving workflows in clinical environments and especially the radiology workflow is gaining importance due to limited financial resources, increasing commercial pressure, changing hospital reimbursement e.g. in DRG based systems and an increasing requirement for quality management in medicine. Measuring the current workflow performance and its quality are key to any improvement efforts.

“If you cannot measure it, you cannot control it. If you cannot control it, you cannot manage it. If you cannot manage it, you cannot improve it" [1]. However, as we will show, a reliable data basis is required to determine reliable performance indicators. Poor data can delay decision making, cause bad decisions, or prevent appropriate decision making [2]. Redman [2] estimates that poor data quality costs the typical company at least ten percent of revenue. Here we present a data-driven approach using data mining techniques to detect causes for poor data quality. We will demonstrate that reliability of workflow performance measurement heavily depends upon data quality.

We define data quality according to Juran in [3], cited in [2],[4]: "Data is of high quality if it is fit for the intended uses [...] in operations, decision making and planning". Aspects of data quality comprise e.g. completeness, correctness, comprehensiveness, accessibility, timeliness, objectivity, relevancy, interpretability and understandability [4][5]. Data mining is the process of extracting knowledge from large amounts of data. Typical data mining functionalities comprise clustering, the discovery of concept/class descriptions, associations or correlations, classification, prediction, trend analysis, outliers analysis, deviation analysis, and similarity analysis [6].

Methods

Our working environment is the radiology department of New York University Medical Center (NYUMC). We focused on outpatient examinations of 2 NYUMC radiology sites during the time period 02/2006 to 08/2006. Site *A* performs ultrasound (US), computer tomography (CT), and conventional X-ray (XR) studies in three departments. Site *B* is responsible for magnetic resonance imaging (MRI). Site *A* has three, site *B* one big central unit and both have several smaller so called satellite units either in different buildings/floors or even spread across the city. All units run one radiology information system (RIS). Our source database is derived from this RIS and covered more than 60.000 examinations which are characterized by 30 attributes each. We built a data mining infrastructure in alignment with the knowledge discovery in databases process described in [6] which comprised the sequence steps data pre-processing, key indicator calculation, data mining, and pattern evaluation.

Data pre-processing

The following action sequence was performed:

- The data was loaded from an existing RIS-fed Oracle database containing the raw data into a staging database (Microsoft Access 2003).

- A pre-processing step then excluded extreme outliers and inconsistencies like dangling references, resulting in a pre-processed data base. E.g. we excluded examinations with a specific tag which did not refer to the examined body region
- The next step was data transformation (data normalization and aggregation) and data reformatting (e.g. changing date formats, etc.) We used a combination of SQL queries and VBA scripts to define the sequence of transformation and reformatting tasks. As an example we merged date and time values from two independent string type fields into one date type field.
- Finally data reduction (reduction of data volume without affecting the analytical results, like e.g. data discretization) was performed. We removed attributes such as patient identifiers or accession numbers. Furthermore we reduced the deviation from the preset duration of the examination from minutes to a value between [0;1], specifying the fraction of the preset in percent.
- Then we loaded the cleaned and transformed data into the project dedicated data warehouse (Oracle 10g) which itself is the actual data base for our mining efforts.

Calculation of key indicators (KIs)

Our primary goal was to concentrate on both data quality and workflow performance using a mixed set of key indicators. For workflow performance we defined:

- KI.1: *report-turnaround time*
  How long does it take from completion of an examination to finalization of the corresponding medical report
- KI.2: *adherence to the pre-assigned duration*
  How many minutes does the examination deviate from its scheduled duration. Alternatively the relative deviation in percent of the scheduled duration was used.

It is noteworthy, that the reliability of the key performance indicators *KI*.1 and *K*.2 of a radiology department depend on the availability and correctness of a relatively small set of timestamps. These underlying timestamps are e.g. the exam begin and completion timestamps or the report finalization timestamps. In contrast to the correctness of these timestamps (data correctness indicator *KI*.4) their availability (data completeness indicator *KI*.3) has no direct influence on the reliability of the performance indicators *KI*.1 and *KI*.2. However, a high fraction of unavailable timestamps may lead to a biased view of the performance. To measure data quality we used the following key indicators:

- KI.3: *data completeness*
  Which fraction of items has all relevant information available (no attribute values are missing or undefined)

- KI.4: *data correctness*
  Which fraction of items has "correct data" for all relevant information (no contradictory facts in the data)

Our database, derived from the operational RIS, comprised optional data from manual entry such as patient arrival time, the begin of an examination, and the patient departure time. The end time of an examination is also manually entered, but unlike the previously mentioned timestamps it is required by the system. Report creation and report finalization timestamps are auto-generated by the RIS.

Normally patient arrival (as well as patient departure) should be tracked by the front-desk personnel of the respective unit. The begin examination timestamps are maintained by radiology technologists. In detail *KI*.3 *data completeness* was calculated as the fraction of radiology examinations which do not violate one or more of the following constraints:

C3.1: Patient arrival time is available
C3.2: Begin of examination time is available
C3.3: Patient departure time is available

Data correctness was even more difficult to define. As a coarse correctness indicator we searched for studies, which contain obviously nonsense values for the timestamps. *KI*.4: *data correctness* was calculated as the fraction of items, which do violate none of the following check constraints:

C4.1: $time$(Pat. Arrival) < $^{*}time$(Exam Begin)
C4.2: $time$(Exam Complete) < $^{*}time$(Pat. Departure)
C4.3: $time$(Pat. Arrival) ≠ $^{*}time$(Pat. Departure)
C4.4: $time$(Exam Begin) ≠ $^{*}time$(Exam Complete)
C4.5: 1min < $duration$(Exam) ≤ 5$ScheduledDuration$

This reads as follows: $t_1 < {}^{*}t_2$ means t_1 is earlier than $t_2 \pm 1min$. $t_1 > {}^{*}t_2$ means t_1 is later than $t_2 \pm 1min$. Equality of two timestamps $t_1 = {}^{*}t_2$ is defined if $t_1 = t_2 \pm 1min$. Two timestamps t_1, t_2 are considered to be unequal ($t_1 \neq {}^{*}t_2$) if $t_1 < t_2 \pm 1min$. The following rule (*C*4.6) was retrospectively abandoned due to too many violations.

C4.6: $time$(Exam Completion) ≠ $^{*}time$(Pat. Departure)

Data mining

Data mining was performed on the computed key indicators *KI*.1 to *KI*.4 and the following information: patient sex, patient age, examining site, examining unit, medical category, report transcription time, report signing time, referring physician, modality type, imaging device, technologist, and responsible radiologist. We used the WEKA Software (v 3.5.3) [7] and focused on cluster analysis, outlier analysis, and classification of findings.

For cluster analysis, multiple algorithms were used, such as the Simple-EM algorithm, an expectation maximization algorithm described in [6] or the Farthest-First algorithm described in [8] and implemented in [7]. For outlier analysis we considered instances as outliers if they exceed the following range: $x_i < Q1 - 1.5\ IQR$ or $x_i > Q3 + 1.5\ IQR$. *IQR* is the Inter-Quartile Range, $Q1$ is the first quartile, $Q3$ the third. In addition we used the χ^2-test to determine if data follows a specific distribution and for testing two or more groups regarding statistical independence.

Cluster classification was done primarily by generating C4.5 decision trees as described in [9],[7]. In addition, we relied on the 1R classifier which uses the minimum-error attribute for prediction and discretizing numeric attributes see [10], and a nearest-neighbour-like algorithm using non-nested generalized exemplars as described in [11],[7].

Pattern Evaluation

The findings from the previous step must be evaluated and valuable results should be used for workflow improvement. We concentrated on the following parameters to distinguish interesting and less interesting findings [6]: Simplicity, Certainty, Utility, and Novelty. Simplicity gives information with regard to how easily a finding can be understood. It can be quantified e.g. by measuring an (association) rule length, or the size of the mined (decision) tree. Certainty provides information about the classification reliability, the accuracy, the rule strength or the discriminating weight. The utility measurement quantifies the potential usefulness of a finding and can be quantified by calculating the rule support or noise threshold. And finally, a finding is of interest if it was not previously known or surprising (Novelty).

In this project, a rough pre-selection of interesting findings was done, which then was presented to and discussed with the involved and/or affected clinicians. This sifting through the intermediate findings leads to further open questions, additional issues to be examined, and to new and deeper insights into detected problems. Finally, workflow improvements were derived from the findings in consultation with the affected participants and the corresponding supervisors.

Results

In our case the objective of data mining was to classify the data to detect outliers and to find patterns in the data, which describe the set of detected outliers. Therefore we started the mining process with the application of clustering algorithms on the whole data base, including performance and data quality indicators *KI*.1 to *KI*.4 to detect groups of data items with a high degree of similarity. In this first step we detected three different clusters. To gain more information about the characteristics of those clusters, we used the R1 classification given by [7] which came up with the following rules:

if <Site=A> then <cluster0> and
if <Site=B> then <cluster2>

Using just these rules would classify 89.29% data items correctly to the respective site. The third cluster did not prompt such a clear rule. As a consequence there must be a difference of data entered at site *A* (CT, US, XR) vs. site *B* (MRI) in terms of data quality or workflow performance. We now looked at the two sites separately and continued the same clustering using performance and data quality indicators *KI*.1 to *KI*.4.

For site *A* we could assign two clusters. Classifying these clusters derived the following rule:

if <Site is a satellite> then <cluster1>
else <cluster0>

Using this rule 97.49% of the instances would be classified correctly. The same approach applied to Site *B* resulted in similar findings and exactly the same rule, which would classify 92.68% of Site *B* instances correctly based on their satellite or non-satellite status.

Table 1: Fraction of a) correct and complete, b) incomplete (ℜKI.3), and c) incorrect (ℜKI.4) data items

	a) KI.3 and KI.4		**b) ℜKI.3**		**c) ℜKI.4**	
Dept.	**non-Satellite**	**Satellite**	**non-Satellite**	**Satellite**	**non-Satellite**	**Satellite**
A1	74,36%	29,48%	20,46%	5,20%	6,19%	68,03%
A2	79,26%	n/a	11,91%	n/a	9,04%	n/a
A3	82,56%	45,21%	5,44%	16,05%	12,67%	41,13%
B1	85,37%	79,55%	11,39%	15,53%	4,06%	5,71%

As an intermediate result at this stage we can say that there is a difference between site A and site B with regard to the data quality and/or workflow performance in the examined time period. Furthermore within the sites there is a difference between satellite units and the central unit in both cases. Now we tried to work out which of our key indicators, workflow performance (*KI*.1, *KI*.2) or data quality (*KI*.3, *KI*.4) was responsible, starting with the data quality indicators and comparing satellite to non-satellite units for sites A and B respectively. An overview of the findings is given in Table 1.

The fraction of data items entered that do not violate one of the data completeness rules *C*3.1 to *C*3.3 or the data correctness rules *C*4.1 to *C*4.5 are shown in Table 1 column a). Table 1 column b) and c) give a more detailed view. Table 1 column b) depicts the fraction of data entries having at least one incomplete timestamp (ℜ*KI*.3). Table 1 column c) (ℜ*KI*.4) gives detail about the entries violating one of the data correctness rules of indicator *KI*.4. Department A2 does not have satellite units, but was listed for comprehensiveness reasons.

We found for example that in department A1 the amount of data entries with missing values (ℜ*KI*.3) is much lower in satellite units (5,20%) compared to the central unit (20,46%). But as the indicator *KI*.4 shows, the majority of data entered at A1 satellite units is bogus (ℜ*KI*.4 = 68,03%), whereas the bogus ratio (ℜ*KI*.4) at the central unit is much lower (6,19%). Departments A3 and B1 show also a lower amount of correct entries (Table 1 column a) at satellite units compared to the central unit. But in contrast to the findings at department A1, the satellite units of A3 and B1 perform worse regarding both *KI*.3 and *KI*.4. Obviously, there are differences between satellite and non-satellite units with regard to data quality.

Based on these findings we focused on the detection of coherences between the detected data quality issues at satellite units and front desk staff, technologists, radiologists, devices, types of examinations, patient characteristics, etc.

Therefore we performed different classification analysis based on smaller and more condensed views on the original data. We computed a large set of different transient aggregations comparing satellite units with central units for site *A* and *B* respectively. These aggregated views comprised for example the averaging (*avg*) of:

- *avg*(ℜ*KI*.3) and *avg*(ℜ*KI*.4) per weekday, site, and dept.
  - *avg*(ℜ*C*3.1) per weekday, site, and dept.
  - ...
  - *avg*(ℜ*C*4.5) per weekday, site, and dept.
- *avg*(ℜ*KI*.3) and *avg*(ℜ*KI*.4) per tech., site, and dept.
  - *avg*(ℜ*C*3.1) per tech., site, and dept.
  - ...
  - *avg*(ℜ*C*4.5) per tech., site, and dept.
- *avg*(ℜ*KI*.3) and *avg*(ℜ*KI*.4) per physician, site, and dept.
- ...

The classification based on these condensed data revealed - among other findings - the following rule for site *B*, using the 1R classifier after [10].

if avg(ℜ*C*3.1 per tech, site, dept)
<4.22 or ≥ 12.17 then <is Satellite>=true
else <is Satellite>=false

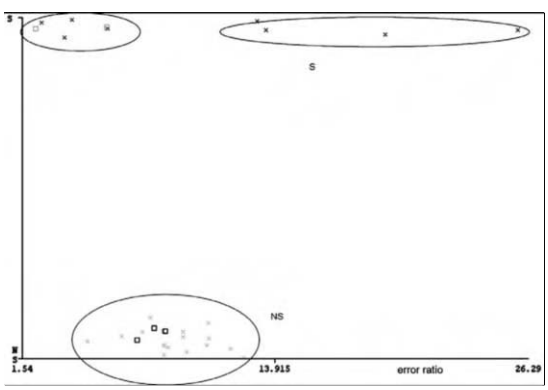

Figure 1 - Classification results based on condensed data

A visualization of the found rule is depicted in figure 1, showing correctly classified instances marked with an x and incorrectly classified instances marked with a square. This rule would classify 83.3% data instances correctly. The rule essentially states that the fraction of missing patient arrival times (ℜ*C*3.1) per technologist at satellite units is different from the fraction of missing patient arrival times at central units. Remember that we said at the beginning that the technologist is responsible for entering the begin examination timestamp but not for entering the patient arrival timestamp which should be entered by front desk personnel. Therefore there should be no correlation between technologist and the violation of indicator *C*3.1; the error ratio for *C*3.1 should be distributed uniformly. We defined the null hypothesis: "the amount of missing patient arrival timestamps should be equally distributed among technologists" and performed a confirmatory data analysis using the a χ^2-test. We detected a highly significant ($\alpha <$ 0,1%) deviation from uniform distribution for both sites *A* and *B* and rejected the null hypothesis at a level of confidence of 99.9%. Comparable results were found when comparing correctness of the patient arrival timestamp (*C*4.1 and *C*4.3) and technologists.

Discussion

Within this study we detected interesting relationships between data quality of timestamps within a hospital RIS system and staff involved in the examination procedure. This information is extremely valuable when considering workflow performance measured on the basis of those timestamps and gives some insight in the likely working procedures. For example, in the satellite radiology units it might often be the case that patient arrival and departure is not encoded by front desk staff of the respective unit. We assume that in such cases the technologist enters those timestamps himself to continue the procedure but does so incorrectly. So there seems to be a defect in the satellite workflow because technologists are forced to track patient arrival. This needs to be confirmed by local workflow analysis projects and will influence our ongoing efforts to measure and optimize workflow performance.

Data mining was performed using data taken directly out of the operative RIS database. We looked into some data quality aspects such as data comprehensiveness, data accuracy, data objectivity and timeliness of the data but did not examine aspects like interpretability, understandability and relevancy of the data within the current project. Our rules for checking data completeness and data correctness have a coarse granularity. If someone entering bogus data into the RIS were to put two minute differences between the timestamps for patient arrival, begin examination and patient departure, we would not detect this currently. This has to be taken into account when evaluating the findings.

Nevertheless, in contrast to the usual common proceeding in workflow improvement projects - which requires workflow analysts or consultants to manually analyze and asses the current workflow by interviewing clinicians or measuring performance - we propose a purely data-driven approach which requires much less effort in order to identify previously unknown areas with potentially suboptimal performance or quality for further analysis. This may well reduce time and expenditure for on-site workflow analysis by narrowing down the problem space in advance. It may also save precious clinician time for interviews during the workflow analysis. Additionally, in contrast to a plain hypothesis-based analysis, which requires the analyst to define the right hypothesis in advance, the given data-driven mining approach is able to lead to new and previously unknown findings.

We selected a set of interesting findings and discussed these with the involved and/or affected clinicians, who attached great importance to this information. For example, no one was aware of the existing differences in data quality between satellites and the main areas. However, the selection of findings for the subsequent and more in depth

mining was done subjectively within this group of informaticians and clinicians with a focus on local activities and improvement potentials. A more objective “utility” for assessing and selecting findings still requires further research and will be part of our future efforts.

Our experiences in using data mining are well aligned with [5] and [12], both stating good results in detecting areas of poor data quality. In contrast, our approach not only focuses on data quality, but also regards workflow performance on a par with data quality. To achieve reliable results during workflow performance measurement it is mandatory to start with sufficient data quality in order to avoid a garbage in - garbage out effect. Not including data quality issues in workflow performance focused improvement projects can result in bogus findings and thus lead to potential counter-productive and expensive decisions based on these bogus findings. For our performance measurement efforts we will definitely take the quality related findings into account and would highly recommend a similar approach to anyone performing such a task.

Abstract

This paper presents a method to support the evaluation procedure of a data mining process using human-system interaction. The post-processing of mined results is one of the key factors for successful data mining process. However, it is difficult for human experts to completely evaluate several thousands of rules from a large dataset containing noise. We have designed a method based on objective rule evaluation indices to support the rule evaluation procedure; the indices are calculated to evaluate each if-then rule mathematically. We have evaluated five representative learning algorithms to construct rule evaluation models of the actual data mining results from a chronic hepatitis data set. Further, we discuss the relationship between the transitions of the subjective criterion of a medical expert and the performances of the rule evaluation models.

Keywords:

data mining, post-processing, human interest, rule evaluation index.

Introduction

In recent years, enormous amounts of data relating to natural science, social science, and business have been stored on information systems. People have been able to obtain valuable knowledge due to the development of information technology. Besides, data mining techniques combine different types of technologies such as database technologies, statistical methods, and machine learning methods. Moreover, data mining has been well known for utilizing data stored on database systems. In particular, if-then rules, which are obtained by rule induction algorithms, are considered to be one of the widely usable and readable outputs of data mining.

However, for large datasets with hundreds of attributes, including noise, the process often results in several thousands of rules. From such a large rule set, it is difficult for human experts to obtain valuable knowledge, which is rarely included in the rule set.

To support such a rule selection, many studies have been performed using objective rule evaluation indices such as recall, precision, and other interestingness measurements [1-3] (Hereafter, we refer to these indices as "objective indices"). Further, it is difficult to estimate the subjective criterion of a medical expert using a single objective rule evaluation index; this is because his/her subjective criterion such as interestingness and importance for his/her purpose is influenced by the amount of his/her medical knowledge and/or the passage of time.

With regard to the above mentioned issues, we have developed an adaptive rule evaluation support method for human experts with rule evaluation models. This method predicts the experts' criteria based on objective indices by re-using the results of the evaluations by human experts.

In Section 2, based on objective indices, we describe the construction method for the rule evaluation model. Then, we present a performance comparison of learning algorithms for constructing rule evaluation models in Section 3. With regard to the results, we discuss the relationship between the transitions of each subjective criterion of a medical expert and the objective performances of the rule evaluation models.

Rule evaluation support with rule evaluation models based on objective indices

In practical data mining situations, costly rule evaluation procedures are repeatedly performed by a human expert. In these situations, the useful information from each evaluation, such as focused attributes, interesting combinations of attributes/attributes and values, and valuable facts are not explicitly used by any rule selection system, but tacitly assumed by the human expert. To solve these problems, we suggest a method to construct rule evaluation models based on objective rule evaluation indices as a way to explicitly describe the criteria of the human expert by re-using the human evaluations. By combining this method with the rule visualization interface, we design a rule evaluation support tool, which can perform more certain rule evaluations with explicit rule evaluation models.

We consider the process of modeling the rule evaluations of human experts as the process that clarifies the relationships between the human evaluations and the features of the inputted if-then rules. Based on this consideration, we find that the construction process for the rule evaluation

model can be implemented as a learning task. Figure 1 shows the construction process based on the re-use of human evaluations and objective indices for each mined rule.

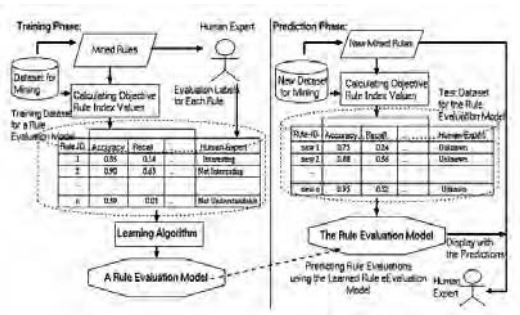

Figure 1 - Overview of the construction method for rule evaluation models

Using this framework, the human expert can evaluate a large number of if-then rules iteratively. The system supports his/her rule evaluation by presenting predictions for unevaluated rules based on a rule evaluation model learned from the evaluated rules. Thus, the human expert can avoid the evaluation of unfamiliar rules or/and uncertain rules based on his/her background knowledge from the first time evaluation process of each rule.

In the training phase, the attributes of a meta-level training dataset are obtained by objective indices such as recall, precision, and other rule evaluation values. The human evaluations for each rule are combined as classes of each instance. To obtain this data set, the human expert has to evaluate the all or a part of the input rules at least once. After obtaining the training data set, its rule evaluation model is constructed by using a learning algorithm.

In the prediction phase, the human expert receives the predictions for new rules based on their objective index values. Since the rule evaluation models are used for predictions, we need to choose a learning algorithm with high accuracy in order to solve the current classification problems.

Comparisons of learning models on chronic hepatitis data mining results

In this section, we present the results of empirical evaluations using the dataset obtained from two hepatitis data mining results [4,5].

First, we obtained a dataset for each rule set from the above mentioned data mining results. The five learning algorithms were then used to construct each rule evaluation model.

Based on the experimental results, we evaluated the availability of each learning algorithm with respect to the accuracies of the rule evaluation models, the minimum costs to construct valid rule evaluation models, and the contents of the rule evaluation models learned.

Since a rule evaluation model requires high accuracy to perfectly support a human expert in the proposed rule evaluation support method, we compared the predictive accuracies for the entire dataset and Leave-One-Out validation.

The accuracy of a validation dataset D is calculated using correctly predicted instances *Correct(D)* as $Acc(D) = (Correct(D)/|D|)*100$, where $|D|$ denotes the size of the dataset. The recalls of class i on a validation dataset are calculated by using correctly predicted instances of the class *Correct(Di)* as $Recall(Di) = (Correct(Di)/|Di|)*100$, where $|Di|$ denotes the size of the instances of class i. Furthermore, the precision of class i is calculated by using the size of the instances that are predicted as $Precision(Di) = (Correct(Di)/Predicted(Di))*100$.

We obtained the learning curves of accuracies of the learning algorithms for the entire training dataset to evaluate whether each learning algorithm can perform in the early stage of the rule evaluation process.

The accuracies of randomly sub-sampled training datasets are averaged for 10 trials on each percentage of subset.

By observing the elements of the rule evaluation models for the meningitis and hepatitis data mining results, we consider the characteristics of the objective indices that are used in these rule evaluation models.

In order to construct a dataset to learn a rule evaluation model, the values of the objective indices have been calculated for each rule by considering 39 objective indices [6], as shown in Table 1.

Thus, the dataset for each rule set has the same number of instances as the rule set. Each instance has 40 attributes, including those of the class.

We applied the five learning algorithms to these datasets to compare their performances as construction methods for the rule evaluation models.

We employed the following learning algorithms from Weka [18]: J4.8 (a C4.5 decision tree learner) [19], a back-propagation neural network (BPNN) learner [20], support vector machines (SVM) [21], classification via linear regressions (CLR) [22], and OneR [23].

A case study on the chronic hepatitis data mining results

In this case study, we used four data mining results for chronic hepatitis, as shown in Table 2. These datasets show patterns of the values obtained from the laboratory tests of the blood and urine of chronic hepatitis patients as attributes.

First, we performed the data mining processes twice to determine the relationships between the patterns of attributes and the those of glutamate-pyruvate transaminase (GPT) as the class, which is one of the important tests required to determine the condition of each patient. A medical expert evaluated these results at different times, which were approximately one year apart. However, the expert held his interestingness concerning the significant movement of GPT values between these two evaluations. Second, we performed other data mining processes twice to determine the relationships between the patterns of attributes and the results of interferon (IFN) therapy. The expert also evaluated these results at different times, which were two weeks apart. For each rule, we assigned a label (EI: Especially Interesting, I: Interesting, NI: Not Interesting, and NU: Not Understandable) according to the evaluations provided by the medical expert.

Table 2 - Description of datasets of the chronic hepatitis data mining results

			Class Distribution			
			EI	I	NI	NU
GPT	Phase 1	30	3	8	16	3
	Phase 2	21	2	6	12	1
INF	First Time	26	4	7	11	4
	Second Time	32	15	5	11	1

Comparison of the classification performances

The results for the performances of the five learning algorithms with respect to the entire training dataset and those for Leave-One-Out are shown in Tables 3 and 4, respectively.

Most of the accuracies for the entire training dataset are higher than those estimated by simply predicting each default class. This indicates that the five learning algorithms can construct valid rule evaluation models for these datasets.

Besides, the accuracies of Leave-One-Out show the robustness of each learning algorithm. These accuracies show the predictive performances of each learning algorithm in the "Prediction Phase" in Figure 1. For GPT1 and GPT2, the medical expert is required to determine "EI" rules by himself/herself, because the learning algorithms cannot predict "EI" instances based on the training datasets. Besides, for GPT1 and IFN1, the accuracies are lower than those simply estimated by predicting default classes because the medical expert evaluates these data mining results without a specific criterion in his/her mind.

Estimating the minimum training subset to construct a valid rule evaluation model

Since the construction method for the rule evaluation model requires the mined rules to be evaluated by a human expert, we investigated the minimum training samples to construct a valid rule evaluation model that works better as compared to simply predicting each default class, as shown in Table 5.

GPT1 and IFN1 require more instances than GPT2 and IFN2 in order to learn valid rule evaluation models. In particular, GPT1 requires significantly larger training instances as compared to GPT2 to construct valid rule evaluation models based on the paired t-test ($t = 0.02 < 0.05$). These results indicate that there is a difference in the criteria of human evaluation when evaluating each data mining result.

Table 5 - Minimum training instances to construct valid rule evaluation models using each learning algorithms

		J4.8	BPNN	SVM	CLR	OneR
GPT	Phase 1	30	3	8	16	3
	Phase 2	21	2	6	12	1
IFN	First Time	26	4	7	11	4
	Second Time	32	15	5	11	1

Rule evaluation models for the data mining result dataset for chronic hepatitis

Figure 2 shows the decision trees of J4.8 for each data mining result dataset for chronic hepatitis. With a decision tree, the class label (label of squared node) of an instance is predicted based on its attribute values of the instance according to each branch of the tree. Hence, these decision trees show the decision models of the medical expert from one of the objective aspects.

As shown in Figure 2, these models consist of not only indices expressing the correctness of rules but also other types of indices. This shows that the medical expert evaluated these rules with both correctness and interestingness based on his/her background knowledge.

In each problem, the variance of indices was reduced in the second data mining process. This indicates that the medical expert evaluated the second data mining results with a more certain criterion than he/she did for the first data mining process.

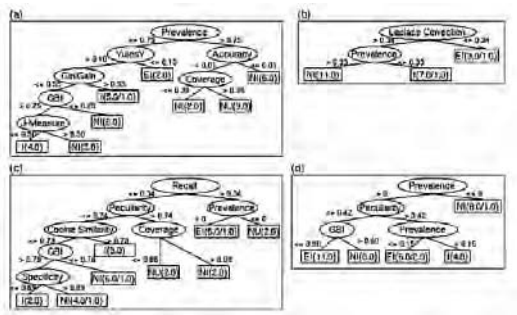

Figure 2 - Rule evaluation models constructed using J4.8 for each data mining result ((a)GPT phase 1, (b) GPT phase 2, (c) IFN first time, (d) IFN second time)

Discussion

Based on the results obtained using the data mining results of chronic hepatitis, it is observed that the performances improve with progress in the data mining processes. In particular, the prediction performances between “I” and “NI” show explicit improvement between the two data mining processes, as shown in Table 4.

The rule evaluation models constructed using the learning algorithms comprise not only indices related to the correctness of each rule but also indices related to other features of each rule, as shown in Figure 2. This result corresponds to the evaluation of the rules based on both their correctness and interestingness by human experts on the basis of their expertise. Furthermore, the variances of the objective indices used in the rule evaluation models decrease with the progress in data mining processes.

The difference between the hepatitis data mining results concerns the certainness of the criterion of the medical expert. The medical expert built up his/her criterion by using iterating data mining processes. Based on these differences, we identified the following three phases of rule evaluation: hypothesis generation, hypothesis validation, and hypothesis refinement.

Then, by considering the differences in performances and the contents of the rule evaluation models, we defined the relationship between these observable differences and the three evaluation phases, as shown in Table 6.

Table 6 - Relationship between the transitions of human criteria and the changes in rule evaluation model.

Phase	Classification Performance	Predictive Performance	Variance of Contents
Generation	low	low	high
Validation	low	improve	decrease
Refinement	high	high	low

Conclusion

In the present paper, we have described the evaluation of five learning algorithms for a rule evaluation support method; rule evaluation models based on objective indices are used to predict the evaluations for an if-then rule by re-using the evaluations of a human expert.

Based on the comparison of performances of the five learning algorithms for the dataset from the data mining results of chronic hepatitis, the rule evaluation models have achieved higher accuracies for simply predicting each default class. Considering the results of the rule evaluation models constructed for four different data mining results of chronic hepatitis, the differences in the human evaluation criteria appear as differences in the rule evaluation models with respect to both their performances and their contents. This result indicates that the proposed approach can detect differences in the human evaluation criteria as differences in the performances of rule evaluation models.

In the future, we will apply this rule evaluation support method to other datasets from various domains.

An Automated Data Pattern Translation Process for Medical Data Mining

Anna Shillabeer

Department of Informatics and Engineering, Flinders University of South Australia, Australia

Abstract

This paper describes the development and application of a medical pattern evaluation methodology. The ADAPT process aims to facilitate the increased use of data mining technologies in medicine by providing a method of translating the language of data mining outputs into that of the medical domain. The research behind this work was developed in response to issues raised both in the literature and in public forums regarding the difficulty of adapting data mining technologies for the unique needs of the medical domain. This paper also responds to the need for automated systems to reflect the methodologies and processes applied in the management and analysis of medical data. The solution presented here shows promise as a method of providing a bridge between traditional data mining and the needs of medical domain users.

Keywords:

automatic data processing, computing methodologies, public health informatics.

Introduction

The acceptance of automated data analysis technology in medicine has been slow to develop [1][2]. While acceptance of data mining and associated technologies is growing, they are not yet an integrated part of the medical data analysis toolkit. Many reasons have been documented for this but one of the primary issues is that the needs of the medical domain are not adequately reflected in the technologies available. This has led to the development of specialised mining tools to suit individual users or data types. Whilst this has enabled the application of the technology in specific scenarios, it has also resulted in the development of a range of similar tools which cannot be utilised outside of the purpose for which they were built. This paper presents further work towards a more flexible solution to many of the documented issues, and introduces a novel process to connect the technical data mining domain with the clinical medical domain through the translation of technical outputs into a language which can be better understood and accepted by medical professionals. The process named ADAPT (Automated DAta Pattern Translator) aims to facilitate greater access to mining technologies for all medical users, and to provide an ability to apply some of the more complex mining technologies without the risk of producing irrelevant or incomprehensible outputs. ADAPT is hereby demonstrated through its relevance to the process of diagnostic decision making, theory validation and hypothesis generation but its potential for use in other areas is high due to its intentionally generalised form.

Terminology

This paper utilises technical terminology which is defined for clarification here as it relies upon an understanding of the data mining process and traditional support metric as applied in data mining systems.

Data mining is essentially an automated data analysis process, however there are almost as many formal definitions of data mining as there are data miners. One of the more commonly quoted definitions is that it is a "non-trivial process of identifying valid, novel, potentially useful and ultimately understandable patterns in data" [3]. These patterns are often described through the standard heuristics of support and confidence.

A pattern is defined as a set of attribute values produced through a process of association rule mining, which occur equal to, or greater than, the minimum support required by the user. Patterns take a general format as shown in the following example; Condition 'A' + Treatment 'B' lead to an outcome of 'Recovery Time C' with support of 20%.

A pattern element is a part of a pattern. In the example above, Condition 'A', Treatment 'B' and Recovery Time 'C' are the three elements of the pattern. Treatment 'B' leads to a Recovery Time 'C' is also an element, as it represents only a part of the pattern.

Support essentially quantifies the frequency with which a pattern occurs within the original data source, expressed as a percentage. The minimum support threshold is generally set by the user at runtime. Further to this, elemental support is the support for an isolated element in a pattern. This concept is explained in detail in foundation work by the author [4].

Confidence quantifies as a percentage the degree to which we can rely on the presence of part of a pattern given another part of the same pattern within the data source. For example, given Condition 'A', the confidence states how often we could expect Treatment 'B' to also occur in the same pattern.

Medical diagnostic decision making

The decision making processes of medical practitioners incorporates subjective and objective aspects and diagnosis generally applies one of two methods; by exclusion or by pattern categorisation [5][6][7]. The evidence required for diagnosis by each of these methods is different. Diagnosis by exclusion involves examining the results of objective clinical tests to eliminate potential diagnoses. The alternative method of diagnosis by pattern categorisation incorporates both objective testing and subjective

experience. A diagnosis is developed by comparing the presenting patient's disease pattern and test results to known patterns of disease and treatment. This frequently requires the doctor to discern which pattern elements exert the greatest influence on the diagnostic process and use these parts to match to longer patterns representing disease progression and treatment outcomes.

For automated processes to be applied and accepted it is important that they are able to mirror or facilitate current practices. This requires the provision of knowledge which is able to be both trusted and descriptive from an objective viewpoint and informative in a way which assists in the subjective appraisal of a patient. Unfortunately many data mining outputs (patterns) are presented in a non-intuitive and frequently opaquely coded form. The above diagnostic methods suggest that there is a requirement for heuristic triggers and substantiated hypotheses which can suggest rather than dictate a course of action based upon pattern similarity. An added complication, as described in the pattern categorisation method above, is the need to be able to deconstruct the pattern into more and less influencing pattern elements upon which to base the diagnosis or treatment. If we accept this requirement, it is a logical step to move towards an automated process of identifying and describing the important elements of patterns derived from the application of data mining technologies and it is this precept that defines current work and the development of ADAPT.

The ADAPT process

Data mining outputs are currently deficient in their application to the medical domain as they are not able to identify which pattern elements directly affect the medical outcome or which have no effect and are therefore little more than confounders, although this is necessary if patterns derived from medical data are to assist in processes such as diagnosis as explained earlier. Whilst previous work by the author has provided a proof of concept discussion for achieving this, it was not formalised or applied in a structured, practical sense.

The ADAPT (Automated DAta Pattern Translator) process aims to provide guidance and structure to the application of translating technical outputs into clinically relevant patterns of diagnosis or treatment, and presents a novel approach to post-mining pattern evaluation. There are six steps identified in the process as follows:

1. Identify a set of interesting patterns.
2. Calculate the representative pattern element weightings.
3. Deconstruct the support for each pattern and determine its elemental supports.
4. Determine the positive, negative and inert elements.
5. Order patterns by their degree of representation.
6. Present patterns with their associated heuristics.

Data mining processes that have attempted to evaluate the patterns presented have focussed primarily on step 1, however approaches taken have often been unsuitable for the medical domain due to the wide range of user types and definitions of interest. Medically focussed solutions have been developed but have generally provided a user specific solution. Unfortunately this step alone presents patterns which are unsuitably formatted, and/or do not inform sufficiently well, and require analysis by domain experts to enable them to be considered for clinical application [8][9][10]. The need to supplement information content to aid understanding of the patterns produced as a result of data mining is the focus of steps 2 to 4[1]. Presentation of patterns in a logical and value driven order is the focus of steps 5 and 6. Steps 1 to 4 are described following.

Identify interesting patterns

The ability to define interest is one which has held the focus of data mining researchers since the birth of data mining and several surveys on interestingness measures have been published including [11][12][13][14]. Unfortunately these measures are usually applied in a fixed and limited manner, and there is little scope to develop a more subjective approach to defining what is interesting to a particular user. This is highly important in medicine as there is a wide range of users and user types. This need was recognised by Shillabeer and Roddick [8] who developed a system of role based pattern evaluation which allows each user to define their own subjective opinion on what is interesting and select and apply measures to apply this definition. Whilst defining and applying interest during mining runs involves a variety of statistical processes, identifying interesting patterns post-mining through ADAPT could be as simple as eliminating patterns which do not contain the particular attributes for a specific investigation as the statistical analysis may have been integrated into the mining process.

Representative element weighting

The determination of element representation has been shown to be possible through the application of a technique commonly used in the field of Information Retrieval (IR) [4]. The technique tested and shown to be applicable in this situation is known as TFIDF. TFIDF is a combination of two calculations TF which quantifies the incidence of a term in a focal document and IDF which is the incidence of a term in the document corpus. In combination these theories describe the entropy of a piece of information. The concept of information entropy was introduced by Shannon [15] who defined it as a measure of the average information content associated with a random outcome. Information entropy relates to the amount of uncertainty about an event associated with a given probability distribution. These calculations have been demonstrated to apply in the medical data mining context to reveal the level at which a pattern is representing the data set from which it was produced [4]. In effect, the application of TF can quantify the frequency with which a pattern element occurs within a particular sub-set of patterns of equal length. The concept of IDF can be applied to determine the occurrence frequency of a pattern element within the original data set. Through a comparison of these two values it is possible to show whether the patterns are representative of the source data set or if they are anomalies and therefore potentially less applicable to a general population but more applicable in a specialised population.

1 These concepts have been discussed in more detail in previous work by the author [4] and are paraphrased for clarity in following sections.

Pattern support deconstruction

Support deconstruction is a method by which we can determine the additive effect of each element in a pattern. This is achieved conceptually by calculating the support for an element before and after adding each other element to the pattern. This is done by identifying the participation of the focal element in all relationships, then subtracting the elemental support for each longer element it participates in from its traditional support. . For each focal element (F) the process can be formally denoted as follows:

$$\mathrm{FEsupport}_{\mathrm{length}n} = \mathrm{FTsupport} - \mathrm{Esupport}$$

(E denotes elemental and T traditional).

The effect of applying this formula is demonstrated in Table 1 by deconstructing a fictitious pattern with its support values.

Table 1 - Comparison of traditional and elemental support

Elements	A	AB	ABC	ABCD	TOTAL
Traditional support %	16	10	5	4	N/A
Elemental support %	6	5	1	4	16

The simplified example in Table 1 shows that the effect of adding element C to element AB is negative in that it has a lower elemental support than AB alone. In contrast adding element D to element ABC increases the elemental support of ABC, and hence denotes an increased incidence of the pattern due to the presence of D. From these examples C would be deemed a negative element and D a positive element. An inert element is one which does not significantly increase or decrease the elemental support.

This method has shown promise in defining how much each element affects the outcome described in the pattern [4]. In a real world example this could be applied to reveal the most or least effective combinations of medications or treatments for a particular condition.

Methodology

ADAPT was tested using data collected from the Royal Australasian College of Surgeons National Breast Cancer Audit[2,3].

Association rule patterns were produced from these data to demonstrate that ADAPT is able to perform well on the most problematic mining algorithm for medical data due to the potential for a large number of patterns to be presented. It is hence the area which stands to benefit most from ADAPT.

The original source data held 23,259 patient records, 53,950 separate surgical procedure records for those patients and 82 attributes with an average of 5 potential values per attribute across three tables. After combining patient records with their surgical procedures, allowing for multiple procedures performed together, then removing duplicate columns and extraneous data including dates, 42,705 records with 39 columns were mined using a simple association rule mining tool with support set at 1%.

ADAPT was applied to test the validity of four theories, and provide information relating to one area of interest described in the data dictionary provided with the data. The 5 cases analysed were:

1. "Some treatment recommendations differ by menopausal status, e.g. Ovarian ablation is not indicated after the menopause."
2. "The omission of axillary dissection should be considered only in the case of small primary tumours and is least desirable in pre-menopausal women but is standard in cases of DCIS"
3. "The presence of a significant amount of DCIS in or adjacent to an invasive tumour is a predictor of high relapse rates following wide local excision and radiotherapy.
4. "For DCIS, 'clear margins' as defined by no tumour within 1mm of any inked margins are associated with a high rate of recurrence."
5. It was also suggested that "correlations between excision technique and cosmetic result may be useful."

Interesting patterns were defined as those which contained the particular attribute values required to test the cases - as described in the results section.

Results

Association rules were developed to provide patterns relating to the five cases listed above using the attributes and values detailed in Table 2. For some cases it was necessary to apply different sets of attributes and develop more than one set of patterns for analysis to test each part of a more complex theory in isolation.

The results of the five test cases are detailed in Table 3 which shows elemental supports and TFIDF values. TFIDF was categorised on whether it fell in the upper or lower values for representativeness. Positive elements are shown in bold, negative in italic and inert in standard text and were classified as described earlier. One is denoted as both positive and negative based upon the elements which preceded it. Table 4 shows the descriptive potential of ADAPT based on these heuristics.

Overall, only one of the theories was fully supported by the data and two were fully discounted with one gaining partial support. The TFIDF value was able to indicate if this result is generally representative. Where the theory pattern was in the lower level of representativeness it suggests that the theory should not be depended upon and its foundation should be investigated further.

Discussion

Data mining has many documented benefits for the medical domain and much work is being done to provide

2 The supplied data has since been superseded and hence results detailed herein may or may not accurately reflect current data or practices within the management of breast cancer in Australia or New Zealand and hence should not be relied upon in a clinical setting.

3 Acknowledgement and thanks are hereby given to the ASERNIP-S Adelaide team for their permission to use this data.

medicine specific solutions to data analysis problems. However this work has focussed on the adaptation of technologies to manage the complexities and non-uniform nature of medical data and while the management of input is being addressed, research by the author has been unable to find evidence of a similar effort in the management and translation of outputs. This is an issue when non statisticians or computer scientists are attempting to make sense of the technology and its products. It has been reported that medical practitioners in general have little experience in statistical analysis and as a result are unable to apply or comprehend results which do not match their sphere of knowledge and understanding and as such they need assistance in translating or deciphering the meaning or content of statistical analysis which is beyond the complexity of a 0.05 p-value or confidence interval of 95% [4][16]. This has a potential two pronged effect, it puts data mining technologies and the like out of the reach of many medical practitioners and, it necessitates the application of only the most basic analytical tools thus negating the potential of the more powerful tools.

The contribution of the work presented here is in its ability to broaden the applicability and marketability for the technology by making outputs approachable to all user types and levels without minimising the complexity or range of processes available. It does not attempt to modify the data mining process as the algorithms and statistical methods available currently are generally applicable and effective for the medical domain and have been used successfully by many medical teams. However these projects are often undertaken by specialists who understand the tools and technologies or they have required manual post mining translation or interpretation of outputs by domain specialists [1][10]. The results presented here show that ADAPT is able to facilitate the ordering and presentation of complex outputs in a more intuitive language and provide the knowledge items required for decision making as described earlier. It is also able to overcome some of the more potent criticisms of the technology, for example the belief that the results of data mining are not always representative of the data set from which they were created and they are often misreported as a result [17][18][19]. Whilst ADAPT pattern descriptions are currently manually created, a future challenge will be to create an automated natural language description of patterns based on the heuristics provided by the process.

Conclusion

Results have been developed from patterns which are far simpler that the technology is capable of providing; however the theories were often binary and did not require the production of multi-faceted patterns. Data mining would not generally be applied to develop such simple patterns but it has proved to be a suitable demonstration of the process in a realistic application. Also, the focus here was on the application of the ADAPT process rather than on the application of data mining technologies and the simplistic patterns provided an unambiguous and non-complex platform from which to work. The logical next step is to process the results of more complex association rule mining through ADAPT and validate the output through empirical testing. This paper tested and demonstrated the potential for ADAPT on essentially one tailed tests, but the real power of the methodology and its parts will become evident when applied to purely exploratory data mining.

Table 2 - Pattern attributes and values for each case

Case	Focal Element A	Element B	Element C	Element D
1	Menopause Status 1	Ovarian ablation 1	NA	NA
2.1	Ax Dis. 3	DCIS 2	NA	NA

A Data Mining Approach to Analyze Non-compliance with a Guideline for the Treatment of Breast Cancer

Amir R. Razavi [a], Hans Gill [a], Hans Åhlfeldt [a], Nosrat Shahsavar [a,b]

[a] *Department of Biomedical Engineering, Division of Medical Informatics, Linköping University, Sweden*
[b] *Regional Oncology Centre, University Hospital, Linköping, Sweden*

Abstract

Postmastectomy radiotherapy (PMRT) is prescribed in order to reduce the local recurrence of breast cancer and improve overall survival. A guideline supports the trade-off between benefits and adverse effects of PMRT. However, this guideline is not always followed in practice. This study tries to find a method for revealing patterns of non-compliance between the actual treatment and the PMRT guideline.

Data from breast cancer patients admitted to Linköping University Hospital between 1990 and 2000 were analyzed in this study. Cases that were not treated in accordance with the guideline were selected and analyzed by decision tree induction (DTI). Thereafter, four resulting rules, as representations for groups of patients, were compared to the guideline.

Finding patterns of non-compliance with guidelines by means of rules can be an appropriate alternative to manual methods, i.e. a case-by-case comparison when studying very large datasets. The resulting rules can be used in a knowledge base of a guideline-based decision support system to alert when inconsistencies with the guidelines may appear.

Keywords:

breast cancer, data mining, decision tree induction (DTI), guideline, postmastectomy radiotherapy (PMRT).

Introduction

The aim of postmastectomy radiotherapy (PMRT) of the chest wall and the regional lymphatics is to reduce recurrence of cancer in the chest wall and improve overall survival [1, 2]. Currently, many patients with breast cancer are treated with breast conserving surgery rather than mastectomy. However, a considerable percentage of women still require or choose the surgical procedure of mastectomy.

Clinical benefits related to PMRT depend on the treatment technique and the risk of breast cancer recurrence. Patients with a large primary tumor (T3), and those with four or more positive axillary nodes or pectoral fascia involvement are at substantial risk for locoregional recurrence, and are often treated with PMRT [3]. However, there is a trade-off between the benefits and adverse effects of this treatment. The proportion of patients who are likely to benefit from this treatment is larger when the risk for locoregional recurrence is high. Furthermore, inclusion of the heart or lungs in the target volume may result in an increased number of non-cancer deaths and a risk for a secondary cancer [3, 4]. Therefore, guidelines based on evidence obtained from different studies are used for prescribing PMRT to patients who have undergone mastectomy as their primary surgical treatment [5, 6].

In general, clinical guidelines are developed to help physicians make decisions about appropriate treatment for specific circumstances [7]. Guidelines can result in improvements in overall healthcare, including clinical practice, and can provide decision support tools for practitioners [6].

Despite their many advantages, physicians' adherence to clinical guidelines is not 100 percent. A number of reasons for this have been studied, such as physicians' disagreement with guidelines [8], poor availability [9], and low outcome expectancy on the part of clinicians [10]. Some of these barriers are also associated with patient-related obstacles [11].

Non-compliance with the guideline in some individual cases is of less general importance. These patients may have refused to accept the treatment. In some cases, physicians prescribe the treatment, despite the fact that it is not recommended or suggested by a guideline, because they believe that the treatment is appropriate for that particular patient. However, it is essential to analyze and investigate systematic disagreement between the actual treatment and the clinical guideline recommendations [12]. If repetitive patterns are identified, then they can be used as rules to alert physicians to follow the related guideline more carefully.

Additionally, there may be useful information in these disagreements. Every institution has its own experience with such treatments and these repetitive patterns can provide the writers of guidelines with new insight that may result in improvements in the guidelines. These patterns may even show that it is necessary to check more clinical information regarding a specific treatment.

Table 1 - Study variables and some statistical information about them

Variable	Valid	Missing	Mean		SD	
			BHMVs	AHMVs	BHMVs	AHMVs

* from pathology report, † Nominal variable

One method for finding these disagreements is to evaluate each case in terms of the guideline and compare the recommendation to the actual treatment received by the patient. When there is disagreement between the guideline and the real treatment, the reason can be analyzed by studying each case separately. The problem is that if there are too many cases, it will take too long to investigate the reason for disagreements, and therefore an automatic or semi-automatic method would be better. A method that ignores sporadic disagreements and can find repetitive patterns is preferable.

Data mining as a method for discovering meaningful new patterns and trends can be applied to the data to find repetitive patterns in disagreements with the related guideline. In this method, instead of evaluating each case with the guidelines, groups of cases that are similar are evaluated. These groups are described by a set of decision rules after a decision tree is trained with the available dataset.

In this study, we show the level of compliance in prescribing PMRT by analyzing a regional dataset from a breast cancer register. Then a data mining method is applied to the dataset to find patterns of non-compliance between the guideline and the real collected figures for PMRT. This is preceded by filtering the dataset using the guideline rules and selecting the cases that received treatment that did not comply with the guideline recommendations.

Materials and methods

In this study, a dataset during a certain time period was initially selected from a regional breast cancer register. Outliers were omitted and missing values were handled. Then a locally modified guideline for postmastectomy radiotherapy (PMRT) was selected and data were filtered in accordance with that guideline. Only cases that were not treated according to the PMRT guideline were selected. Decision tree induction (DTI) was used as the analysis method to find noteworthy patterns for inappropriate PMRT prescription.

Data source and variables

Data were collected from 962 female patients with the diagnosis of malignant breast cancer. Patients were admitted to Linköping University Hospital, and the earliest patient was diagnosed on 1 January 1990 and the last one on 29 December 2000.

Variables from the tumor marker register were linked and matched by using specific identification numbers. The tumor marker register contains information about tumor markers for breast cancer such as S-phase fraction and

receptors for estrogen and progesterone. After matching different data sources, repetitive cases were identified and omitted. There were 858 cases after this pre-processing step.

Thereafter, missing values for continuous variables were handled using the expectation maximization (EM) method [13]. This was done in SPSS. Cases with missing values for nominal variables and PMRT (98 cases) were omitted. With this step, the number of cases decreased to 759. Table 1 shows some descriptive statistics about the dataset before and after handling missing values. One case was omitted because of an incorrect age at the time of diagnosis.

The guideline

In this study, adherence to a local modification of the guideline for postmastectomy radiotherapy was studied [5]. Some important points in the guideline are shown in Table 2. However, the original guideline was changed at Linköping University Hospital in order to conform with local experiences of physicians who have worked in this field for a long time. The main modifications comprise considering age as an important factor and recommending the treatment for patients younger than 75 years, and considering PMRT for patients with any number of lymph nodes with malignant invasion.

Table 2 - Selected parts of the guideline for postmastectomy radiotherapy

Patients with four or more positive axillary lymph nodes. PMRT is recommended for patients with four or more positive axillary lymph nodes.
Patients with one to three positive axillary lymph nodes: There is insufficient evidence to make recommendations or suggestions for the routine use of PMRT in patients with T1/2 tumors with one to three positive nodes.
Patients with T3 or stage III tumors: PMRT is suggested for patients with T3 tumors with positive axillary nodes and patients with operable stage III tumors.
…

Non-compliance with the PMRT guideline

With knowledge of the actual treatment for each patient, a contingency table was drawn showing the recommendations from the PMRT guideline and whether or not the patient received this treatment. Cases that were not treated in accordance with the guideline were identified and extracted for further analysis. In order to process a comparison between the dataset and the guideline, the text guideline was manually converted to rules. The rules were applied to the dataset as SQL queries to filter cases that were not treated according to the PMRT guideline.

Data mining

In the resulting dataset, repetitive patterns of inconsistencies with the guideline were identified by a data mining method. For this purpose, decision tree induction (DTI) was used to analyze the filtered dataset. The algorithm uses information gain as a heuristic for selecting the variable that will best separate the cases into each outcome. In a decision tree, each internal node denotes a test on variables, each branch stands for an outcome of the test, leaf nodes represent an outcome, and the uppermost node in a tree is the root node. Understandable results of acquired knowledge and fast processing make decision trees one of the most frequently used data mining techniques [14].

In this study, DTI was carried out using the J48 algorithm in WEKA [15]. The J48 algorithm is the equivalent of the C4.5 algorithm developed by Quinlan [16]. Post-pruning was also done to trim the resulting tree.

Results

Table 3 is a contingency table showing the outcomes from the PMRT guideline and whether or not the treatment was done for the patient. Decision tree induction (DTI) was used to analyze 51+74 cases whose treatments were not in accordance with the guideline, with accuracy, sensitivity and specificity equal to 97.6%, 0.97 and 0.96, respectively. Despite training the decision tree with twelve variables (Table 1), just three of them (Age, Tumor size, Number of involved LNs) became important nodes in the resulting tree (Table 4).

The tree is shown in Figure 1, with four leaves and an overall size of seven nodes. In this figure, there are two numbers in parentheses in the leaves. The first number shows the number of cases who reached this leaf and the second shows the number of cases for whom the outcome was not predicted to happen. In the boxes, the numbers in parentheses indicate the number of cases assigned to that node, followed by the number of cases that are incorrectly classified as a result. Each path through the decision tree from the root node to the end leaf is a rule, and therefore the tree can be easily transformed to rules. The resulting rules are shown in Table 4.

Discussion

Increasing guideline adherence is of importance in improving the quality of care [17]. Many ongoing research efforts are focusing on the feasibility of using guidelines to increase the quality of care [18]. Finding the reasons for why adherence to guidelines is not 100% would be useful in healthcare management. However, when it comes to detecting and grouping reasons for non-compliance, it can be rather difficult to review each case separately and then categorize the reasons later. This would be exhausting, especially when the number of cases is very large, such as in national registers, and a more efficient method is therefore preferable. Svatek et al. [12] used a rather similar approach for finding non-compliance patterns with the 1999 WHO/ISH hypertension guideline. They used a lim-

ited number of cases (48 patients) to detect and visualize association rules for non-compliance patterns.

Advani et al. [19] proposed the Quality Indicator Language (QUIL) for modeling and creating a quality assessment method to score non-compliances. In contrast to specifying patient-based quality constraints, our approach is used in order to find repetitive patterns while ignoring sporadic disagreements.

By classifying patient data with similar features, an easier and faster methodology has been presented in this study. With this method, good accuracy (97.6%) can be achieved for the resulting rules partition, and rules representing outliers or exceptions can be removed by pruning. Pruning is an intrinsic part of the C4.5, and its equivalent in WEKA (J48), and it is implemented to decrease the size of the tree and make it more robust.

Table 3 - Contingency table for PMRT and decision according to PMRT guideline

		Guideline PMRT	
		-	+
Datset PMRT	-	356	51
	+	74	278

Prior to data mining, the data are filtered by the guideline in order to limit the cases to those with inappropriate treatment compared to the guideline. This is done because the aim is not to predict the prescription of PMRT in new cases but to find patterns of non-compliance with the PMRT guideline.

Table 4 - Rules transformed from the decision tree

1- IF age is younger than 74 years **and**
no LN involvement is present **and**
tumor size is smaller than or equal to 43 mm
THEN PMRT+
2- IF age is older than 74 years
THEN PMRT+
3- IF age is younger than 74 years **and**
no LN involvement is present **and**
tumor size is larger than 43 mm
THEN PMRT-
4- IF age is younger than 74 years **and**
Some LNs are involved (>=1)
THEN PMRT-

Abbreviation: LN: lymph node, PMRT: postmastectomy radiotherapy.

Non-compliance with the PMRT guideline can have different reasons, and these should be carefully studied. Rule number 4 (Table 4) concerns patients younger than 74 with some involved LNs but no PMRT prescription, which is pronounced non-compliance with the guideline.

Occasionally, non-adherence is due to the cut-offs in a guideline. For instance, if the patient is 76 years of age and the cut-off in the guideline is 75 years, should the clinician omit the treatment? If he/she prescribes PMRT for this patient, can this be considered non-adherence to the guideline? Alternatively, when the tumor size is 45 mm, and not larger than 50 mm as stipulated by the guideline for receiving the treatment, is it acceptable to give the treatment? These examples show that the clinician's flexibility in prescribing PMRT can also result in non-compliance with the guideline, but this is not pronounced non-compliance. However, fuzzy set theory can be used to handle this type of non-compliance. Representing states of variables by fuzzy sets in order to quantify them into different intervals can be a good modification of the resulting rules [20].

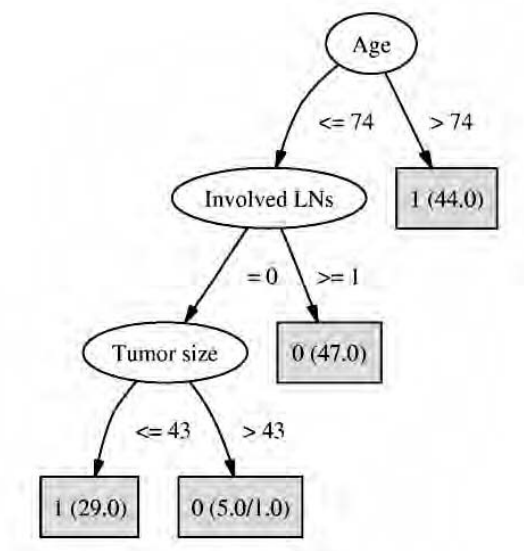

Figure 1 - The resulting decision tree.

In decision support systems, alerts play an important role in increasing the efficiency of healthcare systems [21]. Supporting clinicians in following the guidelines can be done by using the resulting rules as alerts for identifying inconsistencies between clinicians' practices and guidelines. Resulting rules from mining historical data can also be embedded in knowledge bases of guideline-based decision support systems.

In future work, researchers are going to study patient records for the same cases with inconsistencies with the guideline to determine the detailed reasons for non-compliance and any clinical consequences. The reasons will be categorized and compared with the rules from DTI. Furthermore, combining this with fuzzy set theory to analyze

non-compliance with the guideline seems to be a good modification of our current approach.Conclusion

Analyzing cases in which there is non-compliance with the guideline using decision tree induction can reveal patterns of systematic inconsistency between the actual treatment and PMRT. Grouping patients according to decision tree rules makes it easier and faster to categorize reasons for non-compliance as compared to a case-by-case analysis. By embedding the resulting rules in a knowledge base, they can also be used in constructing guideline-based decision support systems to enhance compliance with guidelines.

Abstract

Prognostic models are tools to predict the outcome of disease and disease treatment. These models are traditionally built with supervised machine learning techniques, and consider prognosis as a static, one-shot activity. This paper presents a new type of prognostic model that builds on the Bayesian network methodology that implements a dynamic, process-oriented view on prognosis. In contrast to traditional prognostic models, prognostic Bayesian networks explicate the scenarios that lead to disease outcomes, and can be used to update predictions when new information becomes available. A recursive data analysis strategy for inducing prognostic Bayesian networks from medical data is presented, and applied to data from the field of cardiac surgery. The resulting model outperformed a model that was constructed with off-the-shelf Bayesian network learning software, and had similar performance as class probability trees.

Keywords:

prognosis, statistical models, Bayesian networks, thoracic surgery

Introduction

Prognostic models have become important instruments in medicine. Given information on the condition of a patient, they predict the future occurrence of medical events (e.g., complications, recurrence of disease) and outcomes (e.g., survival). These models are currently used for prediction purposes at levels that range from individual patients (where their predictions help doctors and patients to make treatment choices) to patient groups (where they support health-care managers in planning and allocating resources) and patient populations (where they provide for case-mix adjustment in evaluations of delivered care) [1,2].

Prognostic model are usually induced from historical data by applying supervised data analysis methods such as multivariate logistic regression analysis or decision tree induction. This approach has three limitations. First, supervised data analysis methods apply attribute selection before inducing a model, often removing many attributes that are deemed relevant for prognosis by users of the model (e.g., clinicians). Second, the resulting models regard prognosis to be a one-shot activity at a single, predefined point in time. In reality, however, expectations with respect to a patient's future will regularly change as new information comes available during a disease or treatment process. And third, these models impose fixed roles of predictor (independent variable, input) and predictee (dependent variable, output) to the attributes involved. This ignores the dynamic nature of care processes, where today's outcome helps to predict what will happen tomorrow.

This paper introduces a new type of prognostic model, based on the Bayesian network methodology [3,4], that overcomes these limitations. Since their introduction in the 1980s, a large number of Bayesian networks have been developed for medical diagnosis and therapy selection (e.g., [5,6]). Prognostic applications of Bayesian networks have however been rare [7]. We describe the advantages of prognostic Bayesian networks (PBNs) over conventional prognostic models, and present a dedicated algorithm for inducing this type of network from data. The algorithm is illustrated with an application in the field of cardiac surgery. We compare the predictive accuracy of the PBN that was developed with our algorithm with a Bayesian network that was developed using off-the-shelf software, and with three CART [8] models that were developed based on the same data.

Materials and methods

Prognostic Bayesian networks

Suppose that we wish to build a prognostic model for a particular surgical procedure, using historical data from patients who underwent this procedure. The dataset includes attributes regarding diagnosis, presurgical condition, type of surgery, course of the operation, postsurgical condition, and outcome (at hospital discharge) of each patient. Generally speaking, the surgery type will depend on the diagnosis, the patient's presurgical condition will influence how the operation proceeds, and together with

the type of surgery this will largely determine the patient's condition after surgery. The patient's outcome, finally, will depend on that postsurgical condition. These relations are listed in Table 1. Scenarios of complicated and uncomplicated surgeries are typically cast in terms of these variables and their relations.

Now suppose we build a prognostic model (to predict patient outcomes) from these data using a conventional supervised learning method (e.g. logistic regression analysis). This method first requires us to choose the moment of prediction, e.g. at hospital admission (prior to surgery), or just after the operation. In the first case, the attributes regarding the course of the operation and the patient's postsurgical condition are excluded from the model, as they are not available at the chosen prediction moment. Furthermore, the patient's diagnosis would be removed by attribute selection because it has no value for predicting the outcome once we know the surgery type. The resulting model would therefore predict outcome in terms of presurgical condition and type of surgery (Table 1). Similarly, the postsurgical model would just use the patient's postsurgical state to predict the outcome, as information from earlier phases would not have additional predictive value.

Table 1 – Relations between attributes in surgery example

Causal relations	diagnosis → surgery type surgery type, presurgical condition → operation course surgery type, operation course → postsurgical condition postsurgical condition → outcome
Presurgical model	presurgical condition, surgery type → outcome
Postsurgical model	postsurgical condition → outcome

Summarizing, such a conventional method forces us to reduce the prognostic task to a one-shot, static activity. It creates a simplified representation of the problem domain that supports making prediction at a single moment; updating prognostic expectations when new information comes available is not possible. Because many attributes are not included into these models, their form is couter-intuitive and often misunderstood by domain experts.

This paper puts forward a new type of prognostic model, that builds on the theory of Bayesian networks; a sample network for the surgery example is shown in Fig. 1. Because Bayesian networks allow us to explicitly model, and reason with, probabilistic independency relations, domain attributes can be included into this type of model even when their prognostic influence is indirect and depends on subsequent events. For instance, the network shown in Fig. 1 includes 'diagnosis', even though it has no direct influence on the outcome. Furthermore, Bayesian reasoning methods allow us to make predictions at each moment during the care process, thus doing justice to the dynamic nature of prognosis in clinical medicine. Using the example network, we can make outcome predictions prior, during, and after surgery, for the same patient.

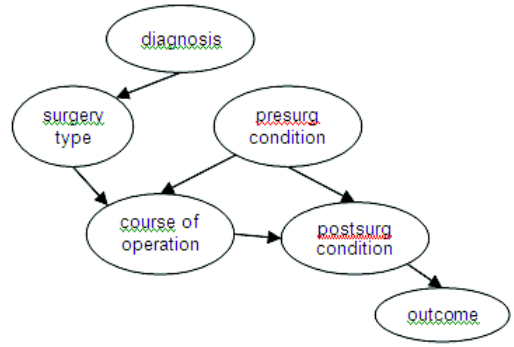

Figure 1 – Bayesian network for the surgery example

Learning Algorithm

Mathematically speaking, a Bayesian network B consists of a pair (G,), where G is a directed acyclic graph, and is a set of conditional probability functions. Each node in the graph G represents one attribute in the application domain; the arcs in the graph represent conditional independency relations between the attributes. For each attribute X_i, there exists a function $_i$ in that describes the estimated conditional probability distribution of X_i given its parents (X_i) in graph G.

In the past 15 years, various algorithms for learning Bayesian networks from data have been developed [9-11]. In these algorithms, learning the network is considered to be an unsupervised learning problem. Starting from an empty graph G, arcs are recursively added to the model to increase the likelihood

$$L(B \mid D) = \prod_{i=1}^{m} P(\gamma_i \mid D) \tag{1}$$

of the model given the data. Each time an arc $X_i \rightarrow X_j$ is added to the graph, the estimated conditional probability function $_j$ is adjusted to reflect the fact that X_j now depends on X_i. As a result, a greedy search through the space of all possible models is conduced, where preference is given to modelling strong correlations between attributes in the data. No single attribute is considered to be more important than any other attribute.

In prognostic Bayesian networks, there exist an outcome attribute, whose accurate prediction is of principal importance, and preference must be given to this prediction task during the construction of the model. For this reason, we developed a modification of the above learning scheme which starts with constructing a complete conditional probability function for the outcome attribute, and recursively builds up the conditional probability functions for the other attributes. As such, the Bayesian network learning task is approached as a set of supervised learning problems instead of a single unsupervised learning problem.

In brief, our algorithm proceeds as follows. Let $\mathbf{X} = \{X_1,\ldots, X_m\}$ denote the set of domain attributes where X_m denotes the outcome attribute. Let G be an empty graph (i.e., no arcs) with nodes corresponding to the attributes in $\mathbf{X}$. Let $I(X_i;X_j)$ denote the mutual information of attributes X_i and X_j. The algorithm now consists of the following steps:

1. Initialisation: Let Q be a priority queue with the outcome variable X_m as its only element.
2. Repeat
   i) X_i dequeue(Q)
   ii) From the non-descendants of X_i in graph G, select a predictive feature subset S_{Xi} for X_i
   iii) For each X_j in S_{Xi}, add an arc $X_j \rightarrow X_i$ to graph G,
   iv) Build a conditional probability model $_i$ for X_i using the attributes in S_{Xi} as covariates
   v) For each X_j in S_{Xi} and not in Q, enqueue(Q, X_j), with $I(X_j;X_m)$ as priority value until Q is empty.

In steps ii and iv, the dataset is used to select a feature subset and build a predictive model for attribute X_i. Any methods for feature subset selection and model building can be "plugged into" our algorithm here, provided that the resulting model provides conditional probability estimates. Examples of such methods are multivariate logistic regression analysis and class probability tree induction.

In step iii of the algorithm, the graphical part of the Bayesian network is extended with arcs leading from the attributes in S_{Xi} to node X_i. To arrive at a meaningful network model, it is possible to use knowledge of the temporal ordering of domain attributes in this step. This requires the specification of a temporally ordered set of attribute strata. Step ii of the algorithm is then modified to select attributes only from non-descendants of X_i in the graph that are not in higher temporal strata than X_i. As a results, all arcs in the graph will follow the flow of time.

Step v of the algorithm adds the selected features in S_{Xi} to the queue Q unless they were enqueued before. Their rank in the queue is determined by their prognostic value: attributes with a strong correlation to the outcome are given a high priority. Thus, the algorithm recursively builds local predictive models for the the outcome attribute and its predictors. The set of all local models eventually constitutes the quantitative part of the prognostic Bayesian network, .

Data

The learning algorithm was applied to data from 10,114 patients who underwent cardiac surgery in the Amphia Hospital, a teaching hospital in Breda, the Netherlands, between January 1998 and November 2004. This dataset contains preoperative patient characteristics (demography and cardiovasculair condition), details of the surgical procedure, measurements during the first 24h of postoperative ICU stay, occurrence of postoperative complications, and clinical outcomes (death, length of ICU stay). Table 2 lists the attributes of the dataset, grouped in temporal strata that were defined in consultation with three domain experts (PMJR, EdJ, BAdM). Strata 1-3 contain preoperative attributes, strata 4-6 details of the operation, and strata 8-10 postoperative attributes. Stratum 7 and 11 define clinical outcomes: death during surgery, death during recovery after the operation, and death during hospitalization. The latter outcome attribute summarizes the former two:

$$\texttt{hospmort} = \texttt{ORmort} \vee \texttt{postORmort}. \qquad (2)$$

Table 2 – Attributes from the cardiac surgery dataset

Stratum	Name	Description
1	age	age
2	bmi	body mass index
	diabetes	diabetes mellitus
	ejfrac	ejection fraction
	precreat	serum creatinin
	pulmhyp	pulmonary hypertension
	surtype	surgery type (intention to treat)
3	emerg	emergency surgery
4	ecctime	extra-corporeal circ. (ecc) time
5	eccacctime	ecc minus aortic cross-clamped time
6	temp	postsurgical body temperature
7	ORmort	death during surgery
8	bicmin	minimal bicarbonate (ICU)
	creatmax	maximal serum creatinine (ICU)
	fiO2	fraction inspired oxygen (ICU)
	meanbpmax	maximal mean blood pressure (ICU)
	meanbpmin	minimal mean blood pressure (ICU)
	ptt	prothrombine time (ICU)
9	ICUlos24h	ICU length of stay longer than 24h
10	cardcomp	cardiac complications
	infect	infection
	neurcomp	neurological complications
	pulmcomp	pulmonary complications
	mof	multiple organ failure
11	postORmort	death during postoperative recovery
	hospmort	hospital death

Two hundred and seventy-seven of the 10,114 patients died during hospitalization (2.7%): 66 patients died in the operation room, 196 died at the ICU, and the remaining 15 patients died at the nursing ward. From the 9,837 surviving patients, 6,232 (63.4%) were discharged from the ICU within 24 hours.

We used the method of class probability trees from the tree building methodology Classification and Regression Trees (CART) [8] as supervised learning method in our network building procedure. Compared to decision trees, class probability trees estimate the (conditional) probability distribution of outcome classes, instead of predicting the most probable class. All tree models were developed using the

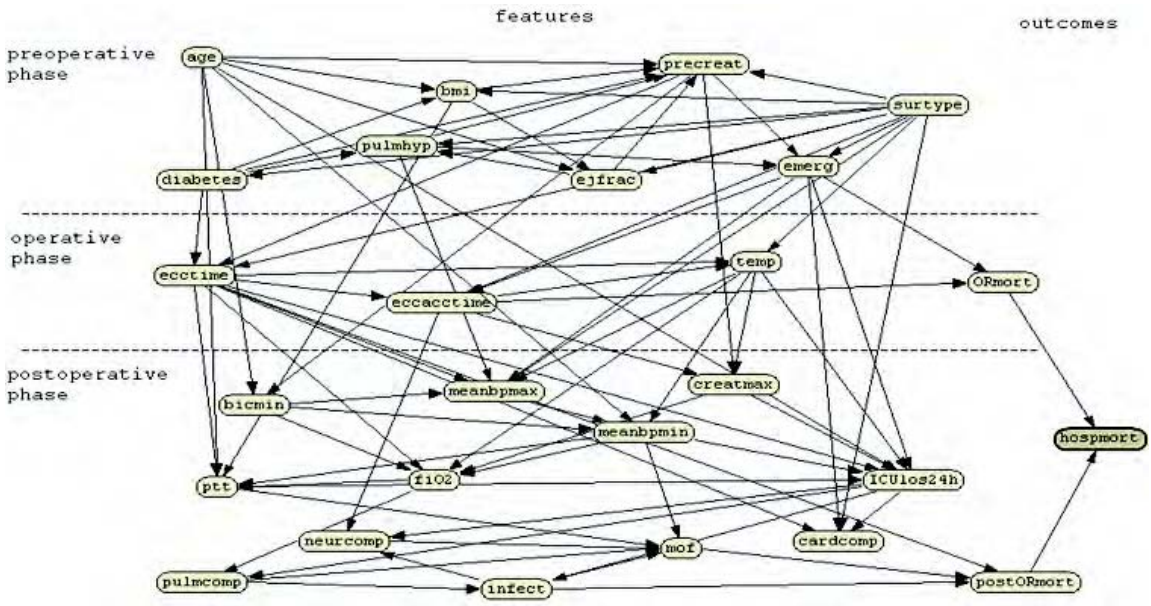

Figure 2 - the prognostic Bayesian network for the domain of cardiac surgery

S-plus library *Recursive Partitioning and Regression Trees* [12], which is an implementation of CART.

Model evaluation and comparison

To evaluate the predictive performance of the network model, the dataset was randomly split into a training set (2/3) and a test set (1/3), and three mortality predictions were made for each patient in the test set: a) using preoperative data only (strata 1-3 in Table 2), b) using preoperative data and information on the course of surgery (strata 1-6), and c) using preoperative data, surgical data, and measurements from the first 24h of ICU stay (strata 1-10).

For each of these three prediction moments, the predictive accuracy of the network model was quantified in terms of area under the ROC curve (AUC) [14]. In the evaluation of postsurgical predictions, patients who died in the operations were removed from the test dataset. In the evaluation of predictions at 24h after surgery, also patients who had died during this first postoperative day were removed.

To place the measured performance in perspective, four additional prognostic models were developed: one Bayesian network was learned using off-the-shelf software (BN Powerconstructor, [11]), and individual tree models were induced for the prediction moments a, b, and c. To enable a fair comparison, the grouping of variables into temporal strata (Table 2) was used to constrain the network topology of the BN Powerconstructor model. The tree models were developed using the class probability tree learning method described earlier, and are regarded as representative for conventional prognostic methodology.

Results

Network model

The prognostic Bayesian network for cardiac surgery is shown in Fig. 2. As appears from the model, the risks of operative death (`ORmort`) primarily depend on elective status of the operation (`emerg`) and duration of surgery (`eccacctime`). Similarly, the risks of postoperative death (`postORmort`) depend on the occurrence of multiple organ failure (`mof`) and infections (`infect`) during postoperative recovery, and again duration of surgery (`ecctime`).

The model incorporates many other relations that are easy to understand from a clinical perspective. For example, patients with low amounts of body fat (low `bmi`) may experience coagulation problems (high `ptt`), leading to an increased risk of multiple organ failure (`mof`). Cardiac surgery requires complete anaesthesia, and therefore a lengthy operation (high `eccacctime`) may yield brain damage (`neurcomp`). A low postsurgical body temperature (`temp`) increases the risks of shock (low `meanbpmin`), which may lead to multiple organ failure and an extended stay at the ICU (`ICUlos24h`).

Evaluation and comparison

When comparing the network from Fig. 2 to the network that was developed using the BN PowerConstructor (BNPC) software, some remarkable differences in the network structure appeared. The BNPC network is relatively sparsely connected with 48 arcs compared to 85 arcs in our network. Furthermore, the sub-outcome `ORmort` has no parent nodes in the BNPC network, and therefore this model cannot predict operative death better than chance.

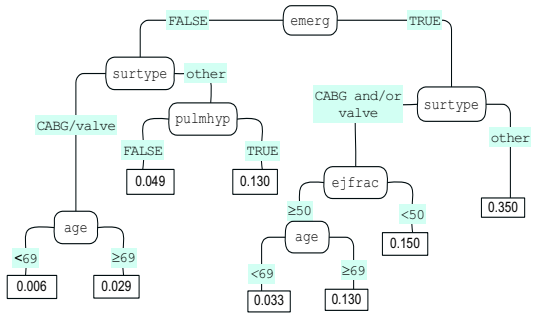

Figure 3 - Tree model for preoperative prediction

The tree model for preoperative mortality prediction is shown in Fig. 3. The model uses the attributes `emerg`, `surtype`, `pulmhyp`, `ejefrac`, and `age` for making predictions. Elective (i.e. non-emergent), uncomplicated procedures (CABG and valve surgery) on patients younger than 69 years have the lowest risk (0.6%), while emergent, complicated operations (e.g. aorta surgery) carry the highest risk (35%).

Table 3 shows the results of the evaluations of the five models on the test set. The network shown in Fig. 2, that was developed with the learning algorithm described earlier, has a moderate predictive accuracy (0.767) prior to the operation, which increases to good (0.834) at 24h after surgery. The PBNC network, however, performs inferior at all three prediction moments. The three class probability trees have similar predictive accuracy as the PBN from Fig. 2.

Table 3 - Predictive performance of models on test set.

	Bayesian networks		tree models
	prognostic learning algorithm	BN Power-Constructor	
prior to operation	0.767	0.693	0.767
at ICU admission	0.782	0.754	0.785
24h after surgery	0.834	0.787	0.834

Conclusion

PBNs overcome the limitations of traditional prognostic models by including all available attributes in the model and making their mutual relationships explicit. This allows for analyzing scenarios that include various stage of care, such as surgery, ICU stay, and subsequent recovery. Furthermore, Bayesian reasoning mechanisms implement a dynamic process-oriented view on prognosis where predictions are updated when new information comes available.

We have presented a learning algorithm PBNs in which local models are recursively learned in a top-down approach, starting at the outcome attribute. In our application, we used class probability trees as local learning method, but other supervised learning methods can be used as well. The PBN for cardiac surgery thus developed outperformed a Bayesian network that was developed using a standard method.

Role of Syndromic Management using Dynamic Machine Learning in Future of e-Health in Pakistan

Aijaz Qadir Patoli

Senior Medical Officer Health department government of sindh Pakistan

Abstract

Sexually Transmitted Diseases (STDs) constitute important primary health issues in Pakistan which face inadequacy of resources required in early detection and investigative procedures for their diagnosis and treatment. Syndromic approach to management of STDs is based on the identification of a consistent group of symptoms and syndromes to classify the exact disease or infection beforehand, so that further investigations are sought for based on these initial criteria. This paper envisions the results based on two different approaches: Human and Artificial Intelligence (AI) along with some examples of on-going usage e of Artificial Intelligence in Medicine.

Pakistan is in an early stage regarding the use of informatics in health care for sustainable health system but is also under international obligation to adapt it & WHO EMRO has developed an e-Health plan for the member countries including Pakistan.

The paper presents an informatics application model for a very common but important problem & development of such e-health applications, as starting point, will certainly have positive impact the future of development of e-Health in Pakistan.

Keywords:

sexually transmitted diseases/infections, artificial intelligence, syndromic management, strategic management, machine learning and neural networks

Introduction

Pakistan like other developing countries has been ravaged by sexually transmitted diseases (STDs). In 1996, the World Health Organization (WHO) estimated that, worldwide, there are 333 million new STD infections per year. The largest number of cases occurs in South East Asia (an estimated 150 million new STD cases annually) and sub-Saharan Africa (65 million cases annually) (Adler, 1996). The serious consequences of STDs include infertility, entopic pregnancy, low birth weight, stillbirth, chronic pain in women who have had pelvic inflammatory disease, late symptomatic syphilis, and mutilating lesions for individuals suffering genital ulcers (WHO, 1991). Further consequences include perinatal infections, ophthalmia neonatorum, spontaneous abortion, cervical cancer, and congenital infections (Costello, et al. 1994).

Perhaps the worst consequence, however, is the increased risk of the transmission of HIV with STDs. Improved management of STDs by primary health care workers in the Mwanza region of Tanzania reduced incident cases of HIV-1 infection by 42% in the treatment communities compared to controls. Ghys, et al. (1997) have shown that shedding of HIV in vaginal secretions is strongly correlated with gonoccocal (odds ratio: 1.9, C.I. 1.2-3.0) and chlamydial infections (odds ratio: 2.5, C.I. 1.1-5.8) and with cervical or vaginal ulcers (odds ratio: 3.9, C.I. 2.1-7.4). Furthermore, treatment resulted in a decrease of the genital shedding of the HIV virus from 42% to 21% (Ghys, et al. 1997). Finally, Wasserheit (1997) reviewed a number of studies examining the risk of HIV seroconversion relative to different STDs

Syndromic management is based upon the premise that there are strong correlations between syndromes (signs and symptoms) and the presence of a particular disease.

Thus, the health care provider diagnoses and treats STDs based primarily on the history and physical diagnosis, rather than upon evidence obtained from laboratory tests or microscopy. The WHO algorithms, eight of which are used in the papers reviewed here, involve the diagnosis of urethral discharge, genital ulcer disease, vaginal discharge and lower abdominal pain.[1.]

In a country like Pakistan, patients in need of an immediate diagnostic approach to their problems require the doctors to assemble a solution within as small a time as is possible andconducting test that would otherwise require a huge sum of money.

dset(VG) = {NG, CT, TV, CA, GV}
where,
VG = Vaginal discharge
NG = N. gonnorthoeae
CT = C. trachomatis
TV = Trichomonas vaginalis
CA = Candida albicans
GV = Gardnerella vaginalis

Fortunately enough, the symptoms and signs caused by a number of STDs are similar to be easily identified clinically. A group of such symptoms and signs, easily recognizable under clinical light is called a *syndrome*.

A combination of signs, symptoms, or phenomena seen in association with each other alerts the physician to compile

an early responsive strategy to work with throughout the course of the treatment of patient. This paper will focus more on an automated version of the course of treatment that would not only assist the *STI* specialists, physicians, or Venereologists but, also common Health Service Providers and Family Physicians Development of such application can be the first step & impart growth stimulating influence on the future of e-Health in Pakistan.

Discussion

Syndromic management for early detection of STDs/ STIs[2].

Sexually Transmitted Infections (STIs) commonly occur together. It is acceptable to manage a number of STIs at the same time in countries where there are poor diagnostic facilities. Doing so is cheaper and more effective, as the diagnosis is about the symptoms and not the cause of the disease. Such management is called *Syndromic Management*.

The pervasive stigma associated with sexually transmitted infections (STIs) inhibits open discussion, and leads to widespread misconceptions and unfounded fears of diagnosis and treatment. Syndromic management partly addresses these concerns by allowing for far less invasive diagnostic procedures[1].

Using Syndromic management, health workers and health service providers make a diagnosis from picking up and observing a collection of signs and symptoms. Evaluations are most likely to mean that a person might be suffering from one of a group of STIs that are *ALL* treatable with *ONE* treatment (usually consisting of more than one drug). This is very much like a broad-spectrum antibiotic that is given because it is effective against more than one microorganism.

dset(VG) = {NG, CT, TV, CA, GV}
dset(ON) = {NG, CT, OPO}
dset(Obs.) = dset(VG) U dset(ON)
where,
VG = Vaginal discharge
ON = Opthalmia neonatorum
NG = N. gonnorthoeae
CT = C. trachomatis
TV = Trichomonas vaginalis
CA = Candida albicans
GV = Gardnerella vaginalis
OPO = Other pyogenic organisms

Physicians declare Syndromic Management techniques as a cost-effective way of clinically identifying STI related diseases. In this technique, all possible syndromes associated to Sexually Transmitted Infections (STIs) may be classified beforehand. The list being small is put up in atabular format for doctors to construct associations with diseases, *refer to Table 1*.

Judgments regarding diseases caused by multiple syndromes in a single patient are evaluated based on a list as mentioned in Table 1. The common procedure of identifying the exact cause in question is based on unifying or intersecting the common causes or sets of diseases *(dset)*.

So, if a patient comes with a complaint of *Vaginal Discharge*, the *dset* for that particular syndrome is obtained from such a list. The doctor then perceives that the patient might have a disease from within that certain set of diseases.

However, if the same patient arrives to the doctor with another complaint regarding yet another syndrome, the doctor might have multiple sets of diseases, $dset_2$.

Common perception would lead the physician to understand that the probable causes would be an amalgamation of both the sets, a theory that medical investigations live

Table 1 - List of common STI syndromes along with their associations

STI Syndrome	Common Causes *(dset)*
Urethral discharge	Neisseria gonnorthoeae, Chlamydia trachomatis
Genital ulcer disease	Treponema palidum, Haemophilus ducreyi, Herpes simplex virus
Vaginal discharge	N. gonnorthoeae, C. trachomatis, Trichomonas vaginalis, Candida albicans, Gardnerella vaginalis
Pelvic inflammatory disease	N. gonnorthoeae, C. trachomatis, anaerobic bacteria, other pyogenic organisms, T.B.
Opthalmia neonatorum	N. gonnorthoeae, C. trachomatis, other pyogenic organisms
Bubo	H. ducreyi, C. trachomatis pyogenic infections
Scrotal swelling	N. gonnorthoeae, C. trachomatis, other pyogenic organisms, viruses and surgical conditions

by for the classification of the syndromic data available for STI compilation.

Once a circle has been etched around the potential STIs, they may be treated accordingly. Identifying a list of potential causes of disease is, still, the first step. Properly diagnosing it is another leap forward in the whole process. A little intelligence helps here.

Artificial intelligence

Alan Turing (1912-1954) was a mathematician, a philosopher, a hacker, and a visionary. He was the father of computer science and the founder of the field of artificial intelligence

Turing was the first scientist to believe that computers could be intelligent some day. In 1950, he wrote his classic paper: *'Computing machinery and intelligence'*

In his paper, Turing presented one simple question – *'Can machines think?'* His answer was *'yes'*. But by *'think'*, Turing actually meant, *'Can a machine make people believe that it can think'*.

Humans tend to think of themselves as the only intelligent creatures in the world. It's hard to accept the fact that language is a skill like any other, because if that is so, you are not the only ones who can acquire it.

Alan Turing had a lot to say about the relationship between computers and humans. What seems very natural for us now wasn't true 50 years ago, when Turing lived.

The different research branches in the field of Artificial Intelligence (AI) are in many ways analogous to various functions of the brain.

The foundation for the philosophy of AI was the infamous Turing Test, defined by Turing in 1950. He held that the computers by time would be programmed to acquire abilities rivaling human intelligence.

As part of his argument Turing put forward the idea of an *'imitation game'*, in which a human being and a computer would be interrogated under conditions where the interrogator would not know which was which, the communication being entirely by textual messages. Turing argued that if the interrogator could not distinguish them by questioning, then it would be unreasonable not to call the computer intelligent.

To sustain a live conversation, a machine should be able to effectively understand the different questions put forth and learn from each and every one of them. In his paper, Turing introduced a simple ideal conversation, useful to grasp the concept at hand.

Q: Do you play chess?

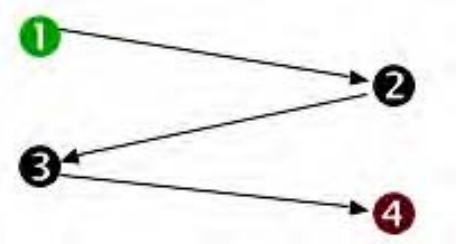
A: Yes.

Q: I have K at K1, and no other pieces. You have only K at K6 and R at R1. It is your move. What do you play?

A: (After a pause of 15 seconds) R-R8 mate.

In this simple example, a computer was asked if it knew how to play chess. The computer said, "Yes". But when a complicated text message is put in the next statement, it was obvious that the computer would think that the statement was related to the previous and it certainly was. The computer understood that it was being asked of a chess move. Such ability of a computer to understand and relate two separate entities after collecting relevant information is called *Dynamic Machine Learning ability.*

Machines that gather information follow a certain path to reach to the acquired information. Such course is referred to as simply *'path'* here, is a series of *'information blocks'* or *'nodes'* linked together.



When asked if the computer played chess, the computer responded affirmative. The computer makes up four information blocks: (1) Human asks about Chess, (2) Chess is game that can be played, (3) Human knows how to play chess, (4) I can play chess too.

Eventually only the two nodes, 1 and 4 would matter. Number 1 being the question and number 4 being the perceived evaluation. (1) Human asks about Chess, (4) I can play chess too corresponds to the reply of the computer in the Turing experiment.

Q: Do you play chess?

A: Yes.

Computers these days are intelligent enough to come to such a conclusion eventually, but the real matter at hand is not coming to the conclusion, but coming to it *'fast'*. For a situation where there are over a thousand nodes, interwoven into a web of *'information blocks'*, a computer might confuse itself into choosing wrong paths and making incorrect decisions.

Choosing the right beginning and ending node is half the challenge. Choosing how to traverse through various others to reach to the end in the shortest possible course and time is what is to be considered at first. Finding the correct shortest path requires the use of *Path-finding algorithms*.

Automated syndromic management

Bringing together all concepts talked about in this paper, we look at Syndromic Management under a new light here. We have come to terms with just how to identify a set of probable causes for the symptoms and syndromes reported for/by a patient.

A step forward in the process would be to pick the correct cause out of the set of all the other causes. Say, the final *dset(Obs.)* obtained in section 2 by unifying *dset (VG)* and *dset (ON)*, we get around six possible common causes for the STI syndromes: Neisseria gonorrhea, Chlamydia trachomatis, Trichomonas vaginalis, Candida albicans, Gardnerella vaginalis, and other pyogenic organisms.

Possible identification of these few diseases helps us to etch a domain around them and to find which the probable cause is.

Now, Syndromic management goes one step further to actually traverse through all the appropriate causes to pin-point the exact cause for the particular STI syndrome in inspection.

A proposed system here would appoint each cause as an *'information block'* in a series of webbed blocks. Each disease would be treated independently and randomly of the other in such a way that as each disease gets treated for, an indication of whether the disease was actually present in the patient gets marked as positive, and vice-versa.

Each positive node would be aligned in a path. Using path-finding algorithms on the given data, an appropriate path is identified for the disease. Such paths serve as a basis for a machine to identify a path. Several such paths are kept in an information storage unit, from which and where they can be obtained and summarized to form information useful for further such cases.

As for the machine, the machine should learn at every consecutive analysis of the patient using its Machine Learning abilities, such as if such a scenario occurs again, the machine would know how to respond to it in faster response time.

Artificial intelligence in medicine

The potential of AI in medicine has been expressed by a number of researchers. Hoong (1988) summarized the potential of AI techniques in medicine as follows:

- Provides a laboratory for the examination, organization, representation and cataloguing of medical knowledge.
- Produces new tools to support medical decision-making, training and research.
- Integrates activities in medical, computer, cognitive and other sciences.
- Offers a content-rich discipline for future scientific medical specialty.

Many intelligent systems have been developed for the purpose of enhancing health-care and provide better health care facilities, reduce cost and etc.[3]

Role in sustainable health systems[4]

Syndromic Management of STDs imparts a positive impact on the objectives of the sustainable Health System.

Strong focus on primary healthcare & prevention, accessibility to health by all irrespective of place time and other handicaps, expertise through expert systems with optimal technology use & appropriate resources usage.

It also facilitates semantic interoperability and among the systems.

Conclusion

Developing Applications that use automated Syndromic Management of STDs will not only bring dramatic improvements in achieving the objectives of the strategy but also will also serve the first stone for use of eHealth in Pakistan where yet an initiative in this regard has to be take.

Such development is eHealth in Pakistan will also aid Knowledge Management operations which encompass certain vital issues like digital divide & e-Health.

With such existing glaring opportunities Pakistan and those countries, which have not yet been able to determine change management process in Health care delivery system, can have uplift.

To start with Pakistan may develop her National Knowledge management strategy in line with WHO EMRO. Such move will open the avenues of e-Health development in Pakistan and capability to development of strategies for sustainable health system in light of recommendations of 05th Regional Conference WHO EMRO in Cairo in June in the current year.[5&6]

Combining Lexical and Semantic Methods of Inter-terminology Mapping Using the UMLS

Kin Wah Fung, Olivier Bodenreider, Alan R. Aronson, William T. Hole, Suresh Srinivasan

National Library of Medicine, Bethesda, Maryland, USA

Abstract

The need for inter-terminology mapping is constantly increasing with the growth in the volume of electronically captured biomedical data and the demand to re-use the same data for secondary purposes. Using the UMLS as a knowledge base, semantically-based and lexically-based mappings were generated from SNOMED CT to ICD9CM terms and compared to a gold standard. Semantic mapping performed better than lexical mapping in terms of coverage, recall and precision. As the two mapping methods are orthogonal, the two sets of mappings can be used to validate and enhance each other. A method of combining the mappings based on the precision level of sub-categories in each method was derived. The combined method outperformed both methods, achieving coverage of 91%, recall of 43% and precision of 27%. It is also possible to customize the method of combination to optimize performance according to the task at hand.

Keywords:

Unified Medical Language System, controlled terminology, inter-terminology mapping.

Introduction

The need for mapping between biomedical terminologies commonly arises when data encoded in one terminology is reused for a secondary purpose that requires a different system of encoding. Imagine an electronic patient record system that captures clinical information using SNOMED CT codes. It will be a big efficiency gain if ICD9CM and CPT codes can be generated automatically for billing purposes. For this to happen, mappings from SNOMED CT to ICD9CM and CPT are required.

A lot of research has been done on the creation of inter-terminology mappings by algorithmic methods. Generally speaking, the algorithms can be divided into lexically-based or semantically-based methods [1-7]. Lexical methods rely on the lexical properties of terms in a terminology. Terms are first normalized or broken down into components before they are compared and matched. On the other hand, semantic methods find matches by utilizing semantic links between terms from the terminologies being mapped.

The UMLS, with over 130 terminologies represented in one common format, is a useful resource for creating inter-terminology mappings. We have previously reported on the use of the UMLS to create semantic mappings between two clinical terminologies [7]. In this report, we describe the use of a UMLS-based tool (MetaMap) to generate lexical mappings between the same terminologies. The performance of the two methods is compared and one way to combine the two methods is described.

Semantic mapping (IntraMap)

The IntraMap algorithm (a modification from the Restrict to MeSH algorithm) makes use of semantic relationships between UMLS concepts to find mappings [7, 8]. Starting from the source concept (the UMLS concept containing the term in a source terminology from which mapping is sought), the algorithm looks for target concepts (UMLS concepts containing terms in the terminology being mapped to) which are related to the source concept either through synonymy or explicit mapping relationships provided by some source terminologies. Failing to find a target concept, the search will widen by using ancestors of the source concept as starting points to look for target concepts. If that fails again, ancestors of the children of the source concept and finally, ancestors of the siblings of the source concept will be used for target concept searching.

Lexical mapping (MetaMap)

MetaMap is a program developed by the NLM to map biomedical text to concepts in the UMLS [9, 10]. The algorithm of MetaMap is as follows: the input text is first parsed into noun phrases. For each phrase, lexical variants are generated. A candidate set of all UMLS concept names containing at least one of the variants is retrieved. Each candidate is then evaluated using a linguistically principled evaluation function. Finally, complete mappings are constructed by combining candidates involved in disjoint parts of the phrase. If one uses the terms in one terminology as the input text and limits the mapping to UMLS concepts containing terms from a specific target terminology, one can use MetaMap to find inter-terminology mappings. MetaMap operates on English terms from the UMLS Metathesaurus.

Selected for best paper award.

Methods

To evaluate the two mapping methods, we used them to find mappings from SNOMED CT terms to ICD9CM terms. As the gold standard for comparison, we used the January 2004 version of the SNOMED CT to ICD9CM mappings provided by the College of American Pathologists. All the mappings from one SNOMED CT term to a single ICD9CM term in the gold standard were used (84% of all mappings). The version of UMLS used was 2004AA which contained the same version of SNOMED CT as used in the gold standard. For semantic mapping by IntraMap, we set the target terminologies to ICD9CM or MTHICD9 (a source that provides additional entry terms to ICD9CM codes). The explicit mapping relationships from the source 'SNOMEDCT' were ignored; otherwise all mappings in the gold standard would be found because the gold standard mappings were also included in 2004AA. For lexical mapping with MetaMap, the fully-specified English names of the SNOMED CT concepts were used as input strings. The option of 'term processing' was turned on to bypass parsing of the terms into component phrases. Other settings of MetaMap were the same as the default mode on the MetaMap website. The target terminologies were limited to ICD9CM or MTHICD9. While no semantic type restriction was used in this experiment, we show in the discussion that restricting the output of MetaMap to semantic types of interest can improve precision.

The mappings found by the two mapping algorithms were compared to the gold standard in terms of their coverage (percentage of SNOMED CT terms for which mappings were found), recall (the percentage of mappings in the gold standard that were found) and precision (the percentage of found mappings that agreed with the gold standard). The overlap between the two sets of mappings was analyzed. A method of combining the two sets of mappings based on the precision ranking of the sub-categories was derived and the improvement in performance was analyzed.

Results

Semantic mapping alone

As reported in [7], among the 66,382 SNOMED CT terms that were used, IntraMap managed to find ICD9CM mappings for 57,293 terms (86.3% coverage). Overall recall was 43.3% and precision was 22.1%. On average, there were 2.3 mappings found per SNOMED CT term. The precision of the sub-categories of mappings were: mapping by synonymy 78.4%, mapping by explicit mapping relationships 50.1% and mapping by ancestor expansion 9.2%. The mappings found by children and sibling expansion were too small in number to warrant further consideration. The results are summarized in Table 1.

Table 1 - Overall and sub-category performance of semantic mapping by IntraMap

	Sub-category of mapping			Overall
	Synonymy	Explicit mapping	Ancestor expansion	
Coverage	19.5%	17.0%	47.2%	86.3%
Recall	16.6%	13.0%	13.0%	43.3%
Precision	78.3%	50.1%	9.2%	22.1%
Mapping per term	1.1	1.5	3.0	2.3

Lexical mapping alone

MetaMap was able to find mappings for 44,452 out of 66,382 SNOMED CT terms (70.0% coverage). The overall recall and precision was 28.4% and 14.7% respectively. There were on average 2.9 mappings found per SNOMED CT term. Among those mappings that were considered to be perfect matches (MetaMap score of 1000), the precision was 85.8%. For those SNOMED CT terms with no perfect matches found, if we only used the top ranking mappings (the mappings with the highest MetaMap score), the precision was 22.6%. The results are summarized in Table 2.

Table 2 - Overall and sub-category performance of lexical mapping by MetaMap

	Sub-category of mapping		Overall
	Perfect mapping	Top mapping	
Coverage	9.7%	57.2%	70.0%
Recall	8.6%	18.3%	28.4%
Precision	85.8%	22.6%	14.7%
Mapping per term	1.0	1.4	2.9

Overlap between the two sets of mappings

A total of 29,468 mappings (distinct pairs of SNOMED CT and ICD9CM codes) were common to both sets of mappings. This represented 22.6% and 22.9% of all IntraMap and MetaMap mappings, respectively. This set of common mappings covered 35.7% of the SNOMED CT terms, with recall and precision of 22.5% and 50.8% respectively. The mappings that were only found in one algorithm but not the other were higher in coverage but lower in precision (Table 3).

Table 3 - Mapping performance according to the method of mapping

	Both IntraMap and MetaMap	Only from IntraMap	Only from MetaMap
Coverage	35.7%	57.4%	51.9%
Recall	22.5%	20.8%	5.9%
Precision	50.8%	13.7%	3.9%
Mapping per term	1.2	2.6	2.9

Altogether 13,797 correct mappings were found by semantic mapping alone and missed by lexical mapping. Among these, mappings found by synonymy, explicit mapping relationship and ancestor expansion constituted 9%, 48% and 43% respectively. One example was the mapping from SNOMED CT term '3072001: Hormone-induced hypopituitarism' to ICD9CM term '253.7: Iatrogenic pituitary disorders'. The failure of MetaMap to find this mapping was expected as it was unlikely that the similarity in meaning between 'hormone-induced' and 'iatrogenic' could be detected by lexical matching alone.

On the other hand, there were 3,906 correct mappings that were found by lexical mapping but missed by semantic mapping. Among these, one was deemed to be a perfect match in MetaMap. This was unexpected as almost all perfect lexical matches were genuine synonyms and should normally belong to the same UMLS concept. If so, the mapping should be identified by IntraMap as well. Indeed, this was an anomaly caused by an editing error in the UMLS. In 2004AA, the ICD9CM term '241.9: Unspecified nontoxic nodular goiter' was assigned to a UMLS concept (C1313958) which was different from the UMLS concept (C1318500) containing the SNOMED CT term '190236006: Non-toxic nodular goiter'. This error has since been corrected and the two terms now belong to the same UMLS concept (C1318500). All the other cases in which the correct mapping was found only by MetaMap had less than perfect MetaMap scores. On inspection of a small sample, many of these were mappings from a narrower to a broader concept. One example was the mapping from the SNOMED CT term '67600007: Vascular-biliary fistula' to the ICD9CM term '576.4: Fistula of bile duct' by way of the synonym 'biliary fistula' in the same UMLS concept. This mapping was not found by IntraMap because the two UMLS concepts containing the two terms were not linked by any hierarchical or mapping relationships in the UMLS.

Combining the semantic and lexical mapping sets

Since semantic and lexical mapping are fundamentally different approaches, they are orthogonal and thus can be used to validate and complement each other. To make use of both sets of mappings simultaneously, we derived a method based on the precision level of each sub-category of mapping. First we created a 'precision ladder' according to the precision of each sub-category of mapping. (Table 4)

Table 4 - Precision ladder according to precision of each sub-category of mapping

Rank	Sub-category	Precision
1	M-PM (MetaMap perfect match)	85.8%
2	I-S (IntraMap synonymy)	78.3%
3	C-O (Combined overlapping)	50.8%
4	I-EM (IntraMap explicit mapping)	50.1%
5	M-TM (MetaMap top score)	22.6%
6	C-IO (Combined IntraMap only)	13.7%
7	I-AE (IntraMap ancestor expansion)	9.2%
8	C-MO (Combined MetaMap only)	3.9%

Next we pooled all the mappings together and arranged them in descending order of precision. If the same mapping appeared in more than one sub-category, only the one in the highest ranking sub-category was kept. If there were multiple mappings for the same SNOMED CT term, only the one with the highest ranking was kept and the alternative lower ranking mappings were discarded. The combined set contained 107,172 mappings for 60,454 SNOMED CT terms (coverage 91.1%). The overall recall and precision of the combined set was 42.9% and 26.6% respectively.

The fact that the mappings were arranged in the order of precision allowed us to further fine-tune the way in which the mappings could be used. By setting different cut-off points on the precision ladder (i.e. ignoring mappings below a certain sub-category) we could obtain different combinations of coverage, recall and precision. As expected, the further down we go on the precision ladder, the higher the coverage and recall but the lower the precision. (Table 5)

The mapping performance did not change further with inclusion of mappings ranking lower than rank 6. This was expected because the mappings in rank 7 (IntraMap mappings found by ancestor expansion) were already included in higher sub-categories (ranks 3 and 6). Mappings from rank 8 did not contribute to the overall performance because rank 1 and rank 5 already covered every SNOMED CT term for which a mapping was found by MetaMap.

The F-score (the harmonic mean of precision and recall) is frequently used as an overall indicator of performance. We calculated the F-scores for each cut-off point with equal weight to precision and recall by the following formula:

$$\text{F-score} = (0.5/\text{precision} + 0.5/\text{recall})^{-1}$$

Looking at the F-scores, rank 4 is the optimal cut-off point if one wishes to optimize equally on recall and precision.

Table 5 - Mapping performance according to the cut-off point on the precision ladder

	Cut-off point on the precision ladder							
	Rank 1	**Rank 2**	**Rank 3**	**Rank 4**	**Rank 5**	**Rank 6**	**Rank 7**	**Rank 8**
Coverage	9.7%	19.5%	38.1%	50.8%	71.0%	91.1%	91.1%	91.1%
Recall	8.6%	16.6%	24.4%	34.0%	38.2%	42.9%	42.9%	42.9%
Precision	85.8%	78.4%	52.0%	51.6%	39.3%	26.6%	26.6%	26.6%
Mapping per term	1.0	1.1	1.2	1.3	1.4	1.8	1.8	1.8
F-score	0.16	0.27	0.33	0.41	0.39	0.33	0.33	0.33

Discussion

The two mapping algorithms

Semantic and lexical mapping algorithms have their own strengths and weaknesses. In general, semantic mapping is considered to be more precise. This is confirmed by our results (precision of IntraMap 22.1%, precision of MetaMap 14.7%). However, for semantic mapping to work there needs to be a pre-existing knowledge base to provide the semantic linkages. In our study, the UMLS is used as the knowledge base, containing over a million concepts and tens of millions of semantic relationships. The performance of semantic mapping depends heavily on the density and quality of these relationships. If there is no semantic relationship linking two concepts a mapping cannot be found.

On the other hand, lexical mapping does not depend on a pre-existing knowledge base. One can perform lexical matching based solely on the lexical properties of the terms from the terminologies being mapped. However, the mapping algorithm of MetaMap does utilize resources from the UMLS which include the rich collection of synonyms and the SPECIALIST lexicon, which have undoubtedly bolstered its performance.

Further refinement

There are possible ways to fine-tune the performance of each of the mapping algorithms. For IntraMap, it is possible to selectively exclude the relationships contributed by certain source terminologies, if such relationships are less likely to result in correct mappings. Restricting the extent of ancestor expansion (e.g., limiting just to level 1 and 2 ancestors) has been found to improve precision [7].

In MetaMap, there is a built-in option to restrict the target concepts by semantic type (STY). In the original run, no restriction on STY was used. In a subsequent run, we restricted target concepts to 18 STYs related to diseases or findings (e.g. Finding, Disease or Syndrome, Acquired abnormality and Congenital abnormality). This restriction was appropriate because the SNOMED CT terms being mapped were all disorders or findings. As ICD9CM also contained terms for procedures, by excluding STYs like Therapeutic or preventive procedure and Diagnostic procedure some incorrect mappings could be avoided. One example of such error was the mapping of the SNOMED CT term '168943003: Abdominal aortogram abnormal' (a finding) to the ICD9CM term '88.42: Aortography' (a procedure). In the re-run, 2,588 mappings that were present before were dropped because of the STY restriction. Among these dropped mappings, most of them (97%) turned out to be incorrect. This resulted in a small increase of precision from 14.7% to 14.9%.

Apart from STY, one can further refine the mappings by term type (TTY) information in the UMLS. In ICD9CM, only the lowest level terms (the leaf nodes) are valid for coding. Therefore, in the gold standard, all mappings are to the lowest level terms. In the UMLS, these lowest level terms are given TTYs of PT (preferred terms) while higher level terms have TTYs of HT (hierarchical term). However, the two mapping algorithms did not distinguish between ICD9CM PT and HT terms. If we discard all mappings to HTs, the precision would increase from 22.1% to 32.1% for IntraMap and from 14.7% to 25.0% for MetaMap, without impact on recall.

Enhancing performance through combination

The prospect of combining semantic and lexical mapping is particularly exciting. We showed that by pooling all the mappings together according to their anticipated precision ranking, while removing duplicates and lower-ranking alternative mappings, the overall mapping performance was significantly better than either mapping method used alone. Another advantage of combining the mappings by the precision ladder approach is the possibility of adjusting the recall-precision profile of the combined mappings to suit the task at hand. For instance, if the task is automatic code translation, one would prefer a mapping algorithm with high precision. One way to achieve this is by taking only the first two rungs of the precision ladder which will give highly precise mappings (precision close to 80%) to about 20% of SNOMED CT terms. On the other hand, a more likely use case of the mapping algorithms is to suggest candidate mappings to human editors to assist them in their task of creating mappings. In that situation, one will need a mapping algorithm with high coverage. If one takes

every rung from the precision ladder, one will find candidate mappings for over 90% of SNOMED CT terms, with a precision of 27%. However, in this particular use case, even the incorrect candidate mappings may serve some useful purpose. If we compare only the first three digits of the ICD9CM codes in the candidate mappings and the gold standard mappings, the precision jumps to 49.5%. This means that one out of two of the candidate mappings will either be exactly correct or will bring the editors closer to the correct mapping.

Generalization

Except for validating the method, there was little need for creating a mapping between SNOMED CT and ICD9CM, since one already exists as part of the SNOMED CT distribution. However, the strategy presented here can be applied to virtually every pair of terminologies in the UMLS. In future work, we plan to test the algorithms on other terminologies that do not already have known mappings e.g. between SNOMED CT and MeSH.

Conclusion

Semantic and lexical mapping between two terminologies can be done using resources available in the UMLS. The performance of semantic mapping is generally better than lexical mapping. When the two sets of mappings are combined according to the anticipated level of precision of individual mappings, the overall performance is better than either algorithm used alone. One further advantage of this approach of combining semantic and lexical mapping is the possibility of customization of the trade-off between coverage, recall and precision according to the task at hand.

Biomedical Vocabularies – the Demand for Differentiation

Josef Ingenerf, Siegfried J. Pöppl

Institute of Medical Informatics, University of Lübeck, Germany

Abstract

The need of biomedical vocabularies is well known for various tasks, e.g., supporting structured data entry, decision support and electronic data exchange as well as retrieval and statistical evaluation of the data. Due to a considerable diversity of artifacts like interface terminologies, classifications and thesauri it seems to be reasonable to demand for a massive reduction and, finally, to end up with just one unique "multi-purpose world terminology". Concept-based reference terminologies like SNOMED CT® might be candidates for that idea. Unfortunately, the above mentioned kinds of vocabularies cannot be replaced because of their specific purpose-dependent nature. Their mutual distinctive characteristics are outlined and compared with inherent purpose-less concept systems that are based on formal approaches like description logics. For supporting interoperability the different kinds of purpose-dependent vocabularies can and should be improved by mappings to machine-processible reference terminologies. As a side-effect, this paper may contribute to the meta-terminology in this field of medical terminology.

Keywords:

vocabularies, controlled, terminology, semantics, medical informatics/standards

Introduction

In the nineties, several studies have been conducted for evaluating biomedical vocabularies, basically focusing on domain-completeness. Cimino´s desiderata, published in 1998, stimulated a discussion of qualitative criteria [1]. In ISO/TC 215 Working Group 3 this work gave reason to the creation of the standard ISO/TC 17117 "Controlled health vocabulary - Structure and high-level indicators" [2] that is actually revised with a new title "Criteria for the Categorization and Evaluation of Clinical Terminologies". In this paper, the term "biomedical vocabulary" is used as a general term subsuming specific variants like classifications, terminologies and thesauri.

The characteristics of a vocabulary influence its utility and appropriateness in clinical applications. Cimino [1] and ISO/TC 17117 ([2]: scope) refer to health terminological systems (terminologies) that are primarily designed to be used for clinical concept representation. The set of desirable criteria as a guideline for evaluating terminologies are based on one dominant characteristic, namely "concept orientation". Concepts are the basic units of a clinical terminology with unique and non-ambiguous identifiers. Different but synonymous terms are denoting the same concept. This leads to non-redundancy, non-ambiguity, non-vagueness and internal consistency.

Amongst others, the demand for domain-completeness gives rise to compositional approaches. Patient data should be represented as detailed as necessary suitable for clinical use. In compositional terminologies concepts are expressed in terms of at least two other concepts, ideally joined by relations. Precoordinated concepts are represented already within the terminology with an equivalent single unique identifier (non-semantic codes). The full power of compositional terminologies is given by the support for creating new postcoordinated concepts. Without postcoordination no terminology can escape from the phenomenon of exponential explosion when enumerating all combinations of concepts [3]. Consequently, compositional terminologies cannot longer be delivered as books. According to the slogan "defining concepts instead of building hierarchies" software (classifier) is needed for computing the hierarchy and relations from concept definitions "on the fly". For doing that, formal terminologies shall use suitable representation formalisms (*e.g.*, description logics) and terminological models (schemata, ontologies) for enabling complete and correct inferences of conceptual knowledge.

In Figure 1 reference terminologies like SNOMED CT® (Systematized Nomenclature of Medicine - Clinical Terms) [4] are shown as one type of biomedical vocabularies. Due to the primary functions shown in Figure 1 their value to support health information management has been widely recognized. They are required for precise data representation, accurate interpretation of data and interoperability among information systems exchanging such data. At the same time they can serve as an Interlingua by providing mappings to all other biomedical vocabularies. Sensibly coordinated vocabularies benefit from such a mapping by getting support for tasks like maintenance, error detection, re-engineering and translation.

There are a lot of other concept oriented terminologies that theoretically should conform to the criteria mentioned above as well. Most of them are domain specific and have several structural limits, *e.g.,* LOINC® [5]. As they have almost no reference characteristics they are candidates for

mappings to them. They are not discussed in this paper in more detail.

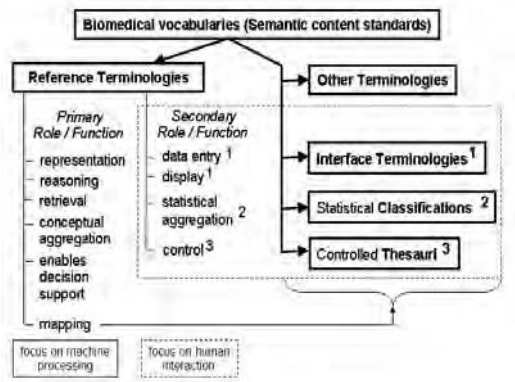

Figure 1 - Types of biomedical vocabularies (modification of Annex A2 in the actual version of ISO 17117 [2])

In principle, reference terminologies have the ability to serve also the secondary functions shown in Figure 1. However, there are intrinsic conflicts between the needs of users (*e.g.*, clinical pragmatics) and the needs of machines (*e.g.*, logical strictness), see chapter "Reference terminologies". For that reason there are other types of vocabularies that are specialized in supporting those functions.

- Interface terminologies, see corresponding chapter => structured essentially with respect to "terms", with colloquial phrases for data entry by clinicians, *e.g.*, MST (Minimal Standard Terminology) [6].
- (Statistical) classifications, see corresponding chapter => structured essentially with respect to "classes", with guaranteeing comparable aggregations, *e.g.*, ICD (International Classification of Diseases) [7].
- (Controlled) thesauri, see corresponding chapter => structured essentially with respect to "subjects", with control mechanisms for using keywords reliably, *e.g.*, MeSH (Medical Subject Headings) [8].

In the next chapter these types of vocabularies[1] are discussed with a focus on features distinguishing them from concept based terminologies. After that, the results are summarized, followed by a discussion. To make it very clear: This paper is not about questioning the importance of reference terminologies in general. Just the ability to support the secondary functions in Figure 1 is critically analyzed opposed to specialized types of vocabularies being in place for a very long time.

Different types of biomedical vocabularies

Early work on the differentiation of biomedical vocabularies has focused on levels of structural complexity from hand-crafted fixed hierarchies based on "enumeration" to computed dynamic concept systems based on "formal definitions" [10, 11]. Differentiating types of vocabularies has a long history only with respect to terminologies and classifications [12]. Due to an increasing maturity of reference terminologies this is still an ongoing issue [13]. The different nature of interface terminologies and thesauri opposed to reference terminologies has been recognized, but studied much less systematically.

Reference terminologies

Terminologies are defined as a system of concepts with terms used for naming concepts. As mentioned earlier, the demand for expressiveness gives rise to the emergence of formal compositional terminologies. Based on suitably defined concepts the subsumption hierarchy can be created automatically. Table 1 gives just an impression of a concept definition based on description logics used by SNOMED CT® [4]. The precoordinated concept "397825006" has already been classified into the concept hierarchy. All those concepts are delivered with unique identifiers, descriptors and mappings (*e.g.*, to ICD). Postcoordinated concepts are built analogously by refining value restrictions (*e.g.*, Pyloric antrum) and adding relations (*e.g.*, Causative agent) with value restrictions (*e.g.*, Helicobacter pylori). With that, they also can be classified, *e.g.,* as a subconcept of the available concept "89662003 Helicobacter-associated pyloric ulcer". However, there are still challenges with respect to identifiers, descriptors and mappings that have to be generated automatically, *i.e.*, for coded data exchange.

*Table 1 - **Example** from SNOMED CT® [4]*

CONCEPT: 397825006 Gastric ulcer
DESCRIPTORS (TERMS): Gastric ulcer (1777426014, preferred), Stomach ulcer (1785985013), GU - Gastric ulcer (1785986014), Gastric ulceration (1785987017)
DEFINITION: Fully defined by ... - *Is a* 64572001 Disease (disorder) - Group - *Associated morphology* 56208002 Ulcer - *Finding site* 69695003 Stomach structure
INFERRED SUPERORDINATE CONCEPTS (by a classifier) - 29384001 Disorder of stomach - 40845000 Gastrointestinal ulcer

Besides questions of expressiveness and tractability of the used logical representation formalism it becomes clear that the approach is heavily dependent on suitable definition and organization principles, especially with respect to the top-level hierarchy. The logic used by terminologies like SNOMED CT® guarantees only that if the premises are true then the conclusions will be true. For achieving suitable concept models, ontological principles have to be applied thoroughly like avoiding isa-overload (*e.g.*, Helicobacter pylori *isa* Infectious agent) and epistemologically

1 All mentioned vocabularies are included in UMLS (Unified Medical Language System) [9].

loaded terms (*e.g.*, Ulcer without bleeding *or* Tuberculosis, histologically specified) [14].

The compliance with ontological principles again corresponds with re-usability, *i.e.*, one of the main targets of reference terminologies with respect to the primary functions in Figure 1. However, this should not be confused with the "multi-purpose" characteristic. Quite reciprocally, the support of the secondary functions is weakened. For them pragmatic clinical conventions, epistemological terms for the observation of reality instead the reality itself and clinical knowledge instead of terminological knowledge has to be considered.

Interface terminologies

Interface terminologies (entry or point of care terminologies) are used for clinical data entry. They "interface" between clinician's own unfettered, colloquial expressions and machine-processable conceptual expressions. They range from simple pick-up lists to structured terms with attributes and relations that are optimized for an easy and meaningful data entry. The desiderata for interface terminologies [15] differ from Cimmno's desiderata for reference terminologies [1] mentioned in the introduction, *e.g.*; with much more focus on terms and language instead of conceptual knowledge.

*Table 2 - **Example** from MST [6]*

Headings	Terms	Attributes	Attr.Values	Sites
Excavated lesions	Ulcer	Number	Single (Solitary), Few, Multiple	Site(s)[other table]
		Size	Largest dia-meter in mm	
		Bleeding	Yes: Spurting/ Oozing, No	
Mucosa	Ulcerated mucosa	Continuity	Discontinuous/ Continuous	Site(s) [other table]
		Bleeding	Yes/No	
There are more tables for anatomy, extend/limits/reasons for examination (*as below*), diagnostic/therapeutic procedures. The tables are linked suitably.				
Extend and limits	Limitation	Reason	Patient unstable: Specify	Site(s)

Table 2 shows selected entries for recording findings in the colon or the stomach. A subtle distinction is made between ulcer findings difficult to anticipate in reference terminologies: "*Endoscopists felt that there may be a conceptual distinction between ulcers that are multiple and mucosa that was ulcered diffusely* [6]. Particular attention has been paid to include just those terms, attributes and values that avoid ambiguity and misuse. In contrast, reference terminologies would produce enormous noise. Hierarchies like "Diagnostic procedures: Biopsy (Purpose: Helicobacter pylori test) / Chromoscopy (Type: Staining)" reflect local needs. Furthermore, metric data (*e.g.*, Size) and epistemological terms (*e.g.*, Patient unstable) have to be regarded. Diagnoses and procedures are represented primarily as precoordinated terms. The linkages from findings to sensibly selected procedures and diagnoses cannot be inferred by terminological knowledge. They represent clinical knowledge, a consensus between experts or local factors. These and other features of interface terminologies have been studied by Rosenbloom et al. [15]. They postulate desiderata being in conflict with reference terminologies:

- Presence of relevant assertional knowledge
- Balance between pre- and postcoodination
- Adequate synonym coverage

These findings motivated the author of this paper and his colleagues not to realize a data entry system directly linked to the GALEN terminology [16]. Although the GALEN approach is quite innovative in providing "sensible statements" the data entry system works in two phases. First, the GALEN terminology enables the creation of data entry forms enhanced by multilingual language generation and code conversion. Second, the resulting items have to be rearranged, rephrased and enhanced due to local needs. More realistic, interface terminologies are already existent. Of course, they are not perfect [17]. For that reason, they do profit from a mapping to reference terminologies like GALEN [16] and SNOMED CT® [18].

Statistical classifications

Statistical classifications (aggregation or report terminologies) support the comparison of data within populations over time and between populations at the same point in time, as well as the compilation of nationally consistent

data. They have well known unique characteristics. The basic components are classes as clusters of objects in a mutual disjoint and exhaustive partition of a given domain. For guaranteeing exhaustiveness of classes, residual classes "Other ..." are introduced at every stage of subdivision. Disjointness is enforced by special instructions, amongst others inclusion and exclusion criteria.

*Table 3 - **Example** from ICD-10 [7]*

K25	Gastric ulcer
K25.0	acute with haemorrhage
K25.1	acute with perforation
K25.2	acute with both haemorrhage and perforation
K25.3	acute without haemorrhage and perforation
K25.4	chronic or unspecified with haemorrhage
...	...
K25.9	unspecified as acute or chronic, without haemorrhage or perforation

The example in Table 3 illustrates a typical combination of criteria at the same level. The special interest in haemorrhage and perforation as co-morbidities of ulcers according frequencies and practical relevance leads to the integration of these and other criteria of interest into one category. This kind of mono-hierarchical subdivision of all diseases is not without problems, *i.e.*, the loss of information (*e.g.*, with K25.4 the criterion "chronic" is lost) or the problem of context-dependent interpretations of residual classes.

This and other findings are well known so that classifications should not be used as input, but output systems [19, 20]. The crucial question is whether aggregation for all purposes can be carried out by conceptual aggregations in a reference terminology or whether there is a need for mappings to statistical classifications. Stuart-Buttle et al. [21] investigated classifications with their essential features:

- Stability over time *(enabling long-term comparison)*
- Exhaustiveness *(concentrating on usual phenomena)*
- Mutual exclusivity *(avoiding double counting)*

It is quite clear that classified data can only be as good as the original clinical record. Here, terminologies should be used for representing data as detailed as the clinician is willing to enter it. It remains to be seen if the frequent updates of terminologies and the variability of ways to enter the same data affect their potential for statistical aggregations. Inherent non-disjoint concepts in multiple hierarchies have to be restricted to single hierarchies and freezed for a fixed period of time. The process of bridging fine grained information collected for patient care to coarse grained reporting for management or planning may be obvious to humans, but it must be made explicit for machines. Crucial concerns are stated by Rector [3].

At least the context of patient care is almost not possible to be made as explicit as necessary. Due to the purpose-dependence of classifications a relevant amount of context is already reflected in the structure of classifications and even more important, in the rules for assisting users in the selection of information and categories. For the same reason, mapping concept representations to statistical classifications is inherently an interactive task, involving clinical judgements based on the whole episode that relates to a patient [19].

Controlled thesauri

Thesauri are used as controlled vocabularies in the stricter sense of the word for indexing and retrieval purposes in library and information science. The basic components of thesauri are subjects [22], also called descriptors, (main) headings or keywords. They are related by three relationships "Broader-than" (*BT*), "Related-to" (*RT*) and "Used-for" (*UF*). The relationships and other means (*e.g.*, annotations, scope notes) are used to avoid variation between those indexing and those retrieving data. Analogous to classifications, the purpose of matching documents with information needs is reflected in the structure of well chosen descriptors and (entry) terms. Misunderstandings due to ambiguity, synonymy and inconsistent use of language should be minimized.

*Table 4 - **Example** from MeSH [8]*

D005767 Gastrointestinal Diseases	
BT D013272 Stomach Diseases	*: D-codes are identifiers*
BT D010437 Peptic Ulcer *	*: for descriptors.*
BT D013276 **Stomach Ulcer**	*: Codes for placing them*
BT D010437 Peptic Ulcer *	*: into hierarchies are*
BT D013276 **Stomach Ulcer**	*: not shown here.*
* RT (see also) D000897 Anti-Ulcer Agents, ...	

Precoordinated descriptors like "Stomach Ulcer" in Table 4 should be used by MeSH coding instructions, although "Stomach" and "Ulcer" exist independently. The descriptor is placed in two hierarchies for helping the human user in discovering the keyword by top-down searching the MeSH-hierarchy. Synonymous (entry) terms like "Gastric ulcer" are added only when their use in the user community is as reliable, predictable and comparable as possible. Beyond the combination of descriptors, MeSH offers so-called qualifiers (*e.g.*, "/therapy") and major/minor tags for indicating the actual content of a document. However, compared with concept based terminologies, it is neither possible nor desirable to define compound descriptors by employing non-ISA-relationships as "Located-in" and to classify them automatically into the hierarchy.

There are ontologically valid hierarchical relations like "Stomach Diseases *BT* Stomach Ulcer" and also debatable relations like "Stomach *BT* Pylorus" or "Diagnosis *BT* Diagnostic Errors". Opposed to ISA-relations between concepts, *BT*-relations between descriptors are defined in a completely different manner:

"Should a search for documents dealing with A find all (or most) documents dealing with B? If yes, A is broader than B (and conversely, B is narrower than A)." [23]

The reader is invited to look up the MeSH term "Vocabulary, controlled". All kinds of biomedical vocabularies are included as narrower terms because the average user (*e.g.*, of MEDLINE) and even the experts in this field would not conform reliably to the subtle differences outlined in this paper.

Often, thesauri are referred to as concept-based vocabularies. However, the main idea of language control resides solely at the level of descriptors aggregating concepts. Available mappings to a concept layer are helpful for maintenance or translation [23]. However, it is not visible to MeSH users. The following characteristics differentiate thesauri from reference terminologies that are discussed in more detail in [24].

- Language control *(more than just offering concepts)*
- Carefully chosen descriptors *(minimizing ambiguity)*
- Hierarchies with respect to relevance *(≠ subsumption)*

Results/Discussion

The specific features distinguishing interface terminologies, classifications and thesauri from concept based reference terminologies have been presented in the last chapter. Separating primary and secondary functions in Figure 1 seems to be the key for distinguishing reference terminologies from the other types of biomedical vocabularies. In order to satisfy the primary functions they have to conform to logical and ontological principles that, reciprocally, weaken their potential to support also the secondary functions. At the same time it is rather nonsensical to apply ontological principles to interface terminologies[2], statistical classifications and thesauri [24].

The different types of biomedical vocabularies challenge the task of mappings between them for enabling interoperability. With the help of reference terminologies the number of mappings can be minimized, as shown in figure 2.

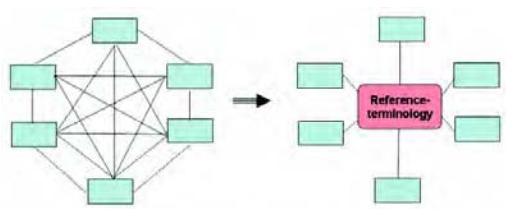

Figure 2 - Reference terminologies

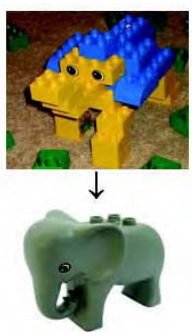
Besides the reasons outlined in the last chapter the value of a reference terminology is to keep the number of mappings between biomedical vocabularies small, *see* figure 2.

2 As "terminology" is used as a short form for concept oriented (reference) terminologies we prefer the term "Interface vocabulary". However, it is uncommon to do so.

As the borderlines between the types of vocabularies are quite tricky the results of this paper will be clarified by three short analogies. Analogies might demonstrate the agreement of phenomena in some respects but they do not work for others. Looking to the first analogy reference terminologies are specialized in supporting the primary functions in Figure 1. At the same time they behave like generalists when looking to the secondary functions in Figure 1. Only the latter are sketched by the three analogies. If available, the secondary functions should be carried out by specialized vocabularies mapped to reference terminologies for reasons outlined in the last chapter.

- IT world
  In information technology and other fields the generalists/specialists tradeoff is well known. Specialized software systems are favored especially by users for supporting their particular needs. General solutions offering mostly limited functionality are favored by central divisions responsible for integrating all systems. Both approaches will co-exist so that a careful coordination of them is needed permanently.
- Lego world
  Compositional terminologies behave like Lego. Basic building blocks can be used for virtually all purposes according to given instructions. Due to pragmatic reasons users often favor extra items like animals although they can be created also with "pure Lego" in principle. However, the extra items are badly suited for reusing.



- Animal world
  Given gazelles (interface terminologies) being able to run very well, dolphins (classifications) specialized in swimming and eagles (thesauri) that are very good in flying. Then there are also animals representing multipurpose reference terminologies: ducks. They are skillful in all these tasks, but within clear limits; see also the animal school fable.

Abstract

Taxonomies provide schemas to help classify entities and define the relationships between them. Early computing enabled the development of ontologies and Medical Subject Headings (MeSH), the first modern classification of medical terminology as applied to medical literature. Later developments, such as MEDLINE, expanded MeSH to include a number of medical informatics terms. However, a lack of specificity in MeSH and other existing informatics taxonomies for terminology used to describe the growing field of health information technology (health IT) created the need for the development of a specialized taxonomy. Experts associated with the Agency for Healthcare Research and Qualitys (AHRQs) National Resource Center for Health Information Technology (NRC) created and evaluated a taxonomy for health IT, to enable users of a public health IT Web site to efficiently identify resources within an online, searchable repository.

Keywords:

controlled vocabulary, internet, information systems, medical informatics applications, computer communications networks

Introduction

Taxonomy is derived from two Greek words: taxis, meaning order or arrangement, and nomos, meaning law. Common definitions include a focus on the laws of classification and natural history, including the relationships among entities organized in a hierarchical structure [1][2].

While taxonomies have historically been applied to a variety of different content areas, the focus remained on the classification of those areas and the hierarchical structure that explained vertical relationships. During the twentieth century, computers enabled the development of ontologies, data models that represent concepts and facilitate understanding of relationships, particularly in the definition of ambiguous concepts and their concomitant associations.

The science of taxonomy and its related ontologies enabled the development of Medical Subject Headings (MESH) and its classification structure (e.g., tree), the first true classification of medical terminology as applied to the worlds medical literature. Its genesis was in the early work of John Shaw Billings and the publication of *Index Medicus* in 1879. However, the first major expansion of the terminology did not come until 1958, recognizing the specialization of the profession of medicine [3].

The creation of the specialized taxonomy for medicine enhanced the ability of users to retrieve information from printed materials. However, without the use of a computer to facilitate the application of the classification schema, albeit through punched cards and high-end photographic equipment to print the newly reconstituted *Index Medicus*, the foundation for the current MESH would not have been laid [4].

The computerized MEDLINE followed over a decade later, with its MESH expanded to include a number of tangential concepts. The vocabulary and its hierarchical relationships have been developed over time and have incorporated a number of medical informatics terms.

However, there is a lack of specificity of concepts and granularity in the health information technology (health IT) area, particularly as it relates to current practices in electronic health record (EHR) implementation. The MESH vocabulary also lacks terminology to encompass dynamically growing areas like health information exchange and consumer health informatics.

In trying to develop a searchable knowledge core for the Agency for Healthcare Research and Qualitys (AHRQs) National Resource Center for Health Information Technology (NRC) Web site, a major first step was the creation of a taxonomy to define the interrelationships among concepts around health IT planning, implementation, and evaluation.

Because health IT bridges medical informatics and hospital and clinical practice organizations, it became imperative in the development of a taxonomy to understand the scientific and sociological issues impacting health IT. MESH offered some concepts, but the major sources of the taxonomy development came from divergent vocabularies. This supports the premise that a good taxonomy must be developed on the basic principles of a hierarchical and interrelated classification schema, searchable within a Web environment.

Materials and methods

In March 2005, a panel of experts with a wide array of experiences in implementing health IT systems was convened to design a national, searchable Web site for persons interested in the implementation and evaluation of health information technologies. These experts, drawn from medical informaticians across the United States, agreed that a basic system of categorization would be useful to organize content into a searchable knowledge base. The experts also expressed a desire for the taxonomy to be used as a method for educating visitors about common terminology used in the field of health IT.

The panel began design of the taxonomy using a structured brainstorming exercise. The brainstorming involved thinking through the various types of content the Web site would feature, which stakeholders the Web site would target, and what topics best matched the goals of the Web site designers, stakeholders, and potential users. A preliminary confluence of ideas was slowly organized into logical buckets by the end of the brainstorming session. The buckets top level terms and the terms contained therein branches as used in most controlled vocabularies comprised the first draft of the taxonomy.

The panel next looked to a number of existing taxonomies to refine each top level term and its branches. The EHR Mind Map, created by the Healthcare Information Management Systems Society (HIMSS), provided some useful terms, but it was found to be narrowly focused on EHR systems, neglecting technologies such as telemedicine and health information exchange [5]. The panel also considered the ACMs Computing Classification System (CCS), but it consists primarily of computer science terms (e.g., programming languages, mathematical theory, and data structures) whereas the target audience for the Web site is clinical and health administration leaders engaged in health IT implementation activities [6]. Finally, the panel considered MESH but found it too lacked sufficient granularity to cover the complete technical (e.g., EHR, HIE, telemedicine) and sociological (e.g., adoption, process redesign, project management) spectrums that encompass the field of health IT [7].

To create a taxonomy for health IT, the panel created a draft using terms from the three major taxonomies it examined. The group then organized the list into clusters of related terms under broad categories, and it began to search for additional terms that would fit into its categories. The organized list became version 1.0 of the taxonomy.

Since the panels original meeting, the taxonomy has been expanded and refined. A first round of edits came after a second expert review was conducted by experts associated with the NRC who could not attend the original expert panel meeting. A second round of edits came when two of the authors (Dixon and Zafar) used the taxonomy to classify journal articles and other resource documents in the online library the taxonomy was developed to support. A third set of modifications was made when two NRC experts (Dixon and Samarth) applied the taxonomy to the more than 120 health IT grants and contracts awarded by AHRQ within the last two years (FY04 and FY05).

The taxonomy was also evaluated on two subsequent occasions to ensure comprehensiveness and usability. A formal review of the taxonomy was conducted in late 2005 by the large panel of experts on staff with the NRC. The recommendations of the panel were implemented as part of the development version of the AHRQ health IT Web site.

In early 2006, a second type of evaluation took the form of usability testing, a critical component in software and Web development. Health care and IT professionals from leading non-profit and government organizations were asked to use an online, interactive version of the taxonomy to search for health IT resources. Testing was conducted at the National Library of Medicine (NLM) usability lab in Washington, D.C. User experiences were observed, recorded, and analyzed by NLM and NRC staff.

Based on recorded user experiences, the taxonomy and its appearance on the Web site were altered. For example, a minor category EHR Systems was renamed Implementation of Health IT after some users confused it with the EHR minor category. Users also reported that they did not associate the term clinical decision support with the EHR minor category, so it was renamed Electronic Health. Other users commented on the taxonomys appearance, noting that they would prefer to see terms such as electronic health records and health information exchange as entry points (e.g., major categories) to the taxonomy. Instead of altering the major dimensions of the taxonomy to accommodate user requests, prevalent terminology was summarized together under its parent branch for display on the Knowledge Library main page.

Results

The taxonomy is organized into six major and 28 minor categories (high-level terminology) with two additional sub-levels for controlled vocabulary terminology (discrete, classifiable concepts) and a dictionary for controlled vocabulary terminology synonyms. Based on the results of the usability testing, a subset of the 400+ terms and synonyms were selected to drive terminology browsing of the online resources.

When users click on a term, a search is performed in the background, and results are displayed for the user to browse through. Resources from the core collection, those tagged by an NRC expert, are promoted to the top of the result list. Partner contributions, online resources aggregated from a variety of health IT-focused organizations, fill out the result list and are sorted based on the prevalence of the selected term within the resource.

Of the 6872 online resources available through the AHRQ health IT Web site, 702 (10.2%) reside in the core collection. Table 1 presents the major and minor categories along with the number of core collection resources belonging to them.

Organizational strategy

Technology is implemented in order to solve problems and improve processes. Strategies designed to address specific problems and processes will ensure the successful implementation of technology within organizations.

- Financial strategies create initial and sustained revenue for the deployment and maintenance of technology.
- Strategic planning helps technology deployment meet the needs of an organization and ensure that technology solutions adhere to the mission and vision of an organization.
- Strategies for process change give implementers tools for addressing the human component of technology adoption.
- Implementation of health IT strategies provide roadmaps to help organizations procure and adopt technologies. In health care, these strategies should be crafted to ensure interoperability and the protection of privacy for personal health information.
- Policy strategies address legal issues, such as federal and state regulations related to the sharing of patient data across state lines. Strategic policies can also include those designed to ensure technology meets certification requirements and accreditation criteria.

Technology

Technology in this taxonomy is broadly defined, and its definition includes individual components such as hardware (e.g., PDA, tablet PC) and complete systems (e.g. laboratory information system - LIS, computerized physician order entry - CPOE).

- Mobile computing is important to health care since the workforce is by-and-large mobile, traveling from room-to-room or clinic-to-hospital.
- Infrastructure is a critical component of all technology projects as it describes how data is communicated.
- Security is a major priority in health care as we strive to provide the right amount of data to the appropriate group of individuals providing care to a patient.
- Standards enable interoperability, the ability for two disparate information systems to seamlessly share data. Many standards are available in the market, however, so distinguishing between them becomes important when exchanging information.

- Electronic Health is a broad concept that encompasses complete systems (e.g., PACS, EMR, CPOE), functions (e.g., clinical messaging, results reporting), and components (e.g., knowledge base, dashboard, rules engine).
- Telehealth describes technologies deployed that allow care to be provided remotely, including remote monitoring of patients in their homes.
- Health Information Exchange (HIE) involves the exchange of patient data between providers and disparate clinical information systems. HIE includes various labels (e.g., LHII, NHII, NHIN), policy elements (e.g., governance, data sharing agreements), technical components (e.g., architecture, interface engine), and applications (e.g., research, public health reporting).
- Consumer Health encompasses technologies that engage patients in the delivery and management of their health.

Value

Evaluation is a core discipline in health IT as the tolerance for mistakes is extremely small. Research and outcomes are also important to demonstrate return-on-investment (ROI) and IT system impacts on patient safety and the quality of delivered care.

- Research includes study designs, data analysis techniques, evidence based medicine (EBM) practices, institutional research board (IRB) policies, and grant writing resources.
- Evaluation outcomes focuses on results of published studies and outcomes of non-academic lessons learned by professionals in the field in a variety of areas (e.g., safety, quality, ROI, patient satisfaction, etc.).

Laws and standards

Laws and standards affect the development, implementation, and adoption of health IT.

- Sample Legal Documents includes a variety of legal documents developed by health care organizations across the nation.
- Privacy includes information on protected health information laws and standards, such as HIPAA.
- Security contains resources on administrative, physical, and technical security as well as security audits.
- Government includes resources on state and federal regulations as well as government standards related to the national health information network (NHIN).

Organizations

There are many entities involved in the field of health IT, and each organization has an agenda and a role to play in development and adoption of technology in health care. It is important to understand these and the ability to tell the difference between entities.

- Professional societies are member organizations which advocate on behalf of their membership, advance professional ethics, and strive to set standards for the industry.
- Payers include those organizations that reimburse for health care expenditures.
- Governmental organizations include state and federal agencies that support health IT initiatives.
- Nonprofit organizations are independent entities who seek to educate, develop, promote, and research the advancement of technologies for use in health care.
- Magazines include news and trade publications which seek to report on the health IT industry.

Operations

Management of operations is critical to the prolonged use of technologies in health care.

- Governance includes organizational policies related to human and technological resources.
- Project management consists of resources to help manage the implementation and maintenance of health information technologies.
- Systems operation includes resources to help with day-to-day maintenance and operation of health IT systems.
- Dissemination is crucial primarily to those conducting research in the field of health IT. However, sharing best practices and successful implementations can be strategic for many organizations.

The taxonomy covers the broad spectrum of topics discussed in the field of health IT. The controlled vocabulary terms are too numerous to publish here, but many of them can be found on the AHRQ health IT Web site, http://healthit.ahrq.gov. User feedback will contribute to the taxonomys future development.

Discussion

The need for a taxonomy for health IT was driven by the creation of a Web site containing knowledge-based resources to support health IT planning, implementation, and evaluation. No single source existed which could provide a contextual vocabulary with the breadth and depth necessary for efficient and effective access of the online resources. The process to create such a taxonomy involved panels of health IT experts identifying and refining terms, hierarchies, and cross-references. The taxonomy was then evaluated for thoroughness and usability.

The formal reviews and usability testing emphasized the need for robust synonymy within any taxonomy. For example, Electronic Health is the term chosen by our experts for a minor category under Technology. Synonymy is critical to ensure that documents which use terms such as electronic medical records and computer-based patient records will be appropriately selected and ranked when searches are performed against the online library.

Usability testing revealed a strong need for the development of inter-relationships between orthogonal concepts. We found that users not only searched for documents related to computerized physician order entry, but they desired CPOE related documents in specific practice settings (e.g., ambulatory, inpatient). We further found that users desired to distinguish between documents related to

small practices and large medical centers. Based on this feedback, we intend to develop interrelated concepts to address these needs.

Conclusion

While health information technology embodies a set of concepts familiar to medical informaticians and others in the health IT field, its concepts are foreign to many in the health care field and present barriers to effective planning, implementation, and evaluation of electronic health record systems and other health information technologies. Because of the need to provide a national resource for health IT information, and to make this knowledge repository readily accessible, a health IT taxonomy was developed through a series of iterative processes.

The health IT taxonomy provides a hierarchical and interrelated classification schema for use by those engaged in the development, implementation, and evaluation of health information technologies. Its use on the AHRQ health IT Web site enables users to efficiently access the resources created and aggregated by NRC staff. Application of the taxonomy to other NRC activities and external knowledge stores is planned, and we believe it will create better understanding of common terms and their interrelations.

Just as the field of information technology is rapidly changing, the health IT taxonomy must remain dynamic. In addition to continued application of it to other components of the AHRQ health IT web site, additional evaluation is planned. This taxonomy is offered to anyone creating a searchable knowledge repository, and we hope that future development will become a living process with contributions from all who use it.

Acknowledgements

This work was supported by the Agency for Healthcare Research and Quality (AHRQ) as part of the AHRQ National Resource Center for Health Information Technologys (Contract No. 290-04-0016) project to build and maintain a free, public Web site for those interested in the implementation and evaluation of health IT. We would also like to thank the following NRC colleagues who contributed greatly to the development of the taxonomy: Davis Bu, MD, Center for Information Technology Leadership, Mark Frisse, MD, MBA, Vanderbilt Center for Better Health, Anita Samarth, ASTECH Consulting, and Jack Starmer, MD, Vanderbilt Center for Better Health.

A Practical Approach to Advanced Terminology Services in Health Information Systems

Maria Laura Gambarte [a], Alejandro Lopez Osornio [a], Marcela Martinez [a], Guillermo Reynoso [b], Daniel Luna [a], Fernan Gonzlez Bernaldo de Quiros [a]

[a] *Medical Informatics Department, Hospital Italiano of Buenos Aires, Argentina*
[b] *Conceptum, Buenos Aires, Argentina*

Abstract

As the medical informatics field evolves, new functions appear as the focus of interest; a more advanced management of terminology is one of them. Using comprehensive and detailed terminology to represent clinical rules in computer systems, associated with patient information, would allow clinical software to provide patient specific recommendations or alerts. In order to uniform data collection through our HIS, and lay the foundations for future clinical decision support systems, we decided to move from our previous classification- based medical record into new terminology services built around Snomed CT, Spanish Language Version. This paper describes the characteristics of our Terminology Server.

The most important achievements of our new terminology system are the centralization of knowledge representation, using a much more detailed terminology system. Clinical data entered at any place of the institution and level of care, is represented uniformly through the whole health information system.

Keywords:

information storage and retrieval, classifications, terminology services

Introduction

Until recently, implementing vocabulary control in medical informatics implied selecting the most appropriate classification for the specific clinical scenario. This was a reliable solution for the intended objectives, like epidemiological description of reality, billing or simple chronic diseases detection on large populations.

As the medical informatics field evolves new functions appear as the focus of interest; a more advanced management of terminology is one of them. New Health Information Systems (HIS) need to store information in a way it can not only be interpreted by human users, but also by computer powered knowledge management rules (1). Encoding clinical rules in computer systems, associated with patient information, would allow clinical software to provide patient specific recommendations or to focus health professional attention to situations that may otherwise be overlooked (2).

The purpose of this paper is to describe our approach to this advanced knowledge representation system in the electronic medical records at the Hospital Italiano of Buenos Aires, with emphasis on data entry, storing and extraction processes.

Background

The most important new functions of complex knowledge representation systems are interoperability and clinical decision support.

Current HIS are designed to link all levels of care, like the primary care office, nursing stations, intensive care units, rehabilitation, etc. Vocabulary control in this new setting gets more complicated, and as each part of the system uses a different classification or list of terms we run the risk of getting into a Tower of Babel situation. Vocabulary control tools must have the ability to serve all settings, and provide an adequate level of detail to each one, as general concepts for ambulatory reasons for encounter or nursing diagnoses, as well as very specific concepts such as specialist registries.

Clinical information systems are expected to improve the quality of patient care. This can be achieved by linking clinical information stored in their databases with current scientific recommendations to bring decision support to physicians, or by selecting high-risk populations where population level interventions proved to bring clear benefits. These features require a strict vocabulary control of patient data and clinical rules data.

Old Classification-based coding systems, common in current Electronic Health Records (EHR) software, are not up to these new challenges. They fail to provide inter-setting validity, they have not the adequate granularity for different levels of care and they are also unsuitable for linking knowledge rules for clinical decision support systems.

To provide solutions to these new functions of the medical record, an advanced knowledge representation system is needed. Implementing this tool in institution-wide health information systems represents a great challenge.

There are some examples of the state of the art terminology systems with knowledge-based representations of medical concepts, like Snomed CT (3), Unified Medical Language System (UMLS) (4), the Medical Entities Dictionary (MED) (1), Nebraska Medical Center (5) or Kaiser Permanente Convergent Medical Terminology (6). Nebraska and Kaiser are based on Snomed CT.

Snomed CT is a nomenclature originally created by the College of American Pathologists (CAP), and is evolving into an international Standards Development Organization (SDO). This is currently regarded as the most advanced initiative in knowledge-based representations with clinical application. Each of the 300,000 terms included are defined using relationships with other terms, creating a powerful semantic network. Simple algorithms allow easy finding of sub types, super types and attributes of any given term. Snomed CT data model allows the continuous extension of the nomenclature, adding new terms, always following the same compositional concept representation model, called Description Logics (7, 8).

These characteristics give Snomed CT a great role as the first building block of a terminology implementation, as has been proposed in previous experiences, either private as Kaiser Permanente or Cerner (9), and governmental as the cases of health departments of the United Kingdom, Australia, and the United States.

Chute et al. outlined three functions required in a terminology system (10), as it was previously described by the U.S. Computer-based Patient Record Institute (CPRI) during the National Conference on Terminology in November 1997. These three functions or layers are:

Entry Terminology: this is the user interface, the terms used to interact with users during data entry process

Reference Terminology: this is the format used to store data, knowledge information should be stored in this layer

Aggregate Terminology: different data formats outputs for user analysis

Snomed CT provides functionalities in these three layers. As indicated before, it has every important feature of a *reference terminology*. Snomed CT also includes several descriptions that can be used as an *entry terminology*. Finally, Snomed CT has a standard cross mapping model; the official distribution includes data for mapping to ICD-9CM (ICD - International Classification of Diseases). Additional ICD-10 cross map data has also been developed in the UK, but is not as widely available, and more new cross maps are under development, like ICPC-2 or NANDA. Snomed CT is included in UMLS (11), which provides some degree of relationship with many other terminologies. These mappings provide the *aggregate terminology* features to Snomed CT.

In order to uniform data collection all through our HIS, and lay the foundations for future clinical decision support systems, we decided to move from our previous classification-based medical record into new terminology services built around Snomed CT.

HL7 (Health Level 7) organization has published a Common Terminology Services (CTS) standard specification. At this stage of the project we decided to create terminology services to provide a solution to the local terminology needs, in a second stage a CTS compatible API (Application Programming Interface) will be created as a new layer that will allow standard access to our services.

Setting

The Hospital Italiano of Buenos Aires is a 650-bed non-profit university hospital located in Buenos Aires, Argentina. More than 150,000 ambulatory visits and 3,000 hospitalizations are registered every month. It is affiliated with a Health Maintenance Organization (Plan de Salud) that takes care of a population of 140,000 patients.

Since 1998 a full scale HIS has been gradually implemented, including ambulatory Electronic Medical Record (EMR), inpatient discharge summary, administrative systems, scheduling systems, inpatient tracking systems, pharmacy systems and complementary studies report and visualization. Several health informatics standards had been implemented, including HL7, CDA Version 2, ICD-9CM, DRG, ICD10, and ICPC.

Previous vocabulary control system consisted in professionals entering free text descriptions, which were later assigned classification codes by a group of coders (12).

Design objectives

Our main objective was to design a new terminology system, whose objectives can be related to each of the functions of the terminology system previously described (entry, reference and aggregate terminology).

Entry terminology functions:

- Provide an institutional vocabulary for all user interfaces, so our professionals interact with familiar terms, including local jargon and preferences.
- Provide concept lookup functions, with loose lexical matches and options, to be used during data entry process of new items in a problems list or similar user interfaces.
- Provide short pick-lists definitions for more structured data entry in specific use templates, with a short list of valid entries, like occupation, level of consciousness, etc.
- Provide navigational tree interfaces for structured data entry in more complex templates, like cause of liver failure, etc.
- Provide different preferred terms for the same concept in different settings.
- It should include the ability to accept new terms from the user, in case a concept or description is not represented.
- It should detect inappropriate terms for being too general or not valid in a subset, as in the case of problem lists entries Emergency Consultation or Cardiology, etc.

Reference terminology functions:

- The entry terminology should be represented in the reference terminology (Snomed CT Spanish Language Version).
- New concepts should be created for institutional terms that cannot be represented with a standard Snomed CT code.
- The system should provide tools to take advantage of the knowledge stored in Snomed CT relationships, like obtaining more refined or more general terms.
- The system should provide means of updating to new versions of Snomed CT without loosing information, nor requiring large amounts of manual updates.

Aggregate terminology functions:

- Provide output to several standard classifications:
- ICD-9CM (diag & procedures)
- ICD-10 (diagnosis)
- ICPC-2 (diagnosis) (International Classification of Primary Care)
- ATC (drugs) (Anatomical Therapeutic Chemical Classification)
- Local billing nomenclatures
- Aggregate data according to Snomed CT hierarchies

All desired functions should run on a centralized software and data structure, referred to as a Terminology Server. The Terminology Server should provide these functions to all existing applications in the Health Information System in the form of Web Services.

A terminology maintenance software application should also be developed to administrate the institutional terminology, its relationship with Snomed and the mappings.

System description

Entry terminology

The institutional entry terminology is composed of concepts and descriptions. We use Snomed definition of these terms (13), where concepts represent distinct clinical meanings and descriptions are a phrase used to name a concept.

The development of the entry terminology is described with more detail in other paper in process.

Our institutional entry terminology can be divided in several subsets; examples of these are:

- Problems list terminology
- Procedures terminology
- Findings in chest radiography
- Administration routes for drugs
- State of consciousness description
- Physical examination subset
- Liver Failure Diagnosis

Some subsets are very large, including thousands of concepts (i.e. the problems list subset). Others are short lists (i.e. the liver failure subset). Each subset was designed in order to be used as the entry terminology in a specific scenario.

Concepts are defined only once, regardless of its inclusion in more than one subset; therefore, accessing liver cirrhosis from the problems list or from the Liver failure subset brings the user to the same concept.

The process of adding concepts to the entry terminology and organizing them in subsets is manual. This is done by trained coders that were previously working with the same information in secondary coding using classifications (12).

Construction of the problems list subset was one of our biggest challenges. We decided to base our work on the historic database of our EHR with more than 2 million free text inputs since 1998. All problems list entries and discharge notes were processed to extract all different textual descriptions, this strings were originally entered with a 50 character limit. We considered that these texts, entered by our own professionals in a completely unconstrained way, would be representative of the local natural language, including abbreviations and jargon. A manual depuration process, assisted by string normalization functions, led to the creation of the Problems List subset with 24,800 different concepts, with 110,000 descriptions in total.

Other subsets were created using arbitrary lists of concepts selected by the clinical terminology team with user input, like the case of Liver failure or Routes of administration subsets.

New concepts or descriptions were accepted from user interfaces and stored for manual evaluation.

The data model for the entry terminology was the standard Snomed CT data model for concepts, descriptions and subsets (14). New concepts and descriptions were added to the standard Snomed CT distribution following official Snomed rules for creating institutional extensions.

Reference terminology

Implementing the reference terminology involves establishing a very detailed terminology as the format in which clinical information will be ultimately stored. Reference terminology is invisible to the users: therefore, it is necessary to define the relationships of each concept included in the entry terminology with the concepts included in the reference terminology.

We used Snomed CT Spanish Language Version as the reference terminology, but is important to note that all different language versions of Snomed CT share the same concepts and relationships. During the translation process only new descriptions are added.

Both entry and reference terminologies were stored following the Snomed data model, and using Snomed tools to represent the concepts of the entry terminology. Snomed CT defines concepts by its relationships with others, so we created new relationships as part of our Snomed CT extension.

Snomed CT has around 300,000 concepts, but in a clinical setting, health professionals usually use very detailed expressions, adding modifiers to general concepts, like mild ankle sprain. To prevent the exponential growth of the nomenclature, Snomed CT avoids including such level of combination with modifiers, providing the general concepts (ankle sprain), the possible modifiers (mild) and the rules to correctly relate them (using the has severity relationship). Any new concept can be represented using this post-coordination technique, creating more detailed subtypes of existing Snomed CT concepts.

Around 33% of the concepts included in the Problems List subset could be directly mapped with existing Snomed CT concepts; the other 77% needed the addition of one or more modifiers (post-coordination) in order to fully represent the meaning of the entry terminology concept. This rate of post-coordination was dictated by a very permissive policy allowing the use of any term requested by the users, often very specific or personalized. The total of 24,800 concepts was represented with 45,000 new relationships.

Aggregate terminology

The official Snomed CT cross maps model was implemented, a multi-classification interface was created as part of the Terminology Maintenance Software to visualize, test and modify mappings from Snomed to different classifications.

An SQL algorithm was designed (Oracle SQL) to aggregate concepts according to knowledge stored in Snomed CT relationships, like all kinds of diabetes, including diabetes complications and excluding maternal and neonatal diseases. These queries are maintained from a module in the Terminology Maintenance Software.

Terminology server

We developed a set of software services to provide the accesses to the new terminology system to other applications:

Lexical Concept Lookup: introducing a keyword retrieves exact matches or a set of similar concepts from a given subset.

Short List Retrieval: using the subset identifier, retrieves a list of concepts to include in a pick list in user interfaces.

Navigational Tree Retrieval: using the subset identifier, retrieves a list of concepts and its relationships to create tree selector in user interfaces.

New Concept Proposal: this service accepts new concepts and adds them to the pending list in the Terminology Maintenance Software.

Map to Classification: given any entry terminology concept identifier and any available classification provides the resulting code in such classification.

Terminology maintenance software

The Terminology Maintenance Software includes the following modules:

- Entry Terminology Administration: allows the creation of new concepts, description assignment and modeling of each concept with Snomed CT.
- Subset Administration: creation of new subsets, addition and removal of concepts from the subsets, defining hierarchies for tree interfaces.
- Pending Concepts or descriptions: all proposed new concepts or descriptions are stored in a list, waiting to be evaluated and modeled, ordered by the number of proposals
- Cross Maps Administration: existing cross maps can be visualized, edited and tested using this module
- Data Extraction Rules Administration: A software interface to visualize and update Snomed based data extraction queries.

Invalid terms administration

In each subset, professionals usually try to enter terms that are not valid for later use, like trying to write Cardiology in the problems list. We would like the doctor to record the proper diagnosis or reason for encounter instead.

In order to reject these terms we tag them and add an information text so the professional understands the coding guidelines of the institution. This module provides the tools for tagging these terms and editing the information.

Status report

Four trained modelers are maintaining the interface terminology, modeling pending concepts or descriptions, running routine quality control checks, and maintaining subsets.

We created an ad-hoc automatic process to recode all historic data in our clinical repository, using string matching algorithms; more than 2,200,000 entries were processed. Around 85% of the original texts received a concept code of the new entry terminology, 10% of them were recognized as invalid entries: therefore, 75% were finally mapped to Snomed CT.

The coding services are used on-line by our ambulatory and inpatient medical record, receiving around 55,000 requests each month.

Mapping to ICD-9CM from Snomed is not fully functional. It is currently running with an approximate effectiveness of 50%, and is under revision by the modelers. Previous manual codification processes are still in use until cross maps system performance improves. The use of the ICD-9CM cross-map will be addressed in a future paper.

Data extraction from the clinical information repository, using Snomed-based aggregation functions, runs daily to feed lists of target patients to a Chronic Disease Patient Registry (15). Program managers referred a great improvement in patient detection rates as compared to the previous classification-based procedure.

Discussion

Snomed CT provided an excellent structure for the initial organization of our terminology system, even when documentation not always is fully comprehensive and some proposed models will be subjected to changes in the near future due to Snomeds technical board revisions. Snomed CT has been regarded as too complex to use in real world applications; we think that properly defining the entry terminology and cross maps are essential steps in its utilization.

The task of creating an institutional entry terminology demands a lot of work, but provides an excellent service to the users, and also isolates the terminology system from Snomed CT changes in newer versions. Local concepts will always be valid, and in the worst case a correction of modeling against Snomed CT would be required.

We found that Snomed CT cross maps data to ICD-9CM is still not adequate for clinical use in our setting, requiring additional manual work on the maps. This may be caused by a different use of the classification in Argentina and the United States.

Our clinical data extraction process, using rules based in Snomed CT knowledge data, is very effective; however, these rules should be revised for each new Snomed CT version, as changes in hierarchies and models may affect its effectiveness.

Further reduction of manual classification coding will require adjustments of mapping specifications and user interface changes, aimed to reduce the number of new concepts proposals, and enforcing the selection of existing terms. Due to acceptability issues, we have always tried to minimize user interface constrains, thus implementation of these changes will be a slow process.

The most important achievements of our new terminology system are the centralization of knowledge representation, using a much more detailed terminology system. Clinical data entered at any place of the institution, and level of care, is represented uniformly through all the health information system.

Abstract

Semantic interoperability in healthcare can be achieved by a tighter coupling of terminology and HL7 message models. In this paper, we highlight the difficulty of achieving this goal, but show how it can become attainable by basing HL7 message models on SNOMED CT concepts and relationships. We then demonstrate how this methodology has been applied to a set of clinical observations for use in the ePOC project, and discuss our findings.

Keywords:

SNOMED, HL7, interoperability, terminology

Introduction

One of the biggest obstructions to communication in healthcare occurs when there are multiple ways of describing a single concept. Using a standard terminology of clinical concepts is the first step to unambiguous information exchange. If the primary clinical data entered into a system is structured using a standard expressive vocabulary, this data can then be used for secondary purposes in later stages of patient care, such as search of and selective presentation of data, decision support, and statistical evaluation [1].

In the course of constructing the Kaiser-Permanente *Convergent Medical Terminology* (CMT), Dolin, et al have reviewed three major terminologies and described their weak points [2]. The terminologies they employ are *SNOMED CT*, laboratory *LOINC*, and *First DataBank* drug terminology. In particular, with respect to SNOMED CT they conjecture that standardizing certain subsets of concepts for use in HL7 messages would greatly enhance interoperability, but first some research would have to be conducted into where the HL7 RIM and SNOMED CT overlap, and some formal guidelines be developed.

In [3] a proposal and possible solution to ambiguous communication involving basing HL7 message models on SNOMED CT concepts and relationships was discussed. Further to this, SNOMED CT concepts corresponding to a set of clinical observations have been mapped to HL7 message models for use in the *e*POC (*electronic* Point of Care) project, and as a proof-of-concept.

The *e*POC project is a multi-phase, iterative R&D project with a research focus involving the development of a prototype Personal Digital Assistant (PDA) based *point-of-care* information delivery system for The Ambulatory Care Team (TACT), Northern Illawarra, Australia [4]. TACT has a requirement to enter data at the point-of-care about a patient condition and the clinical activities carried out during the ambulatory visit. In its implementation, *e*POC addresses the difficulties of federating disparate data, HL7 messaging, implementation of clinical terminology, and the limitations of the mobile platform within a practical community clinical health service environment.

The terminology we are concerned with in the *e*POC project is SNOMED CT, as we are focusing on clinical data. Laboratory and drug codes are outside the scope of the *e*POC project.

Our preliminary findings from mapping clinical observations data required by TACT to HL7 based on SNOMED CT concepts and their relationships are discussed in the following sections.

Methods

HL7 Version 3

Version 2 of the HL7 standard is widely implemented; however it has been increasingly difficult to support health information interoperability in today's rich computing environment using this methodology. Version 3 of the HL7 standard incorporates a new paradigm for information representation and messaging in comparison to HL7 version 2 in terms of a new information model and intrinsic extensibility [5]. The Reference Information Model (RIM) is the cornerstone of the HL7 Version 3 development process. The RIM is an object model in the form of a large UML-like representation of clinical data and is a powerful abstract model of healthcare [1, 5, 6].

The difficulty arises when trying to represent clinical concepts and constructs within the HL7 framework. This is where SNOMED CT comes into play as a standard terminology for use in conjunction with the information model.

SNOMED CT

SNOMED CT is a universal health care terminology, the aim of which is to make health care knowledge usable and accessible wherever and whenever needed [7]. The SNOMED CT core terminology provides a common language that enables a consistent way of capturing, sharing and aggregating health data across specialties and sites of care. SNOMED CT contains more than 344,000 active concepts: the most comprehensive clinical vocabulary available in any language, covering most aspects of clinical medicine [8].

Clinical observations

Eight clinical observations are made by TACT clinical staff every time they visit a patient. These clinical observations were chosen as the starting point in the *e*POC project for sending messages containing clinical information from the central database to the PDA and vice versa.

The eight clinical observations are:

- Temperature
- Pulse
- Respiration
- Blood Pressure
- Oxygen Saturation (O_2Sat)
- Weight
- Blood Sugar Level
- Urinalysis

After meetings and discussion with TACT clinical staff and domain experts, SNOMED CT codes and data structures for each of these observations were ascertained. From this point, HL7 messages were modeled based on the relationships between the chosen SNOMED CT concepts.

SNOMED-CT concepts and relationships

According to Markwell [9], statements about clinical findings can be divided into two categories: those in which there are two clearly distinct facets (example 1) and those which are often captured as a single "nominalized" expression (example 2):

- Pulse rate = 82 beats/minute (1)
- Has a fracture of his right femur(2)

Looking at (1), the two facets are separated by the equal sign (=); the first being the property which was observed (Pulse rate) and the second the result of the observation (82 beats/minute).

Clinical findings in the second category (2) raise a plethora of issues in where, or even whether, to split the different concepts represented by the statement. Some of the choices are to split them as shown in examples 3 and 4:

- Property = right femur, finding = fracture (3)
- Omit property, finding = fracture of right femur (4)

In (3), the clinical finding has been split into two-facets in an attempt to model the simpler type of finding. In (4), the concepts represented in the clinical finding have not been split at all. It can be seen where problems may arise when different people use different methods of representation, especially in situations where there are many concepts combined to create one finding, hence causing many more forms of representation, e.g., "the patient has a family history of myocardial infarction".

All the clinical observations in our set of eight are of the two-faceted form (except urinalysis which is made up of many two-faceted observations). With this in mind, it was decided not to use SNOMED CT concepts from the *Clinical Finding* hierarchy as the description codes for the property to be recorded, instead it was decided that it is more effective to represent a clinical finding in this context as a SNOMED CT concept from the *Observable Entity* hierarchy, plus a value. This is in line with the two-faceted model, the first facet being the Observable Entity and the second facet its observed value.

Concepts from the Clinical Finding hierarchy are then used in decision support to describe inferred concepts taken from the recorded observation codes and their associated value. For example, if the value recorded for a patient's blood pressure is above a certain point, the concept of *high blood pressure* from the Clinical Finding hierarchy will also be recorded against the patient. We will not go into much detail about decision support, as discussion of the inferred finding aspect of our model is not the subject of this paper.

Figure 1 shows a subset of the SNOMED CT Observable Entity hierarchy used in our messages. The top level concept in this diagram is *vital signs*. Only four of the eight clinical observations required by TACT have corresponding concepts which are subtypes of the *vital signs* concept, the other concepts (corresponding to O_2Sat, Weight, Blood Sugar Level and Urinalysis) are at the same level in the hierarchy as *vital signs*, and are all subtypes of *observable entity*. The "vital signs" subset is used as an example here for simplicity and readability. The circles in the diagram represent the concepts and the arrows depict a *subtype* relationship, the opposite direction being the *IsA* relationship.

The procedures followed to make these observations have corresponding concepts under the SNOMED CT *Procedures* hierarchy, with near-identical relationships. Figure 2 shows a subset of the Procedure hierarchy used in our messages.

HL7 messages based on SNOMED CT structures

One of the findings from Dolin, et al. [2] in the CMT project is that a tighter coupling of SNOMED CT and HL7 would greatly enhance interoperability between healthcare systems. They argue that different implementations of HL7 could use different code sets and coding schemes. This problem can start to be solved by doing away with the HL7 tables and using SNOMED CT code subsets exclusively for all code-type fields, thus setting a standard coding scheme for use throughout the model. The two exceptions to this rule are the HL7 *classCode* and *moodCode* fields, although the allowable codes for these two fields are already defined by standard, non-extensible code sets within HL7, so this will not create a problem.

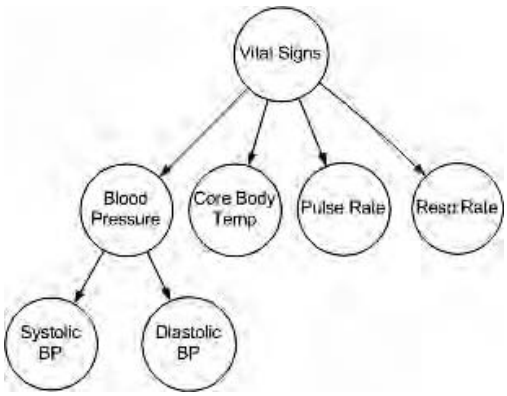

Figure 1 - Hierarchy of a subset of the SNOMED CT codes used in our Clinical Observation. The arrows depict a subtype relationship, the opposite direction being the IsA relationship.

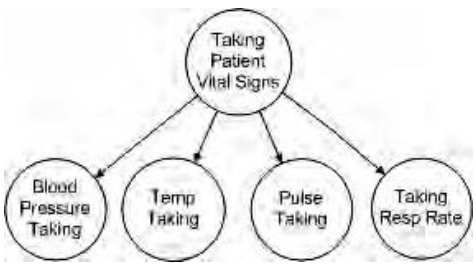

Figure 2 - Hierarchy of SNOMED CT procedure codes corresponding to the subset of observations shown in Figure 1. The arrows depict a subtype relationship, the opposite direction being the IsA relationship.

The eight clinical observations are represented in the HL7 model by instances of the Observation specialization of the Act class. Issues involving the use of terminology in the *Observation.code* and *Observation.value* fields have caused much discussion and debate [9], as discussed in the previous section. However, in the case of the two-faceted clinical finding, the representation is straight-forward. In this case, the *Observation.code* field contains the SNOMED CT code for the observation (or property), and the *Observation.value* field contains the measured value (or finding) for the observation.

The procedures shown in Figure 2 are put into the *Observation.methodCode* field to further enrich the model, by capturing both of the SNOMED CT hierarchies within the one HL7 Act "hierarchy".

The inferred findings discussed briefly in the previous section are put into the *observationInterpretation* field, but no relationships can be inferred between the observations based on this field.

Future SNOMED CT to HL7 mapping will also include the *targetSiteCode* field of the HL7 Observation class, in which the body site will be represented by a SNOMED CT *Body Structure* code.

SNOMED CT hierarchy represented in HL7

The SNOMED CT *IsA* relationship can be considered in two ways when representing it in the information model for clinical observations.

The first is that the parent (destination of the *IsA* relationship) is a *collector* (list) of entries of subtype clinical observations. This SNOMED CT concept hierarchy is preserved by the *code* field in the Observations and the HL7 *component* and *componentOf* ActRelationships. For example, in Figure 1, *blood pressure* is a subtype of *vital signs* and can be said to have the relationship *IsA* with `vital signs`. The SNOMED CT *IsA* relationship corresponds to a HL7 *componentOf* relationship, for this field.

Likewise, the relationships between the Procedure concepts for each Observation in the *methodCode* field are also preserved. For example, in Figure 2, *blood pressure taking* is a subtype of *taking patient vital signs* and can be said to have the relationship *IsA* with `taking patient vital signs`. Thus, the HL7 *componentOf* relationship also represents the *IsA* relationship for this field.

The second way of considering the SNOMED CT *IsA* relationship is to think of the parent as a *generalization* of the subtypes and thus defining a commonly supported pattern of supported specializations. The specializations constrain the allowed use of attributes, and allowed value domains/sets for attributes. This includes coded attributes in the specialization classes being restricted to valid SNOMED CT hierarchies. This has the effect of describing a HL7 v3 model hierarchy of HL7 templates with a messaging model being used as the base such as HL7 Care Provision Domain [10] messaging or Clinical Document Architecture [11].

Figure 3 shows an excerpt of the HL7 model based on the vital signs subset, along with the hierarchies shown in Figures 1 and 2, with arrows showing where the codes for these concepts fit into the HL7 model.

This message model has been implemented in the *e*POC project for use in communication between the PDA and the central database. Field trials of *e*POC are scheduled for May, in which TACT clinical staff will employ the use of the PDA with the *e*POC application in their daily home visits.

Conclusions

By basing HL7 message structures on SNOMED CT relationships a tighter coupling between data model and terminology can be created. The preliminary application of this model for simple observation data has shown that it is possible and applicable. Careful thought is being put into applying the model for more complicated data, i.e. the "nominalized" type of data shown in example (2).

The work shown here is just the beginning of mapping SNOMED CT relationships to HL7 message structures. We are moving toward a semi-automated system for creating HL7 messages on the fly, based on SNOMED-CT concepts selected by clinicians at the point-of care. We say

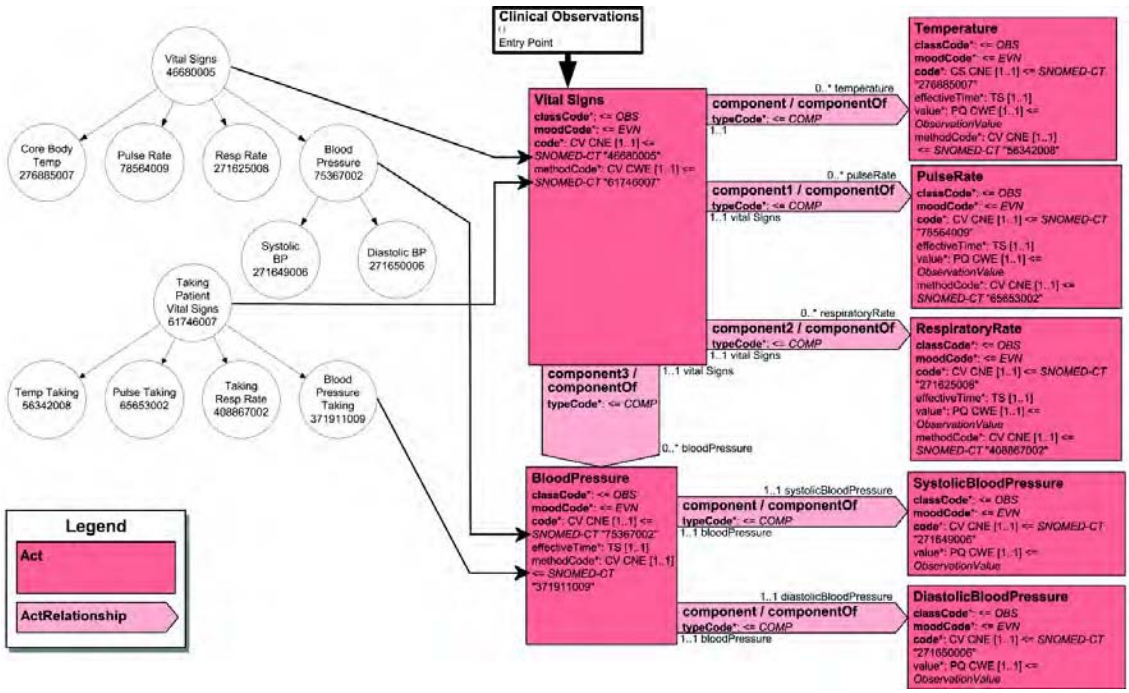

Figure 3 - Excerpt of HL7 model based on SNOMED CT Relationships shown in Figures 1 and 2. The ActRelationships correspond to the arrows in the SNOMED CT figures.

"semi-automated" because we would like the messages to be generated with as little human input as possible, but realize that achieving full automation of this process is highly unlikely. An example rule based on the clinical observation data presented here is that a SNOMED CT Observable Entity must be represented in HL7 as an Observation specialization of the Act class, with the SNOMED CT concept ID populating the Observation.code field.

Future directions of research will focus on furthering semantic interoperability between Healthcare systems using what we see as the best technology in the area.

Abstract

To facilitate the use of standard terminologies in clinical research data collection, members of the Rare Disease Clinical Research Network have developed tools to support study investigators and research staff to code clinical research data using SNOMED CT at the point of research. This tool is customized to help the user find appropriate SNOMED CT concepts quickly, and has implications for the successful implementation of data standards to facilitate high quality research data. This paper gives an overview of an automated tool for accessing, searching, and navigating SNOMED CT real-time, at distributed and remote clinical study locations. Also, the features of the tool that enable complete data are presented, as well as possible metrics for evaluation in terms of compliance, consistency, and reliability of coding.

Keywords:

SNOMED CT, terminology tools, clinical research informatics, data collection

Introduction

The Rare Diseases Clinical Research Network (RDCRN) consists of ten clinical research consortia and a central Data and Technology Coordinating Center (DTCC). The RDCRN conducts numerous research studies and clinical trials in many diverse and rare diseases. One goal of the RDCRN is to encourage data sharing and use of standardized data. The RDCRN is committed to the use of data standards, including SNOMED CT, the Consolidated Health Informatics (CHI) initiative's recommended standard for diagnoses, problem lists, procedures, and anatomy. The Standards Committee of the RDCRN endorses the use of structured data over free-text wherever possible, and supports the use of standardized terminologies or classifications for data coding. The DTCC promotes data standards and tools for efficient study implementation and accurate, complete, and timely data capture. The researchers of the RDCRN are distributed at over 46 sites in the U.S. and abroad, and require tools to facilitate remote, real-time, free access to SNOMED CT for searching and browsing concepts relevant to data collection in diverse studies in rare diseases. This paper describes one such tool and offers preliminary evaluation data.

One of the biggest obstacles in the implementation and widespread adoption of standard terminologies is lack of appropriate tools to access, display, search, and navigate terminologies of varying structures. [1-10] The need for these tools is even greater when the terminologies are large or complex. [9, 11-13] The literature on evaluating terminology coding tools is sparse [14] although many have suggested that interfaces for coding support tools can be an important confounding factor in inter-rater reliability studies. [11, 15-18] Many features can be incorporated into tools to assist users in finding desired concepts thereby increasing the efficiency and compliance of these tools. [19-21] The SNOMED CT Browser described here is the first type of many tools that are required for widespread adoption of SNOMED CT and other terminological standards in distributed clinical research settings.

Informatics principles and tools are entering into the clinical research domain [22-24] and one target area is the use of electronic data capture to increase the speed and quality of data collection in distributed research studies. In general, the items (or questions) on clinical research case-report forms (CRFs) are of 2 types: 1.) Structured, predefined elements [the majority] can be coded once for the entire life of the study. These questions and coded answers do not change for the duration of the study *(e.g., "Claudication? present/absent", ... "WBC count = ____", "Currently on prednisone? yes/no".)* 2.) Open-ended questions [the minority], however, require dynamic coding. The content of open-ended questions is not static for the study, and cannot be predicted before the start of the study. *(e.g., include: "List medications: ____" , "List Allergies: ____" , "Cause of Death: ____" , "Specify Other Findings:____" .)* In the case of open-ended questions, however, the space of potential answers is huge, perhaps infinite. In theory, the coding should be more accurate if it is generated by the individual identifying the concepts or making the observations.

A tool was needed to support real-time SNOMED CT coding at distributed clinical research sites to allow researchers to code concepts themselves at the point of research. This tool facilitates access to standard terminol-

ogy, such as SNOMED CT, "on demand" and can enforce the idiosyncratic rules of each terminology. Additionally, these tools should reduce the time and complexities of the coding tasks, thereby reducing the burden of this strategy on the research team. This paper describes this tool, its implementation status, and preliminary evaluation metrics.

Methods

The DTCC and Apelon, Inc. developed a web-based SNOMED CT Browser that enables distributed clinical research staff to code clinical research data from distributed clinical research settings. This tool was developed to address the following requirements: real-time access to SNOMED CT (both for searching and browsing) for multiple users at distributed sites, little training available, low cognitive burden on user, intuitive for clinical research staff with no SNOMED CT expertise, embedded within existing on-line data collection tools, and efficient return time of selected SNOMED CT concepts.

SNOMED CT browser description

This SNOMED CT browser operates within the context of automated protocol management tools developed by the DTCC to support all RDCRN studies. The browser is embedded in the online Case Report Forms (CRFs) to facilitate coding on demand by clinical research staff. The browsers connect to remote terminology host (Apelon, Inc.) via Web Service. Search terms, filters and other supporting information are tagged in XML, and then transferred to Application Service Provider via SOAP. The remote terminology host uses U.S. National Library of Medicine's public use version of SNOMED CT. The custom interface allows distributed researchers to search for specific terms or to browse SNOMED CT's native multi-hierarchical structure.

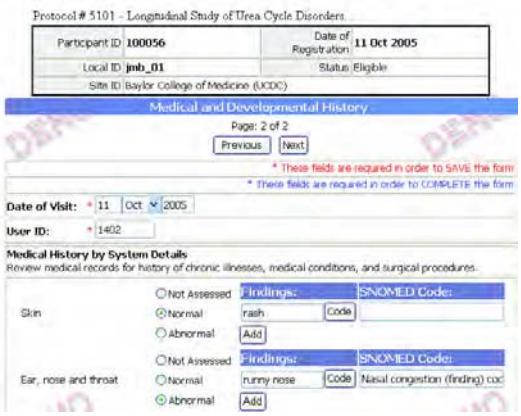

Figure 1 - Context of SNOMED CT browser.

The SNOMED CT browsers are located next to the questions on electronic Case Report Forms.

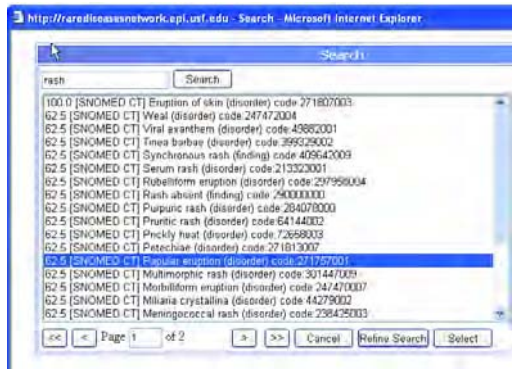

Figure 2 - SNOMED browser – original search results window

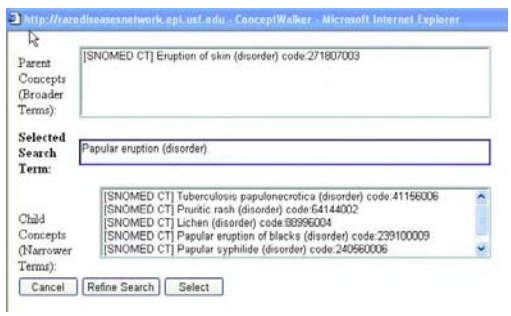

Figure 3 - Browsing broader and narrower concepts window

From the online CRF (Figure 1), the user enters a search string and selects the code button. A new window displays all potential SNOMED CT concept matches. The browser searches SNOMED CT synonyms (including abbreviations) to help search concepts. For example, if the term congestive heart failure is desired, one could type the entire search term or the abbreviation "CHF". [Note: this is part of the SNOMED CT terminological content.] The browser uses an algorithm that ranks returned codes based upon the number of search terms (or synonyms) found compared to the number of words in each returned concept. The returned concepts can span over multiple pages which the user can view. (Figure 2)

If the user does not see the desired concept, any one of the returned concepts can be selected for a "refined search", allowing users to browse related SNOMED CT concepts. A new window (Figure 3) displays all the SNOMED CT codes that are more specific to or direct parents of the refined search concept, and is divided into three parts:

- "Parent Concepts (Broader Terms)" - are displayed in the top most part of the page
- "Selected Search Term"- displays the concept selected for "refine search" in the previous page
- "Child Concepts (Narrower Terms)"- are displayed in the lower part of page below selected search term

The user can further refine the search by selecting a concept in the "Child Concepts" textbox and then hitting the "Refine Search" button. Every time a particular concept and "Refine Search" button is selected, the user will see a refined set of possible parent and child SNOMED CT concept codes.

Features

Certain search features of the SNOMED browser enable users to limit the number of returned SNOMED CT concepts. Users can enter multiple words (with AND, OR, or NOT) to limit a search, or search for exact phrases using quotes (e.g., "heart attack"). A wildcard character is also supported. Codes selected from the browsing tool are populated into the online case report form for later viewing. The stored data includes the SNOMED CT concept name and ID number, and the version of SNOMED CT accessed. The original search strings are stored for later analyses and quality control activities. To limit the number of returned SNOMED CT concepts and to increase likelihood of accurate coding by SNOMED CT novices, only context-relevant subsets of SNOMED CT are returned to users. These subsets are defined by the informaticist at the DTCC and the filters are transparent to users.

To increase compliance, the DTCC considered making the actual SNOMED code a required field for saving and submitting the CRF data. However, because of the chance that desired concepts in rare disease research might not yet be part of SNOMED CT, this feature would frustrate researchers and hinder data collection. Under development are system features to remind the user that they have not selected a SNOMED CT code and a feature to allow them send new code or help requests directly to the DTCC informaticist at the time of data collection.

Results

Implementation status

As of January 2007, the RDCRN has produced 285 electronic case report forms (CRFs) containing more than 26,000 questions for 27 clinical research protocols. Most CRF questions are in the form of structured static questions, which are coded at the DTCC once for the life of the study. A fraction of the CRF questions are open-ended (e.g., "list abnormal skin findings") and appropriate for this real-time remote SNOMED CT coding tool. Approximately 300 SNOMED browsers are included in these RDCRN CRFs. Because a single informaticist at DTCC reviews all case report forms prior to study implementation, there is confidence that these 300 SNOMED CT browsers represent all open-ended questions on case report forms for which SNOMED CT is the appropriate data standard.

Each browser has customized criteria for sub-setting SNOMED CT – i.e., limiting returned search terms by one or more SNOMED CT Parent Concepts based on the context of the CRF question (Table 1).

Table 1. Examples of context-dependent SNOMED CT sub-sets.

CRF Question:	SNOMED CT returns restricted to:
Reason for visit/ admission	Clinical finding (finding)
Kidney and urinary tract history	Urinary system finding (finding)
Muscles, bones and joints history	Musculoskeletal finding (finding)
Nervous system and development history	Neurological finding (finding) Developmental disorder (disorder) Mental disorder (disorder)

Of the 300 SNOMED CT browsers that are embedded within the RDCRN data collection, approximately 75% represent current findings (e.g., context is physical exam, clinical assessment forms) and 25% represent historical findings (e.g., medical history context).

Over 150 investigators and research staff representing over 20 studies in the Rare Disease Network have been trained on this tool. The training on the SNOMED CT Browser Tool is part of a day-long training on the clinical research protocol, and consists of a 15 minute overview of SNOMED CT and a 10 minute instruction on the tool and search techniques. Anecdotally, the tool is intuitive to users and well-accepted.

Future evaluation data sources

Evaluation of this SNOMED CT Browser tool includes assessing whether it is actually used (compliance) and whether the user-coded data is accurate (quality). SNOMED Coding Compliance Reports are generated for the DTCC to monitor quality and compliance. These reports identify and enumerate where free-text data was entered into the browsing tool but no SNOMED CT codes saved. This helps DTCC staff identify and educate users who are submitted free-text data but not applying SNOMED CT codes, and to investigate whether failures to add SNOMED CT codes to free text clinical finding data result from non-compliance to difficulties navigating SNOMED CT to missing clinical research content in SNOMED CT. Using the proportion of SNOMED CT-eligible open-ended data that is actually coded as a measure, comparisons of compliance can be calculated between users, sites, and disease/research domains can be facilitated using these data.

The data on original search strings and user-selected SNOMED CT concepts are being saved for future quality control analysis. These data can be analyzed to research both the "appropriateness" (as determined by a SNOMED

CT expert physician) of the selected SNOMED CT code, and the level of specificity of selected codes compared to the original search string (e.g., "inspiratory wheeze" as a selected SNOMED CT concept is more specific - by only one parent relationship - than the search string "wheeze"). These same quality data could be used to answer questions about variation in level of specificity across users in controlled experiments using test cases. Such questions are critical to address in distributed research settings where multiple researchers are responsible for study data, yet we see few comparisons of coding specificity in the literature. [11, 16] These questions of coding quality and appropriateness are best addressed by those with dual training in both SNOMED CT and in the clinical research domain of interest. The DTCC is in the process of identifying individuals with clinical domain expertise for extended SNOMED CT training and extended quality control roles.

Discussion

In theory, the coding of clinical research data should be more accurate if it is generated by the individual identifying the concepts or making the observations, and tools for coding at the point of research can be important aides for standards implementation. Quality coding requires some understanding of the terminological structure of SNOMED CT, and the browser application described here make the conceptualization of the SNOMED CT structure and term navigation intuitive for the user. Additionally, these browsers can be designed to subset only "reasonable" concepts from the terminology, reducing the cognitive burden and time for the user, and possibly increasing the quality of coded data.

Researchers need "terminology on demand" – reliable, fast access to updated data standards at the point of clinical research. Tools that allow customized views and subset the terminologies can reduce search time and coding burden, and perhaps increase compliance.

Because SNOMED CT is a concept-based terminology, multiple synonyms can be associated with a given concept. This allows local variation in terminology use, but stores the final study data in a uniform way. The use of SNOMED CT and supporting tools can improve data consistency because all clinical centers collect same data in the same format. Management of terminology support (including tools development and maintenance and licensing) is centralized, and the management of terminology server is outsourced. Tools that facilitate intuitive access to complex terminologies reduce the need for training on the terminology structure. Quality of coding and consistent use of this tool should be examined in future. Although the infrastructure and data sources for these types of exploration exist, dual experts (rare disease domain and SNOMED CT) will be required.

A great challenge in permeating data standards such as SNOMED CT in distributed clinical research settings is that the proper use of the standards requires domain knowledge *and* knowledge of the standard. It is more realistic to give the proper standards/terminology training to researchers with domain expertise than the reverse. However, compliance depends on DTCC ensuring a negligent task/work/time burden on the researchers, and maximizing their perception of the value of standard data coding.

Conclusion

The usability and intuitive design of this tool eliminates the need for researchers to study the SNOMED CT terminology structure, and could increase compliance and quality of coding. These tools should reduce the time and complexities of the coding tasks, thereby reducing the burden of standards use on the research team. The browser provides researchers the means to obtain complete, accurate, and timely data which is consistent across multiple clinical centers. In rare diseases, this can increase the efficiency of the research process and eliminate wasted resources, including the time and effort of the study participant resulting from incomplete, inaccurate, or missing data. Future research should focus on quality and reliability of selected SNOMED CT concepts using data sources described above.

Abstract

We hypothesized that SNOMED CT, a granular formal reference terminology, could be used to assist in the creation of a valid crosswalk between two administrative classifications: the International Classification of Diseases, Ninth Revision, Clinical Modification (ICD-9-CM) and the U.S. Veterans Benefits Administration (VBA) disability code set. To establish a baseline, we created an ICD-9-CM terminology server and directly mapped textual descriptions of the VBA disability codes to ICD-9-CM. We next mapped ICD-9-CM and the VBA Disability codes to SNOMED CT. The SNOMED CT mappings were matched across classification systems and terms from related concepts were displayed for an expert coder's review. We report the rate of direct ICD-9-CM to VBA Disability Code mapping (26%), the eventual success of the SNOMED CT based crosswalk (95%) and the rate at which the reviewer had to add codes to complete the mapping (99%). The method using the SNOMED CT crosswalk provided significantly better coverage than the ICD-9-CM direct mapping alone (Pearson Chi Square test; $p<0.001$). We conclude that SNOMED CT can be a useful adjunct to direct mapping between administrative classifications.

Introduction

Networked information systems and communications standards make the mechanics of data transfer (i.e. syntactic interoperability) routine. The transfer of fully meaningful information (semantic interoperability) is a much more difficult challenge. Semantic interoperability requires comparable data, the basis for the practice of evidence-based medicine. Many clinical questions will never be addressed in a randomized, blinded, controlled clinical trial. The best hope for providing clinicians answers to these questions lies with a deeper understanding of the clinical record. Recording information at the granularity with which we practice medicine holds the promise to provide the data needed to gain an improved understanding of what constitutes the "best practice" of medicine

Compositional vocabularies are one potential answer to the problem of providing enough content completeness to be clinically useful. The degree to which a compositional mechanism can provide coverage for the concepts used by clinicians at the point of care is not completely understood. The data from the LSVT trial provides a benchmark of 58% content coverage by a large set of atomic and pre-coordinated concepts.[1] We previously reviewed SNOMED CT's ability to represent 115 complex oncology drug indications containing 1527 unique concepts.[2] We found that SNOMED CT was capable of representing 86.3% of the concepts completely and 60.1% of the linking semantics. Of the errors, 50.5% were drug names that were unknown to the terminology and 40.5% were specific treatments. SNOMED CT covered 64% of concepts used in a general medical evaluation form.[3] The majority (74.4%) of terms were compositions, and appropriate linking semantics were present in SNOMED CT for 80% of a randomly selected subset.

Content coverage alone is not enough to achieve comparable data and semantic interoperability. A major problem is that information is often coded in different terminologic systems and translation is required. Idiosyncratic pre-coordinated terminologies have been used for focused administrative purposes since long before computers became commonplace. As new business needs emerge, such idiosyncratic pre-coordinated terminologies may need to be mapped to national and international administrative code sets such as ICD-9 or ICD-10. Accurate mapping may be difficult because complex pre-coordinated terms may not have exact morph-syntactic equivalents in the corresponding terminology. We suggest that one way to create a mapping between pre-coordinated classifications is to use a granular reference terminology as an intermediary.

In this study our goal was to provide a mapping from the Veterans Benefit Administration's (VBA) Disability codes to all possibly appropriate ICD-9-CM codes. The VBA disability codes are used to classify veterans' disabilities

for the purposes of compensation and pension and to track healthcare delivery to disabled veterans. We evaluated the use of SNOMED CT v1.0 as an intermediary reference terminology to aid in the mapping process.

Materials and methods

We created an initial automated mapping between ICD-9-CM and the VBA Disability codes without using SNOMED CT as an intermediary by using the Multi-threaded Clinical Vocabulary Server (MCVS) concept-based indexing toolset.[4] To achieve this mapping, we loaded the MCVS with ICD-9-CM as the base terminology and serially mapped the VBA Disability Codes (target terminology). When necessary, the MCVS tools attempt to produce compositional expressions using terms from the base terminology to represent the original pre-coordinated term from the classification being mapped. [5, 6]

We used the same MCVS process to create an automated mapping of the terms from SNOMED CT (base terminology) and the ICD-9-CM and VBA Disability classifications (target terminologies). Figure 1 demonstrates the MCVS tool set mapping of the VBA Disability term "Vagus nerve Neuritis" using SNOMED CT as the base terminology. This mapping has two definitional elements – a disorder (neuritis) and a body structure (vagus nerve).

We categorized all mapped SNOMED CT definitional elements as either Kernel concepts, modifiers, qualifiers, severity, or laterality.[7] These distinctions were hand assigned by hierarchy to the SNOMED CT reference terminology (ple). Kernel concepts are defined as a main point of the concept, modifiers change the meaning of a term in a clinical sense (e.g., stage, grade), qualifiers change the meaning of a term in a temporal or administrative sense (e.g. history of, recurrent), severities and laterality follow the SNOMED CT hierarchies for these concepts.

We created an automated "crosswalk" between the target terminologies by joining ICD-9-CM and VBA Disability terms based on common SNOMED CT definitional elements. The first step in the automated matching process was to identify equivalent terms based on shared kernel concepts. At least one kernel concept match was required to join ICD and VBA terms. Matches for terms sharing kernel concepts were subsequently refined by identifying common modifiers, qualifiers, severity, and laterality. The output of the pair-wise crosswalk between these three classifications (figure 2) was then reviewed by two expert reviewers (clinicians), and when they disagreed a third reviewer was employed to establish consensus. When no exact match was available, the reviewers used a browser capable of displaying each of the target terminologies and determined whether 1) There was no appropriate match between the two terminologies (hence SNOMED CT legitimately could not and should not have connected the two terminologies or 2) b) The was an appropriate match between the two terminologies and SNOMED CT did not provide the appropriate mapping. In the case when SNOMED CT failed to map two synonymous concepts, a failure analysis was employed that noted what was missing in SNOMED CT that would have facilitated the mapping and as well as which classification contained the unrecognized content and/or semantics. All failures were double checked by the reviewers using a SNOMED CT terminology browser.

A web-based system (four-tier architecture with a relational database back end) was designed and implemented to facilitate the review and grading of the acceptability of the crosswalk. The system showed the reviewer the original terms, their matches and the compositional expressions to which they mapped in SNOMED CT. The interface was available to the reviewers to view and grade the output of the systems matches to the VA disability terminology and to ICD-9-CM. We also provided a set of Web based services and interfaces to allow coders to review the crosswalk between the VA disability terminology and to ICD-9-CM using SNOMED CT. This interface allowed the coders to pick the correct mapping or approve the automated mapping as warranted by the review.

The results are reported from a SNOMED CT perspective. True positives are concepts from the classifications that were found to have at least one valid match between the two classifications using SNOMED CT. The mappings were reviewed by an expert ICD-9-CM coder who had access to VBA staff in the case that questions arose regarding a VBA code's meaning. A correct mapping rate of 93% was arbitrarily judged to be acceptable accuracy for clinical use. This rate is similar to or better than many of the sensitivities for common confirmatory diagnostic tests.[8]

VBA Code	VBA Term	SNOMED Mapping
8310	Vagus nerve Neuritis	Neuritis (disorder) [84299009] [has Finding Site] Entire vagus nerve (body structure) [362466001]

Figure 1 - SNOMED-CT Mapping of a VBA Disability term

Crosswalk Mappings			Direct Mapping
VBA Term	SNOMED Mapping	ICD9 Concept	ICD-9 – VBA Term
Abscess, brain (8020)	Abscess brain [60404007]	INTRACRANIAL ABSCESS (disease) [324.0]	Abscess brain
Accommodation, paralysis of (eye) (6030)	Accommodation paralysis of (eye) [68158006]	PARESIS OF ACCOMMODATION (disease) [367.51]	eye

Figure 2: Crosswalk examples. VBA terms and ICD-9 concept are joined based on common SNOMED CT mappings. The corresponding direct mapping of VBA term to ICD-9 concept was successful for brain abscess and not successful for accommodation paralysis.

Results

SNOMED CT version 1.0 as loaded into the MCVS toolset contained 333,325 concepts and 874,391 terms. ICD-9-CM as loaded included 20,069 concepts and 29,958 terms. The investigators added 712, 294 synonyms to SNOMED CT and 36,731 synonyms to ICD-9-CM within the MCVS tool set to improve automated mapping performance. VBA Disability code terms numbered 752.

Based on automated mappings from the MCVS, 25.5% (192/752) of the VBA Disability codes mapped to a single SNOMED CT concept and 560/752 (74.5%) required a compositional SNOMED CT expression. Of the 560 VBA Disability code terms that were mapped to multiple SNOMED CT concepts, 250 required 2 concepts, 142 required 3 concepts, 64 required 4 concepts, 49 required 5 concepts, 22 required 6 concepts, 15 required 7 concepts, 8 required eight concepts, 5 required 9 concepts, and 5 required 10 concepts.

The MCVS provided an automated mapping to ICD9-CM for 359 of the 752 VBA Disability codes. Of these, 259 mapped to a single ICD-9-CM concept and 100 required multiple ICD-9-CM codes linked with Boolean operators. Of the 100 VBA Disability code terms that were mapped to multiple ICD-9-CM expressions, 84 required 2 concepts, 9 required 3 concepts, 4 required 4 concepts, 2 required 5 concepts and 1 required 7 concepts.

The ICD-9-CM direct map correctly mapped 26% of the VBA codes after expert human review. The addition of the automated SNOMED CT crosswalk to the direct map provided at least one suggested code in 98% of the cases. At least one of these suggested codes was considered an appropriate match by an expert reviewer in 95% of the cases.

The expert coder added additional codes to almost all of the suggested mappings (99%) and removed many inappropriate suggestions. When we compared the rate of direct ICD-9-CM mapping to that of the ICD-9-CM direct map plus the crosswalk the later provided significantly more coverage (Pearson Chi Square test; $p<0.001$).

Examples of mappings between base and target terminologies

Case 1: One to One Match
VBA Disabilty Term: Thrombo-angiitis obliterans (Buerger's disease)
SNOMED Term: Thromboangiitis obliterans (disorder) [52403007]
ICD-9-CM Term: THROMBOANGIITIS OBLITERANS (BUERGERS DISEASE) (disease) [443.1]

Case 2: One to Many Match
VBA Disability Term: Disseminated intravascular coagulation with renal cortical necrosis
SNOMED Terms: Disseminated intravascular coagulation (disorder) [67406007] [AND]
Renal infarction (disorder) [45456005]
ICD-9-CM Terms: ACUTE RENAL FAILURE WITH LESION OF RENAL CORTICAL NECROSIS (disease) [584.6]
[AND] DEFIBRINATION SYNDROME (disease) [286.6]

Case 3: Match Requiring Clinical Judgment
VBA Disability Term: Dementia of unknown etiology
SNOMED Terms: Dementia (disorder) [52448006] [AND]
[UNKNOWN] . Etiology (attribute) [134198009]
ICD-9-CM Terms: PRESENILE DEMENTIA (disease) [290.1]
DEMENTIA IN CONDITIONS CLASSIFIED ELSEWHERE (disease) [294.1]
PRESENILE DEMENTIA, UNCOMPLICATED (disease) [290.10]
SENILE DEMENTIA, UNCOMPLICATED (disease) [290.0]
All four ICD-9-CM terms were assessed as appropriate by an experienced coder.

Case 4: Partial Match

VBA Disability Term: Paralysis of musculocutaneous nerve
SNOMED Terms: Paralysis (finding) [44695005] - [has Finding Site]
Entire musculocutaneous nerve (body structure) [181019000]
where [has finding site] is a SNOMED relationship.
ICD-9-CM Terms: INJURY TO MUSCULOCUTANEOUS NERVE (disease) [955.4]
which only approximates the meaning of the original input string.

Discussion

SNOMED CT was useful in providing suggested mappings for a crosswalk between the VBA administrative terminology and ICD-9-CM. The SNOMED CT based crosswalk provided significantly more correct mappings than a direct ICD-9 mapping alone. Despite this improvement, additions and deletions based on expert human review were required to complete the mapping.

Mapping between two highly pre-coordinated administrative classifications is an inherently difficult task for several reasons. First, administrative classifications are likely to have been developed to meet different business needs and the existence of reliable mappings should not be assumed. Second, implicit pre-coordination is more difficult to manage algorithmically than explicit definitions and coordinations grounded in formal logic. Third, classifications are designed to group granular entities under high-level concepts based on organizing principles. Different classification systems are likely to have subtly or even significantly different underlying organizing principles that impact meaning and make cross-mapping difficult.

The MCVS crosswalk was designed to sensitively identify potential mappings between VBA Disability codes and ICD-9-CM. Due to this design choice and the fact that ICD-9-CM and the VBA Disability code systems have considerable meaning that is only defined in the user's manuals, our expectation of rejecting numerous inappropriate partial matches was realized. Furthermore, these classification systems are designed for different purposes. The authors believe the automated mapping system would yield improved results if the additional knowledge in the user's manual were included in the mapping system's rule base. We did not do a comparative study regarding how long it would have taken to perform the same task without the crosswalk but we believe that this method linked with a good user interface significantly shortened the review time. Further, we believe that the automated mapping suggestions helped the reviewer to be more complete as it found matches across hierarchies that may have been missed if not cued to the reviewer by the crosswalk system.

SNOMED CT should be considered as a useful reference terminology for providing a set of suggested matches using the crosswalk method outlined in this manuscript to map between and among administrative classifications.

Practical Issues in Using SNOMED CT as a Reference Terminology

Senthil K. Nachimuthu, MD, Lee Min Lau, MD, PhD

Department of Biomedical Informatics, University of Utah, Salt Lake City, Utah, USA
3M Health Information Systems, Salt Lake City, Utah, USA

Abstract

SNOMED CT® was created by the merger of SNOMED RT (Reference Terminology) and Read Codes Version 3 (also known as Clinical Terms Version 3). SNOMED CT is considered to be among the most extensive and comprehensive biomedical vocabularies available today. It is considered for use as the Reference Terminology of various institutions. We review the adequacy of SNOMED CT as a Reference Terminology and discuss the issues in its use as such. We discuss issues with content coverage of various clinical domains, data integrity and validity, and the update frequency of SNOMED CT, and why SNOMED CT alone is not adequate to serve as the Reference Terminology of a healthcare organization.

Keywords:

SNOMED CT, reference terminology, implementation issues.

Introduction

SNOMED CT® (Systemized Nomenclature of Medicine – Clinical Terms) is one of the most extensive and comprehensive biomedical vocabularies currently available, with 370,702 concepts (US Edition, core distribution, July 2006). It is recommended for use as the provider of data dictionary for several electronic health information systems. The SNOMED CT Technical Reference Guide January 2006 release mentioned that "SNOMED CT is the most comprehensive clinical reference terminology available in the world."[1] The July 2006 release of this document redefines it as "SNOMED CT is a comprehensive clinical terminology that provides clinical content and expressivity for clinical documentation and reporting."[2]

We examine the issues concerning use of SNOMED CT as the exclusive reference terminology for an electronic clinical information system. These issues include the coverage of concepts in various clinical domains included in the terminology, data consistency and the frequency of update. We examine these issues, and provide comparisons of several clinical domains of content present in SNOMED CT and another reference terminology. We use a set of objective criteria to evaluate SNOMED CT, and these criteria and methods may be used to evaluate any clinical vocabulary for its use in a clinical information system.

These three analyses have different objectives and assess different aspects of SNOMED CT. Hence, the materials and methods, results and discussion are presented individually for these three analyses for the sake of coherence.

1. Coverage of content

Materials and methods

All the active concepts in SNOMED CT (US Edition, July 2006 release) were included in the first experiment. A reference terminology created by 3M Health Information Systems, namely the 3M Healthcare Data Dictionary (3M HDD) was used to aid these comparisons.

The 3M HDD is a concept-based reference terminology that serves as the interlingua for multiple biomedical vocabularies which are mapped to it. The content included in the HDD is derived by importing various standardized terminologies such as SNOMED CT, LOINC, ICD-9-CM, CPT, HCPCS, First Databank NDDF, etc. The HDD also includes various legacy (homegrown) vocabularies such as the US Department of Defense lab, pharmacy and other clinical codesets and those from various other community and university hospitals.

Two subsets of the HDD were created for these comparisons – one including content provided by SNOMED CT alone, and another including content from the rest of the HDD excluding SNOMED CT. These two HDD subsets will here onwards be referred to as "*SNOMED CT ONLY dataset*" and "*NON SNOMED CT dataset*". The reason that the rest of the HDD was used for comparison is to provide a real world equivalent of concepts present in reference terminologies of very large enterprises. Similar results may be expected by comparing the content coverage of SNOMED CT with that of the enterprise reference terminology of any large multi-facility multi-specialty hospital organization, or to a standard reference terminology such as the UMLS.

SNOMED CT includes various domains of clinical concepts. The content of SNOMED CT is organized into 19 top-level hierarchies shown in Table 1. Various subhierarchies of concepts are organized under these nineteen top level hierarchies. The fully specified name of each SNOMED CT concept includes a suffix which roughly corresponds to the clinical domain that concept belongs to.

The suffix helps to disambiguate between two concepts that might belong in different top level hierarchies, but have the same textual name. For example, the suffix can help to differentiate between a disease and a finding at a glance without having to query its location in the SNOMED CT hierarchy. Two such examples are Endometriosis (disorder) vs. Endometriosis (body structure) and Aspirin (substance) vs. Aspirin (product).

Table 1 - SNOMED CT top-level hierarchies

Body structure	Procedure
Clinical finding	Qualifier value
Environment or geographical location	Situation with explicit context
Event	Record artifact
Linkage concept	Social context
Observable entity	Special concept
Organism	Specimen
Substance	Staging and scales
Physical force	Pharmaceutical / biologic product
Physical object	

Table 2 provides a partial listing of suffixes. Each top-level hierarchy may contain concepts with one or more suffixes.

Table 2 - SNOMED CT concept suffixes (partial list)

body structure	organism
disorder	specimen
procedure	substance
event	occupation
finding	product

We chose some of the clinical domains denoted by the top-level hierarchies or concept suffixes listed in tables 1 and 2 to compare the extent of coverage. We compared the concepts present in *SNOMED CT ONLY dataset* with the *NON SNOMED CT dataset*. The following results reflect comparisons of several domains of content included in SNOMED CT with NON SNOMED CT content included in the real world clinical information systems of various hospitals, both home-grown and vendor-developed. Examples of concepts present in these datasets are given for some of the domains to better explain the results.

Results

a. Pharmaceutical ingredients

The SNOMED CT Substance top-level domain contains pharmaceutical ingredients under the 'Drug or medicament (substance)' subhierarachy. This is a clearly definable clinical domain without any ambiguity, and hence this domain was used for comparison. It is more constrained and universal, and it is included in the core SNOMED CT data. This is in contrast with pharmaceutical *products* which vary from one country to another. In case of the US, pharmaceutical products are included in the SNOMED CT US Drugs Extension, which is not available free of cost, rather than the core US Edition.

Comparison was done by querying the specific domain of content in the NON SNOMED CT dataset and the SNOMED CT ONLY dataset. The results of comparison of various 'levels' of pharmaceutical ingredients are presented in Table 3. First Databank's National Drug Data File (NDDF) was one of the primary pharmacy content providers for the 3M HDD.

Comparisons were made at the level of Therapeutic class (Antibiotics, Antipyretics, Sedatives, etc.), Drug Class (Penicillins, Aminoglycosides, Calcium Channel Blockers, etc.), Ingredients (Diclofenac, Ampicillin, etc) and Ingredient-salt (Diclofenac Sodium, Diclofenac Potassium, Ampicillin Sodium, etc) levels. At all these levels, the NON SNOMED CT dataset had significantly better coverage for pharmaceutical ingredients than the SNOMED CT ONLY dataset. For example, 'Ketanserin' and 'Moxaverine' are some concepts present in NON SNOMED CT dataset but not in SNOMED CT ONLY dataset.

Table 3 - Pharmaceutical ingredients

DOMAIN	NON SNOMED CT	SNOMED CT ONLY
Therapeutic Class	134	22
Drug Class	873	118
Ingredient	7,265	2,647
Ingredient Salt	3,167	1,135

b. Microorganisms

Microorganisms constitute another domain of content that can be clearly defined, and hence the coverage of this domain was compared between SNOMED CT ONLY dataset and NON SNOMED CT dataset. We compared coverage of the entire microorganisms domain as well as some subdomains.

The following results in Table 4 show that the SNOMED CT ONLY dataset had about 80% to 90% content coverage compared as that of the microorganisms domain of the NON SNOMED CT dataset. For example, 'Heterosporium

species' is a concept present in NON SNOMED CT dataset but not in SNOMED CT ONLY dataset.

Table 4 - Microorganisms

DOMAIN	NON SNOMED CT	SNOMED CT ONLY
Microorganism	13,766	11,516
Bacterium	8,080	7,393
Fungus	1,545	1,321
Parasite	3,128	2,899
Virus	1,959	1,835

c. Problems

The clinical problems domain is among those that are not standardized and are highly variable. This domain will undergo much refinement over time. However, this domain is often used for picklists or dictionaries to manage electronic problem lists. This clinical domain is becoming increasingly important as clinical information systems try to implement problem-oriented documentation and maintain a longitudinal or historical record of patients' problems. Several authors have found that SNOMED CT has around 80% to 90% coverage of problems included in medical problem list domains of individual enterprise reference terminologies.[3][4][5]

We compared the problems domain of SNOMED CT with that of our reference terminology, which is the union of multiple enterprise reference terminologies, and our results indicate approximately 75% coverage. This domain is highly subjective and variable; however, the results still show very significant differences. The high variability of the domain is reflected in the concepts. For example, the NON SNOMED CT dataset contains the concept 'Intercostal bulging' which is not present in the SNOMED CT ONLY dataset.

Table 5 - Problems

DOMAIN	NON SNOMED CT	SNOMED CT ONLY
Problem	48,971	36,633

d. Specimens

Clinical specimens are an important part of medical records, and are an essential component of most biochemistry, pathology, microbiology and immunology lab orders. The following table shows the numbers of clinical specimens present in the NON SNOMED CT dataset and the number of specimens in SNOMED CT ONLY dataset. SNOMED CT ONLY dataset contained a significantly larger number of specimens compared to the NON SNOMED CT dataset, which is not surprising considering that SNOMED was created by the College of American Pathologists. For example, the concepts 'Liver cyst fluid' is present in NON SNOMED CT dataset but not in the SNOMED CT ONLY dataset. On the contrary, the concept 'BCG site swab' is present in SNOMED CT ONLY dataset but not in the NON SNOMED CT dataset.

Table 6 - Specimens

DOMAIN	NON SNOMED CT	SNOMED CT ONLY
Clinical specimen	823	1,048

e. Body Structure

The body structure domain contains concepts denoting various normal and abnormal anatomical structures at the organ, organ system or tissue level. The results in Table 7 show that the NON SNOMED CT dataset has significantly higher coverage compared to the SNOMED CT ONLY dataset.

Table 7 - Body structure

DOMAIN	NON SNOMED CT	SNOMED CT ONLY
Body Structure	34,257	31,999

f. Procedures

The procedures domain includes medical and surgical procedures performed for diagnostic or therapeutic procedures, administrative procedures (admission, discharge, transfer, billing, etc.), and so on. Procedures form an important part of several orders, clinical or administrative. The following results in Table 8 show that the NON SNOMED CT dataset contained significantly higher number of procedures compared to SNOMED CT ONLY dataset.

Table 8 - Procedures

DOMAIN	NON SNOMED CT	SNOMED CT ONLY
Procedure	59,311	53,052

Discussion

The results above show that SNOMED CT contains an extensive coverage of concepts but still lags behind a reference terminology which serves as the superset of several standardized and legacy vocabularies. Part of this difference is due to the differences in granularity. But a reference terminology will need to provide concepts with

varying granularities, and may not expect the users to perform the composition-decomposition themselves. Lack of concepts with differing levels of granularity causes problems with internal data storage as well as external data exchange. Some of the differences are due to the absence of several concepts in SNOMED CT which are present in other standard or local vocabularies. These results show that continuous authoring and updating of concepts will be required to keep SNOMED CT comprehensive and up to date for its use as a reference terminology.

Studies by other authors have also shown that SNOMED CT has anywhere between 30% to 90% coverage for various clinical domains.[6][7][8] These studies have each compared a single domain of content between SNOMED CT and a single enterprise reference terminology. Comparing multiple domains of content between SNOMED CT and the superset of multiple reference terminologies also yields similar results as shown above by this experiment.

Furthermore, we have not discussed several domains of content which are not covered by SNOMED CT, such as billing and reimbursement vocabularies, lab test names (provided by LOINC, etc. This denotes that several vocabularies need to be used together to complement each other and to build the enterprise reference terminology of a healthcare organization.

2. Data consistency

Materials and methods

The SNOMED CT 'core' consists of three tables – concepts, descriptions and relationships. We used the core tables provided by SNOMED CT and the US English dialect subset (both obtained from the US Edition, July 2006 release) to assess data consistency in SNOMED CT. We examined the compliance of the descriptions table to the constraints defined in SNOMED CT Technical Reference guide and User guide.

Table 9 - SNOMED CT representations

Representation	Type
Fully Specified Name	Scar (morphologic abnormality)
Preferred Term	Scar
Synonym	Scar tissue
Synonym	Fibrous scar
Synonym	Cicatrix

These constraints guide the importing of SNOMED CT into the reference terminology of an institution, use of SNOMED CT as the exclusive reference terminology of an institution, creating subsets, applying extensions to the core content, versioning and updating, and so on. The subset mechanism is especially important as SNOMED CT is too large to be used directly for a clinical application. SNOMED CT Subsets are often created for specific clinical domains or applications.

According to the SNOMED CT User Guide, each concept has one fully specified name, one preferred term and zero or more synonyms.[9] The fully specified name gives the definition of a concept, and is more explanatory than its preferred term. Preferred term is a more concise name which is used in clinical records. Synonyms are concise forms as well, and may be used as alternatives for the preferred term. An example is given in Table 9 – all these representations denote a single concept. We encountered some problems and inconsistencies while importing the SNOMED CT representations (textual names or surface forms of concepts) into the 3M HDD. We present the results below.

Results

The US Edition of SNOMED CT contains both American and British English representations for several concepts. The representations table in the core distribution denotes both the US (en-US) and UK (en-GB) English representations with an "unspecified type" for several concepts and a preferred term is not defined in these cases. The SNOMED CT US Dialect Subset redefines one of these representations as the Preferred Term and the rest as synonyms (often including the en-GB representation) for US English.[10] We first imported the core representations table into a relational database, and then applied the US Dialect Subset to it.

After applying the US dialect subset to the core descriptions table for the July 2006 US Edition, we found that 10,852 concepts had multiple preferred terms, often with different statuses (active, retired, limited, etc). The correct preferred term needs to be selected based on the concept status in these cases. Not all of these 10,852 concepts' preferred terms could be automatically selected based on the concept status and/or description status alone. 335 concepts had multiple preferred terms with the same status. E.g. ConceptId *103497003*, "*Streptococcus penumoniae 3 (organism)*" [sic] has two preferred terms in a "current" status.

Several of these occurrences are in direct violations of data integrity constraints defined in the SNOMED CT User Guide. These caused issues in automated importing SNOMED CT data into our reference terminology. This was overcome by defining one of the preferred terms or synonyms as the preferred term for some concepts by one of the authors. This task was labor intensive, and required several hours of the domain expert's time.

Discussion

The above results show that SNOMED CT needs stricter quality analysis before it is released to the end users. Failure of data consistency and violation of such constraints will lead to problems in importing and using the terminology by the target organizations. More studies of data consistency and integrity need to be done which involve other components of SNOMED CT. However, the authors

wish to mention that SNOMED CT is one of the well designed terminologies, and has less data consistency issues than many other standard vocabularies.

3. Frequency of update

Updates to SNOMED CT content are done through the regularly scheduled versioning mechanism. A new version is published once every six months, in January and July of every year. SNOMED has a web-based request mechanism for users and contributors to request changes. These changes include new concepts, representations, subsets, or extension namespaces through which third parties can extend the content in SNOMED CT. The users can also request modifications to existing content. However, these changes are incorporated and published once every six months through the regular release mechanism. Each new version of SNOMED CT has introduced anywhere between 2,500 and 8,000 new concepts. Statistics of changes in various core SNOMED CT tables over the years have been studied by other authors.[11]

Most organizations update their data dictionaries on a continuous basis, and some enterprise reference terminologies are updated as often as every day. This makes it harder to use SNOMED CT as the exclusive reference terminology for an organization. This can be overcome by creating local extensions to SNOMED CT via the SNOMED CT extension mechanism. The extension may be reconciled with the subsequent SNOMED CT version by inactivating the concepts in the extension and superseding them with equivalent concepts that are added to SNOMED CT. This process needs specialized expertise in vocabulary and ontology creation and maintenance, and requires contribution from subject matter experts in several content domains. An alternative is to use an enterprise reference terminology which includes SNOMED CT as one of the vocabulary sources along with other vocabularies.

Conclusion

The above analyses show that SNOMED CT does not have the necessary coverage to be the exclusive content provider for the enterprise reference terminology of an organization. SNOMED CT has one of the most extensive coverage among biomedical vocabularies, and has a well defined ontology and semantic relationships. These features make SNOMED CT as an essential component of an enterprise reference terminology. However, it needs to be complemented with other standard vocabularies, and in most cases, 'homegrown' vocabularies to build a reference terminology. SNOMED CT also has some data inconsistency issues which need manual intervention for implementation. We expect that these issues will be addressed in future releases. SNOMED CT also has a slower update schedule than would be required for the maintenance of a production enterprise reference terminology.

Due to these reasons, we conclude that most healthcare organizations will need further work to implement or adapt SNOMED CT for their requirements and use it in combination with other biomedical vocabularies, and may not be able to use it as a plug-and-play vocabulary.

Statistical Selector of the Best Multiple ICD-coding Method

Eiji Aramaki[a], Takeshi Imai [a], Masayuki Kajino [b], Kengo Miyo [a], Kazuhiko Ohe [a]

[a] *The University of Tokyo Hospital, Japan*
[b] *Japan Research Group for Medical Ontology, Japan*

Abstract

The International Classification of Diseases 10th version (ICD-10) is one of the standard and most important disease classifications. Since computerized ICD-10 coding systems have drawn a great deal of attention in the medical field, a great number of different coding systems have been proposed. Thist paper proposes a hybrid architecture of different coding systems. First, given an input disease name, three coding systems output codes with their confidence scores. A C4.5-based system selector then selects the best output by using both input statistics and the confidence score from each system. The experimental results demonstrated that the selector significantly boosts the overall performance (+3.4 points).

Keywords:

ICD-10, International Classification of Disease codes, coding, decision trees, natural language processing

Introduction

International Classification of Diseases 10th version (**ICD-10**) [1] was endorsed by the 43rd World Health Assembly in 1990 and came to be used by World Health Organization (WHO) member countries from 1994. ICD-10 has become the international standard diagnostic classification for all general epidemiological purposes and many health management purposes, such as the analysis of the general health circumstances of population groups and monitoring of the incidence and prevalence of diseases [2].

Therefore, many medical doctors or coders (who are the special staff for the ICD coding) have selected a suitable disease code for each patient. As pointed out in a previous study [3], the coding task is an important semantic issue because it requires a very high level of understanding of the meaning of the patient data.

In such a situation, in order to reduce the heavy burden of coding, a number of automatic coding systems/methods have been proposed. For example, systems that output a code from a discharge summary [4-6], a coding system for autopsy reports [7], a coding system for input disease names [8], coding frameworks [9] [10], and a machine learning coding for a diagnostic text [11], have been proposed. Although there are numerous system variations, the approaches are basically classified into two types.

One approach is to directly capture the relation between an input and an ICD category [4-7][9][10]. In the present study, we refer to such systems as **direct systems**.

However, direct systems often suffer from complex language phenomena. For example, given the term "*leg eczema*", which should be classified into an ICD-10 code **[L309]** "*inflammation of the skin*", in order to realize successful coding, a direct system requires knowledge such as:

(1) "*Leg*" has "*skin*",
(2) "*Eczema*" is-a-kind-of "*inflammation*".

In order to obtain such knowledge, most systems utilize an ontology/knowledge-base. However, it is difficult to fully cover such knowledge.

Another approach [8] [11] is to retrieve the most similar coding example from a database, and output its code as is. We herein refer to such systems as **example-based systems.** The example-based system easily realizes the above coding, if the system can find a coding example, as follows:

(Input) "*Leg eczema*",
(Coding-example) "*Foot eczema*"-> **[L309].**

However, such a good example is not always available because of two difficult problems: (1) capturing the similarity of a precise example is difficult, and (2) the number of examples is not sufficient for covering all ICD categories.

In summary, both approaches have different strengths and weaknesses. Therefore, the present paper proposes a hybrid architecture, which selects a suitable system for each input. First, given an input, three coding systems output codes with their confidence scores. Then, a selector based on a C4.5 decision-tree [12] decides the best output by using information from both the confidence score of each system and input statistics.

The experimental results demonstrated that the selector significantly boosts the overall performance.

It should be noted that previous studies use various input types/forms, such as a discharge summary [4-6], an autopsy report [7], and a disease name [8]. In this paper we use a disease name as a system input, since it is the most informative clue in the coding task.

Selected for best paper award.

Although the proposed system does not depend on language, we conducted experiments using disease names in Japanese.

Material

This section describes ICD10 [1]. The ICD10 has a tree structure, in which a leaf code consists of one alphabetical character <A-Z>, three digit numbers <1-9>[1] and its description. We call the description an **ICD-term**.

Figure 1 shows an example of an ICD10 code with its ICD term "*Cholera, unspecified*". The first alphabetical character <A> indicates a top level category, and the second <0> indicates the second level category. In the same manner, the third and fourth numbers indicate the third and fourth level categories.

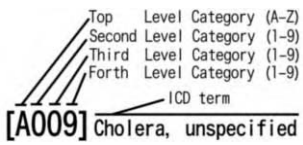

Figure 1 - Example of ICD-10 code and ICD-term

Methods

The task to be solved is to output a suitable ICD-code (**code**) for an input disease name (**input**). The idea of the proposed method is to dynamically select the best output from three systems. We first explain the three coding systems of the present study and then present the system selector.

Direct system

As mentioned above, most direct systems utilize knowledge-base/ontology. However, such resources are not always available in Japanese and other non-English languages. Therefore, the direct system of the present study utilizes ICD-terms, because ICD-terms are available as a knowledge-base in native languages in most countries.

The present direct system captures the similarity between an input and the ICD-terms. First, this system searches all of the ICD-terms, and extracts the ICD-term that is most similar to an input. For calculating the similarity, we used two measures: (1) a BM25 [13] and (2) an edit-distance [14].

BM25: The BM25 (*simBM25*) is a word-based similarity, which is employed in a state-of-the-art information retrieval system, the Okapi-system [15], which is defined as follows:

$$sim_{BM25} = \sum_{t \in T} (W_d \times W_q),$$

where

$$W_d = \frac{(k_1 + 1)tf}{k_1((1-b) + b \times dl/avdl)},$$

$$W_q = \log \frac{N - n + 0.5}{n + 0.5}.$$

In this formula, *T* is the set of words appearing in both the input and the ICD-term, *tf* is the number of occurrences of a word *t*, *dl* is the length of an ICD-term, *avdl* is the average length of the ICD term, *N* is the total number of ICD-terms, *n* is the number of extracted ICD-terms, and k_1 and *b* are the constants determined from the preliminary experiments[2]. For details, see [13].

Edit-distance: The edit-distance similarity (*simED*) is a character-based similarity, which is based on the minimum number of point mutations required to change an input into an ICD-term, where a point mutation involves: (1) changing a character, (2) inserting a character, or (3) deleting a character. For details, see [14].

The final similarity is a weighted sum of *simBM25* and *simED*, as follows[3]. We refer to this similarity as a **direct-sim**.

$$\textit{direct-sim(input, ICD-term)} = W_1\, simBM25 + W_2\, simED\,.$$

The final output code is decided by the code of the most similar ICD-term.

Example-based system

The example-based system retrieves the most similar coding example from a database (in experiments, we used 15,551 coding examples) and outputs the code of the retrieved example. In addition, in this similarity calculation, a weighted sum of BM25 and the edit-distance was employed. We refer to the similarity between an input and a coding-example as an **example-sim**.

The final output code is decided "as is" by the code of the most similar example.

Combination system

In preliminary experiments, the example-based system demonstrated high performance in rough classification, judging only the matching of the first and second digits. Considering this example-based advantage, we designed another system, referred to as the **combination system**.

The combination system first decides the first and second ICD-code using the example-based system. For example, if the example-based-system outputs **[L309]**, then **[L3**]** is the scope of the following searches. A detailed code (third and fourth digits) in the scope is then decided by a direct system.

These system frameworks are illustrated in Figure 2.

1 Some diseases have one more digit (one alphabetical character and four numbers). Since such codes are rare (7.6%), the present paper does not handle them.

2 We set $k_1 = 1.5$ and $b = 0.75$ in the experiments.

3 We set $W_1 = 0.9$ and $W_2 = 0.1$ in the experiments.

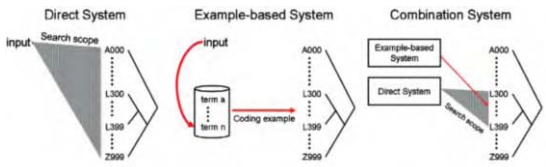

Figure 2 - Workflows of three systems

Statistical selector

The selector decides the suitable system for each input. Here, the selector uses two types of information (features): (f1) information from each system and (f2) information from an input. The detailed features are described in Table 1.

By using a training-set, the selector learns the relations between the features and which system is correct. In this learning, we utilized C4.5 [12], because it clearly shows the effectiveness of each feature.

Note that if the selector estimates that two or more systems are correct, we give the following priority: EXAMPLE-BASED > COMBINATION > DIRECT. For example, if the selector estimates that both COMBINATION and DIRECT are correct, then a COMBINATION output is employed.

In the same way, if the selector estimates that all systems are incorrect, an EXAMPLE-BASED output is employed. This priority is based on preliminary experimental results.

Table 1 - Features for system selector learning

(f1)	**Max Direct-sim:** The maximum direct-sim in the *k*-best ICD-terms*.
	Min Direct-sim: The minimum direct-sim in the *k*–best ICD terms.
	Example Code Variations: the number of second level category variations in extracted *k* coding-examples. For example, given [L309] [L300] and [B100], this value is 2 ([L3**] and [B1**]).
	Max Example-sim: The maximum direct-sim in the *k*–best coding-examples.
	Min Example-sim: The minimum direct-sim in the *k*–best coding-examples.
(f2)	**Input Length:** The number of the input words.
	Input Headword: The headword (last word) of an input. (We assume a head-final principle).
	Dictionary: Whether the input is found in the dictionary entry.

* In experiments, we set k=10.

Experiments

Experimental settings

To investigate the performance, we used two sets of materials: (1) a set of coding examples [16] consisting of 15,551 pairs (Japanese disease name and its corresponding ICD code), and (2) 995 disease names, which are input in several Japan

hospitals. We divided (2) into two sets as follows: a training-set (for selector training) and a test-set (for evaluation).

Both sets were annotated with their correct codes (gold standard). If the gold standard code is ambiguous for only the disease name, we removed it. The number of codes in each set is shown in Table 2.

To acquire the Japanese word units[4] in a term, we used a morphological analyzer developed in a previous study [17].

Table 2 - Number of coding examples

	# of codes
Coding-example	15,551
Training-set	495
Test-set	500

In the evaluations, we used three measures (1-3) and compared the following four systems (a-d), as follows:

1. **EXACT**: The exact (three digits) match.
2. **ROUGH**: Only the first and second digits match, e.g., **[L309]** and **[L303]**.
3. **10-BEST**: The system outputs 10 candidates, which are judged as to whether they contain the gold standard.

a) **DIRECT**: The direct system.

b) **EXAMPLE**: The example-based system.

c) **COMBINATION**: The combination system.

d) **PROPOSED**: The proposed system, selecting the best from the above three systems.

Results

The results are shown in Table 3. For two measures, PROPOSED showed the highest accuracy. In particular, in EXACT, the proposed system demonstrated significantly higher accuracy than the other systems in the McNemar test [18] ($p = 0.05$).

On the other hand, the ROUGH accuracy of the PROPOSED system is slightly (although not significantly) lower than EXAMPLE-BASED system. One reason for this is that the selector performed training based on the EXACT metrics.

Table 3 - Results

	(1) EXACT	(2) ROUGH	(3) 10BEST
a) DIRECT	33.6% (168)	52.8% (264)	61.2% (306)
b) EXAMPLE-BASED	63.6% (318)	**81.6% (408)**	65.0% (352)
c) COMBINATION	52.4% (262)	74.2% (371)	81.6% (408)
d) PROPOSED	**67.0% (335)**	80.4% (402)	**83.2% (416)**

* Numbers in bracket indicate the number of the correct outputs. The underlined value in (d) indicates significantly higher values than (a), (b) and (c).

Table 4 - Frequencies of appearance of each system in the proposed hybrid system (PROPOSED)

	Selected frequency
DIRECT	67
EXAMPLE-BASED	223
COMIBINATION	210

4 A word boundary in Japanese language is not explicit.

Table 5 - Output examples

Input disease name [SELECTED SYSTEM] coding example	Gold standard (a correct code & its ICD term)
HCV antibody test positive [EXAMPE-BASED] HBc antibody test positive [R768]	[R768] immunological injury of serum
E incompatibility [EXAMPLE-BASED] D incompatibility [O360]	[O360] maternal care for RH allogeneic immunity
hemolytic streptococcus infection [COMBINATION] coliform bacillus infection [A498]	[A491] chain coccus infection
type-LL Hansen's disease [COMBINATION] Type-I Hansen's disease [A300]	[A305] leper mass type lepra
palpebra tumor mass [DIRECT] *	[H029] palpebra trouble
lips of mouth sore [DIRECT] *	[K130] lips of mouth disease

* In the case that DIRECT is selected, a coding example is not used.

Table 4 shows the frequency of each selected system, and Table 5 shows some output examples.

Discussion

We then investigated an important clue for the selector. In a decision tree produced by the selector, the first branch is "*if the max example-sim > X, use EXAMPLE-BASED*", and the second branch is "*if example code variation < X, use EXAMPLE-BASED*". Based on this observation, we can see that the selector provided several opportunities for the EXAMPLE-BASED system.

For more detailed discussions, we investigated each system performance using the following measures:

Precision = # of correct outputs / # of outputs,
Recall = # of correct outputs / # of test-set.

In this investigation, a system will reject an output if the similarity is less than various thresholds. We examined two systems: (1) the DIRECT system (which relies only on direct-sim) and (2) the EXAMPLE-BASED system (which relies only on example-sim) (Figure 3).

As shown in the figure, EXAMPLE-BASED generally showed higher performance, but in some parts (top-left in the figure) DIRECT is better than EXAMPLE-BASED. Considering the potential of EXAMPLE-BASED, the strategy of the selector, which gives the first chance to EXAMPLE-BASED, is reasonable.

Finally, this figure also shows that we can freely control the system precision and recall. This can be a strong advantage from a practical point of view.

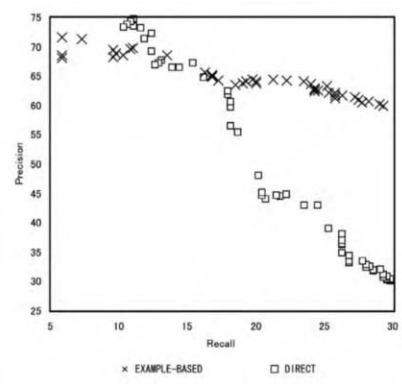

Figure 3 - Precision and recall of two systems (DIRECT and EXAMPLE-BASED)

Related studies

Thus far, a number of studies have investigated automatic coding [4-11, 19, 20, 22-25]. Most of these studies have focused on methods for knowledge representation such as a semantic frame-based ICD representation [9], a conceptual graph-based representation [5], a semantic markup [10], and an analytical index [19]. It is difficult to compare these systems to that of the present study for three reasons: (1) their inputs were different from ours, (2) we dealt with the Japanese language, and (3) more importantly, the present study focuses on the hybridization of systems. We can expect that the present system will have higher performance by incorporating the advantages of their methods.

Another important aspect of coding studies is the coding algorithm such as frequency statistics [20], a Naïve-bayes classifier [11], and an open registry algorithms [22]. Although various approaches have been proposed, each system has strengths and limitations, as pointed out in a study [23], motivating the proposed hybrid approach.

Note that some studies focused on a limited domain. For example, Tagliabue[22] dealt with a cancer domain, and Schnitzer [23] concentrated on a child injury domain. Such a limited domain enables a more finely-tuned system to be developed, leading to higher performance. In the future, we intend to incorporate such domain-limited systems into the proposed hybrid framework.

At present, automatic coding accuracy systems have not yet been perfected. However, Hohnloser [4] reported that their coding system improves human coding quality. In addition, several systems have been investigated in hospitals for years ([24]: five years, [25]: one year). In the future, we intend to examine the performance of the proposed system in a real-world environment.

Conclusion

The present paper proposed a hybrid architecture of different coding systems. First, given an input disease name, three coding systems output codes with their scores. A C4.5-based selector then decides the best output by using information from both the input and each system. The experimental results demonstrated that the selector significantly boosts the performance. In the future, we will attempt to incorporate more approaches/systems into our hybrid framework and will perform a system test in a real environment.

Creation and Evaluation of a Terminology Server for the Interactive Coding of Discharge Summaries

Hernán Navas, Alejandro Lopez Osornio, Analía Baum, Adrian Gomez, Daniel Luna, Fernan Gonzalez Bernaldo de Quiros

Department of Medical Informatics, Hospital Italiano de Buenos Aires, Argentina

Abstract

Free text entry versus structured data has been proposed as models in data entry in health information systems. A new user interface was developed with the objective of improving data capture. It also implemented a modification of the discharge summary data entry user interface that allowed the selection of already coded terms from a local terminology in the context of an inpatient electronic medical record. This software interacts online with a terminology server to provide feedback on data entry to clinical users in order to automatically code data. To evaluate the impact of this new software, we measured user satisfaction and the impact on autocodification rate. The new system had good acceptance from the users who ranked it high using QUIS (Questionnaire for User Interaction Satisfaction) and the auto codification rate improved from 61.5% to 88.39%.

Keywords:

automatic data processing, user-computer interface, computerized medical record

Introduction

For a long time there has been a discussion regarding the use of free text versus structured text for data entry that later must be codified [1]. Free text has the advantage of allowing physicians to express themselves freely, but the disadvantage is the need for a laborious codification process to allow data analysis. Structured text allows a quick codification process but has the disadvantage of being time-consuming for the physician and constrains expression to the level of detail of the selected entry terminology.

Since 2000, physicians at the Hospital Italiano of Buenos Aires have used an inpatient electronic medical record for creating the discharge summary using free text. The discharge summary is a structured abstract of the hospitalization episode where data are registered for caring and management purposes [2].

This paper describes our experience when introducing a more restrictive user interface that will require users to select terms from an existing list. The new system should have functions that can facilitate migration from the previous unconstrained text entry model and author kit is designed to assist in preparing the submission. It is an exact representation of the format expected by the editor.

Objectives

The objectives are to:

- Develop and implement a modification of the discharge summary data entry user interface that allows the selection of already coded terms from a local terminology
- Measure the usability of the new software prior to its implementation will be measured
- Assess the impact automatic codification rate after implementation.

Methods

Information contained in discharge summary is structured in several domains. This structure has the purpose of collecting all the necessary information to group episodes using diagnostic related groups (DRG). The different domains are shown in Table 1.

In each of these fields, the physician entered free text descriptions. The previous version of the discharge summary software tried to automatically code the entered text using the terminology server. If the term did not match an existing entry in the local terminology, it was addressed to the terminology team for secondary manual codification. The terminology team reviewed all the discharge summaries, assigned ICD-9CM codes and manually grouped them into a DRG [3].

The Terminology Server (TS) [4] is software composed of a local interface vocabulary (thesaurus) mapped to a reference vocabulary, SNOMED CT. The thesaurus is a list of terms created from almost 2 million free text inputs extracted from the clinical data repository. The terms included in the thesaurus are divided into concepts (real clinical entities) and descriptions (different ways of naming these clinical entities). The TS also has capabilities to reject invalid terms already flagged as not appropriate for the intended use.

The TS was used for several months in the background without interacting with the users, coding exact matches and ignoring invalid and new terms [5].

Table 1 - Description of discharge summary fields

Domain	Description
Principal diagnosis	Syndrome or disease that best explains the patient's condition on admission to hospital
Other diagnosis	Diagnosis made during hospitalization not related to the principal diagnosis or not caused by it
Clinical history	Diseases suffered by the patient prior to, and not related to, the current hospitalization
Surgical history	Procedures experienced by the patient prior to, and not related to, the current hospitalization
Co-morbidities	Preexisting diseases, currently active, that generate actions by the physician
Complications	Conditions that appear during the episode that are related to the principal diagnosis or procedures
Principal procedure	The main invasive procedure undergone by the patient, related to the principal diagnosis
Other procedures	Procedures that do not meet criteria to be considered a principal procedure

New requirements

It was established that changes in the discharge summary interface would enforce the selection of terms already included in the TS by interacting with the user during data input. The TS should also provide interactive information for refining concepts. This feature of the TS is achieved using semantic information included on SNOMED CT, navigating the sub-types/super-types hierarchy.

The new user interface should:

- Provide automatic coding for known terms
- Offer more detailed instances of a concept for refinement
- Suggest similar terms as alternatives for unknown terms.

Interactive model

Every time the physician enters a term, two situations can take place:

- Automatic codification: when there is an exact match, the entry term is automatically codified using the code of the institutional vocabulary term (e.g. measles)
- Non-autocodifiable text: refers to the situation where the physician enters text that is unknown, invalid or can be refined. It also takes into account spelling mistakes and synonyms, all contained in our server. The three different variants are outlined below.

Unknown text

If the physician enters a term that is not included in the institutional thesaurus, the system offers the user a list of possible valid terms so can they can select one of them. If the physician considers none of these terms exactly reflects the intended meaning, it is possible to choose to save the original text for manual revision.

Invalid text

If the physician enters a term that is manually marked as 'non-valid for this domain', the system alerts the user and offers, in some cases, an alternative valid term but does not allow the invalid term to be saved. If the system doesn't offer valid alternatives, the physician must enter a new term.

Refinable text

The text is related to a valid concept but there are more specific concepts available. The system displays more detailed options so the physician can choose one and make a more specific entry (e.g. arterial hypertension). The text is valid but the system will offer more specific options such as primary arterial hypertension or secondary arterial hypertension.

Impact of the new system

The impact of the automatic codification process was easily measured through the ST records using rates of automatic coded terms of May 2006 and June 2006, prior and after the software implementation respectively.

Evaluation of usability

We decided to evaluate the usability of the software prior to its implementation. We choose 5 physicians from different specialties to represent the users of the discharge summary software. A resident physician of the Medical Informatics service observed while these physicians used the software in their usual workplace. After observation, the physicians were asked to complete the QUIS (Questionnaire for User Interaction Satisfaction) Spanish version 7.0. QUIS was developed and validated by the Human-Computer Interaction Laboratory of Maryland University [7]. We used the brief version of the questionnaire due to the limited time available with the physicians. QUIS uses the Likert scale from 1 to 9. It is divided into 12 parts, 5 of which were not applicable in our setting. Part 1 evaluates the experience with the system; part 2 the experience in general when using computers; part 3 examines the general impression of the user; part 4, the screen design; part 5, the terminology used; part 6 makes reference to the learning capacity; and part 7 evaluates system qualities such as velocity, consistence and facility to use it.

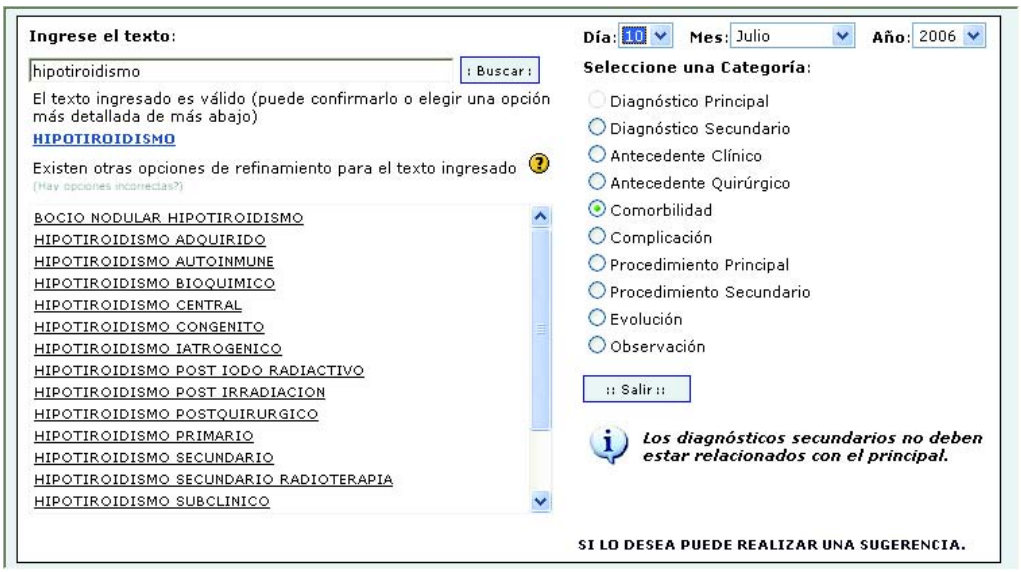

Figure 1 - New interactive coding application

Implementation

The software was successfully implemented in June 2006. The software was programmed in Java, as are all our electronic medical records. The access to the terminology services was made through store procedures programmed in PL-SQL in an Oracle 10g base. The user interface screen is showed in Figure 1.

Results

Using the previous discharge summary software, only 12,830 (61.5%) terms were automatically coded from a total of 20,862 terms in one month. During the month after the implementation of the new user interface, 16,826 (88.39%) were automatically coded from a total of 19,036 terms, as shown in Figure 2.

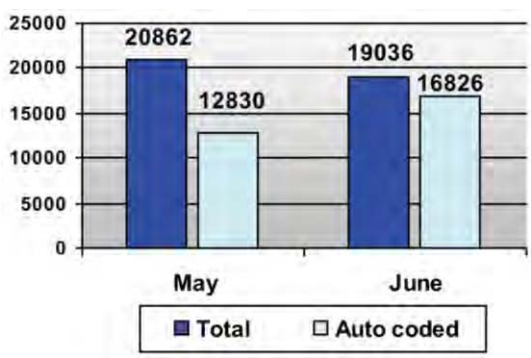

Figure 2 - Automatic code rate pre and post implementation

In spite of the modifications made to the interface, resident physicians were completely satisfied and none needed help while using it. QUIS results are shown in Figure 3.

Part 1: Experience with the system. Users had at least 1 or 2 years using the system, between 1 and 4 hours weekly.

Part 2: Prior experience. All users had prior experience using Windows OS ® and were users of previous clinical applications including discharge summary, order entry and results manager.

Part 3: Users general impression. Users rated the discharge summary screen as good, stimulating, easy to use, adequate and flexible.

Part 4: Screen design. Users found screens to be easily readable, with a clear sequence. Highlighted elements in screen were of medium utility, as well as screen format.

Part 5: Terminology and information about the system. Users found the terminology to be consistent and appropriate. The on-screen messages were clear and consistent. The system usually informed about what it was doing. The error messages were helpful.

Part 6: Learning. The users think the system is easy to learn and tasks were done mostly without complications. Names and instructions were easy to remember.

Part 7: System capacity. Users found the system to have a good working speed. It was easy to correct mistakes. The usability was directly related with the user's level of experience.

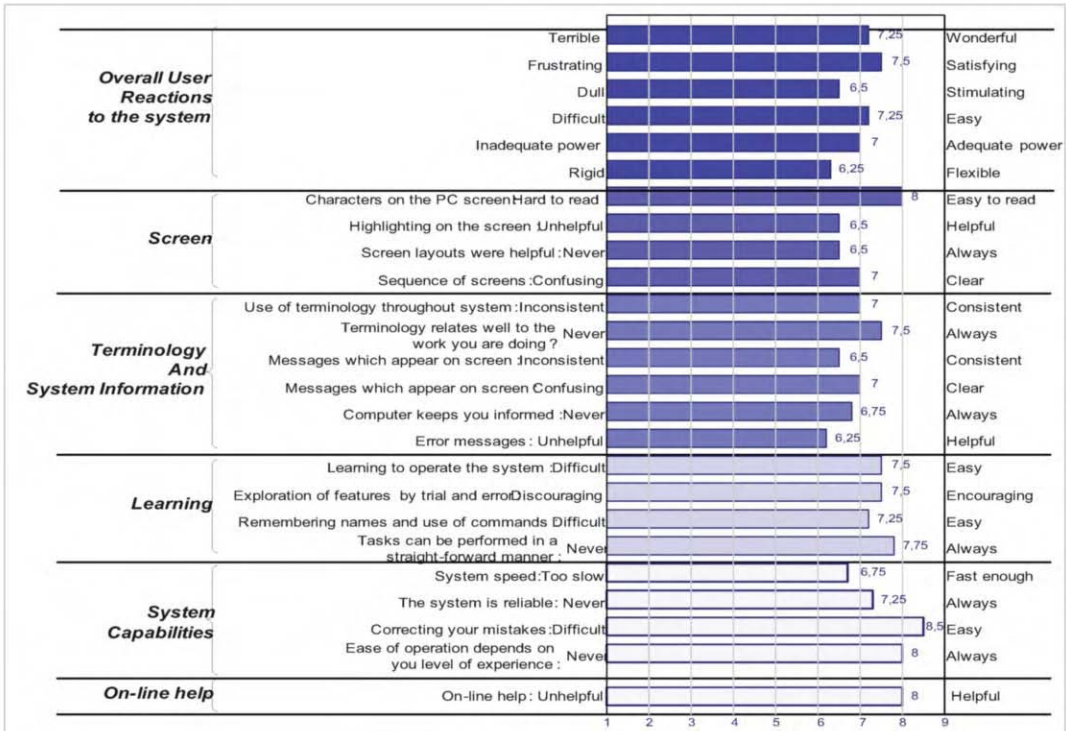

Figure 3 - QUIS results

Discussion

Health care organizations currently pay attention to systems usability [8, 9] and this can be carried out with few resources. Systems usability can be evaluated by a trained person with a notepad and five users who are representative of the users' population [10]. We decided to use QUIS as a validation instrument because we wanted to ensure before implementing the new system that medical residents would not have any problems using the new interface, and that it would not interfere with their complex daily tasks.

We think this improvement relies greatly on the important amount of text (synonyms, abbreviations and local jargon) available in the terminology server, and the relationships established between the different terms through the use of SNOMED CT.

The availability of online consultation about the terminology and input terms created acceptance among users, and led us to maximize the benefits of free and structured texts.

After going through the process of manual revision of new terms, a new version of the user interface will further restrict the data entry process, and disallow the clinical use of unknown terms. A mechanism to propose new terms will be maintained, but new terms will not be assigned to a patient until they are approved by the terminology team.

Abstract

The construction and maintenance of a medical thesaurus is a non-trivial task, due to the inherent complexity of a proper medical terminology. We present a methodology for transaction-based anomaly detection in the process of thesaurus maintenance. Our experiences are based on lexicographic work with the MorphoSaurus lexicons, which are the basis for a mono- and cross-lingual biomedical information retrieval system. Any "edit" or "delete" actions within these lexicons that undo an action defined earlier were defined as anomalous. We identify four types of such anomalies. We also analyzed to which extent the anomalous lexicon entries had been detected by an alternative, corpus-based approach.

Keywords:

thesaurus, quality control

Introduction

A thesaurus is a collection of semantically related terms, used to represent document contents with the purpose of improving document classification and content retrieval [1,2,3]. Especially in Medicine and Health, there is an ever-growing volume of texts, scientific publications, electronic textbooks, web-based health information for laypersons, and last but not least, a huge amount of text in electronic patient records.

Medical terminology is complex, rapidly changing, and highly productive. New acronyms, abbreviations, single and multi word compounds are continuously generated, and English terminology increasingly permeates non-English medical documents. Multilingualism is an important issue here, due to the global tendency of using English as the primary language of research, whilst the local idioms are used for patient-related documentation and communication [4]. All these factors hamper the use of simple text retrieval techniques such as popularized by Web search engines. So we claim that text retrieval in the biomedical domain should be supported by an underlying thesaurus that covers intra- and interlingual synonymy.

Thesaurus engineering is an iterative process, generally involving numerous domain experts. Their activities are generally directed by guidelines, but also encompass individual arbitrariness. Controversies especially come up with relation to boundary decisions such as:

- Whether to consider or not a term pertinent to the domain and therefore relevant for the thesaurus;
- Whether to include composed or derived terms if their components or base forms are already in the thesaurus;
- Whether to consider two terms as synonymous;
- Which other semantic relations to use between terms;
- Which senses to be needed to be distinguished when dealing with ambiguous terms;
- Whether to consider additional senses which are of marginal importance for the domain.

The most common method to track modifications in a database is the procedure register or log [5]. The log system has the property of recording all state changes. In this work maintenance problems in a medical thesaurus are analyzed, and a method is proposed which helps to detect anomalous change patterns in order to increase the efficiency of the thesaurus building process.

Material and methods

The subword approach

The application context of this work is given by *MorphoSaurus*, a large multilingual thesaurus for clinical medicine [6,7]. The main difference between MorphoSaurus and any other medical thesaurus such as MeSH [8] is that the inclusion of lexical entries into the repository is strictly guided by criteria of semantic atomicity. This resulted in the introduction of a new kind of lexical item, the so-called *subword* entry, assuming that neither fully inflected nor automatically stemmed words constitute the appropriate granularity level for lexicalized content descriptions [9,10].

The building of a subword thesaurus requires a scrutiny of the following aspects of language:

- Orthographic variations such as in *oesephagus* vs. *esophagus*;
- Derivations that modify a word's part of speech and/or its meaning, e.g.: *diabetes, diabetic, antidiabetic*;
- Proper string delimitation of what constitutes a valid subword entry, e.g. *nephr, nephro*, or both;

Figure 1 – Morphosemantic indexing by MorphoSaurus

- Composition that builds complex word forms out of simple ones, such as *high blood pressure* (multi word composition) or *hyperprebetalipoproteinemia* (single word composition);
- Synonyms and translations: *nephro*, *renal*, *rim*, *kidney*, *niere*...;
- Acronyms: *AVC*, *ECG*, *DPOC*, *AIDS*,... and their possible expansions;
- Proper Names, such as substance names, trade names, or eponyms: *Diclofenac*, *Viagra*, *Parkinson,...*
- Ambiguous terms, i.e. terms which have different meanings, such as *head*, *ventricular,...*

The MorphoSaurus system

Particularly in the medical sublanguage we observe complex word forms such as in *`pseudo|hypo|para|thyroid|ism', 'append|ectomy'*, or in *'tooth|ache'*. The MorphoSaurus system does not register these complex terms, as long as their meaning can be derived from their components. Instead it focuses on so-called *subwords* as lexicon entries, which are registered together with attributes such as language and subword type (word stem, prefix, suffix, infix, invariant word). Instead of medical *terms*, MorphoSaurus includes the *building blocks* of medical terms.

In the MorphoSaurus database, each entry is assigned to one synonymy class. In the beginning of the thesaurus building process, there is one class for each entry, but in the following classes are increasingly fused, containing not only intralingual synonyms but also interlingual translations. Each synonym class is identified by one language-independent descriptor, called MorphoSaurus identifier (MID). Every MID represents a unique meaning. MIDs are further divided between those which are relevant for indexing (here marked by #) and those which have grammatical functions only (e.g. auxiliary verbs, inflection suffixes, conjunctions, etc., marked by %).

For instance, the MID *#liver={liver, leber, hepar, hepat, figad, ...}* represents the sense of "liver", whereas the MID *%ness={-ness,-idade ,-keit}* groups semantically irrelevant suffixes, just as *%be={be, is, are, sao, e, ist, ...}* groups forms of the verb "to be", which should be ignored for document indexing.

MorphoSaurus provides two semantic relations between equivalence classes:

- *has_sense*: This relation links ambiguous MIDs to their senses, e.g., the MID *#head* is linked to the MIDs *#caput* and *#boss* by *has_sense*;
- *has_word_part*: This relation links an MID having a composed meaning to each of its parts, e.g., the MID *#myalg={"myalg-", "mialg-",...}* to both *#muscle={myo-, muscle, mio, muscul, ...}* and *#pain={pain,-algy, -algi, -algia, dor, schmerz,... }*. The reason for this is to deal with composed meanings even in cases where a compound cannot be properly dissected.

The MorphoSaurus indexing engine converts text into into an interlingual representation by a three-step procedure, as

depicted in Fig. 1 for a parallel text. In the first step, The first step deals with general and language specific *orthographic normalization*. In a second step, the text is split into sequences of semantically plausible subwords, which are then checked for morphological plausibility using a finite-state automaton (*Morphological Segmentation*). Thus invalid segmentations such as segmentations without stems or ones beginning with a suffix are rejected. Finally, each meaning-bearing subword is replaced by its MID. This constitutes the interlingual output representation of the system. The bold MIDs in Fig. 1 are evidence of the high interlingual correlation on the level of semantic atomicity.

Pragmatics of thesaurus building in MorphoSaurus

Modeling decisions for a subword thesaurus are more complex than decisions for word-based thesauri. Thus, the proper delimitation of what constitutes a lexical entry is often subject to argument. These boundary decisions are even influenced by the performance of the word segmentation algorithm. The following example may provide a flavor of the daily problems in the maintenance of MorphoSaurus: The word *nephrotomy* used to be erroneously divided into *nephr|oto|my* instead of the correct *nephr|o|tomy.* This was solved by the inclusion of *nephro* as a synonym of *nephr* into the thesaurus, which may be considered linguistically unsound, but which produced the required result. Another controversial issue is how to deal with utterly short stems. For instance, the MID *muscle* can be erroneously extracted from many words due to the frequency of the character combination "my". The decision made in this case was not to include *my,* but to add the common compounds (*myosis, myalgy, ...*) instead and to use, in a second step, the *has_word_part* relations as introduced above in order to represent their meanings.

Anomaly detection in logged data

With the purpose to collect data about the changes in the MorphoSaurus database during a given time interval we collected 86 backups of the MorphoSaurus database for the period between July 14th, 2005 and March 30th, 2006, representing regular intervals of approximately three days. A script extracted all alterations for each single data object. This data volume then served as a basis for the detection of anomalies.

We here introduce the notion of thesaurus management anomalies as sequences of such actions done by the thesaurus curators that consume effort without any positive impact on the quality of the thesaurus.

We distinguish the following four anomaly types:

- A relationship anomaly is defined as a sequence of editing steps in which a semantic relation (*has_sense or has_word_part*) between two equivalence classes is first eliminated and later restored,
- A type anomaly is defined as a sequence of editing steps in which a lexicon entry is first moved from one equivalence class to another one and later happens to be moved back into the original class,
- A delimitation anomaly is defined as a sequence of editing steps in which the string delimitation of a lexicon entry is modified in a first step but is later restored to its original form,
- A permanence anomaly is defined as a sequence of editing steps in which an existing lexicon entry is first deleted, but recreated in a later phase.

According to these anomaly types, the whole body of logged user data from the backup data was analyzed.

Corpus-driven error detection

For further validation of anomalies, we used the following additional resources:

- Related corpora analysis: in a parallel study, the MorphoSaurus database was checked against real data in order do detect imbalances of MID distribution. In particular, this study used closely related corpora in different languages. All these texts were indexed by the MorphoSaurus system (yielding an output as shown in Fig.1), and the distribution of MIDs was pairwisely compared. The hypothesis was that anomalous MIDs exhibited the most unequal distribution patterns.
- Discussion Forum: a list of ill-distributed MIDs (ranked by degree of disproportion and overall frequency) was used as a basis for manual cleansing of the thesaurus by our team of lexicographers. Each of these MIDs was submitted to a thorough analysis, and the result was discussed in an online forum. Whenever the lexicographers reached a consensus, the MID entry was modified accordingly.

Joining the anomaly data from the log analysis with the data from the forum then provides a measure of relevance of the anomaly data.

Results

Analysis of anomalies

The log analysis yielded a total of 146 anomalies. Interestingly, there were many multiple occurrences in the case of relationship anomalies. So, we identified 23 MIDs

Analysis of problems addressed in the discussion

which exhibited a relationship anomaly more than once during the observation period. Counting the multiple occurrences only once, we got 99 anomalies, as shown in Table 1.

The discussion forum focused on English, Portuguese, and German and addressed 325 problems as shown in Table 2.

Comparison between anomalies and discussed problems

So far, the acquisition of anomaly data was completely independent from the analysis of problem discussions. Bringing together both sources we can now analyze the anomalous MIDs which were picked up in the discussion.

The data show that 36 out of 99 anomalous MIDs were not addressed in the forum discussions, and that forum discussions covered far more cases than could be identified by the log analysis, cf. values in parentheses in Table 1.

An inverse view is given by Table 2. Here the values in parentheses show the frequency of those MIDs which had also been spotted by the log analysis.

Finally, Table 3 gives a closer view of multiple occurring anomalies.

Table 1 – Number of occurrences of anomalies found by log analysis. Numbers in parentheses indicate anomalies also picked up in the discussion forum

Anomaly Type	Count
AR - Relationship anomaly	76 (28)
AT – Type anomaly	18 (18)
AD - Delimitation anomaly	0 (0)
AP - Permanence anomaly	5 (4)

Table 2 – Number of occurrences of problems in the discussion forum. Numbers in parentheses indicate the cases where the same problem was posted to the forum and had been identified by the log analysis independently

Problem Type	Count
PR - An expected relation between an ambiguous MID and MIDs (*has_sense* type) or an expected expansion relation (*has_word_part* type) was missing.	86 (24)
PC - Entries assigned to one MID did not cover all languages.	80 (6)
PU - The same sense is represented by two unrelated MIDs.	70 (8)
PM - Lexicon entries are assigned to one MID diverge in meaning.	11 (1)
PL - Language specific entry do not translate to other languages.	11
PO - Orthographic errors.	16 (1)
PI - Similar senses are represented by two unrelated MIDs, one of them of the type "excluded from indexing".	31
PD - Errors caused by incorrect subword delimitation	16
PS - Errors caused by incorrect functioning of the segmentation engine.	4

Table 3 – Anomalies AR: multiple changes related to one MID found by log analysis (left col.). Number of MIDs which exhibit multiple changes (right col.) Numbers in parentheses indicate the anomalies picked up in the discussion forum

# Changes	Count
2	4 (1)
4	16 (6)
5	2 (2)
6	2 (0)
7	23 (10)

Discussion

The correct handling of lexical ambiguities is the most error-prone step in the thesaurus management process [11]. This was evidenced not only by the frequency of the relationship anomaly (AR, cf. Table 1) but also by its occurrence in the discussions. Moreover, this anomaly was the only one where up to seven repetitions of editing occurred. This sheds light at a considerable waste of resources and lack of communication.

The assignment of subwords to an equivalence class (MID) was also subject to changes (AT anomaly), but here all cases were addressed in the discussion forum. This shows the effectiveness of the corpus-based detection of disproportions in the MID distribution and its good take-up by the lexicographers.

It was quite surprising that no anomaly of string delimitation (AD) could be observed. This is probably due to the fact that observed segmentation problems were solved by adding new string variations (e.g. "*-otomy*" in addition to "*-tomy*") and not by modifying the existing ones, in accordance with the guidelines used in the thesaurus building and maintenance process.

Finally, the awareness of the permanence anomaly was shown by its high coverage in the discussion forum. This kind of anomaly elicited the major disproportions in the corpus analysis, due to the fact that lexemes with a borderline semantic importance occur with high frequency. For instance, the phenomenon that the preposition "*from*" was assigned to the MID type "marked for indexing", and the Portuguese translation "*de*" was assigned to another MID marked as "excluded from indexing", put the first MID on top of the ranked list of lexicon disproportions, and was

therefore preferentially addressed in the discussions. These types of "*stopwords"* are frequent and equally distributed across the whole document space. Hence, they are irrelevant for distinguishing documents in text retrieval scenarios [3,12]. On the other hand they can acquire importance as context modifiers, such as in complex terms like *Removal of foreign body from stomach*, which could be matched to *Removal of stomach* in case that the preposition *from* is neglected.

The anomaly detection process would have an additional value if the anomalous MIDs would be detected in runtime so that the lexicographers would get an immediate feedback whenever an action executed earlier is undone. A new version of our lexicon editing tool MorphoEditWeb, currently under development, implements this functionality.

Conclusion

Thesaurus management is a highly dynamic process, and the kind of decisions which have to be done continuously imposes challenges on the lexicographers upon which the creation and continuing maintenance is incumbent. The waste of resources due to the phenomenon that one person undoes an action which another person has done before is considerable.

Unfortunately no guideline for thesaurus management can ever foresee all borderline cases which can only be solved by consensus. The proposed technique of user action based anomaly detection is useful to discover them and is complemented by other techniques such as the corpus-based check for disproportion of semantic identifiers. A seamless integration of such quality assessment routines in the thesaurus management tools is of utmost importance for achieving higher process effectiveness.

Harmonizing Clinical Terminologies: Driving Interoperability in Healthcare

Abstract

Internationally, there are countless initiatives to build National Healthcare Information Networks (NHIN) that electronically interconnect healthcare organizations by enhancing and integrating current information technology (IT) capabilities. The realization of such NHINs will enable the simple and immediate exchange of appropriate and vital clinical data among participating organizations. In order for institutions to accurately and automatically exchange information, the electronic clinical documents must make use of established clinical codes, such as those of SNOMED-CT, LOINC and ICD-9 CM. However, there does not exist one universally accepted coding scheme that encapsulates all pertinent clinical information for the purposes of patient care, clinical research and population heatlh reporting. In this paper, we propose a combination of methods and standards that target the harmonization of clinical terminologies and encourage sustainable, interoperable infrastructure for healthcare.

Keywords:

interoperability, terminology, standards, UMLS, HL7, unstructured text

Introduction

The most important characteristics of clinical and healthcare related documentation are precision and accuracy. As more and more of this documentation becomes electronic, computers will begin to assume part of the responsibility for ensuring document integrity. As such, clinical documentation will need to migrate from free-form physician notes to something more structured and processable by machines. The use of codes from established clinical terminologies within electronic clinical documents and the electronic infrastructure designed to support them will enhance machine processability and ensure comparable, if not improved, document precision and accuracy.

The need for clinical codes within electronic clinical documents poses a significant challenge to architects of NHIN efforts who desire to share information across healthcare institutions. Most healthcare organizations use codes today in a variety of use cases. Each organization, however, makes use of multiple clinical terminologies (including some that are organizationally proprietary) that do not necessarily align with terminologies used by other organizations. NHIN efforts, as well as integration efforts on a smaller scale (i.e., intra-institution and among regional institutions), must solve a translation problem to ensure that exchanged clinical information is as accurate and precise when presented to another institution as it is to the institution that created the information.

Translation among clinical terminologies is not a new problem. Concrete systems like UMLS [1] and LexGrid [2] have been under development for years and begin to attack this problem. In this paper, we outline the fundamental characteristics of this problem and requirements for a complete, automated solution. We first discuss the two key characteristics of any terminology, and how they can be leveraged to search a terminology and ultimately produce a mapping between codes. Next, we highlight the limitations of nave application of these search methods by discussing how additional factors impact the mapping of codes. Finally, we discuss how healthcare IT standards provide an infrastructure base that supports code mapping efforts.

Methods

Two approaches to search

In this section, we discuss various techniques that attempt to solve the problem of mapping from a *source* code (or lexical phrase) to a *target* code, which may belong to a different terminology. These techniques exploit the fact that every terminology has a notion of *structure* as well as *textual descriptions* of the concepts it represents [3]. The structure of a terminology can be represented as a graph that models the underlying relationships among different codes. The textual description is a human-readable word or phrase associated with each code. These fundamental characteristics aid in automated navigation within and among terminologies and can be exploited to find the target code which is the best match to a given source code or lexical phrase.

Each of the fundamental characteristics suggests a corresponding method for navigating a terminology: an unstructured lexical search or a structured graph search. Lexical searches are performed by matching the textual descriptions of codes in the target terminology. Structural searches are performed by navigating the relationships between codes in a given terminology. In order to direct

both approaches towards finding the best match, we introduce the notion of a *score*, which represents how similar two objects are to each other, and ranges between the values 0.0 (dissimilar) and 1.0 (equivalent).

For the lexical analysis, the score denotes the similarity between a phrase and the description of the code, or the similarity between the description of one code and another. For example, if we are searching for snake bite, then the code with the description snake bite will have a perfect score (*i.e.*, 1.0), whereas the code with the description squirrel bite will have a lower score. In an IBM prototype system for exploring mapping technologies, we used the Apache text search engine Lucene. Lucene constructs a text index for a data set and uses it to support searches for records or documents containing particular words or phrases. Lucene has the ability to ignore words that are used too frequently, such as a, an, and the, and can be configured to ignore additional domain-specific words. Furthermore, Lucene includes the ability to do *loose* matching, and retrieve documents or records whose text only approximately matches the desired word or phrase.

Between any two codes in a given terminology, there exists a path of relationships. For the structured search, the score of a path is calculated based on both the length of the path and the types of relationships traversed. For example, the path between the codes representing snake bite and bite will typically have a higher score than the path between the codes representing snake bite and heart attack, because (in most terminology systems) the codes for bite and snake bite are closely related, whereas the codes for heart attack and snake bite are very distant. Moreover, since the relationship type is a factor when scoring a path, it is possible that the path from bite to snake bite will have a higher score than the path from snake bite to bite. Intuitively, the reason for this behavior is that all snake bites are bites but not all bites are snake bites.

Scoring a path can be done in a number of different ways. In the IBM prototype implementation, we make use of an area of mathematics called *fuzzy set theory*. Fuzzy set theory is based on the notion that elements can have degrees of membership in particular sets. For our purposes, codes (our elements) are not simply classified as equivalent or dissimilar, but rather they range over a spectrum of similarity. If we assign a score to each individual link in a path based on the type of the relationship the link represents, we can use fuzzy set theoretic techniques to compute the score of the entire path. For example, if we were to use one of the fuzzy techniques of intersection on a path with three links having scores 0.8, 0.5, and 0.5, respectively, then the score for the *total path* would be 0.8*0.5*0.5 = 0.2.

In order to exploit structural graph searches to solve the code mapping problem, we must create *bridges* between the source and target terminologies. A bridge is some concept that is represented in both the target and source terminology. Once a bridge between two terminologies has been established, then it is possible to navigate between the source and target terminology via the closest bridge. Determining which concepts can be used as bridges is a non-trivial issue. In the IBM prototype implementation we used UMLS which is designed to relate different terminologies to each other. Thus, leveraging relationships defined by UMLS allowed us to construct bridges between the source and target code. UMLS recognizes many different types of relationships between concepts; we scored each of them differently. For example, we gave a child-to-parent relationship a higher score than a parent-to-child relationship. By scoring UMLS in this manner, we have constructed a means to perform a guided search over all the UMLS entries. We have found this technique of immense value in UMLS, since codes that are quite similar are often linked by some relationship, rather than being classified as the same concept.

The two notions of similarity (lexical and structural) can be used in isolation or in conjunction as methods for solving the code mapping problem. Currently, we are investigating blending these two approaches. While the unstructured or lexical approach is useful for finding a best match code, given a descriptive phrase, it is possible that we miss related concepts because they use different words for similar concepts. Structured search, on the other hand, requires a code to start navigating the underlying graph structure of the terminology, and may become stuck navigating an area of the graph that is only weakly related to the desired concept. Thus, structural search can in isolation return results that are of little value. By resorting to a lexical search when this happens, we can discover additional starting points for structural search that may more closely resemble the target code. This technique, which can be used iteratively, is similar to the technique of simulated annealing which is used for many global optimization problems. By combining these two approaches in this and other ways, we hope to construct an algorithm that minimizes their individual disadvantages for attacking the code mapping problem.

Additional factors impacting the code mapping problem

Several additional factors further complicate the code mapping problem. First, coding systems often allow several codes to be combined in order to describe a concept for which no specific code has been defined. For example, system A may have a specific code for lower-back pain, whereas system B may utilize one code for pain and another to designate its location as the lower back. In system A, the coding for lower-back pain is said to *be pre-coordinated*, whereas in system B the same concept is described with a *post-coordinated* pair of codes. Thus, in general, the mapping between codes in different systems is not necessarily one-to-one; it may be one-to-many or many-to-many.

Second, completely different mappings may apply depending on the clinical context in which a code appears. For example, the code for a stroke may appear in reference to the patients current condition, it may appear as an item in the patients medical history, or it may appear as an item in the patients familys medical history. Depending on how the source and target coding systems are structured, the desired target code for a mapping may be different in each of these three situations. Such examples illustrate the necessity of supporting multiple (partial) mappings between coding systems, together with machine-processable rules that can be used to select the proper mapping for a particular context.

Complicating factors such as these have significant impact on automated search for a matching code. Automated search, as previously described, would need to be configured in many different ways to be effective across disparate terminologies. The task of developing configurations for all of them would be daunting.

Discussion

A truly universal, sustainable, automated code matching method would need the codes presented to it in a consistent way so that it would be effective atop any terminology. Here is where we turn to healthcare-related IT standards in order to further the solution.

Impact of healthcare IT standards on implementation

The automated mapping techniques described in the previous sections assume that it is possible to represent knowledge about relevant coding systems in a machine-processable form, so that both the textual descriptions of codes and the structural relationships among codes can be explored by mapping algorithms. It is in this area that standards must play a critical role.

The ability to identify the correct concept mapping between code systems is further complicated in that vocabulary sources differ not just in content, but in structure. Vocabulary sources are often created for specific purposes, and as such the representational structure and description logic used by any individual source will be developed to meet the specific needs for that vocabulary source. Additionally, coded concepts are complex datatypes consisting of many properties and relationships to other attributes. Vocabulary sources will select a sub-set of the available properties to meet the specific needs for the source. Attributes such as *language* may be left out by a local code system, but a more mature and widely used vocabulary source may require a *language* attribute to be specified.

In an effort to make the mapping of coded concepts between terminology sources more transparent and predictable, Standards Development Organizations (SDOs) such as Health Level Seven Inc. (HL7) and informatics organizations like Mayo Clinics Division of Biomedical Informatics have developed standard interfaces and models for the specification of coded concepts and their associated properties**,** and for the representation of vocabularies in a consistent format.

The concept descriptor information model

One specification for the representation of coded concepts can be found in the HL7 Data Types Abstract Specification. The purpose of HL7s Data Types Abstract Specification is to define the meaning (semantics) of data values that can be assigned to a data element. Meaningful exchange of data requires that we know the definition of values so exchanged [4]. For the purpose of defining vocabulary elements, the HL7 Data Types Abstract Specification defines seven data types (or more accurately, data structures) that can be used to represent coded concepts and their associated properties (see. Figure 1).

These vocabulary data types include:

- Concept Descriptor (CD)
- Concept Role (CR)
- Coded Value (CV)
- Coded Simple Value (CS)
- Coded Ordinal (CO)
- Coded With Equivalents (CE)
- Character String with Code (SC)

The CD datatype is the most comprehensive of the vocabulary datatypes and includes identification attributes for coded concepts, including the unique *Code* for the coded concept*,* the *Display Name, Code System* and unique *Code System Identifier* as well as an optional *Code System Version.* To support operations such as concept mapping operations additional attributes have been specified.

The *Original Text* attribute can be used to represent the text or phrase used as the basis for the coding often reflecting content of physician notes [4].

The *Qualifier* attribute is used to specify additional codes that increase the specificity of the primary code.[4] For example, combining the concept identifier for *Family History* to the concept identifier for *Stroke* to indicate that there is a history of stroke in a patients family. Additionally, *Qualifier* can be used in concept mapping. For example, one can equate the concept *low back pain* in code system A to a combination of the concepts *pain* and *lower back* in code system B.

Translation is used to capture alternative concept descriptors in order to translate a coded concept from one code system into concepts from others. This is useful for cases where, say, both ICD9 and CPT codes are needed.

An attribute that greatly assists in concept mapping is *Equality.* This attribute allows us to directly equate one concept to another.

The HL7 Data Types can be expressed in several formats, including the Unified Modeling Language, to express data type attributes and the interrelationships between the vocabulary data types, as well as XML Schema. These formats provide a basis for syntactically interoperable transmission of data types between systems.

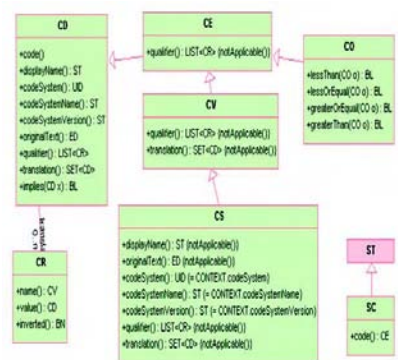

Figure 1 - The concept descriptor information model [4]

As is apparent from Figure 1, HL7s Concept Descriptor Information Model is a hierarchical model that defines specializations of vocabulary representations. These spe-

cializations act as constraints on the allowed properties of the CD data type, and are useful when communicating concept information when the semantics of a communication are agreed upon in advance, or in use case specific communication such as concept mapping.

The HL7 vocabulary data types provide a standardized syntax for communicating coded concept information between systems. Coded concepts from separate code systems can be represented in a common format, simplifying automated mapping algorithms by providing a common denominator for concept comparison.

The lexical grid

Just as the HL7 Datatypes can be used to coordinate the representation of individual coded concepts, robust vocabulary models can be constructed to define how disparate vocabularies can be represented. As terminologies are developed with specific use cases in mind, the representational structure and description logic used by any individual source will be developed to meet the specific needs for each terminology. This further complicates terminology access and mapping as programmatic access of the terminology source must be customized to the logic and structure of each source being accessed. While the semantics of individual vocabulary sources will understandably remain distinct, the ability to represent various vocabularies in a common format with a common set of tools would significantly simplify and improve concept mapping operations. This is the goal of the Lexical Grid (LexGrid).

At its core, LexGrid is a model of terminology that can represent the content of disparate vocabulary sources. Vocabularies represented in a LexGrid compliant format are available to be accessed programmatically using common tools such as HL7s Common Terminology Services Specification (CTS). CTS is an HL7 ANSI standard defining the minimum requirements for vocabulary interoperability across disparate healthcare applications. For example, when performing concept level mapping across code systems, a semantic mapping model is required to automate the mapping process. LexGrid provides a foundation and lowest common denominator for which these mapping semantics can be represented.

LexGrid, like the HL7 Vocabulary datatypes can be used to provide a common syntax for communicating across vocabulary sources. By controlling the way the semantics of a vocabulary are represented, operations such as concept mapping can be more accurately controlled, helping to reduce errors in mappings, and improve the consistency in the mapping algorithms.

Future work in combining the LexGrid model with enhanced vocabulary services APIs is underway as part of HL7s CTS 2 project. HL7s CTS 2 builds on the common set of methods and APIs specified in the CTS, with the goal of providing additional functionality of a general-purpose nature that falls outside the scope of the HL7. CTS 2 will include additional APIs for vocabulary query, authoring, and mapping. These API are only practically implementable across vocabularies when a common representation model is employed.

Conclusion

Standards such as the HL7 Datatypes and HL7s Common Terminology Services embodied by Mayo Clinics Lexical Grid, provide a consistent syntax to represent the semantic structure of a variety of existing vocabulary sources. This plays a key role in enhancing the accuracy of automated mapping techniques. The combination of search methods that exploit the fundamental properties of terminologies with standards-based data structures and APIs provide significant components of a completely automated, sustainable solution to the code mapping problem. With technology present to not only create system level but semantic level interoperability, we make a significant step towards realizing national health information networks, potentially revolutionizing healthcare for all.

Abstract

Data sets with many discrete variables and relatively few cases arise in health care, ecommerce, information security, and many other domains. Learning effective and efficient prediction models from such data sets is a challenging task. In this paper, we propose a new approach that combines Metaheuristic search and Bayesian Networks to learn a graphical Markov Blanket-based classifier from data. The Tabu Search enhanced Markov Blanket (TS/MB) procedure is based on the use of restricted neighborhoods in a general Bayesian Network constrained by the Markov condition, called Markov Blanket Neighborhoods. Computational results from two real world healthcare data sets indicate that the TS/MB procedure converges fast and is able to find a parsimonious model with substantially fewer predictor variables than in the full data set. Furthermore, it has comparable or better prediction performance when compared against several machine learning methods, and provides insight into possible causal relations among the variables.

Keywords:

Markov Blanket, Bayesian Networks, machine learning, Tabu Search, health care decision support.

Introduction

The deployment of comprehensive information systems and online databases has made extremely large collections of real-time data readily available. In many domains such as genetics, clinical diagnoses, direct marketing, finance, and on-line business, data sets arise with thousands of variables and a small ratio of cases to variables. Such data present dimensional difficulties for classification of a target variable, and identification of critical predictor variables [1]. Furthermore, they pose even greater challenges in the determination of actual influence, i.e., causal relationships between the target variable and predictor variables. The problem of identifying essential variables is critical to the success of decision support systems and knowledge discovery tools due to the impact of the number of variables on the speed of computation, the quality of decisions, operational costs, and understandability and user acceptance of the decision model. For example, in medical diagnosis and healthcare decision support, the elimination of redundant tests may reduce the risks to patients and lower healthcare costs [2]. In this study, we address this problem of efficiently identifying a small subset of predictor variables from among a large number, and estimating the causal relationship between the selected variables and the target variable, using *Markov Blanket* (MB) and *Tabu Search* (TS) approaches.

We propose a two-stage Tabu Search enhanced Markov Blanket procedure that finds a parsimonious MB Directed Acyclic Graph (DAG). This two-stage algorithm generates an MB DAG in the first stage as a starting solution; in the second stage, the Tabu Search metaheuristic strategy is applied to improve the effectiveness of the MB DAG as a classifier, with conventional Bayesian updating. Classification using the Markov Blanket of a target variable in a Bayesian Network has important properties: it specifies a statistically efficient prediction of the probability distribution of a variable from the smallest subset of variables; it provides accuracy while avoiding over-fitting due to redundant variables; and it provides both a classifier and some insight into causal relations between a reduced set of predictors and the target variable. The TS/MB procedure proposed in this paper allows us to move rapidly through the search space of Markov Blanket structures and escape from local optima, thus learning a more robust structure.

Background knowledge

A *Bayesian Network* is a graphical representation of the joint probability distribution of a set of random variables. A Bayesian Network for a set of variables $X = \{X_1, ..., X_n\}$ consists of: (i) a directed acyclic graph (DAG) S that encodes a set of conditional independence assertions among variables in X; (ii) a set $P = \{p_1, ..., p_n\}$ of local conditional probability distributions associated with each node and its parents.

P satisfies the *Markov condition* [3] for S if every node X_i in S is independent of its non-descendants and non-parents in S, conditional on its parents. The Markov Condition implies that the joint distribution p can be factorized as a product of conditional probabilities, by specifying the distribution of each node conditional on its parents. In particular, for a given structure S, the joint probability distribution for X can be written as

$$p(X) = \prod_{i=1}^{n} p_i(x_i \mid pa_i) \quad (1)$$

where pa_i denotes the set of parents of X_i; this is called a Markov factorization of P according to S.

Given the set of variables X and target variable Y, a *Markov Blanket* (MB) for Y is the smallest subset Q of variables in X such that Y is independent of $X\backslash Q$, conditional on the variables in Q. P is *faithful* to the graph S with the vertex set X if and only if there are no conditional independence relations in P other than those entailed by satisfying the Markov condition for S. If P is faithful to the graph S, then given a Bayesian Network (S, P), **there is** a unique Markov Blanket for Y consisting of the set of parents of Y, the set of children of Y, and the set of parents of children of Y.

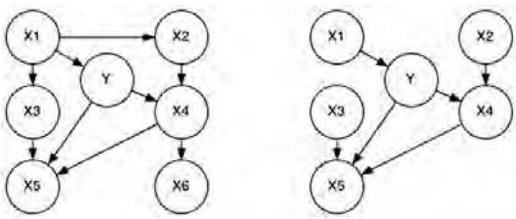

Figure 1 - (left) A Bayesian Network (S, P), and (right) the Markov Blanket for the variable Y

For example, given the two DAGs in Figure 1, the factorization of p entailed by the Bayesian Network (S, P) is

$$p(Y,X_1,...,X_6) = p(Y \mid X_1)\cdot p(X_4 \mid X_2,Y)\cdot p(X_2 \mid X_1)\cdot p(X_5 \mid X_3,X_4,Y)\cdot p(X_3 \mid X_1)\cdot p(X_6 \mid X_4)\cdot p(X_1) \quad (2)$$

The factorization of the conditional probability for the Markov Blanket of Y: $p(Y \mid X_1, \ldots, X_6)$ is the product of those (local) factors in equation above that contain the term Y:

$$p(Y \mid X_1,...,X_6) = C\cdot p(Y \mid X_1)\cdot p(X_4 \mid X_2,Y)\cdot p(X_5 \mid X_3,X_4,Y), \quad (3)$$

where C is a normalizing constant independent of Y.

Recent research in classification problems has tried to identify the Markov Blanket variables of the target class variable by filtering predictor variables using statistical tests of conditional independence [4]. Few of the proposed methods, however, have been used to generate the Markov Blanket from real-world data, and tests on real-world problems have usually involved only a small number of variables. Furthermore, while all the previous studies use the notion of Markov Blanket as a minimal set of dependent variables, none of them actually generate and retain the graphical structure of the Markov Blanket corresponding to a specific data set, nor have they used the structure for Bayesian inference in order to perform the classification. Our algorithm addresses all these limitations. Details are available in [5].

Tabu Search is a powerful meta-heuristic strategy that helps local search heuristics to explore the solution space by guiding them out of local optima [6]. Its strategic use of memory and responsive exploration is based on selected concepts that cut across the fields of artificial intelligence and operations research. It has been applied successfully to a wide variety of continuous and combinatorial optimization problems, capable of reducing the complexity of the search process and accelerating the rate of convergence. In its simplest form, Tabu Search starts with a feasible solution and chooses the *best move* according to an evaluation function while taking steps to ensure that the method does not re-visit a solution previously generated. This is accomplished by introducing *tabu restrictions* on possible moves to discourage the reversal, and, in some cases, repetition of selected moves. The *tabu list* that contains these forbidden move attributes is known as the short term memory function. It operates by modifying the search trajectory to exclude moves leading to new solutions that contain attributes (or attribute mixes) belonging to solutions previously visited within a time horizon governed by the short term memory. Intermediate and long-term memory functions may also be incorporated to intensify and diversify the search.

TS/MB model

A sketch of the algorithm is presented in Figure 2. The detailed algorithm is presented in [5]. Our algorithm first generates an *initial Markov Blanket* for the target variable. However, the initial MB may be highly suboptimal due to the application of repeated conditional independence tests and propagation of errors in causal orientation [5, 7]. Therefore, Tabu Search is applied to improve the initial MB. Four kinds of moves are considered in the procedure: edge addition, edge deletion, edge reversal and edge reversal with node pruning. At each stage, for each allowed move, the resulting Markov Blanket is computed, factored, its predictions scored, and the current MB modified with the best move. The algorithm stops after a fixed number of iterations or a fixed number of non-improving iterations.

Computational results

We tested our algorithm on two biomedical data sets [8, 9]. Table 1 provides a brief characterization of the data sets. Prostate cancer (PCA) data set concerns diagnosis of prostate cancer from mass spectroscopy of human sera [8]. Arrhythmia data set concerns classification of subjects into 8 disease categories from clinical and EKG data [9].

The parameters in our experiments are: data-splits, scoring criteria, starting solution structure, the depth of conditional independence search (***d***), and significance level (α). We use a nested, stratified cross-validation scheme [10]. In the inner layer, the procedure trains and optimizes the Markov Blanket on training data for each parameter configuration. The configuration that yields the best MB according to the scoring criterion is chosen as the best configuration. The outer layer of cross-validation estimates the performance of the optimized Markov Blanket classifier on the testing data. We report both the AUC and prediction accuracy on the testing set to evaluate the classification performance of the generated models.

Figure 2 - A sketch of the TS/MB algorithm

Table 1 - Characteristics of Data Sets

Task	Vars.	Samp.	Var. Type	Target Var.
PCA diagnosis	779	326	Discretized	Binary
Arrhythmia diagnosis	279	417	Ordinal	8 Categories

Table 2 presents the average best-fitting classification results for PCA data and the comparison against several state-of-the-art classifiers in three different ways. Details of the classifiers and the motivation for their choice in this study are discussed in [5]. We report both the AUC[1] and prediction accuracy on the testing set as well as the size of reduction in the set of variables. The size reduction was evaluated based on the fraction of variables in the resulting models. All metrics (variable size reduction, AUC, and accuracy) were averaged over cross-validation splits.

Comparison I (columns 1 and 2) presents the results when using the *full set* of variables as input. Comparison II (columns 3 and 4) uses the *same number* of variables as identified by TS/MB, as input for all the other classifiers. These variables for the classifiers in the comparison set are selected using information gain (IG) criterion [11]. Comparison III (columns 5 and 6) uses the *exact same* variables identified by TS/MB as input variables for all classifiers. Comparisons II and III are used to test the source of the differential in the observed accuracy and AUC values in the full data set.

1 Since AUC is only applicable to binary classification problems, we report only the accuracy for Arrhythmia data.

Table 2 - Five-fold cross validation results of various classifiers on 779 peaks; on 19 peaks selected by information gain; and on the exact same 19 peaks selected by the TS/MB classifier for the PCA data. Best performance figures are in ***bold***

Input	All Peaks		Peaks selected by IG		Peaks selected by TSMB		
Method	**AUC %**	**Accuracy %**	**AUC %**	**Accuracy%**	**AUC %**	**Accuracy%**	**# Peaks selected**
MB	95.3	87.1	95.3	87.1	95.3	87.1	19
TS/MB	98.3	90.3	98.3	90.3	98.3	90.3	19
Naïve Bayes	97.5	89.3	67.5	63.2	77.4	69.4	
SVM	97.1	98.5	63.3	62.0	72.6	69.9	
Voted Perceptron	73.9	58.0	65.2	59.2	75.4	67.8	
Max. Entropy	87.4	98.8	64.7	64.1	74.9	70.9	
K-NN	96.3	88.6	65.6	58.6	72.1	65.3	
Logistic Reg.	Failed	Failed	73.6	56.4	98.1	90.0	

The results clearly indicate that TS/MB dominates on the AUC metric and performs well on the accuracy measure, except in one instance. In addition, there is an almost 98% reduction in the number of variables used for this prediction. It is also interesting to note that all competing classifiers perform better with the variables provided by TS/MB than using the IG criterion (Comparison II vs. Comparison III) on both accuracy and AUC. Figure 3 shows the MB DAG learned from PCA data that achieves the best accuracy on the testing data. All the directed edges are robust over almost all cross validation runs, with very small variation. Further study and interaction with clinicians is necessary to identify the clinical significance of these variables in actual settings.

Table 3 presents the average best-fitting classification results for Arrhythmia data and compares them against the results obtained from several state-of-the-art classifiers. Figure 4[2] shows the MB DAG that achieves the best accuracy on the testing set of Arrhythmia data. The classifier in [9] achieved an accuracy of 62%, which obviously is not sufficiently good for clinical use. The best result from TS/MB achieved average accuracy of 96.8% with a 95% reduction in the number of variables required for the prediction, a significant improvement over the earlier study.

Discussion and conclusion

On average, the TS/MB classifier reduces the set of predictor variables by at least 95% from the full set of variables. In some cases it is reduced to a sufficiently small set for entry into hand calculators, or paper and pencil decision procedures that are easy to use in clinical and other decision settings. At the same time, when compared to the state-of-the-art classification methods, the TS/MB classifier procedures excellent classification results, especially in real world applications where the cost of misclassification has significant implications. Moreover, the algorithm generates a graphical structure that represents the relationships between the variables and provides additional insight into causal discovery. These experiments, as well as more results we have obtained on data sets from other domains, such as Internet marketing and sentiment extraction, suggest that for problems where the ratio of samples to the number of the variables is small or the independence assumption is not appropriate, the two-stage MB classifier is superior in terms of the prediction performance, effectiveness in identifying critical predictors, and robustness [5].

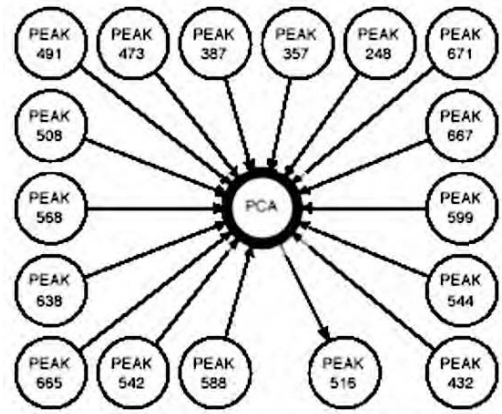

Figure 3 - The best fitting MB DAG for the PCA

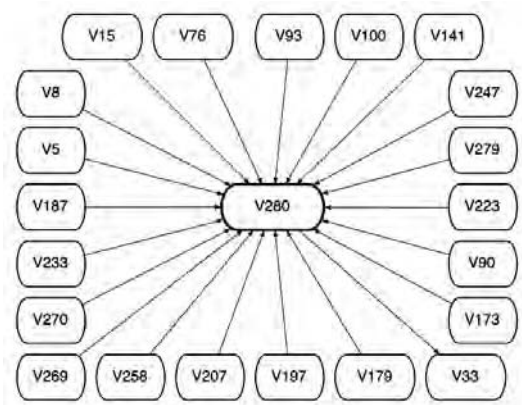

Figure 4 - The best fitting MB DAG for arrhythmia

It is possible that different Markov Blanket graphical structures that are consistent with the TS/MB classifier output would give slightly different classification results. Because any undirected and bi-directed edges are deleted after the edge orientation step, these deletions might result in suboptimal decisions. Tabu Search iteratively investigates alternative orientations and further edge additions to minimize the extent of sub-optimality. On the other hand, theoretically, two DAGs that have the same Markov factorization are Markov equivalent. In our case, two Markov Blankets can be Markov equivalent even if some edges are oriented in a different, but statistically non-differentiable way.

The results of this study need to be validated against clinicians' interpretation of the variables and their value in actual diagnosis settings. This research can also be extended to address the interesting problem of simultaneously building classifiers for all variables in a large variable data set, discovering a causal model for all variables in such data, or automatically classifying medical documents into categories. Future research will explore these issues.

2 The class variable "V280" has 8 categories, encoding 8 different diseases.

Abstract

Purpose: It is useful to convert free-text diagnostic reports into structured diagnostic reports by semantic analysis for the secondary investigation of their contents. In this study, we propose a system in which description units are automatically extracted to create structured text reports and we evaluated its usefulness.

Methods: We defined the rules to create description units and developed the system that can automatically extract these description units from free-text diagnostic reports. We applied this system to reports of cerebral perfusion scintigrams and obtained 5 dictionaries of description units, increasing the number of scintigrams from 100 to 500 in increments of 100. Each dictionary was used to analyze another 100 scintigrams. The results obtained using each dictionary were compared with the results of physicians' interpretation.

Results: The recall rate of this system to the physicians' interpretation increased when correlated with the number of scintigrams but with 300 cases was almost saturated at 85%.

Conclusion: We propose a semantic analysis system and show its usefulness in the semantic evaluation of the reports of cerebral perfusion scintigrams.

Introduction

In recent years, intrahospital information such as medical records and diagnostic images tends to be managed as electronic data [1]. And, statistical analysis of medical information and computer-aided diagnosis of imaging tests are being actively investigated by utilizing digitalization.

Reports of diagnostic imaging tests also tend to be digitally created using electronic devices such as personal computers. These electronically created reports are often used as references to evaluate intra-individual interval changes. The digital information of these reports is, however, less often used to electronically analyze the contents of the reports.

The main reason is that the diagnostic reports are generally expressed using free-text format, and it is difficult to systematically analyze the descriptive contents of these reports [2-6]. If the descriptive contents of the reports are semantically analyzed and then converted into structured text reports, they can be effectively reused [7-12]. For example, if we can use such a system, similar clinical cases can be quickly picked up from the database of previous reports. If these analyzed, structured data are saved with the format of DICOM-SR, secondary investigations using large-scale accumulated data to evaluate the tendency of findings in some entities of diseases can be easily performed [13-14].

In the present study, we have developed a system to automatically create structured text reports from the reports with free-text format, which uses a text mining tool that extracts semantic information from the contents of free-text format referring to dictionaries. We assessed the usefulness of this system by applying it to actual clinical diagnostic imaging reports of cerebral perfusion scintigraphy, which is attracting significant attention from many researchers as an important test to detect the early stages of Alzheimer disease.

Materials and methods

In this study, to convert the sentences with free-text format into structured formats, we used a text mining tool that consisted of two algorithms: the first was the morphological analysis algorithm that divided text data into units of words and the second was the structuring algorithm that extracted units of words from sentences with the free-text format. The extracted units of words, called description units, were classified into two types: finding units and

diagnostic units. The finding units included "finding", "modifier", "region", "regional modifier", and "confidence" and diagnostic units included "diagnosis",

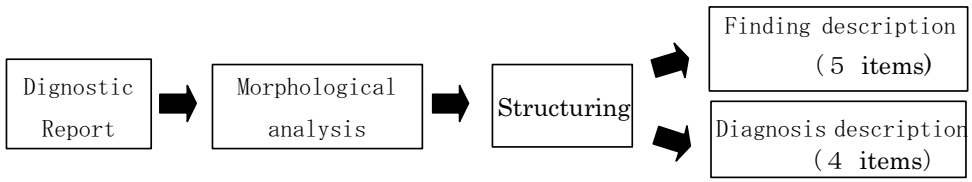

Figure 1 - Text mining processing

"region", "regional modifier", and "confidence". As requisites for description units, we defined that finding units must contain words related to "finding", "region", and "confidence" and diagnosis units must contain words related to "diagnosis" and "confidence". The concept of the structuring process is shown in Figure 1.

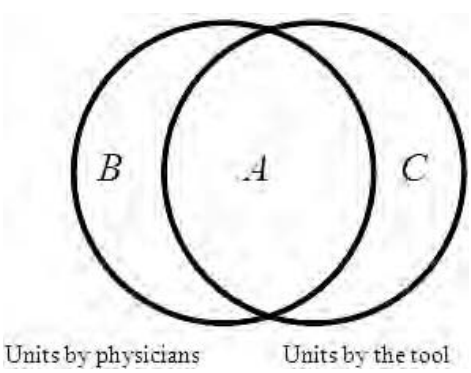
At first, to create dictionaries of description units, we manually picked up the words that can be considered description units from free-text reports of the diagnostic imaging test that we wanted to analyze.

After that, we applied this system with these created dictionaries to cerebral perfusion scintigraphy. We used the reports of this test created in the actual clinical situation; no information about structuring was given to the clinical staff who wrote diagnostic reports.

We made 5 dictionaries of description units by increasing the number of free-text reports used for picking up description units (learning reports) from 100 cases to 500 cases in increments of 100 cases.

We prepared another 100 cases of reports of cerebral perfusion scintigraphy. Each dictionary was applied to these new 100 cases and description units were automatically extracted using these dictionaries. Description units were also manually extracted using the same 100 reports by physicians. More than two doctors discussed the extraction of each unit, reaching a consensus when there were discrepancies among their opinions, and the results of physicians' analyses were considered the gold standard.

We evaluated the usefulness of this system using the following rates: the recall rate, the mismatch rate and the unexpected description unit rate (Figure 2).



A the number of identical description units automatically generated by the text mining tool.

B the number of manually generated description units that do not match description units automatically generated by our system.

C the number of automatically generated description units that do not match manually generated description units.

The recall rate is *A/(A+B)*.

The mismatch rate, that is, the false negative rate, is *B/(A+B)*.

The unexpected description unit rate, that is, the false positive rate, is *C/(A+B)*.

Figure 2 – The evaluation of the system

Results

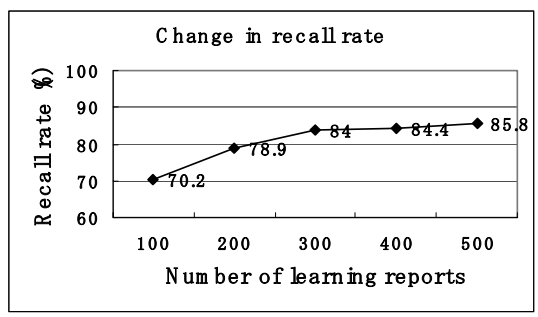


Figure 3 - Change in recall rate

Figure 3 shows the correlation between the recall rate and the number of learning reports. Although the recall rate was 70.2% when the number of learning reports was 100, it reached 85.5% when the number of learning reports was increased to 500. When the number of learning reports was 300 or more, the recall rate tended to saturate and became nearly constant. These results also suggested that there remained a certain mismatch rate even when the number of learning cases was increased.

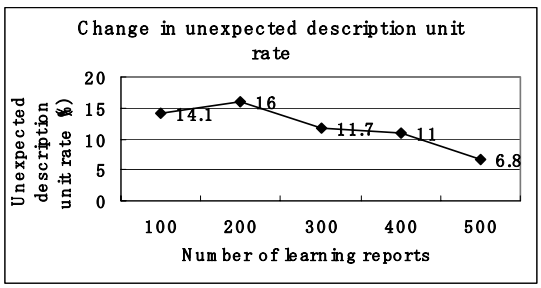

Figure 4 - Change in unexpected description unit rate

Figure 4 shows the correlation between the unexpected description unit rate and the number of learning reports. Although the unexpected description unit rate was about 15% when the number of learning reports was small, it dropped to 6.8% when the number of learning reports was increased to 500. These results indicated that increasing the number of learning reports can reduce the number of unexpected description units.

Discussion

The methods by which description units are extracted from sentences and are structured have been investigated by some researchers. Imai, et al. [15] attempted to analyze the radiological findings that appeared in the electrical medical textbook using this type of method and reported that they could successfully build a medical ontology. Anei, et al. [16] tried to apply this method to free-text diagnostic reports. They extracted "medical knowledge", which corresponds to "description units" in our study, using a "support vender machine," but, the results obtained were not excellent. The rate of accurate extraction was only 42%. The main reason for this poor result was that they did not register the extracted knowledge in the dictionary. They analyzed sentences using only the combination of the attributes of the words.

We built a system for the structuring of free-text diagnostic reports by modifying the shortcomings of previous studies stated above. And, in this study, we evaluated the usefulness of our system using the recall rate, which is the accuracy of the structuring, and the unexpected description unit rate.

The recall rate using our text mining tool improved as the number of registered words increased. This result indicates that this structuring system works well.

The recall rate almost plateaued around 85%. If it is demonstrated that this rate, 85%, is clinically acceptable in the diagnosis of cerebral perfusion scintigraphy, we can create the dictionary by analyzing the reports of as few as 300 cases and use it for structuring the free-text reports.

If a higher recall rate is required in the actual clinical situation, we must consider methods for further improvement of the recall rate.

To develop methods to improve the recall rate, we investigated why our text mining tool incorrectly extracted description units. The reasons are as follows:

1. There were some mismatched description units and unexpected description units. This could be caused by an insufficient number of registered words because this phenomenon often occurred when reports with the words that were not included in the learning reports were analyzed. To resolve this issue, we must increase the number of the learning reports. It would also be useful to provide a function permitting the operator to easily register an unregistered word while creating a report.

2. Mismatched description units were often found in the reports with misspellings or typographical errors. This phenomenon was caused by human error during the input of the text. To overcome this issue, a function for proofreading of input text data before the process of structuring could be added.

3. Mismatched description units and unexpected description units were also found when reports with grammatically imperfect sentences, such as sentences without the subject, were analyzed. The use of expressions specific to individual physicians or clinical institutions might also cause this kind of error. To overcome this issue, it would be convenient to add a function that lets the operator know the grammatical error and suggests a correction of the sentence.

To evaluate the recall rate, we also have to verify the effectiveness of description units extracted by physicians because these description units were used as the gold standard. In this study, description units were always extracted by more than two doctors with significant experience. And the discrepancies among them were resolved by discussion. Therefore, we believe that manually extracted units could be used as the gold standard although we did not calculate inter-rater agreement among the physicians.

We should also investigate methods to secondarily effectively utilize structured text reports.

The information of the reports with free-text format can be semantically managed if they are converted to structured text reports by the text mining tool. As a result, they can be reused for other purposes.

If the information of the reports is expressed by description units, it can be easily translated into another language. The Japanese that we commonly use is a language whose grammar is quite different from English; however, English is commonly used in the field of science. Thus, it is difficult to directly analyze the information of the reports written by Japanese. But if the reports were converted into a structured format with clearly expressed description units, the information could be easily translated into English. Following is an example.

•Cerebral perfusion scintigraphy report

両側頭頂葉、後部帯状回、楔前部において著明な血流低下を認めます。 典型的なアルツハイマーの画像所見です。

•Extracted description units

No	記述単位	部位(必須)	部位修飾(任意)	所見(必須)	確定度(必須)	修飾(任意)
1	所見	頭頂葉	両側	血流低下	断定	著明な
2	所見	帯状回	後部	血流低下	断定	著明な
3	所見	楔前部		血流低下	断定	著明な

No	記述単位	部位(任意)	部位修飾(任意)	診断名(必須)	確信度(必須)	-
4	診断	-	-	アルツハイマー	断定	-

Figure 5 - Extracting process example in Japanese

•Cerebral perfusion scintigraphy report

Remarkable hypoperfusion is noted in bilateral parietal lobes, posterior cingulate gyri and precuni, typical of Alzheimer disease.

•Extracted description units

No	Units	Region	Regional Mod.	Findings	Confidence	Modifier
1	Findings	Paretal	Bilateral	Hypoperfusion	Strongly positive	Remarkable
2	Findings	Cingulate gyri	Posterior	Hypoperfusion	Strongly positive	Remarkable
3	Findings	Precuni		Hypoperfusion	Strongly positive	Remarkable

No	Units	Region	Regional Mod.	Diagnosis	Confidence	Modifier
4	Diagnosis	-	-	Alzheimer	Strongly positive	-

Figure 6 - Extracting process example in English

Figure 5 shows description units extracted from a brain perfusion scintigraphy report written by Japanese using the text mining tool. Figure 6 shows the description units translated into English. As shown in these figures, the contents of Japanese diagnostic reports can be easily converted into English.

This example suggests that structuring the diagnostic reports that currently use a free-text format might be useful to discuss the information about the report with people whose native languages are different from each other. We have not, however, demonstrated yet whether sentences from foreign languages composed of converted description units can accurately indicate the meaning of the sentences of the original languages. We can now say that the meaning of description units can be understood in a foreign language without complicated translation algorithms when reports written in the original language are structured into description units using our text-mining system and these units are then converted into a foreign language.

If our structuring system can accurately translate the meanings of sentences from the original language into the second one, this system could also be applied to teleradiology between foreign countries. The more complicated the information of the report is, the more accurately speakers of other languages would discuss it with each other.

In this study, we demonstrated the usefulness of structuring reports that use a free-text format. There are, however, some limitations in our current investigation.

We studied only the reports of cerebral perfusion scintigraphy. Although this study is an important test to detect the early stage of Alzheimer disease, the findings of this imaging test are rather limited. Therefore, we might successfully analyze the reports with free-text format by a text mining tool. We must confirm the usefulness of the semantic analysis by applying our structuring system to the modalities whose diagnostic reports are more complicated, such as computed tomography.

Conclusion

Structuring of diagnostic reports in free-text format was performed using the automatic system with the text mining tool, which extracts description units. When this system was applied to the reports of cerebral perfusion scintigraphy created in the actual clinical situation, it successfully converted the reports with free-text format into the structured ones expressed by description units.

Although the usefulness of this structuring system must be validated for the modalities whose diagnostic reports are more complicated, this system could possibly compile the information obtained from the reports of many cases and to effectively reuse it.

Semantic Issues in Integrating Data from Different Models to Achieve Data Interoperability

Rahil Qamar[a], Alan Rector[a]

[a] *Medical Informatics Group, University of Manchester, Manchester, U.K.*

Abstract

Matching clinical data to codes in controlled terminologies is the first step towards achieving standardisation of data for safe and accurate data interoperability. The MoST automated system was used to generate a list of candidate SNOMED CT code mappings. The paper discusses the semantic issues which arose when generating lexical and semantic matches of terms from the archetype model to relevant SNOMED codes. It also discusses some of the solutions that were developed to address the issues. The aim of the paper is to highlight the need to be flexible when integrating data from two separate models. However, the paper also stresses that the context and semantics of the data in either model should be taken into consideration at all times to increase the chances of true positives and reduce the occurrence of false negatives.

Keywords:

medical informatics computing, semantic mapping, term binding, data interoperability

Introduction

The field of medical informatics is growing rapidly and with it informatics solutions to improve the health care process. One of the more important issues gaining the attention of clinical and informatics experts is the need to control the vocabulary used to record patient data. Terminologies covering various aspects of medicine are being developed to bring about some standardisation of data. However, these terminologies are seldom integrated into information systems which are used to capture data at various stages of the health care process.

The paper briefly discusses a middleware application developed to map back-end data model terms to clinical terminologies. However, the main focus of the paper is to highlight the issues encountered when integrating the terminology and data models to achieve the common objective of interoperable patient data through the use of controlled vocabularies.

Archetype models, commonly referred to as archetypes, and the SNOMED CT terminology system were used to test the mapping process. Therefore, the issues discussed are focussed on these two modeling techniques.

Background

Archetype models

In this paper, archetypes refer to the *open*EHR archetypes. Archetypes are being put forward by the *open*EHR organisation as a method for modeling clinical concepts. The models conform to the *open*EHR Reference Model (RM). Archetypes are computable expressions of a domain content model of medical records. The expression is in the form of structured constraint statements, inherited from the RM [1]. The intended purpose of archetypes is to empower clinicians to define the content, semantics and data-entry interfaces of systems independently from the information systems [1]. Archetypes were selected because of their feature to separate the internal model data from formal terminologies. The internal data is assigned local names which can later be bound or mapped to external terminology codes. This feature eliminates the need to make changes to the model whenever the terminology changes.

SNOMED CT terminology

SNOMED-CT, also referred to as SNOMED in the paper, aims to be a comprehensive terminology that provides clinical content and expressivity for clinical documentation and reporting [3]. SNOMED has been developed using the description logic (DL) Ontylog [4] to allow formal representation of the meanings of concepts and their inter-relationship [5]. SNOMED concepts are placed in a subsumption i.e., 'is_a' hierarchy. Two concepts may also be linked to each other in terms of role value maps, and defining or primitive concepts[7]. The SNOMED hierarchy is easy to compute, which was the primary reason for selecting the terminology for the research. The July 2006 release of SNOMED was used for testing the mapping approach. It has approximately 370,000 concepts and 1.5 million triples i.e. relationships of one concept with another in the terminology.

Data integration issues

The aim of the research is to enable health care professionals to capture information in a precise, standardised, and reproducible manner to achieve data interoperability. Data interoperability can be defined as the ability to transfer data to and use data in any conforming system such that the original semantics of the data are retained irrespective of its point of access. Standardised data is critical to

exchanging information accurately among widely distributed and differing users.

Matching clinical data to codes in controlled terminologies is the first step towards achieving standardisation of data. The research focuses on accomplishing the task of performing automated lexical and semantic matches of clinical model data to standard terminology codes using the Model Standardisation using Terminology (MoST) system. A list of candidate SNOMED codes generated by MoST are presented to the modeler who chooses from the list the most relevant codes to bind the archetype term to. However, the matching task is made difficult because of two main reasons. First, the size and complexity of the terminologies makes it difficult to search for semantic matches. Second, the ambiguity of the intended meaning of data in both the data models and terminology systems results in inconsistent matches with terminology codes. The paper will focus on the second issue and suggest some of the solutions that were developed to resolve ambiguity of purpose and use of archetype terms with respect to SNOMED.

In this paper, the term 'modeler' is used to denote a person with clinical knowledge who is engaged in the task of modeling clinical data for use in information systems. Four modelers were used to conduct the study and provide their feedback on the results of the mapping. The second author was also involved in the evaluation process.

Issues with archetype models

Archetypes can be regarded as models of use. Archetypes based on the *open*EHR specification have four main ENTRY types i.e. Evaluation, Instruction, Action, and Observation [12]. For the research, only Observation archetypes were considered as they are the most commonly used model type with the maximum number of examples. However, there is no strict guideline used to categorise archetypes. Also all archetype terms contained in a particular archetype model do not necessarily belong to the same archetype model category. For example, the 'autopsy' archetype[1] belongs to an Observation type. However, the 'cardiovascular system' term contained in the model could belong to either the SNOMED category 'body structure' or 'finding' based on the intended meaning of the modeler. The SNOMED category 'clinical finding' is referred to as 'finding' and 'observable entity' is referred to as 'observable' in the paper.

1) *Determining the semantics of use:* The main issue encountered when looking up matches for archetype terms in SNOMED was the semantics of use. As stated earlier, there are no strict guidelines to categorise either the archetype models or the terms contained in them. The main reason being that archetype models are intended to be used as archetypical representations of a particular clinical scenario. In addition, archetype modelers do not always have SNOMED in mind when modeling clinical scenarios. For example, the recording of the apgar score of a neonate at 1, 5 and 10 minutes from birth will not only require assessment of the breathing, color, reflexes, heart rate, and muscle tone but also the total score calculated at the end of the assessment. Using SNOMED, the assessment terms can be categorised as observables or findings, among other intended semantics, while the 'total' could be a qualifier value or an observable with a value. Therefore, it is important when working with two different models that loose semantics are maintained initially unless stated otherwise. Too much reliance on the categorisation of terms in a particular model will result in fewer matches with terms categorised differently in another model. Strict adherence to categories can only be maintained when working within the same modeling environment as it can be assumed that the hierarchies are logically sound and classifiable.

2) *Determining the source of semantics:* Another issue that was commonly observed was determining the main source of the semantics of an archetype term. For example, in the 'blood film' archetype, the term 'haemoglobin' had a local meaning of 'the mass concentration of haemoglobin', shown in Figure 1. The modeler was questioned whether he would prefer a match for 'haemoglobin' or 'haemoglobin concentration'. The suggestion was that a match for the later term would be closer to its intended meaning. However, based on this suggestion, the assumption of assigning more weightage to the term definition proved incorrect in the 'autopsy' archetype. Conversely based on the above weightage, the term 'cardiovascular system' defined in the model as 'findings of the pericardium, heart and large vessels' should have resulted in 'findings' of the cardiovascular system instead of the 'body structure' itself. However, in this case the modeler stated that the use of the term was intended to serve as a label i.e. 'body structure' rather than the actual values i.e. 'findings' to be entered during data-entry. Therefore, it is advisable not to depend on any single semantic source when looking up matches for an archetype term.

3) *Spelling errors leading to incorrect or no matches:* Finally, there was the issue of resolving spelling errors in the model. For instance, 'haemoglobin' using U.K. English was spelt as 'haemaglobin' in the 'blood film' archetype. Such spelling errors can give rise to incorrect or no results.

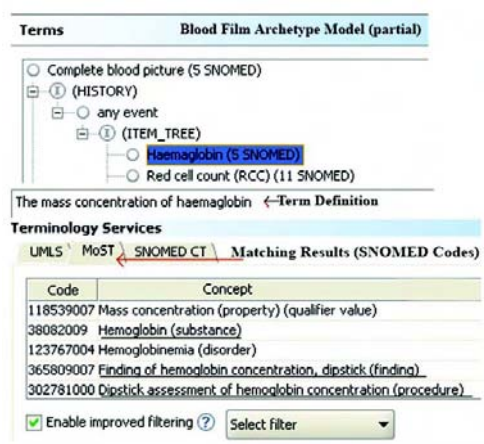

Figure 1 - Haemoglobin-related issues in blood film archetype

1 openEHR archetypes obtained from http://svn.openehr.org/knowledge/archetypes/dev/html/index_en.html

Issues with SNOMED CT

SNOMED can be regarded as a model of meaning. It is a reference terminology for clinical data that provides a common reference point for comparison and aggregation of data about the entire health care process [5]. The multi-axial hierarchy and concept definitions are easily computable to determine the category in which the concept belongs as well as its definition in the model.

1) *Discrepancies in categorisation:* Although SNOMED has a well-defined list of categories; it is not always clear what the basis is for differentiating a concept from being an observable, procedure, or finding. Concepts in the 'observable' hierarchy represent a question or procedure which can produce an answer or a result [6]. On the other hand, concepts in the 'finding' hierarchy represent the result of a clinical observation, assessment or judgement, and include both normal and abnormal clinical states. For example, 'colour of nail' is an observable whereas 'gray nails' is a finding [6]. However, the problem arises when discrepancies occur in the categorisation of certain concepts. For instance, the term 'pregnancy' occurs as a sub type of 'urogenital function' in the observable hierarchy. Clearly, a value cannot be assigned to pregnancy. However, it can have a present/absent or positive/negative value, which would then categorise it as a 'finding'. Such discrepancies in categorisation often lead to problems in correctly interpreting the semantics of a concept.

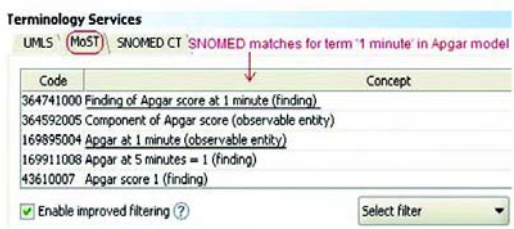

Figure 2 - SNOMED matches obtained for term '1 minute' in the Apgar archetype model

2) *Multiple representations and categorisation of similar concepts:* Another feature of SNOMED is that it allows composition or post coordination i.e. the ability to combine two or more existing concepts in the terminology to represent new meanings [5]. However, this very feature results in multiple representations of the same concept, some of which may contend with the category definitions provided in the SNOMED documentation. For instance, an 'apgar score at 1 minute' can be represented as an 'apgar at 1 minute (observable)' with a value (say 0), or with the help of a pre-existing concept 'apgar at 1 minute = 0 (finding)'. Interestingly, SNOMED has a concept 'apgar at 1 minute', which is a 'finding' as well. Its fully specified name (FSN) is 'finding of apgar score at 1 minute', as shown in Figure 2. Therefore, two concepts with similar names i.e. 'apgar at 1 minute' belong to two different categories i.e. observable and finding. Also, Figure 3 shows that the concept 'finding of apgar score' has a synonym 'observation of apgar score', which leads to concerns about the differentiation between an observation and a finding as stated by the SNOMED community. It may be easy for the human eyes to differentiate between the two and perform either post-coordination or simple semantic mapping. However, it becomes difficult to train a computer application to follow any strict rules for drawing inferences based on the documentation available. A similar example of ambiguity arising from close similarity of observables with findings is the presence of two very similar concepts e.g. 'Finding of reflex hearing response (finding) *is_a* Audiological test finding (finding)' and 'Reflex hearing response (observable entity) *is_a* Audiological test feature (observable entity)' in the July 2006 edition of SNOMED. In terms of aiding computation, it might be helpful to insert disjoint axioms in the hierarchy to enable applications mining through the large corpus of SNOMED data to differentiate between disjoint or non-similar concepts.

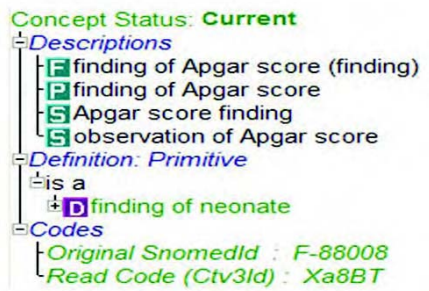

Figure 3 - List of SNOMED terms belonging to the concept 'finding of apgar score' in the July 2006 SNOMED release.

Issues arising from mapping

In the previous two sections we discussed some of the issues present in Archetypes and SNOMED. The issues highlighted in this paper mainly concern disambiguating the semantics of concepts with respect to their categorisation in both models. This issue has been found to be one of the most difficult to resolve when automating the process of finding matches of archetype terms to semantically similar SNOMED concepts[2][10][13].

1) *Grouping SNOMED categories to improve matches:* In relation to finding matches for terms of Observation type archetypes, three main SNOMED categories were identified to which several archetype terms could generally belong to. These categories were 'observable', 'procedure', and 'finding'. The assessment was made by manually inspecting the most common category (ies) to which relevant archetype term matches in SNOMED belonged. The relevance of a match was determined by the modeler. However, this assumption is not intended to mean that matches from other SNOMED categories were irrelevant or not possible. The initial hypothesis had to be modified such that archetype terms from an Observation type archetype model may not necessarily belong to a SNOMED 'observable'. 'Finding' was the next closest category a SNOMED match could belong to followed by 'Procedure'.

2) *Providing detailed SNOMED concept information to make informed decision:* When discussing the issues with archetype models, we exemplified how the archetype term and its definition helped in determining the intended use of

the term. In the 'blood film' archetype, the archetype term 'haemoglobin' found more than one SNOMED match. Among the SNOMED matches obtained, two of the results worth considering were 'hemoglobin' categorised as a 'substance' and 'hemoglobin concentration' categorised as a 'finding' in SNOMED. At first, the modelers on general lexical lookup of the results were of the opinion that the second match was more relevant. However on examining their SNOMED definitions and FSNs, it became obvious that the 'haemoglobin concentration' matches were synonyms for two different FSNs, namely, 'Dipstick assessment of hemoglobin concentration (procedure)', and 'Finding of hemoglobin concentration, dipstick (finding)', as shown in Figure 1. Both the matches were associated with the device 'dipstick', which was not necessarily the intended method to determine the haemoglobin concentration. Hence both the 'heamoglobin concentration' results were later rejected by the modelers as suitable mappings for the archetype term 'haemoglobin'. Therefore, providing the modeler with more information about the SNOMED results rather than a simple, non-informative lexical list helped in reducing incorrect mappings.

3) *Including archetype context:* Archetype models follow an object-oriented style of modeling, which means that each element in the model conforms to some entity or the entity's attribute in the Reference Model. The elements and their values in archetypes are represented in a post coordinated or composite manner. For instance, in the 'apgar score' archetype, the element 'breathing' is constrained by the values 'no effort', 'moderate effort', and 'crying', as shown in Figure 4. In a pre coordinated form the same concepts could be represented as 'no effort breathing', 'moderate effort to breathe', and 'crying or breathing normally'. Therefore, when looking up matches for archetype terms in SNOMED it is necessary to include the context in which the particular term has been used in the model. Well-stated terms can often lead to pre coordinated matches in SNOMED. However, certain terms which are verbose or ambiguous can be unhelpful in finding sensible SNOMED matches despite considering its context of use and stated meaning. Some examples are the terms 'Grimace and cough/sneeze during airways suction' as a constraint value of the element term 'reflex response' in the apgar archetype shown in Figure 4, and 'Needs help but can do about half unaided' as a constraint value of the element term 'Dressing/undressing' in the barthel index archetype. The presence of such terms in archetypes often leads to irrelevant or no matches. However, these searches expend valuable processing time to simplify the term.

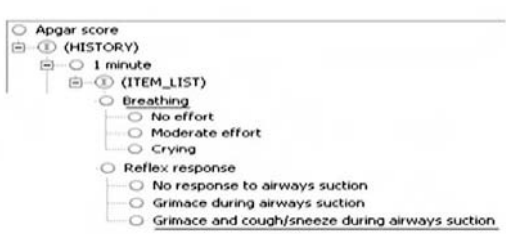

Figure 4 - Apgar score archetype with a post-coordinated 'Breathing' term and verbose 'Reflex response' values

Methodology to address issues

The MoST system was developed to perform automated matches of archetype terms to SNOMED. In the process of obtaining lexical and semantic matches, several of the issues discussed above were addressed and computable solutions were developed.

The entire SNOMED content was imported into a MySQL database and various SQL queries were run at different stages to extract the required information. The Archetype Models were parsed from their local Archetype Definition Language (ADL) format to a simpler XML format which retained only the class containment (element-value pair) hierarchy along with its data types and some other useful information. Language specific information was discarded as it was not required for the matching process. Each term (element or value) was sent to the SNOMED database to look for matches and extract their definitions. Details of the MoST matching process has been discussed in [11].

The spellings of archetype terms were checked against the GSpell spell checker provided by the National Library of Medicine (NLM). However, GSpell performed erratically when encountered with numerics such as 'apgar 1 minute', prepositions, and certain words such as 'width' or more specific archetype data labels such as 'DateTime'. A list of SNOMED and local stop words i.e. words to eliminate from a query terms to prevent too many results or superfluous spell checks, were used to improve results.

MoST utilised already established Natural Language Processing (NLP) systems to perform lexical processing. Initially, the archetype terms were sent to the Emergency Medical Text Processing (EMT-P) service, which processes raw text entries before looking up matches in UMLS [7]. Other NLP techniques used to help in constructing the search queries were word sense disambiguation using GATE [8], and English term synonyms using WordNet [9]. Local techniques applied were removal of stop words enhanced with SNOMED stop words, replacement of numeric and conjunctions with words upon unsuccessful searches, and removal or replacement of special characters and arithmetic notations. The advantage of using a resource like UMLS is that it has a large library of over a million concepts and more than 100 controlled vocabularies and classifications [10]. The semantic groupings of these concepts were used for additional semantic information on the query terms. A training data set was also used to increase the search base by including a list of clinical synonyms generated both locally as well as from the SNOMED July 2006 release.

Resolution of issues

1) *Resolving issues of semantics of use:* In order to address the issue of range of permissible categories to which matches could belong to, rules regarding inclusion of SNOMED categories such as observable, finding, and procedure were introduced. Results that were lexically or semantically similar to the archetype term were returned as results whether or not they had been clearly stated as intended categories by the modeler at the outset. It was also noted that certain other SNOMED categories such as situation (earlier known as context dependent category), qualifier value, attribute, and disorder could also be some

other categories results from which may be worth including in the final result set, if appropriate.

2) *Resolving issues of source of semantics:* The issue of ambiguity of whether the term itself or its definition and context in the model are to be weighted higher was resolved by including all result variants. This may lead to a higher rate of false positives in some cases but will reduce the number of false negatives, which is more important. Therefore, both 'haemoglobin', as well as 'haemoglobin concentration' matches was included as results if it met other filtering criteria, as shown in Figure 1. Similarly, the archetype term 'total' used to record the total apgar score resulted in both SNOMED concepts 'total (qualifier value)', and 'total apgar score (observable)'.

However, certain issues such as training the application about the guidelines to follow in eliminating results form certain SNOMED categories if the terms belonged to Observation archetypes could not be implemented in a strict form. The reason was primarily the ambiguity of term categorisation when working with two separate models that differ in their fundamental objectives. While archetype models include all terms required to record a particular clinical scenario, SNOMED models the logical position of a concept in the given domain and how it relates to other concepts in the hierarchy. All these related concepts may or may not be used by an archetype model to represent a particular clinical record.

Discussion

All the results obtained at the end of the matching process were presented to the modelers who then chose the most relevant i.e. semantically similar SNOMED result code(s) to map the archetype term to. However, not all archetype terms found relevant SNOMED codes. The MoST system thus helped the modeler to codify the local terms to a standardised terminology code. 87.4% of the SNOMED codes were found to be relevant at the end of the first phase of the evaluation involving 300 archetype terms. Details of the MoST system and the evaluation can be obtained from [11], as it is beyond the scope of this paper.

With more and more archetypes being bound to SNOMED codes, the data entry process will become more standardised. Data stored in Electronic Health Records (EHRs) will begin to conform to a single reference terminology. This will increase the ease, speed, and accuracy with which data from the EHRs will be interpreted and used by health organisations irrespective of its place of capture and storage. Interoperable data will help the interoperability of clinical information systems, ultimately leading to the safe use of data and reduction in medical errors originating from incorrect data.

Conclusion

The paper focused on the semantic issues of archetype models and SNOMED, as well as the issues encountered when automating the task of matching terms from the archetype model to SNOMED terminology codes. Although specific models were chosen to test the methodology i.e. archetypes and SNOMED CT, the approach can be tested using other similar models. However, due to the disparities in the objectives and use of the different models, care needs to be taken to address the issues arising from the disparities. Suitable solutions need to be developed to address these issues at two levels of granularity. The first level is the local level where a knowledge layer needs to be added to resolve local issues, which has been discussed in this paper. However, a second, higher level of resolution needs to be adopted when the issues concern the fundamental principles on which the models and their content are based. This will require raising a change request to each of the modeling communities.

It is important to raise issues if any real work on integrating data to achieve quick and accurate data interoperability is to be achieved. This paper hopes to start a discussion on more issues encountered by other such similar integration efforts. The work will be helpful to organisations such as the NHS in the UK who have proposed to use SNOMED CT as the standard medical terminology, and openEHR Archetypes as one of the clinical data modeling techniques.

Medication Reconciliation Using Natural Language Processing and Controlled Terminologies

James J. Cimino, Tiffani J. Bright, Jianhua Li

Department of Biomedical Informatics, Columbia University, USA

Abstract

Medication reconciliation (MR) is a process that seeks to assure that the medications a patient is supposed to take are the same as what they are actually taking. We have developed a method in which medication information (consisting of both coded data and narrative text) is extracted from twelve sources from two clinical information systems and assembled into a chronological sequence of medication history, plans, and orders that correspond to periods before, during and after a hospital admission. We use natural language processing, a controlled terminology, and a medication classification system to create matrices that can be used to determine the initiation, changes and discontinuation of medications over time. We applied the process to a set of 17 patient records and successfully abstracted and summarized the medication data. This approach has implications for efforts to improve medication history-taking, order entry, and automated auditing of patient records for quality assurance.

Introduction

The medications a patient takes are not always the medications the patient is *supposed* to take. Errors and drug interactions can occur when patients are treated without full knowledge of the medications that have been previously ordered, especially at transition points such as hospital admissions, transfers and discharge.[1]. For example, Beers and colleagues found that 83% of hospital admission histories failed to record the use of at least one medication the patient claimed to use or recorded at least one medication that the patient denied using; 46% had three or more such errors [2].

The process of creating an accurate list of a patient's medications, for the purposes of resolving discrepancies and supporting accurate medication ordering, is referred to as *medication reconciliation* (MR) [3]. Many processes have been developed for MR, such as manual audits and surveys. With the increasing availability of electronic patient records, such processes can be better integrated into the clinicians' workflow, but they remain largely manual tasks [4,5].

Poon and colleagues provide an excellent review of the problem of MR and describe a pilot test of a system they developed to support creation of a preadmission medication list (PAML) [6]. Their system extracts patient medication information from four different sources and presents it to the clinician, who then creates the PAML by consolidating and reconciling the information from the various sources into a single coherent list. The system assists the user by converting medication terms into, and then grouping them by, their generic names. The PAML was successfully used at the time of hospitalization to guide admission orders and at the time of discharge to assure that previous outpatient medications, where appropriate, were continued.

The PAML used data from multiple sources, each of which encoded medication data using a different controlled terminology. One of the challenges encountered by Poon and colleagues was the reconciliation of these different terminologies. The PAML did not use narrative text sources (such as discharge summaries or clinic notes) but had it done so, they would have also had to reconcile the free-text terms found in those reports.

In this paper, we describe an approach to automatically analyze medication information from a mixture of coded and narrative text sources, and use controlled terminology to support reasoning about MR. We describe the application of our method to a set of 17 patient records and discuss ways in which the results might be exploited for automated support for medication reconciliation in a variety of clinical situations.

Materials and methods

Our approach to MR involves the collection of patient medication data from multiple coded and narrative text sources, conversion of all data into coded form (using natural language processing where necessary), and then obtaining classification information for each medication. Patient medications can then be viewed over time, grouped by class, and organized into a matrix that can be used to identify points at which medications were introduced, changed or removed from the patients' ordered medications.

Sources of patient medication information

New York Presbyterian Hospital (NYPH) makes use of two major clinical information systems: the commercial product Eclipsys XA order entry system (Eclipsys, Boca Raton, FL) and the internally developed WebCIS documentation and repository system [7]. Eclipsys allows clinicians to order medications that are initiated and discontinued at various points during a hospitalization. Clinicians also enter medication information in narrative text, as part of the patient's discharge instructions. WebCIS provides narrative medication lists as parts of clinic notes, admission notes and discharge summaries, as well as coded medications from the outpatient medication order entry system and inpatient pharmacy system.[1] Together, the sources provide medication lists that correspond to twelve points in time related to hospital admissions, as shown in Table 1.

Table 1 – Data sources for patient medication information

Data Source	System	Data Type
Prior Clinic Note	WebCIS	Narrative
Prior Outpatient Medications	WebCIS	Coded
Admission Note[2]	WebCIS	Narrative
Admission Note Plan[2]	WebCIS	Narrative
Admission Orders	Eclipsys	Coded
Admission Pharmacy Orders	WebCIS	Coded
Active Orders at Discharge	Eclipsys	Coded
Discharge Pharmacy Orders	WebCIS	Coded
Discharge Instructions	Eclipsys	Narrative
Discharge Plan	WebCIS	Narrative
Clinic Note After Discharge	WebCIS	Narrative
Outpatient Medications after Discharge	WebCIS	Coded

Natural language processing

As noted in Table 1, the medication lists from clinic notes, admission notes, discharge summaries and discharge instructions are in narrative form. In order to convert them to coded form, we use a natural language processing system called Medical Language Extraction and Encoding system (MedLEE) [8] to parse the reports, and identify medication terms. Where possible, MedLEE provides Concept Unique Identifiers (CUIs) from the US National Library of Medicine's Unified Medical Language System (UMLS) [9].

Medication classification

All coded information obtained from Eclipsys (medication orders) and WebCIS (outpatient medication orders and inpatient pharmacy orders) are coded using our internally developed Medical Entities Dictionary (MED) [10]. The MED includes UMLS CUIs for many of its terms. Thus, we were able to obtain MED Codes for all coded data and, through UMLS mappings, for narrative data for which MedLEE provided UMLS CUIs.

Medication terms in the MED are organized into a hierarchy based on the American Hospital Formulary Service (AHFS) Codes, which classify drugs according to function and purpose [11]. For each medication term (including MedLEE-coded terms), we obtained the AHFS class code or codes, based on its location or locations in the MED hierarchy.

Evaluation

We chose a convenience sample of records for patients followed by one of us (JJC) in the NYPH medical clinic. For each patient, we identified the most recent hospital admission for which a discharge summary and at least one clinic note were available. We also obtained, where available, all WebCIS and Eclipsys medication data (as described above) that were recorded prior to, during, and after the hospitalization. Data were coded with AHFS codes, as described above. The data for each admission were organized into a matrix in which each row corresponded to a data source and each column corresponded to an AHFS code. The success of capturing, coding and organizing the data were measured at each step in the process.

Results

Patient data

A total of 70 patient records were reviewed and 30 hospitalizations were identified. Thirteen hospitalizations were excluded because they lacked a discharge summary and/or at least one clinic note prior to or following the hospitalization. Data from the remaining 17 hospitalizations were extracted from WebCIS and Eclipsys; narrative text was processed with MedLEE.

In general, MedLEE was successful at identifying medication terms in the narrative text. Manual review identified approximately 30 instances where MedLEE missed medication terms in the text. It also occasionally extracted nonmedication terms, such as "medication" and "po". MedLEE did not distinguish between medications that were being ordered and those that were being discontinued.

The twelve sources contributed data to a case an average of 12.7 times (range: 7-17), with a total of 1563 medications found (91.9 per case; range: 25-159). Table 2 shows the

1 Medication orders from Eclipsys are transmitted to the pharmacy system, converted into dispensing orders and transmitted to WebCIS.

2 In cases were admission notes were not available, admitting history was obtained (if present) from the discharge summary

numbers of medications obtained from each source for all 17 patients.

Table 2 – Data obtained from 17 patient records

Data Source	Meds	Records w/Data	Meds per Patient
Prior Clinic Note	157	17	9.2
Prior Outpatient Medications	211	13	16.2
Admission Note	102	14	7.3
Admission Note Plan	41	12	3.4
Admission Orders	88	8	11.0
Admission Pharmacy Orders	152	14	10.9
Active Orders at Discharge	93	8	11.6
Discharge Pharmacy Orders	171	14	12.2
Discharge Instructions	60	7	8.6
Discharge Plan	123	16	7.7
Clinic Note After Discharge	140	16	8.8
Outpatient Medications after Discharge	225	13	17.3

Coding medication data

Of the 623 terms it identified in the narrative text sections, MedLEE provided UMLS CUIs for 545. Of the remaining 78 medications, 30 were instances of five non-medication terms ("antiinflammatory", "cream", "lotion", "lozenge", and "po"). The other 48 were instances of eight medication terms ("INH", "MVI", "Os-Cal", "asa", "darvocet", "hctz", "niacin", and "toprol") for which UMLS CUIs were readily identified using the UMLS file MRCONSO.

Thus, UMLS CUIs were obtained for 593 of the MedLEE-identified terms, representing 169 unique terms and 165 unique CUIs. Eighty-five of these CUIs (representing 359 term instances) were found in the MED. The remaining 80 CUIs (representing 234 term instances) were mapped manually to the MED.

The coded data and the MedLEE-extracted data together comprised 1563 terms, of which 1533 were coded in the MED (444 unique terms) and the remaining 30 consisted of the instances of the 5 non-medication terms identified by MedLEE. Of the 1533 MED-coded terms, AHFS codes were available for 1517 (442 unique terms). The remaining 16 terms were instances of "oxygen" and "medication" that, while technically medication terms, do not have AHFS codes. Due to the multiple hierarchy of the MED, and multiple ingredients and/or uses of the medications, 270 terms (85 unique terms) mapped to two or more (maximum five) AHFS codes.

Creating medication matrices

The patient data for each case were grouped into an average of 22.8 AHFS codes (range: 10-37), and thus, given the twelve data sources, the matrices had an average of 273 cells (range: 120-444). Not every data source had data for every AHFS code; cases had data in 88 cells, on average (range: 28-164), with an average of 1.26 terms per cell (range: 1.09-1.55). An abbreviated example of a matrix is shown in Figure 1. The full matrix contains the original data from each source (row), along with the MedLEE abstraction, if appropriate, along with the 10 to 37 AHFS class columns.

Patient #9	201204: Anticoag-ulants	240400: Cardiac Drugs	240800: Hypoten-sive Agents	280000: Central Nervous System Agents	281604: Antidep-ressants
Prior Clinic Note	coumadin	verapamil	cozaar		cymbalta
Prior Outpatient Medications	Coumadin 5 mg Tab	Verapamil 180 mg Extended Release Tablet	Losartan Potassium 100 mg Tablet	Pregabalin 50mg Capsule	
Admission Note	coumadin	verapamil	cozaar		cymbalta
Admission Note Plan	coumadin				
Admission Orders	Warfarin Sodium Oral 10 MG	Verapamil SR Oral 240 MG	Losartan Oral 50 MG		
Admission Pharmacy Orders	WARFARIN TAB 5 MG 10 MILLIGRAM	VERAPAMIL SR TAB 240 MG	LOSARTAN POTAS-SIUM TAB 50 MG		
Active Orders at Discharge		Verapamil SR Oral 240 MG	Losartan Oral 50 MG		
Discharge Pharmacy Orders		VERAPAMIL SR TAB 240 MG	LOSARTAN POTAS-SIUM TAB 50 MG		DULOX-ETINE CAP 20 MG
Discharge Instructions					cymbalta
Discharge Plan					cymbalta
Clinic Note After Discharge	coumadin	verapamil			cymbalta
Outpatient Medications after Discharge	Coumadin 5 mg Tab	Verapamil 180 mg Extended Release Tablet	Losartan Potassium 100 mg Tablet	Pregabalin 50mg Capsule	

Figure 1 - Sample medication reconciliation matrix

The abbreviated view of the matrix in Figure 1 illustrates some of the information that can be obtained from these medication summaries. In particular, it shows instances where medications, such as Pregabalin (a Central Nervous System Agent) and Cymbalta (an Antidepressant), are listed in the outpatient note or ordering system prior to admission, but then do not appear in the admission note or orders. Cymbalta, at least, eventually appears in the discharge instructions and plan, but the Pregabalin does not, although it continues to be present in the outpatient medication system, raising the issue of whether it should be discontinued.

In addition to the appearance and disappearance of medications, the dosage of medications changes over the

course of care. In this example, we see admitting orders for Coumadin (an Anticoagulant), Verapamil (a Cardiac Drug), and Cozaar (a Hypotensive Agent) variously increasing or decreasing, relative to the preadmission orders, only to return to their original doses after discharge. The discharge plans and discharge medication orders do not address these medications at all.

Discussion

We have successfully extracted patient medication information from a variety of sources and organized it using a standard drug classification system to support a chronological summarization by medication class. This approach is similar to that carried out by Poon and colleagues as part of their PAML application [6] but differs in two important ways: medication class and chronology.

When the medications from a particular source were grouped into an AHFS class, we tended to find approximately one drug per class. This makes clinical sense, since few patients take more than one anticoagulant or antidepressant at one time. These small groupings may help support rapid assessment of the data to detect possible problems. Furthermore, the grouping by class (as opposed to Poon and colleagues' grouping by generic ingredient) accommodates changes in medication within a class and treats them as potentially acceptable. So, for example, the fact that a patient was taking one diuretic prior to admission, a different diuretic during the admission, and returned to the previous one after discharge may reflect an intentional change (perhaps due to restrictions in the hospital formulary).

The chronological arrangement of the information in the matrices acknowledges the fact that medication lists are created and maintained at points in time and that a list that was created a year ago may not be as valid as one created a week ago. Unlike Poon and colleagues, we have not yet created a medication reconciliation application, but we believe that when patient data are displayed in such an application, the relative age of the data will be relevant to those trying to resolve differences in medication lists.

Before the present methods can be employed in an MR application, some improvements to MedLEE and the MED will be needed. Some improvements in MedLEE parsing will be needed, particularly to allow it to differentiate between mentions of medications that are being continued and those that are being discontinued. MedLEE did extremely well at providing UMLS CUIs for the terms it did find - it missed only 8 unique terms out of 172 legitimate unique medication terms, for a 95% success rate. Our experience suggests that only a small effort will be needed to improve this rate.

The automated translation of UMLS CUIs to MED Codes was less successful, at slightly over 50%. This result is not due to the methodology but rather to the heretofore-low incentive for having UMLS CUIs in the MED; the mappings have not been updated for some time. However, we are confident (based on the success of our manual mapping) that the MED can be easily brought up to date and will perform this mapping function more successfully in the future.

Finally, while we believe that the matrices provide a useful organization of the data, they are probably not adequate for use directly by clinicians. Some applications, such as the PAML, will be needed to present the information to users in a way that reduces the cognitive overload that might otherwise be produced by a 164-cell matrix.

Alternatively, a program that attempts to identify discontinuities in patient medications, in order to alert clinicians at appropriate times, might use the information in the matrices. For example, when a patient is admitted and a previous outpatient medication is not ordered, the clinician might be asked, "The patient was previously taking X; do you wish to continue it?" The clinician might have a perfectly good reason for not continuing the drug, but inadvertently overlooking such information is unfortunately frequent [1]. Later, when the patient is discharged, the commonly used shorthand "continue all previous medications" is ambiguous - was X deliberately stopped or not? And, if deliberately stopped, is reinstatement really desired? A system that can track these discrepancies has great potential to reduce medication errors.

The approach described in this paper cannot, by itself, determine if a medication discrepancy represents a true error in medication ordering. Only discussion with the clinicians caring for the patient and/or chart review can identify the reasons for medication changes. However, if an ordering clinician overlooks a prior medication, or adds a previously undocumented one, it will be identified in our matrix because, at least for inpatient medications, the Eclipsys data are the gold-standard for the patient's intended therapy. Such identification is a necessary first step in preventing or correcting errors in medication reconciliation.

Conclusions

We have successfully extracted patient medication information from multiple systems and applications, and classified the information based on drug class. The resulting matrices of medications organized chronologically by class provide a new way to summarize such information and have the potential to support automated medication reconciliation.

Abstract

It is well known that medical coding practice is inconsistent and that differences in usage may exist even at the institutional level. In this paper we introduce a novel method for investigating code usage patterns in clinical documentation corpora. By applying the Compression-based Dissimilarity Measure to calculate similarities between encounter notes, we find that certain notes can be associated with a number of different classifications and that a given classification code can be documented in fundamentally different ways. The effect is that some notes need to be understood in the context of the classification code, a finding which has implications for data mining or information extraction tasks. In addition, the method opens for a number of interesting application areas that include highlighting code use anomalies, measuring how coding practice changes over time, comparing code usage across institutions, and, perhaps most importantly, provide valuable feedback to developers of classification coding systems.

Keywords:

classification, ICPC, Kolmogorov complexity.

Introduction

The electronic patient record (EPR) is the main tool for recording, communicating and remembering information about healthcare activities. Current electronic patient records exist in a multitude of more or less structured formats, and a major share of the useful information is in the form of unstructured free-text.

For the general practice EPR, which is our main concern in this paper, the unstructured free-text comes in the shape of a sequence of encounter notes that, when taken together, constitute the patient history. Alongside the encounter notes are different types of associated information such as prescriptions, referrals, laboratory results, and, in many cases, one or more diagnosis or classification codes. Classification codes may have several purposes: The underlying reason for the encounter; the patient's health problems; the administered treatment; or simply a diagnosis of an identified disease. On the administrative and mercantile level, coding is used for tasks such as reimbursement, statistics, epidemiology, insurance claims, and resource management.

An example of a classification code is the International Classification of Primary Care (ICPC), which was designed for the particular needs of primary care [1]. An early study of ICPC usage found that GPs in general do "accurate and careful work in coding" and that "data appear to be of acceptable quality for further analysis" [2]. Later studies do, however, differ in their conclusions. Nilsson et al. [3] find a high level of completeness and correctness of diagnostic codes. Other studies for both primary [4, 5] and specialist [6-8] care calls the reliability and validity of coded data into question, though some of these studies cover coding schemes other than ICPC. Accuracy appears to be domain independent [9].

ICPC is unique in the sense that it is based on epidemiological practice from several different countries, in contrast to other expert consensus-based medical classification systems. Still, there are many known unknowns when it comes to how both ICPC and other classification systems are used in clinical practice, as highlighted by the aforementioned studies. Even though coding systems are coupled with guidelines that outline their intended usage, these may in themselves be ambiguous and open to interpretation [10]. Clinical practice is local by nature; coding practice may be equally so. Without ways of comparing and evaluating code usage, the validity of any application or analysis where coding is a mainstay may be called into question.

As a means towards investigating code usage, we have chosen to consider how the free-text content of the encounter note relates to the associated classification code. Our approach is to group encounter notes according to their textual similarity. We have two main reasons for doing so:

- To learn if we can identify cases where similar types of encounter notes can have different classification codes. In such cases, the encounter note can not be clearly differentiated from other encounter notes and can therefore not be understood without the extra information that is provided by the code.
- Conversely, to learn if we can identify cases where a single classification code is documented in different ways.

The outcome will be a measure of the relationship between text and coding which, while simple, may be extended for comparative purposes as outlined above. A secondary motivation for this approach is to follow up on earlier attempts at automated ICPC coding of general practice encounter notes [11], which indicated that a more thorough examination of the relationship between encounter note and classification code was needed.

Materials and methods

We have restricted our selection of data to patient records from general practice encoded with ICPC. The primary reason is data availability; the secondary reason is the aforementioned high quality of ICPC coding in primary care. To evaluate our method, we rely on a dataset from a medium-sized Norwegian general practice care center. The full dataset consists of the complete EPR database for the period from 1992 to 2006. In order to ensure a somewhat homogenous sample we have only considered data from the last five years. This is in part to avoid changes in coding practice that might occur over time, but also because the last major system upgrade was in 2001—this upgrade led to slightly different documentation practices that might influence the result.

Of the data available to us, we have focused exclusively on the free-text clinical encounter notes and their associated ICPC codes. Notes with more than one code were not considered, this in order to ensure a one-to-one correspondence between the encounter note and its code.

Since the data originates from a general practice care center, notes will be written by a number of authors that may differ in the way they express themselves. In particular, the primary language of the documenting physician may be in one of three slightly different languages: Standard Norwegian ("bokmål"), New Norwegian ("nynorsk") and, in a minority of cases, Danish. Syntactically, all these languages are very similar and should not confuse our choice of similarity metric too much. All in all, there are more than 20 different authors of the source material. We chose not to let authorship influence our data selection, this in order to get a broad representation of different documentation styles.

The compression-based dissimilarity measure

In order to measure the similarity between notes we have based ourselves on the Universal Similarity Metric (USM), as defined by Li et al. [12, 13]. The USM is founded on the concept of Kolmogorov complexity, or algorithmic entropy. The Kolmogorov complexity $K(x)$ of a string x is defined as the length of the shortest program for a universal Turing machine U needed to compute x [14]:

$$K(x) = \min\left\{|P|, P \text{ a program and } U(P) = x\right\} \quad (1)$$

The USM is defined as:

$$d(x,y) = \frac{\max\{K(x \mid y^*), K(y \mid x^*)\}}{\max\{K(x), K(y)\}}, \quad (2)$$

where x^* and y^* denote the shortest programs required to produce x and y. $K(x \mid y^*)$ is thus the length of the shortest program to produce x with y^* as an input. Kolmogorov complexity can be shown to be non-computable but only upper semi-computable; $K(\cdot)$ will therefore have to be estimated. To make this estimate we have employed a methodology [15], similar to [13] and [16], where $K(x)$ is approximated by $C(x)$, the size of the compressed version of x:

$$C(x) \approx \left|\text{gzip}(x)\right| \quad (3)$$

In other words: $C(x)$ is the result of applying the basic gzip compression algorithm to the encounter note that is x. The distance measure between two notes x and y can then be defined as follows [15]:

$$d_c(x,y) = \frac{C(x \mid y) + C(y \mid x)}{C(xy)} \quad (4)$$

Here, xy is the concatenation of notes x and y. $C(x \mid y)$ is the compression when first training on y and then compressing x. Based on the results from [15], we chose to use the further simplified Compression-based Dissimilarity Measure (DSM) for this paper:

$$CDM(x,y) = \frac{C(xy)}{C(x) + C(y)} \quad (5)$$

In this case, the dissimilarity is close to 1 when x and y are unrelated and smaller than 1 if x and y are related. Smaller values indicate closer relatedness. We refer to the cited papers for further proofs of these relationships.

Hierarchical clustering

The CDM can be fed directly into many standard clustering algorithms. For this experiment, we use hierarchical clustering. Clustering is a way of partitioning data into subsets, or clusters, so that the clusters have something in common—in this case the syntactical similarity of the encounter notes. With hierarchical agglomerative (bottom-up) clustering [17], clusters are gradually merged into successively larger clusters. The result can be visualized as a tree data structure known as a dendrogram.

Results

Experiments were run with datasets of respectively 50, 100, 200 and 1.000 randomly sampled notes for each code—that is, for a code to be included in the experiment it had to have at least the given number of occurrences. The experiment with 200 notes seemed to be the best compromise between code coverage and data set size — for the 1.000 note experiment, only a relatively small number of codes had more than 1.000 notes available in the data set. Accordingly, only the result from the 200 note experiment is discussed in this paper.

Figure 1 shows the results of clustering the available encounter notes in the form of a dendrogram where codes with similar encounter notes are grouped together. Codes on the left are the most similar. The major share of the

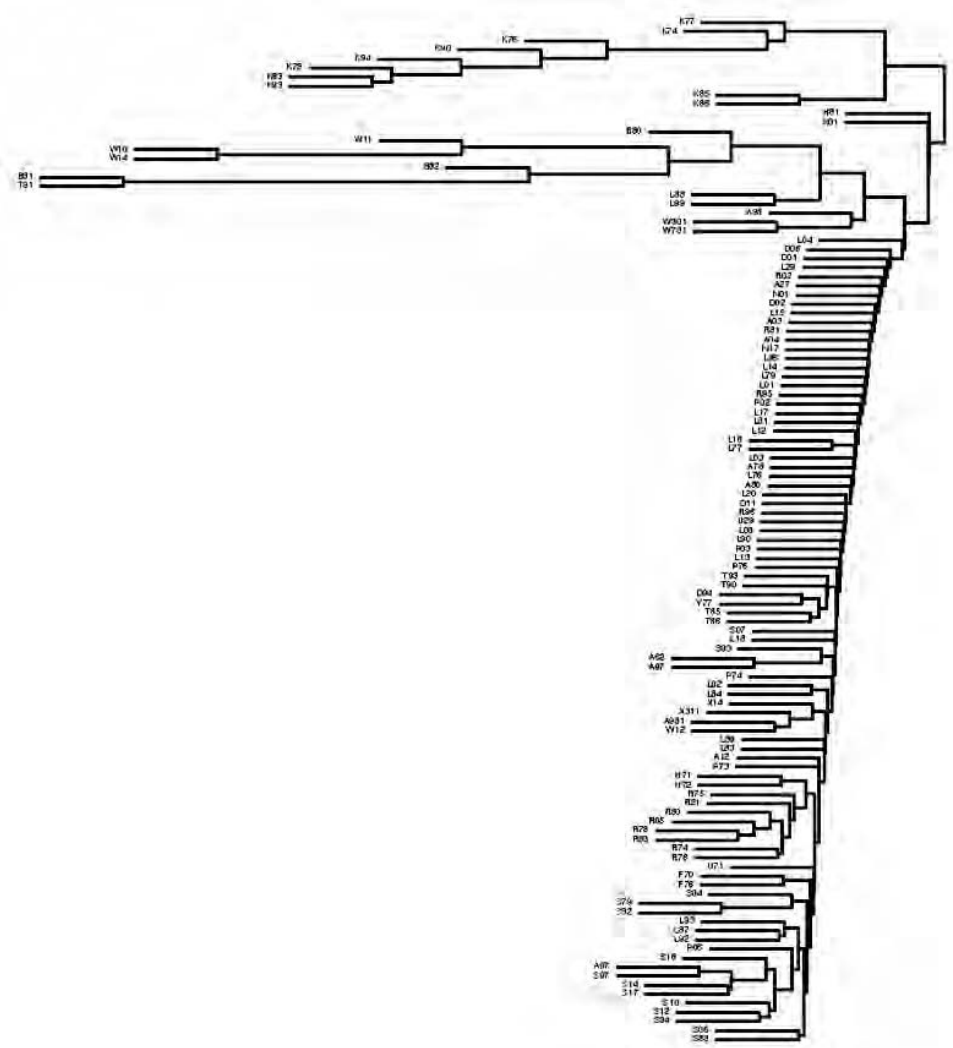

Figure 1 - Code similarity dendrogram

codes will, as seen in the long tail towards the bottom, not have much in common with other codes, signifying that there typically is something unique about the documentation for that code. The two longer branches towards the top of the graph indicate clusters of codes that are documented in a somewhat similar manner. We also notice smaller clusters towards the bottom.

Table 1 is a selection of the ICPC codes found in the most prominent clusters, based on manual inspection. The rightmost column describes the most typical text occurrence in notes with the given code.

Discussion

Referring to the manual review in Table 1, a common factor of notes being found similar would appear to be that they describe some sort of treatment that is used along with several different ICPC codes. The most prominent example is for the codes K74, K76, K77, K78, K83, K90, K93 and K94, all of which deal with different cardiovascular-related states. The combining element is, apparently, the use of the drug Marevan as an essential part of the treatment plan. A typical note will therefore describe the prescription of Marevan and not much else. There are, however, exceptions to this pattern. Take the code K83 as an example. A typical K83 note might look like this:

> Marevan 2 tbl. 7/7 Ctr. 2 weeks.[1]

Then again, a minority of the notes represent a complete break with the pattern, such as this example:

> Stressed before Christmas, occassional dizziness. 185/85 p70 reg. Cor-sbgr 4, pm 2hicr, pulm-. Pat does not want med.tmnt., promises to ”calm down”.[1]

Through manual review and counting, 20.5 % of the K83 notes used in the experiment fall into the latter atypical

1 Approximate translation from the Norwegian.

category. Thus we observe that there are internal differences in the way codes are documented. In this case, a possible explanation is that the atypical notes represent treatment milestones, such as first consultations for an emerging problem, occasions when the treatment does not go according to plan, or, simply, wherever and whenever the physician feels the need for more thorough documentation.

A similar pattern is seen for the other code clusters. Most of the clusters have the ICPC chapter code in common, but there are a few exceptions to this, such as for B81 (Anaemia, Vitamin B12/folate deficiency) and T91 (Vitamin/nutritional deficiency), where in both cases Betolvex or Vitamin B-12 is used to treat the condition. Again, the common denominator is the choice of treatment.

Table 1 - Selection of most similar codes

Code	Code description	Summary of manual note review
A97	No disease	Driving license attestation
A87	Complication of medical treatment	Wound dressing
B80	Iron deficiency anaemia	Cosmofer/Jectofer/ Vitamin B-12
B81	Anaemia, Vitamin B12/ folate def.	Betolvex/Vitamin B-12
B82	Anaemia other/unspecified	Marevan/Betolvex/ Vitamin B12
K74	Ischaemic heart disease w. angina	Marevan
K76	Ischaemic heart disease w/o angina	Marevan
K77	Heart failure	Marevan
K78	Atrial fibrillation/flutter	Marevan
K83	Heart valve disease	Marevan
K90	Stroke/cerebrovascular accident	Marevan
K93	Pulmonary embolism	Marevan
K94	Phlebitis/thrombophlebitis	Marevan
L88	Rheumatoid/seropositive arthritis	Methotrexate
L99	Musculoskeletal disease, other	Methotrexate
R78	Acute bronchitis/ bronchiolotis	Cold, fever, cough
R83	Respiratory infection other	Cold, fever, cough
S14	Burn/scald	Burns/scalding
S17	Abrasion/scratch/blister	Wound dressing/ suture removal
S79	Neoplasm skin benign/ unspecified	Mole/suture removal
S82	Naevus/mole	Mole/suture removal
S97	Chronic ulcer skin	Wound dressing
T91	Vitamin/nutritional deficiency	Betolvex/Vitamin B-12
W10	Contraception postcoital	Depo-Provera
W11	Contraception oral	Depo-Provera
W14	Contraception other	Depo-Provera

Conclusion

Through the use of the Compression-based Dissimilarity Measure in conjunction with hierarchical clustering we have identified cases where 1) the content of an encounter note can be the same for a number of different classification codes, and where 2) a single classification code can be documented in a lot of different ways. In other words, there is not always a one-to-one relationship between the classification code and its encounter note, but rather one-to-many relationships between certain codes and encounter notes, and vice versa.

One of the main implications is that encounter notes can not always be understood without their classification code, and that classification codes are sometimes only fully understood in terms of their associated encounter notes. Moreover, a classification code does not imply that the associated encounter note carries any useful information beyond the trivial. Accordingly, for a given classification code one might have to consider earlier encounter notes with the same (or a similar) code in order to find all relevant information for this code. In effect, certain encounter note/classification code pairs need to be considered in the context of their encompassing episode of care to be of use. This has implications for any kind of information extraction or data mining that is applied on primary care patient records.

Limitations

We have not attempted to run the experiment with a different clustering algorithm or a different similarity measure. While this may influence the results, our main purpose has

been to verify the existence of ambiguous codes and encounter notes.

Our view of the patient record is somewhat simplified. We have not considered the additional information that often comes with each encounter, such as lab results and prescriptions. To compare full encounters rather than notes alone, a similarity measure that considers all available information might produce different results.

Future work

In light of finding intra-code documentational variance, a natural follow-up would be to find and utilize internal clusters for single codes—that is, to identify documentational archetypes or patterns for each code and to compare these with patterns for all other codes. This might grant us a clearer picture of the different types of documentation that occurs in the primary care patient record.

The most interesting aspect of the proposed method lies in a number of potential application areas for evaluation of various healthcare documentation activities. In particular, we believe this method can prove very useful as a foundation for doing comparative studies of medical coding practice. By comparing the outcome of similarity measurements when applying the same method on different data sets, any differences may highlight variations in coding practice. In turn, this may prove to be a very useful input to those who create and maintain coding standards. Moreover, coding standards are often translated to other languages. By comparing code usage between data sets in different languages one might identify possible interpretational problems that have occurred during translation as well as differences in health care practice between countries. Other interesting approaches would be to evaluate how coding practices change over time and to compare coding practices between people and institutions. While we have only performed experiments on a data set that uses ICPC, the method should in theory be equally applicable for data sets that follow other coding standards.

A Scale-Free Network View of the UMLS to Learn Terminology Translations

Chintan O. Patel, James J. Cimino

Department of Biomedical Informatics, Columbia University, New York, NY, USA

Abstract

The UMLS Metathesaurus belongs to the class of scale-free networks with few concept hubs possessing a large number of relationships. The hubs provide useful links between the concepts from disparate terminologies in the UMLS; however, they also exponentially increase the number of possible transitive cross-terminology paths.

Towards the goal of using machine learning to rank cross-terminology translations, we propose a traversal algorithm that exploits the scale-free property of the UMLS to reduce the number of candidate translations. We characterize the concept hubs into "informational" and "noisy" concept hubs and provide an automated method to detect them.

Using gold standard mappings from SNOMED-CT to ICD9CM, we found an average 20-fold reduction in the number of candidate mappings while achieving comparable recall and ranking results. A hub-driven traversal strategy provides a promising approach to generate high quality cross-terminology translations from the UMLS.

Keywords:

UMLS, scale-free networks, terminology, mapping, machine learning

Introduction

The Unified Medical Language System® (UMLS) [1] is a large compendium of biomedical terminologies that integrates synonymous *terms* from disparate source terminologies into a *concept*. As a result, the source-asserted relationships between the terms provide cross-terminology relationships across the concepts in the UMLS. Various informatics applications pertaining to terminology translation, [2, 3, 4] information retrieval [5] and knowledge discovery [6] perform transitive traversal of these relationships to find mappings, links and sub-networks across biomedical terminologies in the UMLS.

One of the critical challenges in performing such transitive traversal of the UMLS relationships is the exponential increase in the number of possible paths. For example, starting with the concept *Hemoglobin* in the UMLS, there are 868 direct relationships to other concepts, which in turn have 450,692 relationships to a different set of UMLS concepts. Identifying the relevant concepts of interest (such as *Anemia*, *Methemoglobinemia*, etc.) with high accuracy among all the candidate paths entails a significant computational burden.

We found that the enormous increase in the number of transitive paths can be attributed to the scale-free property [7] of the UMLS. A graph is said to have a scale-free property when a few nodes (or "hubs") have most of the edges and large number of nodes are each connected by only a small number of edges. An indicator of scale-free characteristics for a network is whether it obeys the *power-law*, which states that the probability p(k) of a given node connected to k other nodes is proportional to k^{-c}, where c is an arbitrary constant. On plotting the power-law for the connectivity distribution of the UMLS 2005AA Metathesaurus (when viewed as a network with concepts as nodes and relationships as edges), we found the constant c=3.0032, strongly indicating the presence of scale-free characteristics for the UMLS.

Another relevant class of network is the small world network wherein the transitive edge traversal distance between any two nodes in the network is very small. For any scale-free network with c=3 (where c is the power-law constant), the average shortest path distance between any two nodes of the network is close to *ln N/ln ln N*, where N is the number of nodes in the network [8]. For the UMLS Metathesaurus, the distance is 5.29 (N=1179179), hence, for a given concept in the UMLS, any other concept can be reached by traversing on average 5.29 transitive relationships.

It has been shown that many real-world networks, such as the World Wide Web, biological networks, and social networks, are also scale-free [7]. However, the meaning of hubs (the nodes with large number of edges) is different across all networks and has important implications in transitive traversal of edges across the hubs. Consider, for example, the p53 molecule, which is an important hub for pathways across regulatory networks. In contrast, for metabolic networks, the water molecule hub acts as noise and produces irrelevant pathways.

In this paper, we characterize the concepts that act as hubs in the UMLS and propose a method to computationally identify the "informational" and "noisy" hubs. We propose a hub-driven algorithm for transitive traversal of relationships in the UMLS to minimize the exponential growth and generate high quality transitive paths. We evaluate the proposed approach with gold-standard mappings from SNOMED-CT to ICD9CM.

Related work

Existing approaches for traversing the UMLS to find mappings, links, and sub-networks have largely relied on expert-designed heuristics that exploit the semantics of relation-

ships. Cimino et al. (1993) [2] presented an approach of using the relationships in the UMLS for translating ICD9 terms to MeSH. The *restrict to MeSH algorithm* [3] starts by traversing hierarchical relationships (parent, broader), followed by associative relationships, until a concept from MeSH is reached. A method [4] to map SNOMED-CT and ICD9CM using the UMLS resulted in recall of 42% and precision of 20%. In our previous work, [5] the exponential rise in the number of links was shown as the critical limitation for applying machine learning approaches to identify cross-terminology translations.

Datasets

UMLS

The Metathesaurus (Meta) of the Unified Medical Language System (UMLS) integrates synonymous terms from different terminologies into concepts. The source terminology relationships are abstracted into 11 top-level relationship types (REL) such as *Parent (PAR), Sibling (SIB) or Child (CHD)*. The REL can have a relationship attribute (RELA) that provides further granular meaning such as *clinically_associated_with, mapped_from etc*. The relationships are provided in the MRREL file of the UMLS. The UMLS 2005AA distribution was used for the experiments reported in this paper.

SNOMED-CT to ICD9CM mappings

The SNOMED-CT vocabulary in the UMLS provides mappings from SNOMED-CT to ICD9CM terms, for example, *Massive Hepatic Necrosis* (SNOMED-CT) to *Acute and subacute liver necrosis* (ICD9CM). These mappings exist as separate relationships in the UMLS with relationship attribute type *mapped_from and mapped_to*. We used 65,417 such concept mappings from the 2005AA distribution of UMLS as our gold-standard.

Approach

Connection definition

Two given terminologies in the UMLS are labeled as the source terminology and target terminology that provide the source concepts and target concepts (respectively). We define a *connection* as a set of transitive relationships between a source concept and a target concept connected by zero or more intermediate terminologies through the relationships in MRREL.

- *0-Step Connection* – The source concept and the target concept are identical.
- *1-Step Connection* – A direct relationship between a source concept and a different, unique target concept.
- *2-Step Connection* – A set of two transitive relationships, wherein the source concept is related to a second concept, which in turn is related to the target concept.

Hub identification

Several different metrics can be used to categorize a given node as a hub or non-hub such as the *degree* (number of edges for a given node), *betweenness centrality* (how often a given node is encountered in shortest paths across the network) and the *"authority" measure* (as determined by algorithms such as the PageRank or HITS) [9]. Given that our goal is to spot the concepts responsible for linking a large number of disparate concepts, the node degree provides a desirable metric for identifying hub concepts in the Meta.

The degree for a given concept in Meta is calculated based on the number of relationships present in MRREL to different unique concepts (i.e. if there are multiple relationships between two concepts, it is considered as a single relationship edge). The concepts are then sorted in descending order based on concept degree to rank the highly connected concepts first. A threshold variable, k (*Hub cutoff*), is used to label the top k concepts as the hubs.

Characterizing concept hubs in meta

In our analysis of the hub concepts in the Meta, we observed a systematic semantic pattern in the type of hubs:

1. *"Noisy" Concept Hubs*: The set of concepts that do not generate meaningful transitive connections across them. Several of these concepts are found at the top of the hub list (see Figure 1a). We can further classify these into:
   a) *"Property" Concept Hubs*: The hub concepts that are used as "attributes" or "properties", for example, *metabolic aspects,* which relates cells, organs and diseases with metabolic biochemical changes

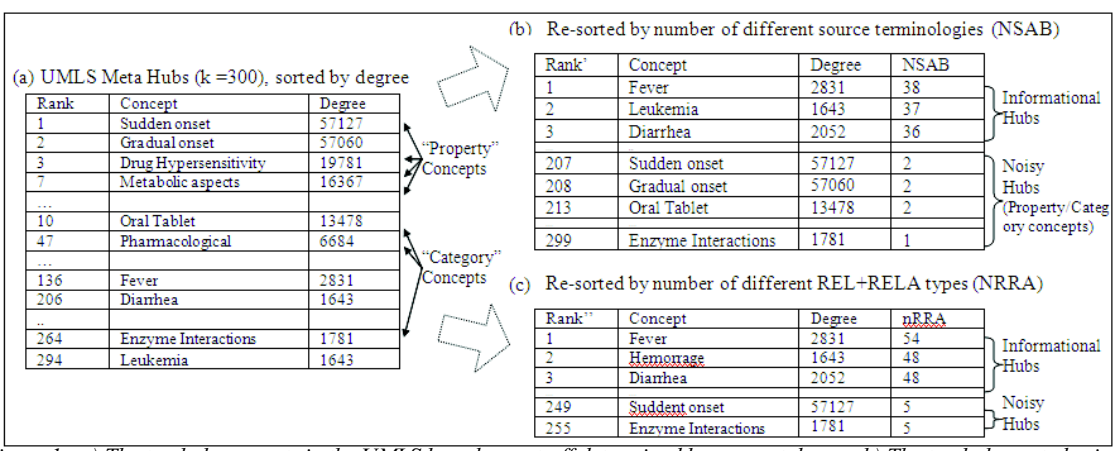

Figure 1 - a) The top hub concepts in the UMLS based on cut-off determined by concept degree. b) The top hubs sorted using the number of source terminologies for a given concept. c) The top hubs sorted using the number of unique relationship types

or *immunologic,* which provides immunological attributes to different concepts.

b) *"Category" Concept Hubs*: The hub concepts that are used as "containers" to group other concepts, for example, *Oral Tablets* (Methotrexate, Nitoman, etc.), or *Microbiological* to group organs, animals, etc used for microbiologic studies.

2. *"Informational" Concept Hubs*: In the concept hub list, we also found several concept hubs that are indispensable for generating useful cross-terminology connections across the Meta such as *Fever, Diarrhea, Edema, Hypertension, etc.* We were able to filter these "informational" concept hubs by re-sorting the hub list based on the number of source terminologies contributing to the Meta hub concept (Figure 1b). Another approach that produced similar results was sorting based on the number of different REL and RELA types associated with the concept e.g. *Fever* has 54 different types of relationships such as *RO_associated_with,RB_inverse_isa, RB_mapped_from* and so on (Figure 1c).

By using a threshold variable, *t (NSAB cutoff)*, the number of different source terminologies, we separate informational hubs from noisy hubs. We consider informational hubs as having number of source terminologies equal to or greater than *t* and the rest are labeled as noisy hubs. The noisy hubs are thrown away during the transitive traversal and the informational hubs are retained. The informational hubs nevertheless have significantly high degree and hence can possibly lead to explosion in number of possible connections. In the next section, we propose a strategy that deals with this explosion problem without eliminating any asserted relationships from the Meta.

Concept hub decomposition

To limit the exponential growth in the number of possible connections generated via hub concepts, we propose an approach to decompose the hubs. The core idea is to traverse relationships only from a single terminology when passing through a hub. Formally, if we have a connection of type $Concept_1 – Relationship_1 – Concept_2$ *(labeled as Hub)* $– Relationship_2 – Concept_3$ then the source terminology contributing the $Relationship_1$ should be same as the source terminology for $Relationship_2$ (Figure 2). The hub decomposition leads to a significant reduction in the number of possible connections, consider if we have a hub concept with *n* relationships all from different source terminologies, a naïve traversal would produce total *n*(n-1)* paths however with proposed approach we generate only *n* paths. An interesting aspect of the proposed approach is that informational hubs generally tend to have a large number of source terminologies, (Figure 1b) which further helps in reducing the number of connections.

Hub driven connection generating algorithm (CoGen)

We summarize here the connection generating algorithm (CoGen) that uses the aforementioned hub-based traversal strategies to generate high-quality connections from the Meta.

Algorithm: CoGen (SCUI, TSAB, n, k, t)

Input: *SCUI: Source Concepts, TSAB: Target Terminology, n: length of connection (n-step), k: Hub cutoff, t: NSAB cutoff*

Output: *Candidate Connections*

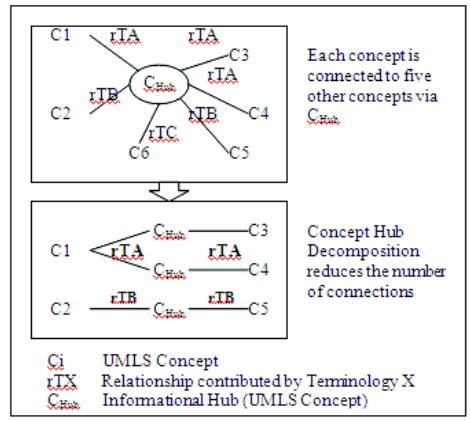

Figure 2 - An illustration showing how decomposing hub concepts reduces the number of connections by traversing only single source asserted terminology relationships via informational hubs

1. **[Clean Meta]**: *Remove all the relationships (REL) of type SIB (sibling), AQ (allowed qualifier) and QB (qualified by).*
2. **[Identify Hubs]**: *Sort the concepts in the cleaned Meta based on their degree. Label top k concepts as hubs.*
3. **[Differentiate Hubs]**: *Re-sort the hubs based on the number of source terminologies (or different relationship types). Label top t concepts as informational hubs and the rest as noisy hubs.*
4. **[Traverse Meta]**: *Generate Candidate Connections by traversing all n-step transitive connections from SCUI to concepts in TSAB, if encounter a concept of type*

   a. Noisy hub: break the traversal.

   b. Informational hub: use Concept Hub Decomposition.

Note that we added a pre-processing step to clean the Meta by removing all relationships of type SIB (sibling), AQ (allowed qualifier) and QB (qualified by) that do not generate meaningful connections in the transitive sense.

Learning features and training set

Towards our goal of using machine learning to identify and rank terminology translations from all possible connections, we describe here strategies for choosing learning features, developing training sets, and ranking the connections (refer to [5] for more details). The Semantic Network and Meta provide broad semantic categories for all concepts (Semantic Types, TUI) and relationships (REL, RELA). A connection can be abstracted into these broad semantic categories, which then creates learning tuples of the form $<REL_1, RELA_1, I_1TUI, REL_2, RELA_2$*:Decision Class*> for 2-step paths where $REL(A)_i$ indicates i^{th} step relationship, I_1TUI is the Semantic Type of intermediate concept and *Decision Class* can be *Positive* or *Negative*.

The positive examples are generated from the gold-standard terminology translations. However to generate negative examples we randomly sample 'strict' N-step connections i.e., the connections where the corresponding source and target concepts do not have any connection that is less than

N steps. The underlying rationale is that when the given concepts are related only by a 'strict' N-step connection, it implies they are relatively "unrelated" or "distant" as compared to the concepts related by less than N-step connection [5]. Once the connections are classified (using a supervised machine learning algorithm), we rank them based on the weighted difference of the number of positive and negative connections between the concepts. For example, given all 2-step connections between *Thyroid_Gland - Hypothyroidism*, 193 connections are classified as positive and 23 connections are classified negative, the connection rank is given by w_p*193-w_n*23, where w_p and w_n represent the average of confidence weight (for positive and negative connections respectively) obtained from a given classifier such as the likelihood of testing instance in Naïve Bayes.

Methods

1. The gold-standard mappings (SNOMED-CT to ICD9CM) were used to create the training sets. We randomly selected 1000 gold-standard mappings as positive training instances and 1000 'strict' 2-step connections as negative instances. The 2-step training connections were generated using the cleaned Meta (without SIB, AQ and QB).
2. Using the proposed CoGen algorithm, all possible 2 step connections were generated for 100 randomly selected source SNOMED-CT concepts to all possible candidate concepts in ICD9CM. The source concepts that were used for generating training sets were not included. Different set of connections for same source concepts were generated by varying each of the following thresholds
   a) The top k hub threshold *(Hub cutoff)* with values k=1000, k=5000 and k=9000
   b) The informational hub threshold *(NSAB cutoff)* with values t=5, t=10 and t=∞ (all hubs are considered as noisy)
3. Using simple transitive traversal (without scale-free view) over cleaned Meta, a different set of 2-step connections to ICD9CM were generated for the same 100 source SNOMED-CT concepts.
4. The training connections were used to learn a Naïve Bayes classifier. The test (candidate) connections were evaluated using the classifier and the likelihood was recorded for each connection. The connection rank was calculated for the classified connections.
5. The following measures were used to evaluate the results of the proposed approach.
   a) Recall: Number of source concepts, for which the correct (gold-standard mapped) target concept was *retrieved*.
   b) Top Rank: The number of correct target concepts ranked in the first position (top1), within top 5 and within top 10.

Results

For the randomly chosen 100 source SNOMED-CT concepts, 31 had the same target concept (0-Step Connection) and were excluded from further analysis. Considering the number of candidate connections generated (Figure 3a), the simple transitive traversal produced 315,329 connections, which was about 21.1 times more than the number of connections generated using CoGen (average 14,967.44). Subsequent analysis of connections produced by simple transitive traversal revealed 11,120 unique candidate ICD9CM concepts that represent 58.2 % of all ICD9CM concepts in the Meta. Within CoGen results, the increase in Hub cutoff parameter led to an overall reduction in the number of candidate connections and the reduction was more prominent for t=∞ (about 80% decrease from k=1000 to 9000), implying the importance of hub concepts in keeping the network connected. On removing all hubs (i.e. t=∞), 4,309 average connections were generated (62.3 connections per source concept) as compared to average 22,343 connections for t=5 (323.8 connections per source concept).

The 69 source SNOMED-CT concepts under analysis had gold standard mappings to 72 ICD9CM concepts. The simple transitive traversal retrieved a marginally higher number (57) of gold-standard ICD9CM concepts as compared to the

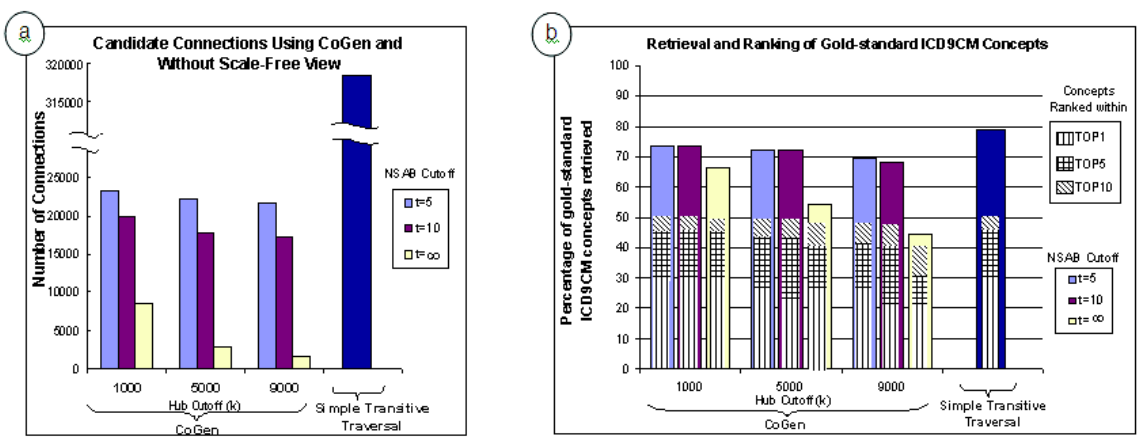

Figure 3 - a) the number of candidate 2-step connections generated for 69 source SNOMED-CT concepts to target ICD9CM using CoGen (with different parameters, k, t) and using simple transitive traversal. b) Percentage of total gold-standard target ICD9CM concepts (72) retrieved and the corresponding ranking after applying connection learning

CoGen results (54) (Figure 3b). The machine learning training set gave 10-fold cross-validation AUC (area under ROC curve) score of 0.97 for Naïve Bayes. No significant difference was observed in the ranking of gold-standard targets, despite of the large reduction in the number of candidate connections, indicating the high specificity of hub-based approach towards irrelevant translations. On average, 25.2% of time the gold-standard target ICD9CM concept was ranked in the top position and 48.9% of time in top 10 positions.

Discussion

Existing research on the UMLS has explored the semantic and linguistic aspects of the Meta at a greater depth, however, little analysis has been done to understand the large-scale structure and network of the Meta. Our results indicate that the hub concepts play a critical role in the Meta for applications that perform a transitive traversal of the relationships. We observed a 20-fold reduction in the number of candidate connections generated by proposed hub-based algorithm when compared to simple transitive traversal while the gold-standard connection ranking produced similar results; implying a significant decrease in the computational effort to traverse and rank the candidate connections. An argument can be made that all the connections corresponding to gold-standard mappings do not generally traverse through hubs. However, when we excluded all hubs ($t=\infty$) in the candidate connections, there was a significant decrease in recall for k=5000 and k=9000 and a marginal decrease for k=1000 (Figure 3b). This finding reflects the essential characteristic of all scale-free networks, where the few top hubs form the backbone of the network and removing them can cause the network to break apart.

Interestingly, the machine learning based ranking of connections was found to be independent of the size of the candidate set and the recall. This suggests that our machine learning approach is resilient to noisy connections. Secondly, it implies an inherent limitation in learning and detecting specific types of gold-standard connections. A possible solution would be to use different training sets to mine different types of connections.

Choosing an optimal value of cutoff parameters for the CoGen algorithm requires further analysis. Consider the following gold-standard connection,

Aircraft accidents – PAR - accidents (hub) – RN - Accident to powered aircraft, other and unspecified, injuring other person.

The hub concept *accidents* was removed when the hub cutoff changed from k=1000 to k=5000. Similarly, here is an example where change in NSAB cutoff led to disconnection of the gold-standard target

Acrokeratosis – RO – Hyperkeratosis (hub) – associated_with – Acquired Keratoderma

Hyperkeratosis is an informational hub at t=5 but becomes a noisy hub at t=10. Our experiments indicate that as more concepts are considered as hubs, (increasing k) a higher variation in the size of candidate connections is obtained for different values of NSAB cutoff parameter. We found that the optimal values of candidate size and ranking occur at around t=5.

In comparing our approach to the method by Fung et al. [4] over the same gold-standard dataset, our approach would obtain a higher recall given that we fetch all possible n-step connections for all relationship types and intermediate terminologies, instead of terminating the traversal when the first target terminology concept is found. Furthermore, our approach produces a ranked list of connections, thereby making it difficult to perform an exact comparison with the results obtained by Fung et al.

Our future work includes validating the approach on LOINC to CPT mappings and investigating the CoGen parameter settings for other terminological applications pertaining to knowledge discovery and information retrieval. Coupling other network properties of the UMLS (such as clustering coefficient, cohesion, and betweenness) to its semantic aspects might result in further improvements to our approach.

Conclusions

The inherent scale-free topology of the UMLS Metathesaurus provides a powerful feature to reduce the number of candidate cross-terminology connections without sacrificing the recall and ranking performance. Our experiments on gold-standard mappings from SNOMED-CT to ICD9CM showed a 20-fold decrease in the number of candidate translations by using a scale-free network view of the Metathesaurus. Generalizing the approach for terminology applications (other than translation) requires further investigation into optimal parameter settings of the proposed algorithm.

Assigning Categorical Information to Japanese Medical Terms Using MeSH and MEDLINE

Yuzo Onogi[a], MD, PhD

[a] *Clinical Bioinformatics Research Unit, Graduate School of Medicine, the University of Tokyo, Japan*

Abstract

*This paper reports on the assigning of MeSH (Medical Subject Headings) categories to Japanese terms in an English-Japanese dictionary using the titles and abstracts of articles indexed in MEDLINE. In a previous study, 30,000 of 80,000 terms in the dictionary were mapped to MeSH terms by normalized comparison. It was reasoned that if the remaining dictionary terms appeared in MEDLINE-indexed articles that are indexed using MeSH terms, then relevancies between the dictionary terms and MeSH terms could be calculated, and thus MeSH categories assigned. This study compares two approaches for calculating the weight matrix. One is the TF*IDF method and the other uses the inner product of two weight matrices. About 20,000 additional dictionary terms were identified in MEDLINE-indexed articles published between 2000 and 2004. The precision and recall of these algorithms were evaluated separately for MeSH terms and non-MeSH terms. Unfortunately, the precision and recall of the algorithms was not good, but this method will help with manual assignment of MeSH categories to dictionary terms.*

Keywords:

medical subject headings, MEDLINE, algorithms, classification, Japanese medical terms

Introduction

Clinical documents are processed and stored in electronic format by many providers in Japan and elsewhere, and this trend will certainly increase in the future. Some clinical data is stored as numbers and codes, for example laboratory examination results and disease names or categories, but the remainder is stored as natural text, for example data relating to a patient's present illness, clinical findings, and radiology reports. If we want to make use of this accumulated information or drive any decision-support system based on the clinical documents, then natural text processing is indispensable, which is very difficult for Japanese-language documents.

Japanese is an agglutinative language, meaning that there are no separators such as spaces between words. There are computer tools for morphological analysis [1] that can segment a whole sentence into parts of speech, and can derive syntactic information. If these tools are used for medical texts, it is necessary for medical terms to be added to the vocabulary, because the above-mentioned tools were originally made for general, non-technical, purposes. However, it is difficult to proceed further with deep parsing because there are very few resources on semantics for Japanese medical terms. Here we define semantic information as relating to the category or categories that a term belongs to. For example, gallbladder (in Japanese) is the name of an anatomical organ, and gallbladder calculus is the name of a clinical finding.

To obtain such categorical information, medical taxonomies are useful, because terms are located within hierarchies of categories, although the categories vary between taxonomies. One such taxonomy is the Japanese medical thesaurus published by the Japan Medical Abstract Society (JAMAS), in which terms are mapped to MeSH (Medical Subject Headings) terms. Furthermore, Japanese MeSH terms have been released by the National Library of Medicine (NLM) since 2002. We verified the validity of the mapping between the JAMAS thesaurus and MeSH terms, so we were able to obtain categorical information for about 20,000 concepts and about 50,000 Japanese medical terms [2].

An English-Japanese dictionary published by the Japan Medical Society (JAMS) comprises about 80,000 entries, and is authored by medical subcommittees within Japan. This dictionary is an authority for standardized medical terminology in Japan. To determine what proportion of this dictionary is covered by MeSH, we compared terms in the dictionary with those in the Unified Medical Language System (UMLS) [3-5] by normalization (norm and lvg programs in the Lexical tools of the UMLS) and found that about 30,000 terms can be mapped to MeSH terms, but that the remaining 50,000 terms cannot be mapped to any existing controlled vocabularies in UMLS, and therefore we cannot obtain any categorical information for these 50,000 terms [6]. We reasoned that if these unmatched terms appeared in the titles and abstracts of articles indexed by MEDLINE, then we could calculate the most relevant MeSH category for the term, because each article is indexed using MeSH terms. Thus, the objective of this study was to assign categorical information to Japanese terms that appear in an English-Japanese medical dictionary using MEDLINE and MeSH.

Methods

The basic premise of this study is that if terms in the above-mentioned English-Japanese dictionary appear in the titles and abstracts of articles indexed by MEDLINE, and that if each article is indexed by MeSH, then a list of relevancies between dictionary terms and MeSH categories could be calculated, so the most precise categorical information for a term in the dictionary could be obtained by selecting the largest (most important) weight category for the term in the list of MeSH categories.

Materials used in this study were as follows: the 2005AA version of the UMLS published by the NLM; the 2005 version of the MEDLINE records leased from the MEDLARS Management Section of the NLM; and the English-Japanese medical dictionary published by the Japan Medical Association, which includes about 80,000 entries in English.

Terms in the dictionary were compared one at a time with titles and abstracts of articles indexed by MEDLINE, with both converted to lower-case letters, for articles published between 2000 and 2004 (a total of 5 years), and the frequencies (number of appearances of each term per article) were obtained. The comparison of terms was performed directly; that is, neither stemming nor inflection conversion was carried out.

Relevancies between dictionary terms and articles were obtained by the TF*IDF weighting method [7] as follows:

$$w_{ij} = tf_{ij} \times idf_i = \frac{freq_{ij}}{\mathrm{argmax}_l \, freq_{lj}} \times \log\frac{N}{n_i} \quad (1)$$

where i represents a term; and j represents a document; w is a weight value for term i in document j; tf_{ij} is a "term frequency," that is, the frequency of term i in document j, and it is normalized against the number of times the most frequent term l appears in the document j; idf_i is the "inverse document frequency for term i, that is, the reciprocal number of documents including term i (n_i), which is also normalized against the total number of documents, N.

Similarly, relevancies between articles and MeSH terms (main headings) were calculated. Here we used both major and minor MeSH terms indexed to an article.

We obtained two weight matrices: one comprised dictionary terms versus articles, and the other comprised articles versus MeSH terms. The inner products of these matrices gave us a weight matrix of relevancies between dictionary terms and MeSH terms as follows:

$$\begin{bmatrix} entry\ terms \\ articles \end{bmatrix} \bullet \begin{bmatrix} articles \\ MeSH\ terms \end{bmatrix} = \begin{bmatrix} entry\ terms \\ MeSH\ terms \end{bmatrix} \quad (2)$$

This method is hereafter referred to as the "proposed method." In order to evaluate the performance of this method, we calculated another weight matrix between dictionary terms and MeSH terms directly from all combinations of dictionary terms and MeSH terms for an article (referred to as the "baseline method) and compared the results.

Evaluations were performed by calculating precision and recall for both algorithms. We constructed two kinds of test sets (gold standards), one consisting of MeSH terms (main headings or synonyms by themselves) existing in the dictionary (9770 terms in total), and the other consisting of non-MeSH terms randomly chosen from the dictionary and categorized manually (100 terms) by a researcher other than the one who developed the algorithms. For each dictionary term, we obtained a list of categories and corresponding weight values in descending order, which were smaller if the category was less relevant. Then precision and recall for rank n was defined as follows:

$$precision_n = \frac{N(retrieved_{rank \le n} \Lambda correct)}{N(retrieved_{rank \le n})} \quad (3)$$

$$recall_n = \frac{N(retrieved_{rank \le n} \Lambda correct)}{N(test\ set)} \quad (4)$$

where N indicates the number of terms. ROC (Receiver Operating Characteristic Curve) can be drawn using a series of precision and recall values for various n values.

This algorithm should not be dependent on the features of the dictionary terms, but if the frequencies were calculated from MEDLINE-indexed articles only, then there might be no difference between the performances of the MeSH and non-MeSH terms. We wanted to investigate this possibility further.

Results

Identification of dictionary terms in MEDLINE

The total number of articles indexed in MEDLINE between 2000 and 2004 (a 5-year period) was about 2.8 million. The number of dictionary terms found in the titles and abstracts of these articles was 49,384 (62% of terms in the dictionary). Of these, 22,296 (28%) were non-MeSH terms; that is, we assigned for the first time some categorical information to these dictionary terms (Table 1). In addition, we compared the dictionary terms with the titles and abstracts of articles indexed in MEDLINE between 1995 and 2004 (a 10-year period), and found that 53,670 terms appeared, of which 25,227 (31%) were non-MeSH terms. This shows that the number of dictionary terms appearing in MEDLINE seems to reach a plateau at around a 5-year period.

We were able to calculate two kinds of weight matrices (dictionary terms versus articles and articles versus MeSH terms) for the 10-year period, but it was impossible to calculate the inner products of the matrices because of the limitations of our computer resources.

Table 1 - Number of dictionary terms in the titles and abstracts of articles indexed in MEDLINE over 5-year and 10-year periods.

	No. of terms (%)
Total no. of terms in the dictionary	80,131 (100)
No. of matched with MeSH terms	33,487 (42)
Five-year period	
No. appearing in MEDLINE	49,384 (62)
No. non-MeSH terms	22,296 (28)
No. unassigned terms	24,348 (30)
Ten-year period	
No. appearing in MEDLINE	53,670 (67)
No. non-MeSH terms	25,227 (31)
No. unassigned terms	21,417 (27)

Evaluation of categorization algorithms

The precision and recall results for the baseline and proposed methods are shown in Figure 1. This shows that the proposed method has better precision and recall (0.83 and 0.78, respectively) for the first rank result in both test sets compared with the baseline method (0.71 and 0.71, respectively). However, the performance results for non-MeSH terms were poor, with the proposed method showing better precision and recall (0.51 and 0.56, respectively) than the baseline method (0.26 and 0.26 respectively).

Table 2 shows a sample result of the categorization of non-MeSH terms in the dictionary using the proposed method. Japanese terms and their corresponding English terms are presented, and the English terms are categorized by using the proposed method to the "Assigned categories. When this category correctly matched the given Answer category, then the symbol in the "Correct column is O, otherwise it is X.

Discussion

Matching of dictionary terms with MEDLINE

Finding the dictionary terms in the titles and abstracts of articles indexed in MEDLINE was partially successful, because we were able to find about 50,000 terms in the present study. However, about half of these were MeSH terms, so we were only able to find 23,000 non-MeSH terms. The number of terms found in MEDLINE using articles indexed during a 10-year period was not significantly greater than that from a 5-year period, and so the number seems to reach a plateau after 5 years. This finding implies that we should use resources other than articles to find the dictionary terms. For the dictionary terms that didnt appear in MEDLINE, we attempted to find the reasons why this had occurred. Three main reasons were apparent. Firstly, we found that most were certainly valid medical terms, but were seldom used in recent articles. They comprised such terms as names of bacteria, infectious diseases, physiological tests or manipulations, and signs and symptoms. Secondly, there were many Latin terms, which also seldom appear in recent articles. Based

Table 2- Examples of categorization for dictionary terms (non-MeSH terms).

on these analyses, it may be better to use older articles in MEDLINE to efficiently find these old terms. Thirdly, we found some terms that may be in common use in English written by Japanese-speakers, but which may not be commonly used by authors from other countries. Next we checked the validity of terms not found in MEDLINE using MerckSource (http://www.mercksource.com/) to determine whether they had corresponding definitions or whether other term was suggested as a substitution, because the system could not find any corresponding terms and supposed to be misspelled. We found approximately 4,000 terms that were specific to Japan (e.g. relating to Japanese legislation) but invalid terms comprised a majority of the unassigned terms. If these invalid terms can be removed, then more terms could be matched with MEDLINE in the future.

We compared the dictionary terms and MEDLINE text directly in the present study, and this may have reduced the number of terms matched. Stemming (or canonical normalization in lvg) may be effective to increase the number of matches, but may be ineffective to calculate relevancies because false matches will increase when using stemming.

We used only titles and abstracts of articles indexed by MEDLINE in the present study, but there is a possibility we could increase the number of matches if we could use the entire text of articles, because the more terms that are compared, the more matches will be found not only with respect to number but also with respect to variations.

Categorization algorithm

The proposed method using the inner products of two weight matrixes (dictionary terms versus articles and articles versus MeSH terms) seems to perform better than the baseline method (dictionary terms versus MeSH terms directly) when the category that has the most significant weight value for each term is selected. However, the baseline method was slightly better when using third and lower ranks. For non-MeSH terms, the proposed method performed better than the baseline for all ranks, although precision and recall were both about 0.5 for the first ranked weight value. This result was not good, with only half of the non-MeSH terms being categorized accurately. The purpose of this study was to assign categorical information to Japanese dictionary terms, and the results so far show that automatically categorizing terms with this algorithm fails to assign terms correctly. However, this does not imply that the output of the proposed method is useless, rather we think that this assignment will help in the manual determination of which category a term belongs to (because only the first-ranked category was chosen in the proposed method). For this purpose, the proposed method, using the inner products of two weight matrices, seems to be suitable.

We expected that there would be no difference in the performance of these algorithms for MeSH terms and non-MeSH terms but, as shown in Figure 1, there were actually differences. We checked the non-MeSH terms and found that the average document frequency was about half that of the MeSH terms, but that the standard deviations were

almost the same. This shows that the non-MeSH terms do not frequently appear, and that the TF*IDF weight value mainly depends on document frequency. However, some non-MeSH terms have very large document frequencies (because we did not eliminate stop words and non-MeSH terms contain stop words such as At - astatine), causing the poor result, which was different from the results for MeSH terms.

The nature of the relevancy data should also be discussed. We obtained relevancies between dictionary terms and MeSH terms, but actually this implies collocation or co-occurrence, rather than the two having a categorization or subsumption relationship as we expected. For example, the term hypertension may have stronger relevancy to the term angiotensin-converting enzyme (drug category) than it does to vascular diseases (disease category) as categorized in MeSH. Furthermore, we cannot identify the meaning of each relevancy based on the TF*IDF method only. However, as is shown by the precision for MeSH terms, subsumption might happen to be the dominant relationship in the relevancies determined in the present study.

Conclusion

In order to obtain categorical information for Japanese terms in a English-Japanese medical dictionary, we calculated weight matrixes between English dictionary terms and MeSH terms with the TF*IDF method using MEDLINE title and abstract data for articles published between 2000 and 2004. To calculate the matrix, we used the inner products of two weight matrices. We found 22,000 non-MeSH dictionary terms and assigned corresponding MeSH categories. Although precision and recall was not good, the results are still useful for our purposes.

Abstract:

MedDRA and WHO-ART are the terminologies used to encode drug safety reports. The standardisation achieved with these terminologies facilitates: 1) The sharing of safety databases; 2) Data mining for the continuous reassessment of benefit-risk ratio at national or international level or in the pharmaceutical industry. There is some debate about the capacityof these terminologies for retrieving case reports related to similar medical conditions. We have developed a resource that allows grouping similar medical conditions more effectively than WHO-ART and MedDRA. We describe here a software tool facilitating the use of this terminological resource thanks to an RDF framework with support for RDF Schema inferencing and querying. This tool eases coding and data retrieval in drug safety.

Keywords:

semantic web, RDF(S), drug safety, graphic navigation

Introduction

The detection of new adverse drug reactions is essential to protect patients from potential harm due to medication. The rapid and effective review of drug safety reports requires 1) the accurate coding of case reports [1] and 2) efficient grouping of similar case reports by the terminology used [2].

Drug safety is an international public health issue. Drug safety reports describe and code observations of adverse reactions after drug administration. These reports are stored in national and international databases. Medical experts must review these reports manually or with the aid of statistical tools if they wish to detect or to confirm a problem related to a particular drug. The databases are huge (3.8 million reports in the WHO international database), but adverse reactions are usually rare events and are therefore rarely reported. The grouping of cases is thus of prime importance for the early detection of problems.

International data sharing is only possible if consistent standardisation is applied to the coding used for drug safety case reports. The coding terminologies used for drug safety are WHO-ART[1] and MedDRA[2], which are used for the indexing, sharing, analysis and reporting of data during clinical trials and for drug surveillance after market release. In the last few years, the focus on drug safety terminology has increasingly shifted from coding to data retrieval and analysis for risk assessment and safety signal detection (data mining).

The main problem faced during statistical analyses based on drug safety terminologies is currently the constraints imposed by regulatory activities. Regulatory authorities require the use of a terminological structure oriented according to surveillance requirements for major public health problems, such as congenital disorders, cancers and cardiac disorders [3]. The WHO-ART and MedDRA terminologies also have a hierarchical structure with restricted multiple inheritances, to avoid double counting of the same case.

There is some debate about the relevance of the structure of these terminologies in data mining [4]. The terminologies currently used for drug safety report coding are not optimal for data retrieval and case review. Indeed, they lack the ability to group cases efficiently when reviewing specific medical issues, particularly those not covered by the requirements of the regulatory authorities.

Structurally, these grouping capabilities are represented by *grouping terms* (e.g. acid base imbalance disorders) and *links* within the terminologies (e.g. duodenal ulcer – is a kind of – digestive system disorder). Although 11% of the reports sent to the FDA in the first three quarters of 2004 were reports of abnormal laboratory results, no link is made between abnormal laboratory results terms and diseases in MedDRA [3]. This results in lower sensitivity for queries concerning medical disorders (e.g. searches for hepatitis-related reports should, but do not always, identify reports of abnormal hepatic enzyme levels).

This is problematic in signal detection, necessitating searches for groupings of appropriate terms related to a medical condition, resulting in delays and variability in the detection of drug-related problems.

SNOMED-CT [5] is emerging as a standard for data coding in clinical domains. It represents signs, symptoms,

1 World Health Organisation – Adverse Drug Reaction Terminology
2 Medical Dictionary for Drug Regulatory Activities

diseases and laboratory examination results. The structure of SNOMED-CT appears to be more appropriate than those of WHO-ART and MedDRA for grouping tasks. We previously extracted the structure embedding the terms used in drug safety from SNOMED-CT [6]. One of the advantages of SNOMED-CT is that this resource embeds within its structure various semantic views of each term and provides detailed definitions for each of its terms. We made use of this asset in the development of our resource.

We decided to use OWL[3] as the representation framework for this resource. All the contents of WHO-ART are included (5267 terms) in this resource, which also includes grouping terms from SNOMED-CT. This resource is semantically rich and provides good results in terms of grouping WHO-ART terms describing related medical conditions. However, OWL software tools are often disappointing in routine use because of problems with scalability, rapidity and technological maturity.

Objective

Our aim was to make the OWL resource operational for routine use in coding and data retrieval from drug safety databases. We aimed to build a browser tool, making it possible to use this resource for intelligent safety data retrieval and coding. This work is part of a large French project with the overall aim of developing a knowledge-based environment to assist drug safety specialists in their work (i.e. a safety database and bibliographical searches, coding). The main problem here is dealing with the size of the resource. The technologies we chose to use are derived from the semantic web. In our previous attempts to use OWL to represent medical terms we have faced the problem of tools not being fast or powerful enough to deal with all of the almost 95,000 terms in our resource.

OWL builds on RDF(S)[4], adding more vocabulary for the description of properties and classes: relations between classes (e.g. disjointedness), cardinality (e.g. "exactly one"), equality, richer typing of properties, characteristics of properties (e.g. symmetry) and enumerated classes.

We believe that OWL is not indispensable for the use of this terminology, but that this formalism is necessary for its development. The use of RDF(S) standard and tools should make it possible to develop an operational and accessible resource.

We first downgraded the resource from OWL to RDFS formalism. This was done by transforming all OWL restrictions into RDFS triples, resulting in half a million such triples. We then built a browser based on, with three main functions: 1) The composition of queries generating groupings of similar terms (WHO-ART, MedDRA and SNOMED-CT), 2) Graphical navigation within the structure of the resource, 3) Case retrieval.

Background

It may be difficult to learn how to use large terminology systems with complex intertwined structures and to navigate within them. Expandable trees, like those from the browser supplied with MedDRA, work well for some tasks, but are of limited value for displaying terminologies allowing multiple contexts. It is also easy to run out of screen space and to lose context if trying to expand and focus on several nodes at once. This is also true with our improved resource. Most browsers for medical terminologies have not taken such requirements into account. The main reason for this is that medical terminologies were mostly used for coding purposes in most commercial software tools, and this task demands little context orientation.

Advanced navigation searches are used in medical terminologies [7], but there are currently no specific researches or implementations in the domain of drug safety. Advanced navigation requires specific resources and tuning for each specific use (i.e. the medical domain) for appropriate adaptation, reducing noise levels and maximising the chances of obtaining an answer to queries.

RDF frameworks with support for RDF Schema inferencing [8] and querying are mature enough for use in this context. Unlike OWL, RDFS does not allow expressive description logics definitions but can be used to represent knowledge as graphs.

RDQL[5] is the standard query language for RDFS, making it possible to describe the patterns of graphs. The answers to queries are the parts of the RDFS graph matching the patterns described in the query. For example, if RDFS was used to represent the genealogical tree of a family using only the “is_child_of” relationship and we wanted to identify all the nephews of given individual called Tom, then a simple query like:

```
Select ?nephews                                          (1)
    from
    (<tom> is_child_of ?father_of_Tom ),
    (?brother_of_Tom is_child_of ?father_of_Tom),
    (?nephews is_child_of ?brother_of_Tom )
```

should give the right answer.

Materials

The resource

The resource is a network of terms. It contains terms from WHO-ART, MedDRA and the parts of Snomed-CT [5] relevant to drug safety. The links are associative relations extracted from Snomed-CT (i.e. “bladder neoplasm” has localisation “Bladder structure”), and “is a kind of” relations used to indicate taxonomic relationship (“renal failure” is a “renal disease”), based on original structure of all the terminologies included. Mapping relationships also connect synonymous terms from different terminologies (e.g “Bladder neurogenic” from WHO-ART is a synonym

3 Web Ontology Language http://www.w3.org/2004/OWL/

4 Resource Description Framework http://www.w3.org/RDF/

5 RDF Query Language http://www.w3.org/Submission/RDQL/

of “Neurogenic bladder” from Snomed-CT). The links and grouping terms (e.g. “renal diseases”) make it possible to group terms in the terminology. This structural information was obtained from Snomed-CT [6].

Open-source technologies

Sesame[6] is an open-source RDF framework with partial inference capabilities, with support for RDF Schema storage, inferencing and querying. The authors of this framework used it to extend RDQL. The new query language, SeRQL, combines the features of other triple-based query languages and adds some of its own. Some of SeRQL’s most important features are: graph transformation, RDF Schema support, XML Schema datatype support, expressive path expression syntax and optional path matching.

Another interesting feature of Sesame is its ability to perform “construct queries”. These queries make it possible to develop persistent inference rules. For example, if we wish to add a new relationship "is_nephew_of" to the example cited above, we need only create a query similar to (1), replacing Select with Construct and specifying that all nodes of the genealogic tree corresponding to the given pattern will be related by the "is_nephew_of" relationship. We have used Sesame as the container of our resource.

The Graphviz layout programs take descriptions of graphs in simple text language, and transform them into diagrams in several useful formats. Graphviz has many useful features for concrete diagrams, such as options for colours, fonts, tabular node layouts, line styles, hyperlinks, and custom shapes. We decided to use Graphviz for graphical representation as it is robust and is appropriate for graph and web representations.

Methods

The work was performed in two steps. We first downgraded the resource from OWL to RDFS formalism. We then built a browser based on Sesame technology,

All the elements from the OWL resource (terms and links) are represented in RDFS formalism. This makes it straighforward to transform queries like “are all WHO-ART terms linked directly or not to renal diseases from SnomedCT” or “are all diseases located in bladder structure” into RDF query language, These queries allow logical compositions (and, or, not), providing greater flexibility in query composition. WHO-ART does not contain terms like “Bladder_structure” (referred to as grouping terms) or associative relations such as “has location” or “has morphology”. By relating the terms in this way, we have greatly increased flexibility and the number of groupings. The resource contains some 500 thousand RDF(S) triplets and 95,000 terms.

The flow of information in PharmARTS[7] is represented in Figure 1. The user connects to PharmARTS via the Internet. The interface is a web browser that interacts with QueryWriter module. During navigation, QueryWriter composes and sends queries to Sesame. The data returned by Sesame is processed by ResultPrint for on-screen display. When graphical navigation is requested by the user, DOTModule translates the data into Graphviz language and ResultPrint displays the image returned by Graphviz.

Once the right terminological cluster has been found, the user can send a request to a drug safety database to which he or she has access and can thus obtain the drug safety reports corresponding to the chosen cluster.

The user interface is a web browser that sends a request to the QueryWriter module. This module transforms the request into Se-RQL, to query the Sesame knowledge base.

The response from Sesame is processed by the ResultPrint module, which displays the result either on a test form or in graphical form. When graphical navigation is activated, the ResultPrint module sends a request to DOTmodule, which translates the information to be printed into dot language. Graphviz processes the dot representation and creates an image file, which is sent by ResultPrint across the Internet to the user.

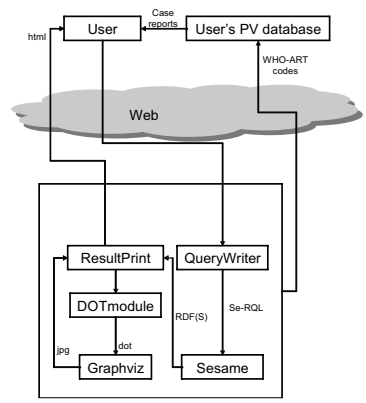

Figure 1 Functional architecture of PharmARTS

Results: The PharmARTS tool

The system was developed in Java and Java Server Pages and runs on a Tomcat server.

Two use cases are envisaged:

1. Data retrieval: The user wishes to obtain drug safety reports related to a specific medical condition.
2. Coding: The user wishes to obtain the most appropriate coding term for a specific drug safety case and navigates through different contexts of related terms.

The browser has four different panels (A to D). In figure 2, panel A includes the controls for free text searches in the terms from the three terminologies. In panel B, the terms resulting from the query are shown. The M: prefix indicates MedDRA, the S: prefix indicates SNOMED-CT and the W: prefix indicates WHO-ART. There are 166 terms

6 http://www.openrdf.org/

7 PharmARTS stands for Pharmaceutical Adverse Reaction Terminology Services

including the string “stomach”. The user can click on the terms displayed in panel B.

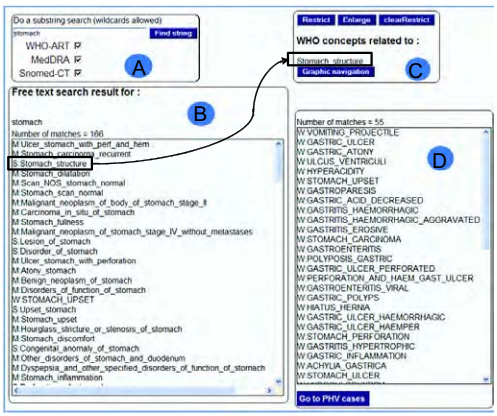

Figure 2 General presentation of the graphical user interface (text mode).

If the user clicks on a term t from panel B, all terms from WHO-ART related to term t are shown in panel D. For example, for “stomach structure” from Snomed-CT, 55 WHO-ART terms are found. There is also a button at the bottom of panel D allowing the user to display all the drug safety case reports coded with at least one of the terms listed in this panel.

The grouping terms are listed in panel C. In our example, “stomach structure”, query refining and graphical navigation are also proposed.

The semantic browser makes it possible to restrict the results of a first free-text search by the results of a second free-text search, using the “Restrict” button in panel C. This operation is actually a logical intersection. For example, in Figure 3, all WHO-ART terms related to haemorrhage in panel D AND located in the stomach structure are shown. Unions can also be created, in a similar manner, using the “Enlarge” button.

The WHO-ART terms related to both the "Haemorrhage" and "Stomach_structure" SNOMED-CT terms can be displayed in the graphical window (figure 4). In graphical mode, it is possible to navigate in the structure of the resource. Once a term of interest is selected, its definition is displayed. A colour code is used to differentiate between the different types of relationship, for example black arrows are hierarchical relationships and red dotted are anatomical localizations. Users can enlarge or restrain their clusters by selecting the ancestors/descendants of the grouping terms. For focusing, a special feature displays the descendants of the grouping terms, enabling the user to select the descendant desired.

Figure 3 - Restraining the "Stomach structure"-related WHO-ART term set to terms relating to both "Stomach structure" AND "Haemorrhage".

The formal definition of WHO-ART terms can be obtained by clicking on the WHO-ART term in question. Figure 5 shows the formal definition of the “Mallory-Weiss syndrome” WHO-ART term. The upper part of the screen shows the WHO-ART ancestors of this term. The middle part of the screen shows synonymous SNOMED-CT and MedDRA terms. Formal definitions of the WHO-ART term are displayed at the bottom of the screen. These formal definitions consist of projections on the morphological, topographic and causal agent axes of SNOMED-CT. For instance the “Mallory-Weiss syndrome” by being linked topographically with “cardia structure”, will be in the same cluster as “achalasia chardiae”, “gastroesophageal reflux” and “cardiospasm”.

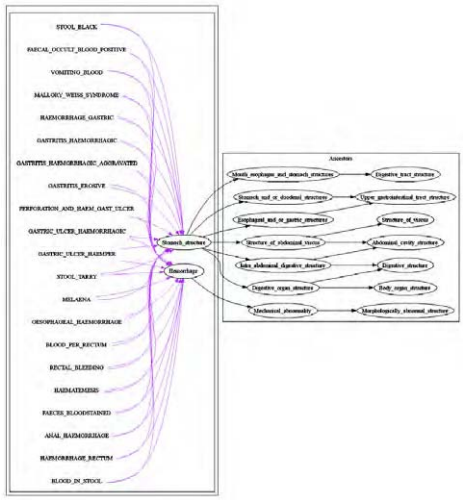

Figure 4 - General presentation of graphic navigator

mode. All nodes on the diagram are interactive.

This tool has been used for evaluation purposes at the WHO Uppsala Monitoring Centre for drug international monitoring. Despite the fact that no formal evaluation protocol was used, some qualitative ad-hoc evaluation has been done. The evaluation involved first restricting a general query (like "stomach"), by navigation. Users then tried to refine the query to obtain the appropriate set of terms. In a second evaluation step, the user tried to retrieve cases coded with the previous set of terms.

This evaluation showed also that 45 minutes of training was sufficient for effective use of the system. The results of these experiments remain qualitative, but the three people at the WHO centre who tested PharmARTS were satisfied with the case retrieval and other functions of this tool. The collaboration for a formal evaluation has been decided with the Uppsala Monitoring centre.

Discussion and conclusion

The semantic browser is a graphical interface communicating with the RDF server. It uses the resource for two main purposes: (1) To facilitate the building of topic-oriented semantic clusters of terms for querying the pharmacovigilance database and (2) To assist with the coding of documents (i.e. case reports) with WHO-ART. This tool provides a graphical visualisation of the context of a coding term defined in the resource. Navigation through the semantic context also helps the user to choose the most appropriate term corresponding to the description of the drug safety report and therefore assist coding procedure. This tool is developed in a web environment, allowing collaborative work for case coding and case retrieval. Drug safety specialists could work together on a cluster related to a specific medical condition.

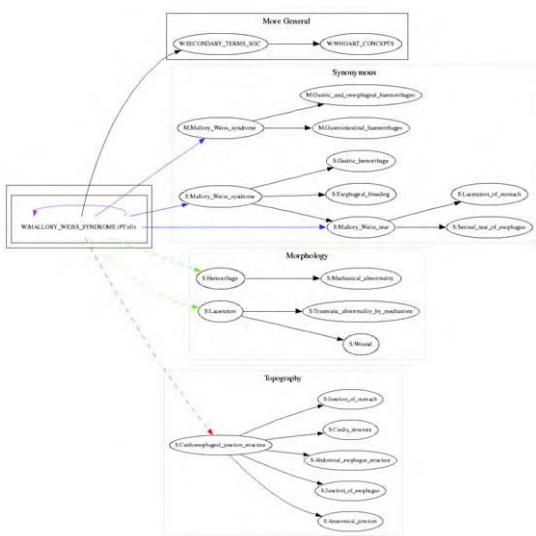

Figure 5 Modelling example of the "Malory Weiss syndrome" term.

Some areas require further development. The ontological resource must be completed. At the moment, only 86% of WHO-ART terms are completely linked to contexts (formal definitions according to SNOMED axes). MedDRA terms have been added for transcoding purposes but are not linked to Snomed-CT contexts. We have carried out feasibility studies for adding SNOMED-CT contexts to MedDRA using OWL, but the main difficulty was related to the number of terms (75,000 terms). The work described here overcomes this size limitation and MedDRA will shortly be added to the resource.

The development features of updating and quality checking must also be considered. The technologies already in use include such features and our future work will involve adapting these features to our needs.

RDF has limited expressivity (i.e. negation) and a low capacity for logical consistency check. It is therefore important to develop and to maintain the resource in OWL but to use RDF to exploit it.

Drug safety databases hold sensitive information and are therefore not made public. The development of internal data management software is required to control access to the private pharmacovigilance database. Users can retrieve cases from the drug safety databases in two ways: using an internal tool to access the database and searching based on the terms from the cluster supplied by the browser or developing an interface using the cluster of terms for automatic querying of the database, followed by display of the results.

Evaluations of Sesame [9] have shown that it performs very well with up to 7 million triples. The entire Unified Medical Language System (2005AC) could be transcribed into 25.5 million triples and Snomed CT, into 3 million triplets. This tool is therefore robust for large queries or intensive use.

Drug safety specialists currently carry out routine manual searches to identify relevant groupings of terms. An evaluation protocol has been developed with the Uppsala Monitoring Centre and will be implemented next year. This protocol will review term groupings for known drug safety signals and will try to determine whether the signals would have been detected earlier with the groupings provided by the terminological server.

In the near future, this tool will be integrated into a complete environment, enabling drug safety specialists to use different resources (bibliographical, report database, drug summary of product characteristics, etc.) and data mining tools (signal detection).

Machine Learning Approach for Automatic Quality Criteria Detection of Health Web Pages

Arnaud Gaudinat, Natalia Grabar, Célia Boyer

Health on the Net Foundation, Geneva 14, Switzerland

Abstract

The number of medical websites is constantly growing [1]. Owing to the open nature of the Web, the reliability of information available on the Web is uneven. Internet users are overwhelmed by the quantity of information available on the Web. The situation is even more critical in the medical area, as the content proposed by health websites can have a direct impact on the users' well being. One way to control the reliability of health websites is to assess their quality and to make this assessment available to users. The HON Foundation has defined a set of eight ethical principles. HON's experts are working in order to manually define whether a given website complies with s the required principles. As the number of medical websites is constantly growing, manual expertise becomes insufficient and automatic systems should be used in order to help medical experts. In this paper we present the design and the evaluation of an automatic system conceived for the categorisation of medical and health documents according to he HONcode ethical principles. A first evaluation shows promising results. Currently the system shows 0.78 micro precision and 0.73 F-measure, with 0.06 errors.

Keywords:

medical web, patient safety, quality of health information, natural language processing

Introduction

The Web proposes an ever-increasing number of medical and health sites, and makes it possible to access quickly and easily several billion of pages devoted to health information. Regarding the overwhelming quantity of information and its uneven quality, how can users, especially patients, judge the information on the Internet? Over the last ten years, the Health On the Net (HON[1]) has responded to the risks and dangers represented by the ever increasing mass of online health and medical information by protecting online citizens by establishing a third party accreditation program, the HON Code of Conduct (HONcode www.hon.ch/HONcode) [2]. This program is now a *defacto* standard adopted worldwide by health web publishers all over the world.

The HONcode principles are a set of quality criteria, i.e *transparency, authority, complementarity, updating of information, authorship, reference, justifiability, sponsorship, advertising*. Each principle is clearly defined by a guideline. The websites that candidate for the accreditation must clearly disclose an explanation of how they respect the eight principles. For instance, the *privacy* principle means that *Confidentiality of data relating to individual patients and visitors to a medical/health website, including their identity, is respected by this website. The website owners undertake to honour or exceed the legal requirements of medical/health information privacy that apply in the country and state where the website and mirror sites are located.* The website must clearly state this (and other principles) in order to be accredited, as the following excerpt demonstrates : *"We respect and are committed to protecting your privacy. 1. We do not monitor individual usage of the website. 2. We collect site usage statistics from our server logs. This data helps us to manage and plan resource updates, and will be used as part of the evaluation of the site."*

The HON's network of experts is working on the inspection of websites that candidate for the HONcode accreditation in order to identify if the site clearly indicates the information required by the HONcode principles. This approach guarantees a high quality review of the websites and consequently allows to certify reliable medical and health pages. However, to remain efficient while the growth of online documents is accelerating, manual compliance reviewing needs to be complemented and systematically executed by automated means.

An interesting but limited study has been presented [3] that aims at filtering the results by using quality criteria. According to the study the system uses regular expressions and heuristics such as the presence of the HONcode seal or not. An automated method, based on the matching of regular expressions, has been proposed [4]. In our work, we assume that machine learning methods will provide more complete and reliable results. Moreover, such methods allow us to detect and modelise linguistic factors which are hardly managed by human experts. Two kinds of machine learning methods can be applied for the automatic identification of quality principles: supervised and unsupervised ones. Supervised methods are based on a learning step, while unsupervised methods are driven by internal proper-

1 Health On Net: *http://www.healthonnet.org*

Selected for best paper award.

ties of the processed data. In the first case expected categories are known, while in the last case they emerge from the data. We have chosen to apply supervised learning methods as they allow us to better characterise and constrain expected categories related to the eight HONcode criteria. Indeed, categorisation methods seem to be helpful in automatic systems working with textual documents, when detecting hostile messages [5] or racist content [6] or when filtering spams [7]. The objective of this paper is to propose an automatic system for the detection of websites which disclose ethical HONcode principles. This paper first describes the material used, and then the proposed methods. We finally present and discuss the results obtained and draw a conclusion.

Material

As far as the automatic text categorisation is concerned, a key component of any system is a knowledge base with positive examples. In our work, the learning dataset is composed of over 5,000 HONcode accredited websites from 72 countries and represents over 1,200,000 web pages indexed in Google.

This unique database is the result of a long experience in the field of health website accreditation. A site is accredited by HON when the site not only complies with the HONcode principles but also demonstrates how each principle is implemented in the site. To make the training dataset even more relevant for the learning process and text categorisation, human experts were asked to extract paragraphs demonstrating the respect of the principle as well as the URL. Thus, we obtain separate datasets related to current principles: *authority, complementarity, privacy, attribution, justifiability, authorship, sponsorship, advertising.* Table l indicates the number of documents available for each principle in four languages (English, French, Spanish and Italian) for the purpose of this study. Please note that we have divided the principle *attribution* in *reference* and *date* elements. As a result, we obtain nine learning datasets: eight HONcode principles and one *date* item.

The data extracted from the English material is the most complete one since the number of accredited websites in English plays a more important role as shown in Table 1. The figures of learning data in table 1 indicate also that, in all the languages, the justifiability principle has a lower number of statements. Although it is difficult to define the optimal size of training data, we are aware that learning on sets with a smaller number of data will show worse results as compared to those where the data is larger and more complete.

Table 1 - Size of the learning data (in number of extracts)

Principle	English	French	Spanish	Italian
Authority	1685	188	123	230

Sponsorship	1473	163	101	163
Advertising	1030	103	86	142

Methods

Automatic categorisation methods consider documents as vectors within a vectorspace. The dimension of this space depends on the number of units (often words) of the whole collection of documents, and the size of each vector corresponds to the frequency of a given unit in a given document. In our application, we aim at categorising sentences and not documents. Indeed, sentences are more suitable for our purpose: (1) a statement about principles can be located in one or more sentences, and (2) the information contained in each sentence is expected to be more homogenous than the information contained in the whole paragraph. The segmentation of paragraphs into sentences is performed by regular expressions based on punctuation marks and html tags.

The features tested within the learning process are the following: (1) with or without use of stopwords (prepositions, determinants, etc.); (2) with or without application of Porter stemming algorithm [8] in order to lexically normalise words, *treating => treat*; (3) learning unit set up to the word combination (n-grams of 1 to 4 words); (4) learning unit set up to the word cooccurencies within sentences, or bag of words.

The unit weight within the sentences is defined by three elements [9,10]: term frequency, inverse document frequency and length normalisation.

The used machine learning algorithms are those proposed by our learning framework [11]: Naive Bayes (NB), Support Vector Machine (SVM), k-Nearest Neighbors (kNN), and Decision Tree (DT). Different combinations of features and categorisation algorithms have been applied to the English data which is the most large one. Features' combinations which showed the most satisfying results have been applied to other languages.

The feature selection aims at reducing vectorspace dimension by selecting the most discriminant features, and thus obtaining more relevant results [12]. We performed feature selection with the document frequency (DF) criterion, which favors units distributed in the largest number of sentences. DF is quick and efficient, and usually allows to reduce about 80% of features [13] without to loose performance. In this study 20% of the features are kept.

The learning and test sets are composed of 90% and 10% of the available documents, respectively.

The evaluation is performed with the following measures in their micro and macro versions: precision, recall and F-measure. Macro precision (*maP*) is representative for the distribution of elements in each category (principle), and micro precision *miP* in each sentence.

Table 2 shows global results obtained with different algorithms and features. First column *Lang* indicates the processed language and the following three columns indicate the setting up of a learning system : *w* = the segmentation of sentences into units (single word *w1*, bigram *w2*, three-gram *w3* ... w_n, cooccurence *cooc* and stemmed single word *s1*); *meth* = the used learning algorithm (Naive Bayes *NB*, Support Vector Machine *SVM,* k-Nearest Neighbors *kNN* and Decision Tree *DT*); *weight* = the weighting of units (first character indicates term frequency: natural *n*, logarithmic *l* or augmented *a*; second character indicates if inverse document frequency is taken into account *t* or not *n*; third character indicates if document length is normalised with cosine *c* or not *n*). The following columns indicate evaluation figures for *precision, recall, F-measure* in their *micro* versions, and *error rates*. The precision figures are included in the interval between 0.59 and 0.78.

Table 3 presents the contingency between precision and recall figures for all nine sets of the considered data. The rows of this table represent the assigned class and the columns represent the correct class. For instance, the cell at row 1 (authority) and column 6 (authorship) is the percentage of assigned authority sentences while the correct are authorship sentences. It allows to observe how successful the categorisation of data is according to the principles during the test step. Best results are observed when the contingency between precision and recall is high, i.e. *privacy* principle with the contingency 0.92/0.90.

Discussion and perspectives

We consider precision figures, which correspond to the percentage of correct categorisations among all the results, to be the most relevant ones as far as the judgement on the performance of the system in the reviewers' daily use is concerned. Furthermore, we consider that micro precision *miP* is more suitable to be taken into account as it corresponds to the precision with which a sentence is assigned to into a given category. According to this, SVM algorithm with unique word *w1* as processed unit and *nnn* weighting shows the best results (tab. 2): 0.78 micro precision. The recall of this setting is 0.69 which is one of the lowest figures, while F-measure is one of the highest (0.73).The error rate of this setting is one of the lowest (0.06). We can thus expect that applying SVM algorithm with such a setting would give results which show a relevance that is closer to the human categorisation.

All the combinations of features (some of them are presented in the first four columns of table 2) have been tested with English data but, globally speaking, the experiments show no significant differences. According to the indicated reasons, *nnn* setting up of *SVM* algorithm, which shows the most interesting results, has been applied to datasets in other languages. Its application to other language datasets, ...

The analysis of the contingency figures from table 3 indicates that the principle the better recognized is *privacy*. Indeed, its precision/recall contingency figures are the highest: 0.92/0.90. This means that on the lexical level, which provides basic data for the categorisation system, these principle statements are formulated with a specific lexicon. For instance, among units with the highest frequencies we can find *identity, personal, respected, individual, confidentiality* or *privacy*. The principle which is the most difficult to recognise is *justifiability as* the precision/recall contingency of only 0.45/0.33 demonstrates. Moreover, it appears to be ambiguous with the *complementarity* principle. Other couples of ambiguous principles are *reference/authority* and *advertising/sponsorship*. As far as the *justifiability* and *reference* principles are concerned, they are sub-populated and do not represent a learning set that is large enough. As for the *advertising/sponsorship* couple, the main reason for the confusion between the two is that, regarding the lexical level, there exist similarities. For instance, both principles mention *funding, acceptance and maintenance*. Furthermore, statements on these principles can be located in the same paragraphs.

As expected, due to the small number of documents referring to the two principles searched for, *justifiability* and *reference*, they could be hardly processed by the system. In this regard, other methods should be tested. For instance, similarity measures between documents [10] as inspired by the information retrieval field. Thus, the similarity can be computed directly with the principle definitions, which exist in various languages, and the small size of the reference data would not represent a limitation.

Furthermore, the role of `url` analyses can be important as they often convey indications about principles [14]. For instance, when a webpage is named *privacy.html* or *policy.html*, this offers a direct indication about the nature of the processed pages and the content that is to be expected. The combination of these different approaches and clues with the machine learning system that is currently used, offers new opportunities.

Currently we aim at the categorisation of sentences even though entire documents should be processed. Indeed, information on quality principles can be distributed among different sentences within a document or even among different pages of a website. Moreover, this information can be found on all the pages and the categorisation system must deal with this. Taking into account whole documents and websites, the categorisation process becomes even more difficult and should decrease the performances of the system. But first evaluations showed that our learning system acquires a database that is necessary for the categorisation of entire pages and websites. Even if a page can contain statements on several principles, the sentences usually deal with only one principle. However, if it happens, the consideration of the whole page will arise the ambiguity.

As discussed, our system categorises sentences according to principles, but it is not sensitive enough to detect in which kind of context, positive or negative, the statement occurs. For instance, a webpage can indicate that privacy policy is not respected on the site, while the system would just detect that this sentence is concerned with the *privacy* principle. This categorisation is correct but managing the nuances that occur with the main information is even more important. The detection of such details remains a challenging perspective [15] and would give interesting complementary indications and weighting of the categorisation resultsAs a next step of our current work, we will deal with this problem.

Another limitation is related to the fact that the statements on the principles can hardly be verified. Web publishers can declare to respect the privacy principle while unofficially they sell information on users. Notice that, in this regard, HON proposes a complaint solution within which three parties (user, web publisher and HON) can anonymously communicate and resolve such situations.

Currently, the evaluation of feature selection is based on the document frequency criterion. It could be interesting to use the Mutual information or the Chi2 criteria for this purpose. We suppose this would enhance the efficiency of the feature selection and improve the categorisation results.

In order to detect webpages which comply with the HONcode principles, we have used a database of positive examples as a training set taken from medical and health pages. But negative examples can also be used if we want to detect pages and sites which do not meet these principles. Each page or site could thus be weighted according to its positive and negative scores, and its global judgement further computed.

The ethical principles of the HONcode are currently translated into 32 languages and the accreditation process is being adopted all over the world. The System which has currently been equiped with for four languages (English, French, Spanish and Italian) can be adapted and applied to other languages. Furthermore, the difficulties related to the quality and transparency of the information on the web are not only reserved to the medical area. Our system can as well be equiped with data from other areas as well. In the medical domain, this system can be tested with other quality principles, which can be different from the ethical ones.

Conclusion

We have presented our work by designing an automatic system for the detection of qualitative and transparent HONcode principles in medical and health documents on the web. These principles respect the EU recommendations[2]. The System is based on machine learning methods for document categorisation. First evaluations show promising results: SVM algorithm with simple words as processed units and *nnn* weighting features shows 0.78 micro precision and one of the highest F-measure (0.73).

2 http://europa.eu.int/information_society/eeurope/ehealth/quality/draft_guidelines/index_en.htm

The error rate of this setting is one of the lowest (0.06). These results seem to confirm the relevance of our approach to the categorisation of webpages in accordance with the ethical principles of the HONcode. We outlined several perspectives which, we believe, will improve our system.

Additionally a manual evaluation is nevertheless needed. A comparison of the pages detected by our automatic system and those already manually categorised by experts, would convey indications about the suitability and reliability of the accreditation of documents that are automatically computed according to the HONcode principles.

Abstract

PROBLEM: Automatic keyword assignment has been largely studied in medical informatics in the context of the MEDLINE database, both for helping search in MEDLINE and in order to provide an indicative "gist" of the content of an article. Automatic assignment of Medical Subject Headings (MeSH), which is formally an automatic text categorization task, has been proposed using different methods or combination of methods, including machine learning (naïve Bayes, neural networks…), linguistically-motivated methods (syntactic parsing, semantic tagging, or information retrieval. METHODS: In the present study, we propose to evaluate the impact of the argumentative structures of scientific articles to improve the categorization effectiveness of a categorizer, which combines linguistically-motivated and information retrieval methods. Our argumentative categorizer, which uses representation levels inherited from the field of discourse analysis, is able to classify sentences of an abstract in four classes: PURPOSE; METHODS; RESULTS and CONCLUSION. For the evaluation, the OHSUMED collection, a sample of MEDLINE, is used as a benchmark. For each abstract in the collection, the result of the argumentative classifier, i.e. the labeling of each sentence with an argumentative class, is used to modify the original ranking of the MeSH categorizer. RESULTS: The most effective combination (+2%, $p<0.003$) strongly overweights the METHODS section and moderately the RESULTS and CONCLUSION section. CONCLUSION: Although modest, the improvement brought by argumentative features for text categorization confirms that discourse analysis methods could benefit text mining in scientific digital libraries.

Introduction

Systems for text mining are becoming increasingly important in biomedicine because of the exponential growth of written information in this domain. The mass of scientific literature needs to be filtered and categorized to provide for the most efficient use of the data. The problem of accessing this increasing volume of data demands the development of systems that can extract pertinent information from unstructured texts, hence the importance of key words extraction, as well as key sentence extraction. While the former task has been largely addressed in text categorization studies [1], the latter has been more rarely studied. In this report, we propose to merge the two ideas to improve the first task. We intend to use sentence extraction and sentence ranking methods to improve text categorization in MEDLINE based on Medical Subject Headings (MeSH). Selecting a set of appropriate sentences likely to improve MeSH assignment is a complex task because, more than key words, the importance of a sentence is dependent on the point of view of every reader. However, as for key words, which can be more or less comprehensively listed in a controlled vocabulary, we believe it is possible to propose task-specific criteria, which can help to define such sentences. Our model is based on the implicit discourse-level information found in scientific reports; in particular, our model uses the argumentative sections as they often appear – sometimes explicitly but usually implicitly – in abstracts. The argumentative categories we are experimenting to rank the sentences originate from professional guidelines (ANSI Z39.14-1979). Indeed, articles in experimental sciences tend to respect strict argumentative patterns with at least four sections: purpose-methods-results-conclusion. These four moves –leaving aside minor variation of labels- are reported to be very stable across different scientific genres and experimental sciences in general (chemistry, anthropology, computer sciences, linguistics…) [4]. They are also confirmed in biomedical abstracts and articles [5][6][29]. Following recent trends, which show that argumentative criteria can be useful to improve various text mining and information retrieval applications such as related articles search [7], blind feedback [27] for ad hoc search, or feature and passage selection for automatic indexing in full-text articles [30], our objective is to evaluate the benefit of using discourse analysis representation levels for keyword assignment in MEDLINE.

Background: argumentative categorization

In this section, we present a set of background methods and already reported results, which are useful to understand the rationales supporting our approach. Our argumentative categorizer is formally defined as a mono class classifier: for each piece of text the system will have to decide whether it is a PURPOSE, or a METHOD, or a RESULT, or a CONCLUSION. Sentences are natural candidate segments for such a classification [8] because they are more self-contained than phrases; however anaphoric phenomena may demand larger segments.

Summarization has a related task

Modern summarization systems use annotated corpora in order to acquire appropriate knowledge; based on textual features summarization tools are able to conduct general summarization tasks. Thus, Kupiec et al. [10] report that in abstracts produced by professionals, 80% of sentences are also found in the source document. In such systems, the complex abstracting task is recast into a more modest sentence selection problem. To do so, experts identify a set of relevant sentences from large corpora; these sentences are then used to train the learning system. Complementary to machine learning approaches, Teufel et al. in [23], who design a task very similar to our one, combine a set of manually crafted triggered expressions, such as *finally, we have shown that, we conclude that*… to classify sentences into seven argumentative classes.

Basic classifiers, features selection and weighting

Choosing *a priori* an appropriate classifier for a given task is a fairly difficult task; therefore, empirical comparisons are often necessary. Among state-of-the-art classifiers for text categorization, such as k-NN [11], SVM [12][28], neural networks [13], and rule-induction systems [14], Bayesian classifiers [15] show a linear complexity, while most top performing algorithms have quadratic complexity; therefore they are often more adapted for rapid application development and exploratory studies [16] [24]. The basic features in text categorization are usually word-based. Possible variants are stems, which often implies stop-word removal, and/or sequences of stems, such as bi- or trigrams of stems. Examples of stemming algorithms are provided in Table 1.

Table 1: String Normalization Methods

Token	Lovins	Porter	S-stemmer
genetic	genet	genet	genetic
genetically	genet	genetically	genetically
genetics	genet	genet	genetic
gene	gene	gene	gene
genes	gene	gene	gene
homogeneous	gene	homogen	homogeneous
plaid	plai	plai	plai
play	plai	plai	plai

Our preliminary studies confirmed that elaborate string normalization and stop-word removal strategies such as Porter and Lovins did not outperform simpler approaches, such as plural normalization, which process morphological variations of plural forms (-s, -ies). This strategy appears sufficient to help the classifiers to generalize without removing interesting features, such as verb tense (as suggested in [4]), which is usually removed by stemming (cf. Table 1).

The last step concerns feature weighting. Indeed naive Bayes classifiers combine the log-likelihood of each feature in order to select the most probable category in the category space; however the real frequency observed in training corpora can follow different refinement and smoothing processes, known as feature weighting [11].

> PURPOSE: While gemcitabine (GEM) is widely accepted for the treatment of advanced pancreatic cancer, capecitabine (CAP) has shown single agent activity and promising efficacy in combination with GEM. […] METHODS: Patients had advanced pancreatic adenocarcinoma, no prior systemic chemotherapy other than that given concurrently with radiation therapy, at lease one measurable disease, and adequate organ functions. […] RESULTS: The objective RR among 45 patients was 40.0% (95% CI; 25.1-54.9), including 1CR (2.2%). The median TTP and OS were 5.4 months (95% CI; 1.8-9.0) and 10.4 months (95% CI; 6.2-14.5), respectively. […] CONCLUSIONS: The combination of GEM with dose escalated 14-day CAP is well tolerated and offers encouraging activity in the treatment of advanced pancreatic cancer. […]

Figure 1 - Partial example of an explicitly structured abstracts in MEDLINE.

We tested 3 weighting methods: tf-idf (term frequency-inverse document frequency), chi-2, and df-thresholding (only features appearing frequenty in each class are selected). Our conclusion is that chi-2 and df-thresholding perform similarly, while tf-idf weighting should be avoided. Indeed, tf-idf weighting is appropriate for weighting content-bearing features, while argumentative content is supported by functional words. Three types of features are linearly combined to get a final probability ranking per class: stems, stem bigrams and stem trigrams. As in [15], length normalization of sentences as been applied in order to overcome biases introduced by too long or too short sentences.

Training and test data

In text classification tasks, two types of strategies are competing: expert-driven and data-driven approaches. While the former, which rely on a domain expert, are often time and labour-intensive, the latter are directly dependent on the availability of large training sets. Fortunately, training data for our task can be acquired in a cheap way. Most abstracts in MEDLINE are unstructured (i.e. provided without explicit argumentative markers, such as METHODS, PURPOSES…); but fortunately, a significant fraction of these abstracts contain explicit argumentative

markers. Using PubMed and its Boolean query interface, we collected a set of 12000 MEDLINE citations containing strings such as "PURPOSE:", "METHODS:", "RESULTS", "CONCLUSION:". This fully automatic data collection process introduces some argumentative noise since some of the explicit markers gather additional argumentative content. Thus, explicit markers such as "BACKGROUND AND PURPOSES:" were also collected as pure "PURPOSES:" markers by this simple method. The collection was then split into two sets:

- set A (10800 abstracts) was used for training and validation purposed,
- set B (1200) was used for the final assessment.

In addition to sets A and B, we also collected a smaller set (C) of marker-free abstracts (100 items). Then, two human annotators were asked to manually annotate this set, using the four selected argumentative classes. In contrast with the automatically acquired sets, here we do not assume that argumentative segments and sentences are overlapping items. As shown in Figure 2, some sentences in set C receive more than one label, because they may express two different argumentative moves in the same sentence. In such cases, we do not attempt to identify segment boundaries (as explored in [18] and [19]) and instead ask the system to provide any of the relevant classes. The interannotator agreement on the C set for argumentative segments is 0.81, when measured by kappa statistics, which indicates that agreement is good.

As mentioned above, our goal is to extract conclusion sentences, but because the information is available in our training data, this binary task has been modified into a four-class problem: {PURPOSE, METHODS, RESULTS, CONCLUSION}. We expect that working with more classes will help the system to discriminate between classes that have been reported to be lexically similar [4][21], such as PURPOSE and CONCLUSION. In the data sets used for the evaluation (B and C), explicit argumentative markers have been removed.

<CONCLUSION> Skin surface proteolytic activity in the living animal was detected </CONCLUSION> <METHODS> by a sensitive, non-invasive methodol. Developed in our laboratory</ METHODS>. <METHODS>A non-leaky well was constructed on the shaved back of an anesthetized guinea pig. The well contained the reaction mixture including the substrate 125I-S-carboxymethylated <GPN> insulin B-chain</GPN> (<GPN>ICMI</ GPN>)</METHODS>. <RESULTS>The proteolytic activity was shown to be time-dependent. The activity was strongly inhibited by <ASP_GPN>pepstatin A</ASP_GPN>, indicating the involvement of aspartic proteinase(s) such as <ASP_GPN>cathepsin D</ASP_GPN> and/or <ASP_GPN>E</ASP_GPN>. Pretreatment of the skin with propylene glycol blocked the proteolyticity</RESULTS>.

<CONCLUSION>The present study demonstrates the presence of proteolytic activity located on skin surface<CONCLUSION> <METHODS>using a unique, non-invasive method for in situ proteinase detn. In the living animal</METHODS>.

Figure 2 - Example of an automatically structured abstracts. Four argumentative classes are annotated with XML tags; Gene and Protein Names (GPN and ASP_GPN), are also annotated.

Combining positions of segments

Optionally, we also investigated the sentence position's impact on the classification effectiveness through assigning a relative position to each sentence. Thus, if there were ten sentences in an abstract: the first sentence has a relative position of 0.1, while the sentence in position 5 receives a relative position of 0.5, and the last sentence has a relative position of 1. The following distributional heuristics are encoded in a distributional model: 1) if a sentence has a relative score strictly inferior to 0.4 and is classified as CONCLUSION, then its class becomes PURPOSE; 2) if a sentence has a relative score strictly superior to 0.6 and is classified as PURPOSE, then its class is rewritten as CONCLUSION.

Categorization effectiveness

Table 2 indicates the categorization effectiveness of our argumentative categorizer. In Table 2, we evaluate the effect of positional information on the categorizer. We also evaluate the performance of the system on explicitly and non-explicitly structured abstracts. Finally, with an F-score (i.e the harmonic mean, with recall and precision having the same importance; cf [22]) above 85%, recall and precision measures are competitive with the trigger-based approach proposed by Teufel et al [23] (F-score ~ 68%), and the SVM learner used in McKnight and Srinivasan [25] (F-score ~ 80%). While recall exhibits excellent levels of performance, precision could still be improved. Thus, expected conclusion segments are well classified, but we observe that some non-conclusion sentences are also classified as conclusion (false positives).

Without sentence positions				
	PURP	METH	RESU	CONC
PURP	80.65%	0%	3.23%	16%
METH	8%	78%	8%	6%
RESU	18.58%	5.31%	52.21%	23.89%
CONC	18.18%	0%	2.27%	79.55%

With sentence positions				
	PURP	METH	RESU	CONC
PURP	93.55%	0%	3.23%	3%
METH	8%	78%	8%	6%
RESU	12.43%	5.31%	74.25%	13.01%
CONC	2.27%	0%	2.27%	95.45%

Table 2 - Confusion matrices expressing the classification effectiveness of the argumentative categorizer, with and without using positional information.

Materials and methods

To conduct our key word assignment experiments and evaluations, we used the OHSUGEN collection [25], which contains more than 300,000 MEDLINE records. From these records, we randomly selected 500 citations with abstracts and keywords to tune our system and 1000 citations with abstracts and keywords to provide the final results. All experiments were conducted with the MeSH 2000 version, which roughly corresponds to the time period covered by the collection. Our baseline system, which was originally developed for the BioCreative challenge 2003 to perform text categorization tasks with Gene Ontology categories, combine a vector space ranker and a pattern matcher. Both stems (Porter) and linguistically-motivated features were used by the system [35]. The system achieved competitive results in the context of the BioCretative challenge; cf. [34] for a comparative presentation and [35] for a comprehensive presentation and evaluation.

In our MeSH categorizer, the ranking was based on the categorization status value returned by the system. Thus, the best candidate categories (i.e. the relevance estimate) obtained the highest score, which directly expresses a similarity between a category and the input abstract. To overweight a given argumentative section, we simply modified the term frequency of the feature in the abstract. Thus, if we wanted to emphasize features appearing in the METHODS section, then every feature in a sentence classified as METHODS by the argumentative categorizer received a boosting factor. The fine-tuning of the optimal model, which includes the calculus of the optimal boosting factor, was based on direct search. We worked with integer values, ranging from 1 to 7 and we strove to maximize the mean average precision of our system, which is the best metric to express the full ordering skill of the system.

Results

Figure 3 provides the expected list of Medical Subject Headings for the abstract in Figure 1.

Assigned MeSH:

Adult; Cystic Fibrosis/genetics; DNA/analysis*; Genotype; HLA-DQ Antigens/genetics; Humans; Research Support, Non-U.S. Gov't; Reverse Transcriptase Polymerase Chain Reaction; Sequence Analysis, DNA/methods*; Spectrum Analysis, Raman

Top-12 categories proposed by the categorizer:
12. dna mutational analysis
11. dna
10. genetics
9. fibrosis [not in NP index]
8. alleles
7. sequence analysis, dna
6. genotype
5. mutation
4. fluorescence
3. oligonucleotides
2. polymerase chain reaction
1. cystic fibrosis

Figure 3: Expected and predicted Medical Subject Headings for abstracts in Figure 1 (PMID: 12404725). Major headings are listed with a star. We do not separate between major and minor headings. Qualifiers are ignored in our benchmark.

We observe that several headings, which relates to age, or population-related groups (*Adult*), and to grants (*Research Support, Non-U.S. Gov't*) cannot be inferred from the abstract; therefore, as is well known, both the average precision and the recall of MeSH categorizers are generally low. In contrast, some categories, in particular major headings, which are more important for annotators, can be relevantly inferred from abstracts. Table 3 provides results of the final evaluation. In particular, we observe that the best combination emphasizes the PURPOSE section (x5 times) and the METHODS and RESULTS sections (each with a multiplicative factor of 2). The overall resulting improvement (+2%) is statistically significant, although quite modest ($p<0.003$) [32]. We also see that another simpler yet quite effective combination can be obtained by boosting just the PURPOSE section (x3 times). It is also interesting to observe that the best combination regarding the mean average precision (MAP), i.e. 0.217, is not the best one for precision at high ranks, as expressed by the Precision at recall = 0. In contrast, the best precision at high ranks (0.93) is achieved by trading recall for precision. Thus, in that setting, only 3064 relevant categories are proposed while 3068 were proposed with the baseline system.

Table 3 - Results of the argumentative boosting on the effectiveness of the MeSH categorizer (C=CONCLUSION, P=PURPOSE; M=METHODS, R=RESULTS, MAP= Mean average precision).

Parameters Kc=C,P,M,R	Relevant Retrieved	Prec. at Rec.=0	MAP
Kc=1,5,2,2	3068	0.927 (+0.8%)	**0.217 (+2%)**
Kc=1,3,1,1	3064	0.93 (+1.1%)	0.216 (+1.4%)
Kc=1,1,1,1 (Baseline)	3068	0.92 (100%)	0.213 (100%)

Conclusion

Our results (precision at high ranks ~ 93%) suggest that argumentative contents as available in abstracts stored in digital libraries are helpful for text categorization tasks, such as automatic assignment of Medical Subject Headings (MeSH). The reported improvement is statistically significant. Although modest (+2%), the improvement confirms that discourse analysis methods are useful for a growing number of text mining applications. Indeed, while attempts to apply linguistically-motivated approaches based on syntactic tools (part-of-speech tagging, shallow or deep parsing) to information retrieval and text categorization were rather inconclusive, methods inherited from discourse analysis could provide a more scalable and dependable improvement. Finally, it would be interesting to evaluate the benefit of argumentative features using more elaborate approaches such as those working with novelty detection [33], full-text articles [30], or with more advanced learners [31].

Abstract

Evaluating journal quality and finding high-quality articles in the biomedical literature are challenging information retrieval tasks. The most widely used method for journal evaluation is impact factor, while novel approaches for finding articles are PubMed's clinical query filters and machine learning-based filter models. The related literature has focused on the average behavior of these methods over all topics. The present study evaluates the variability of these approaches for different topics. We find that impact factor and clinical query filters are unstable for different topics while a topic-specific impact factor and machine learning-based filter models appear more robust. Thus when using the less stable methods for a specific topic, researchers should realize that their performance may diverge from expected average performance. Better yet, the more stable methods should be preferred whenever applicable.

Introduction

The size of the biomedical literature makes it increasingly challenging for researchers to find high-quality articles. Since manually monitoring the literature in its entirety is impractical, quality assessment methods have been developed to aid researchers. Journal quality is typically measured with impact factor [1], which is a citation-based method. A methodological and content criteria-based approach for identifying high-quality articles is the PubMed clinical query filter [2]. Machine learning methods such as polynomial support vector machine (SVM) models [3] have been recently introduced as pattern recognition query filters for identifying high-quality articles.

Previous work showed that machine learning methods outperform citation-based methods for finding articles [4]. On the other hand, citation-based methods are more flexible since they are applicable for multiple uses. Compared to clinical query filters, machine learning models have distinct advantages. They have superior performance, are automatically generated, and allow users to specify a desired sensitivity or specificity. On the other hand, clinical query filters are easier to understand and more suited for use with standard PubMed interfaces.

While prior work studied the average behavior of these methods over all topics in the biomedical literature, the research in this paper examines a subtle but important property: *stability over topics*. A method with excellent average performance may fail in a focused domain. Suppose we have a set of articles about three topics (A, B, and C) where 90% of the articles relate to topic A and the remaining articles are divided equally among B and C. If a method has a sensitivity of 1 for topic A and .1 for the other topics, overall performance is .91. Researchers interested only in topics B or C would experience much worse than expected performance. The present work examines the extent of this performance variability for the three methods. If this phenomenon is prevalent, these tools should be modified accordingly.

Methods

Journal impact factor

The journal impact factor evaluates journal impact regardless of publication size or frequency [1,5,6]. It affects journal readership and helps researchers determine to which journal they submit their work. Essentially, it is the average number of citations received per article published in the journal. It is defined for a year y as the quotient of two terms [1]:

$$\text{Impact Factor} = \frac{\text{Number of citations in year } y \text{ to journal items published in years } (y-1) \text{ and } (y-2)}{\text{Number of journal articles published in years } (y-1) \text{ and } (y-2)} \quad (1)$$

The numerator is the number of citations received in a given year to journal items published in the previous two years. The denominator is the number of journal articles from the previous two years. Items in the numerator include articles, editorials, and letters to the editor, while the denominator consists only of articles [7]. For example, the impact factor of the New England Journal of Medicine (NEJM) for 2004 is the number of citations in 2004 to its published items from 2002 and 2003 divided by the number of articles from 2002 and 2003.

Topic-specific impact factor

Prior work considered the impact factor of topics irrespective of journal by computing the number of citations received by articles in a topic area (e.g. asbestos) [8,9].

However, this metric does not assess journals. To study the sensitivity of impact factor to the distribution of topics *in a journal*, we need a formula that isolates the contribution of a specific topic (arbitrarily defined) to the overall impact factor. We calculate a topic-specific impact factor (TIF) for a journal in year y by considering only publications related to a given topic:

$$\text{TIF} = \frac{\text{Number of citations in year } y \text{ to items published in years } (y-1) \text{ and } (y-2) \text{ that were relevant to topic}}{\text{Number of journal articles published in years } (y-1) \text{ and } (y-2) \text{ that were relevant to topic}} \quad (2)$$

For example, the numerator of the cardiology-specific impact factor of NEJM in 2004 is the number of citations in 2004 to cardiology-related items published in NEJM from 2002 and 2003. The denominator is the number of cardiology-related articles. Determining topic relevance is topic-specific. For example, we can consider an item relevant to cardiology if its MEDLINE record contains the MeSH term "Cardiology", a related topic such as "Cardiovascular Diseases" that is specified in the "See Also" field of the MeSH record, or a term residing in a sub-tree of these terms [10]. When we specify topics, the topics do not need to be exclusive or cover all items for the adjustment to be meaningful.

Topic-mix adjusted impact factor

Impact factor can be adjusted for a mix of topics with a weighted average of the topic-specific impact factors. We define the topic-mix adjusted impact factor for k topics as:

$$\text{Topic-mix adjusted impact factor} = \sum_{i=1}^{k} w_i \times TIF_i \quad (3)$$

TIF_i is the topic-specific impact factor of topic i, and w_i is a weight proportional to the importance of topic i normalized such that the sum of all weights equals one and each weight is between 0 and 1. For example, a researcher interested in gastroenterology twice as much as hematology would weight the topic-specific impact factors of gastroenterology and hematology by 2/3 and 1/3 respectively. If all topics are weighted equally, the topic-mix adjusted impact factor is the arithmetic mean of the topic-specific impact factors for all topics.

Analysis for journal methods

When computing topic-specific impact factors, we do not have p-values or confidence intervals since they are population totals and not point estimates. We calculated the absolute differences of impact factor to topic-specific impact factor to analyze variability. We determined the minimum, median, maximum, and interquartile ranges of the differences to assess the skewness and spread of the values. Interquartile range measures dispersion and is the difference of the third and first quartiles. We would expect little discrepancy between the methods if citations are evenly distributed over topics.

A Bland-Altman plot [11] was used to determine whether topic-specific impact factors are significantly different from impact factors. This plot shows whether a new measurement method agrees with another method by plotting the measurement differences against their mean and illustrating any dependence between the values. We considered the correlation coefficient, but it is not an appropriate method [11].

We also wanted to ensure that the variation was not randomly caused by smaller sample sizes independently of topic. By definition, journal impact factor is calculated on a larger number of publications than the topic-specific impact factor. To determine whether the difference between the two measures is associated with sample size, we computed the regression coefficients of the following regression model:

$$\text{Diff(TIF, IF)} = \beta_0 + \beta_1 * (\text{sample size difference}) + \beta_2 * \text{topic} + \beta_3 * \text{year} + \beta_4 * \text{journal} \quad (4)$$

where Diff(TIF, IF) is the difference between topic-specific impact factor and impact factor, and "sample size difference" is the difference between the number of articles used in each calculation. The "topic", "year", and "journal" variables are categorical variables representing different values for the topic, year, and journal. They were included in the model to account for any possible confounding effects.

Clinical query filters for articles

The clinical query filters were originally designed by Haynes and colleagues [12] and are the most widely available method for identifying high-quality articles through PubMed [2]. These filters are semi-manually constructed Boolean queries of terms in the MeSH headings, publication type, or text of the MEDLINE record. All articles that match a given combination of terms are returned. Performance is measured by sensitivity and specificity. Filters are defined for diagnosis, etiology, prognosis, and treatment with queries optimized for sensitivity and specificity [13]. For example, the specificity-optimized filter for therapy is: (randomized controlled trial [Publication Type] OR (randomized [Title/Abstract] AND controlled [Title/Abstract] AND trial [Title/Abstract])). This query returns all articles with publication type "randomized controlled trial" or with all three words in the title or abstract.

SVM models for articles

Machine learning methods provide another approach to identifying high-quality articles. In previous research, polynomial support vector machine models [14] had superior performance compared to the clinical query filters [3]. These models preprocess fields and text from MEDLINE records for use as features during learning. A kernel function maps the input space to a "feature" space where a hyperplane is calculated to separate the classes of data. We used the models learned from a previous study [3] which includes further details about the learning procedure. Performance is measured by area under the receiver operating curve (AUC).

Analysis for article methods

We compared the absolute differences between the overall performance when ignoring topic and performance for

each topic. For clinical query filters, the metrics were sensitivity and specificity, and for the SVM models, the

Table 1 - Topic-specific impact factors for general topics and journal impact factor in 2004 and 2003

	Journal	Topic-specific Impact Factors for General Topics								Impact Factor

	NEJM	38.05	55.78	33.66	28.78	40.46	39.51	22.42	45.33	34.84

metric was AUC. We also computed the minimum, median, maximum, and interquartile ranges of these differences. Second, we performed Wilcoxon signed rank tests which test the difference between paired measurements. They compare repeated measurements after an experimental manipulation to determine if a value has changed. The null hypothesis is that the difference is zero. A p-value less than .05 means that the difference is significantly different from zero, which implies that the method does not retain performance for individual topics.

Corpus construction and topic identification

We analyzed the corpus from the previous work comparing clinical query filters and SVM models [3]. The ACP Journal Club [15] was the gold standard. It is a meta-publication where experts review the best journals in internal medicine on a monthly basis to identify high-quality articles for categories such as diagnosis, etiology, prognosis, and treatment. All MEDLINE articles from the ACP Journal club during the study period were positive cases or considered high-quality. The remaining articles from the journals during the same period were negative cases and not considered high-quality. For the treatment and etiology categories, there were 15,786 MEDLINE records from July 1998 to August 1999. For prognosis and diagnosis, there were 34,938 MEDLINE records from July 1998 to August 2000. The longer timeline provided a sufficient number of positive cases. Articles were converted into a format suitable for the learning methods by extracting and encoding terms from the abstract, title, MeSH terms, and publication type.

Table 2 - The minimum, median, maximum, and interquartile ranges for the absolute differences between impact factor and topic-specific impact factor in 2004

Topic	Min	Median	Max	IQR
Cardiology	0.09	2.04	17.35	11.58
Endocrinology	0.56	2.09	25.99	15
Gastroenterology	0.33	2.15	35.72	2.92
Hematology	1.31	5.02	10.96	7.53
Medical Oncology	0.23	1.46	10.75	5.61
Nephrology	0.13	6.04	10.64	5.55
Pulmonary Disease	0.45	0.99	11.64	5.1
Rheumatology	1.73	6.86	30.79	12.38

We randomly selected 18 MeSH terms covering a range of topics. The topics were: Bone Diseases, Cardiovascular Diseases, Cysts, Diabetes Mellitus, Endocrine System Diseases, Gastroenteritis, Gastrointestinal Diseases, Heart Diseases, Hematologic Diseases, Hernia, Infection, Kidney Diseases, Lung Neoplasms, Myocardial Infarction, Muscular Diseases, Neoplasms, Respiratory Tract Diseases, and Rheumatic Diseases. Articles were relevant to a topic if its MEDLINE record contained the MeSH term or a term residing in a sub-tree.

Results

Variability of journal ranking for different topics

We measured the variability of impact factor over topics and journals by adjusting it for topic with equation (2). We chose eight general topics of internal medicine according to the MeSH vocabulary and a set of narrowly-defined subtopics randomly selected from Gastroenterology. The 6 journals were Annals of Internal Medicine (AIM), American Journal of Medicine (AJM), British Medical Journal (BMJ), Journal of the American Medical Association (JAMA), Lancet, and New England Journal of Medicine (NEJM). For each journal and topic, we retrieved all MEDLINE records with related MeSH terms and obtained citation counts and journal impact factors from the ISI Web of Knowledge [16] in July 2006.

Our results showed that rankings based on impact factor and topic-specific impact factor were not equivalent. When comparing journals for a given topic, the higher impact journal did not always have the higher topic-specific impact factor, as shown in Table 1. For example, NEJM had a higher impact factor than JAMA but had a lower cardiology-specific impact factor. Of the 120 comparisons among the 15 journal pairs and 8 topics, there were 10 reversals (8.33% of the comparisons, 95% confidence interval 3.39% to 13.28%). There were 3 extremecases where a journal impact factor was 1.5 times greater than another journal while the other journal's topic-specific impact factor was 1.5 times greater. The topics were nephrology (AJM, BMJ), gastroenterology (NEJM, JAMA), and rheumatology (Lancet, NEJM).

Table 3 - The minimum, medium, maximum and interquartile ranges for the absolute differences between overall and topic-specific sensitivity/specificity. The specificity-optimized filter for diagnosis did not return any articles

		Sensitivity				Specificity			
Optimized for	Category	Min	Median	Max	IQR	Min	Median	Max	IQR
Sensitivity	Diagnosis	0.02	0.02	0.15	0.0013	0.015	0.087	0.23	0.097
	Etiology	0.028	0.07	0.07	0	0.00047	0.059	0.22	0.10
	Prognosis	0.031	0.1	0.57	0.15	0.0029	0.053	0.18	0.042
	Treatment	0.0035	0.01	0.026	0.0025	0.0027	0.030	0.17	0.053
Specificity	Diagnosis	-	-	-	-	-	-	-	-
	Etiology	0.16	0.34	0.49	0.28	0.0066	0.13	0.31	0.086
	Prognosis	0.11	0.24	0.52	0.33	0.030	0.099	0.22	0.035
	Treatment	0.034	0.053	0.07	0.023	0.00037	0.048	0.13	0.033

The absolute differences between the two measures as well as the Bland-Altman plot further support that the methods are not equivalent. Table 2 shows the minimum, median, maximum, and interquartile ranges of these differences over all journals for each topic. There was much instability since the maximum differences ranged from about 10 to 35. In Figure 1, the Bland-Altman plot showed that the difference in impact factor and topic-specific impact factor depended on their values, and the divergence increased as the values increased. Also, the difference did not depend on specialty since all topics showed some difference. If the methods were in agreement, all values would lie between horizontal lines at -22.17 and 17.7, which is the range of two standard deviations from the mean difference of -2.24. Three values fall outside this range.

The observations for the eight general topics from internal medicine were also evident for gastroenterology subtopics (data not shown due to space restrictions). As with the general topics, there were a number of ranking reversals. The variation increased for more specialized topics and was most pronounced in the 3 highest impact journals. JAMA had the greatest variability with a maximum topic-specific impact factor that was over 13 times larger than its minimum. For increasingly specialized topics, the overall impact factor became less meaningful. In 2004, JAMA had an impact factor of 24.83, gastroenterology-specific impact factor of 60.55, and topic-specific impact factors for gastroenterology-based subtopics ranging from 6 to 80.07. These data support the idea that researchers studying a specific disease should not rely on overall impact factor for journal evaluation.

To ensure that variation was not a random occurrence unique to a single year, we performed additional experiments. First, we replicated the experiments for 2003 and found consistent results, as shown in Table 1. Many of the relative rankings of the journals were retained, while some of the same reversals existed. Also, ranges of topic-specific impact factors were comparable. Next, we verified that variation was not randomly caused by sampling with the regression model in equation (4). We found that β_1, the regression coefficient for sample size difference, was .0021 and not significantly different from zero (p-value = .6062). Thus, the difference between topic-specific impact factor and impact factor did not appear associated with differences in sample size.

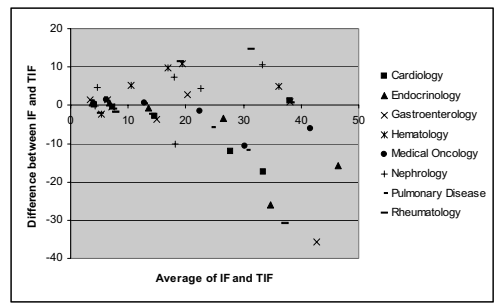

Figure 1 - Bland-altman plot for the differences between impact factor and topic-specific impact factor

For an example of a topic-mix adjusted impact factor, we used the 2004 data and a topic mix where cardiology is weighted three times more than pulmonary disease. JAMA had a topic-mix adjusted impact factor of 40.75 while NEJM was 37.59. In this case, JAMA had a higher cardiology-specific impact factor, while NEJM had a higher pulmonary disease-specific impact factor. Due to the emphasis on cardiology in this example, JAMA had a higher topic-mix adjusted impact factor despite the fact that NEJM had a higher overall impact factor. This example shows that the unadjusted impact factor may not be the best guide in evaluating journals for topic mixes.

Finding high-quality articles for different topics

Performance of the clinical query filters differed for specific topics. Articles were relevant to a topic if its MEDLINE record contained related MeSH terms. The gold standard for high quality articles was inclusion in the ACP Journal Club. Table 3 summarizes the differences between the overall sensitivity/specificity and the observed values. For some categories, there was considerable variability. For example, the sensitivity-optimized prognosis filter had a median difference of 0.1, maximum difference of 0.57, and an interquartile range of 0.15 for sensitivity. These values are relatively large since sensitivity ranges from 0 to 1. The Wilcoxon signed rank tests suggested that performance was unstable for most categories. The p-values were less than .05 for all cases except sensitivity with the sensitivity-optimized diagnosis filter and both values for the sensitivity-optimized prognosis filter.

The SVM models demonstrated more stable results over topics as shown in Table 4. Since AUC values are not sensitivity or specificity values, they cannot be compared directly

with the Haynes' filters results. However, AUC values also range from 0 to 1. Differences are much smaller since the largest interquartile range is .065, and the largest maximum difference is 0.13. The Wilcoxon tests for the SVM models showed that all categories except for diagnosis did not differ significantly from the overall AUC values. These results imply that the SVM models are less sensitive to topic or are more stable for specific topics. One important observation for the diagnosis category is that it had few positive documents. A number of the topics had no positive documents, and most of the topics had fewer than 4 positive cases out of several hundred or thousand articles. With more positive cases, the diagnosis results may be consistent with the results for the other categories.

Table 4 - The minimum, median, maximum, and interquartile ranges for the absolute differences between AUC values

Category	Min.	Median	Max.	IQR
Diagnosis	0.0083	0.038	0.04	0.012
Etiology	0.0027	0.028	0.13	0.05
Prognosis	0.0041	0.045	0.10	0.065
Treatment	0.00054	0.0040	0.041	0.0078

Discussion

Previous research studied impact factor, clinical query filters, and SVM-based models as quality evaluation tools for journals and articles. Performance was measured as an average over all topics. The present study builds on prior work by analyzing the stability of these methods for specific topics. Our results demonstrated that impact factor and clinical query filters are sensitive to topic and vary widely for different subjects. Researchers should realize that average performance cannot be expected for focused searches. Approaches that adjust for topic or are insensitive to topic should be used, if available. The topic-specific impact factor and SVM models are two such options.

Impact factor and clinical query filters are unstable over topics since they are query-independent methods built separately from the learning task. Citation-based metrics (i.e. impact factor) suffer since a citation is not necessarily an endorsement related to the topic of interest. It can acknowledge prior work, identify methodology, correct or criticize, or disclaim the work of others [17]. The reason for the citation may not be relevant to the query topic and distort topic-specific rankings.

The topic-sensitivity of clinical query filters may be due to their manual creation. Experts choose terms that reflect their expertise. Since research areas use different jargon and vocabulary, the coverage of terms may not be exhaustive, and some topics may lack adequate consideration. On the other hand, SVM models automatically learn terms for all topics in the corpus. The machine learning methods should not perform poorly for some topics if they are included in the corpus.

This work's findings have practical implications. Relying on topic-sensitive methods can provide misleading conclusions. For example, researchers interested in gastrointestinal diseases would believe that NEJM is the best journal to read according to impact factor. However, JAMA may be a better choice since it has higher topic-specific impact factors for gastroenterology and gastrointestinal diseases. The variability could result in queries of lower than expected sensitivity or specificity when searching for articles. Taken together, these consequences represent the potential for a habitually flawed literature evaluation. Researchers' work may not be reaching as large an audience as possible, and articles may frequently be misjudged with respect to quality.

We found that the variability problem was not as extensive as the example in the introduction. However, it is still present and should be considered when using the studied methods. This work was the first step in characterizing the application of these approaches for specific domains. Aphinyanaphongs and colleagues showed that it is naive to believe that citation-based metrics can describe all clinical uses [4], and this work shows that it is unrealistic to expect impact factor and clinical query filters to exhibit average performance for all clinical contexts.

A Method for Defining a Journal Subset for a Clinical Discipline using the Bibliographies of Systematic Reviews

Nancy L. Wilczynski, MSc*, Amit X. Garg, MD, PhD†, R. Brian Haynes, MD, PhD*, for the Nephrology Hedges Team

Health Information Research Unit, McMaster University, Hamilton, Ontario, Canada, †Division of Nephrology, University of Western Ontario, London, Ontario, Canada

Abstract

Background: Searching for best evidence for clinical decisions in large biomedical databases is problematic because advances in health care practice that are ready for application are but a very dilute constituent in a much larger pool of biomedical literature. Sensitive search strategies have been developed to help alleviate this problem but search precision is still generally low. If "virtual journal subsets" that are likely to include all relevant articles can be defined for clinical discipline areas or disease content areas this will likely improve search precision.

Objective: *To determine whether studies cited in systematic literature reviews can define a journal subset for a given clinical discipline.*

Design: *Survey of the primary studies included in systematic reviews that are relevant to the clinical discipline of nephrology.*

Methods: *Four data sources were searched to identify systematic reviews relevant to clinical nephrology: the Cochrane Database of Systematic Reviews, McMaster PLUS (Premium LiteratUre Service), MEDLINE, and the Renal Health Library. Three research assistants recorded data pertinent to each of the included primary studies.*

Results: *195 systematic reviews relevant to nephrology were defined and the 2,779 unique original articles they cited were concentrated in 466 journals, with 90% of the articles in 217 titles. This journal subset can be stored online and used when searching the large biomedical databases such as MEDLINE.*

Conclusion: *The bibliographies of systematic reviews can be used to define a journal subset for a clinical discipline area.*

Keywords:

information storage and retrieval, nephrology, medical informatics

Introduction

With the increasing generation of research evidence of high relevance to public health and patient care, ways to manage the knowledge reported in the medical literature are of paramount importance. This is true for the public (who must be able to determine how to best avoid health problems), patients (who must often negotiate for best care), clinicians (who must offer their patients "current best care" and be in a position to provide patients with evidence concerning the many competing claims patients can encounter), managers (who must provide an efficient organizational infrastructure for the best care that is affordable), and policy makers (who must decide on the optimal allocation of scarce resources to support best care). Research to address many of these issues is first widely accessible in the biomedical and health services journal literature. Access to original research and summaries of this evidence is widely and freely available throughout the world through MEDLINE and its PubMed interface, as well as through commercial vendors, including Ovid, Dialog, Aires, and others.

Unfortunately, the task for end-users of accessing, appraising, understanding and applying this literature is difficult mainly because advances in health practice that are ready for application are in very low concentration in a much larger pool of biomedical literature, the vast majority of which is preliminary "scientist to scientist" communication. Thus, the "signal-to-noise" ("ready-to-not-ready") ratio for clinically relevant and ready studies is exceedingly low. To help alleviate this problem we developed search strategies (hedges) for use when searching in MEDLINE and several other electronic databases (e.g., EMBASE). These search strategies were developed to improve the retrieval of clinically relevant and scientifically sound study reports and achieved very high sensitivity (>90%) and specificity (>90%) but with typically low precision (<50%). The search strategies that we developed are available for use on the Clinical Queries page of PubMed (http://www.ncbi.nlm.nih.gov/entrez/query/static/clinical.shtml) and on the Limits screen in Ovid (Ovid (http://gateway.ut.ovid.com/gw1/ovidweb.cgi).

To enhance precision while retaining sensitivity we [1, 2] and others [3, 4] posited that subsets of journals could be defined for given clinical content areas that would contain all or most of the relevant documents that are of sufficient quality to warrant clinical attention. Such journal subsets could be easily implemented as "stored searches" for any number of disciplines, given the computational power of

modern information technology. Rather than searching through the over 5,000 journals that are indexed in MEDLINE the search would be restricted to the journal subset. We hypothesized that using these journal subsets, with a much higher concentration of the relevant documents, would dramatically increase the precision of searching without losing highly relevant reports.

Thus, our preliminary work, in a restricted sample of journals, showed that for even a broad clinical discipline such as internal medicine, 90% of the scientifically valid and clinically important content is captured in 18 journals and 100% in 33 journals [1]. The journal subsets for each of the disciplines of general medical practice/primary care, nursing and mental health are somewhat broader, with just over 30 journals capturing 90% of the content and 40-46 journals capturing 100% [1]. The methodology used to derive the journal subsets for these broad discipline areas involved determining which journals contributed content to 4 evidence-based secondary journals: *ACP Journal Club, Evidence-Based Medicine, Evidence-Based Nursing, and Evidence-Based Mental Health* [1].

In our subsequent work on nephrology we used an alternative method to deriving journal subsets. We hypothesized that journal subsets could be developed for any discipline using bibliographies of systematic review articles because systematic reviews of the medical literature include exhaustive searches for high quality clinical articles (primarily concerning treatment of disease conditions). Using the bibliographies of systematic reviews to derive journal subsets has at least 2 advantages over our previous method. First, it would be possible to use this method for any clinical content area because it is not restricted to locating evidence-based secondary journals on a given clinical content area. Second, this method utilizes a much larger journal set in deriving the subset. Using this approach we found that 49% of nephrology content is captured in 20 journals and the remaining 51% is published across 446 journals [2]. A very different spread of content than observed for the broad clinical discipline areas using an entirely different approach.

Some findings of this research were previously reported [2]. In this paper we describe the detailed methods (not previously reported) of generating a journal subset using the bibliographies of systematic review articles using the clinical discipline area of nephrology as an example.

Methods

The bibliographies of systematic review articles about the management of renal disorders were used to generate a journal subset for the clinical discipline area of nephrology. More specifically, the journals that published the primary studies included in the systematic reviews were tallied and rank ordered to determine where the majority of literature is published for nephrology. To identify potentially relevant systematic reviews 4 databases were searched: the Cochrane Database of Systematic Reviews (CDSR), McMaster Premium LiteratUre Service (PLUS), MEDLINE, and the Renal Health Library. A review was defined as systematic if it included a methods section that outlined the data sources used to identify the primary studies, and the inclusion/exclusion criteria were specified for determining which primary studies were included in the review.

The first database we searched was the CDSR, Issue 3, 2005. CDSR houses systematic reviews that are produced by review groups who use exhaustive database and hand searching techniques and explicitly defined standards of clinical appraisal [5]. We used reviews prepared by the Cochrane Renal Group within CDSR to define the "universe" of reviews for nephrology for each of the following potentially relevant renal subtopics: acute renal failure, diagnostic tests, drugs and the kidney, chronic kidney disease, end-stage kidney disease, general nephrology, process of care, transplantation, urinary tract infection, and urology. All completed reviews (not protocols) listed for each relevant subtopic were included in this study. The subtopics "urinary tract infection" and "urology" were deemed not relevant to the clinical practice area of nephrology by two practicing nephrologists, one of the authors (Amit Garg) and a colleague (Robert Yang). Additionally, the subtropics "diagnostic tests" and "process of care" had no completed reviews.

Data were extracted by 3 research assistants working independently. For each of the relevant Cochrane systematic reviews we initially recorded on an Excel spreadsheet the following data: title of the Cochrane review, renal subtopic group, and the complete citation of all included primary studies. Subsequently, for each of the included primary studies we recorded: the PubMed ID (if indexed in MEDLINE), whether the citation was for a full-text article, whether the citation was for an English language study, whether the included study was a randomized controlled trial, and the year the included primary study was published. The journal titles of included primary studies were tallied and rank ordered by frequency to determine which journals published content relevant to the clinical discipline area of nephrology.

The CDSR contains mainly reviews about treatment. Given that studies researching questions relating to diagnosis, prognosis, and etiology would also be of interest to clinicians working in nephrology we decided to search additional databases.

The second database was McMaster PLUS. McMaster PLUS powers bmjupdates+ (http://bmjupdates.mcmaster.ca/index.asp) which provides access to current best evidence from research, tailored to the specific clinician's health care interests, to support evidence-based clinical decisions. McMaster PLUS contains systematic reviews and primary studies identified from over 130 clinical journals since January 2003. Primary studies and review articles that met specific criteria for scientific merit are categorized for various clinical practice areas including nephrology. The PLUS database was queried for all treatment, diagnostic, prognostic, and etiologic systematic reviews disciplined for Internal Medicine and Nephrology using the advanced searching interface in bmjupdates+.

Cochrane reviews were excluded. Two practicing nephrologists (Amit Garg and Robert Yang) independently assessed each review for having content relevant to nephrology. The definition used to determine relevant nephrology content was based on a list of medical criteria that was being operationalized for a subsequent study. Data collection for each of the primary studies included in the relevant systematic reviews proceeded in the same fashion as outlined for the CDSR.

To further expand the number of systematic reviews in the areas of diagnosis, prognosis, and etiology a third database was searched, MEDLINE using the Ovid interface. On February 2nd, 2006, MEDLINE was queried for the following types of articles: treatment, diagnosis, prognosis, and etiology using the search strategy shown in Table 1. Reviews identified via the previous 2 searches were discarded. All citations retrieved were reviewed independently by 2 nephrologists who determined if the content was relevant to nephrology.

Table 1 - Search strategy used in MEDLINE

18	17 not "cochrane database of systematic reviews".jn.	123419
19	limit 18 to ("reviews (specificity)" and yr="2001 - 2005")	349*

* 349 articles were retrieved, including 113 nephrology reviews not previously identified, 25 reviews already identified through the previous searches, 72 reviews not relevant to nephrology, and 139 articles that were not systematic reviews.

Subsequently, 3 research assistants assessed the relevant reviews for methodological rigor. Data collection for each of the primary studies included in the relevant systematic reviews proceeded in the same fashion as outlined for the previous 2 databases.

The fourth and final database searched was the Renal Health Library (http://www.cochrane-renal.org/renal-healthlibrary.php), an electronic database that is regularly updated by the Cochrane Renal Group and contains non-Cochrane meta-analyses (among many other types of articles). Two nephrologists independently assessed each non-Cochrane meta-analysis to determine if the content was relevant to nephrology, Data collection proceeded in the same way as outlined for the previous 3 databases.

Results

The results are shown in Table 2. A total of 195 unique systematic reviews relevant to clinical nephrology were identified. In these 195 systematic reviews, 3,260 primary studies were included of which 2,779 were unique, published in 765 journal titles of which 466 were unique.

Table 2 - Number of Unique Systematic Reviews, Primary Studies and Journal Titles Generated by Each Data Source

Data Source	Unique Systematic Reviews	Primary Studies	Journal Titles
CDSR	30	513	102
McMaster PLUS	30	726	211
MEDLINE	113	1696	354
Renal Health Library	22	325	98
Total	195	3,260 **Unique** 2,779	765 **Unique** 466

The systematic reviews investigated questions relating to treatment (n=160, 1986 primary studies), diagnosis (n=8, 182 primary studies), prognosis (n=12, 381 primary studies), etiology (n=14, 222 primary studies), and economics (n=1, 8 primary studies).

Ninety percent of nephrology content was captured in 217 journals; 75% was captured in 81 journals. Horizon estimation using Poisson regression was used to estimate how many journals were missed with this 4 search strategy approach. It was estimated that 20 journals were missed for a completeness of 96%.

Discussion

This paper outlines the methods used to define a journal subset for a clinical discipline, nephrology, using the included studies cited in systematic reviews. As indicated

in the introduction, this method led to the derivation of a journal subset with greater dispersion than when content contained in evidence-based secondary journals is used.

At least 2 factors may explain this difference. First, the articles contributing content to the 4 evidence-based journals must meet all of several basic criteria for scientific merit as outlined at http://www.acpjc.org/shared/purpose_and_procedure.htm. Thus, when using the evidence-based journal method to defining a journal subset the resulting subset is based on content of very high quality. Systematic reviews, however, often include studies of lesser merit (for questions of therapy nonrandomized trials and before-after studies may have been included). Thus, this method shows a broader dispersion of the literature including content that is relevant to the clinical topic but not necessarily ready for clinical attention.

Second, the journals contributing content to the 4 evidence-based journals have been accessed for their ability to produce high-quality content. Thus, when using this method a restricted set of high-quality journals is used to derive the subset. When using the method of included studies cited in systematic reviews the pool of potential contributing journals is much larger.

The method used to define a journal subset for a given clinical content area has implications because the resulting subset can be very different. If journal subsets are stored on-line and used when searching in large biomedical databases such as MEDLINE the methods used to derive the subset must be explicitly stated. Various types of journal subsets for the same discipline could be made available, for example, those that were derived to find high-quality content for direct clinical application and those derived to find all content for a given clinical content area. Then, depending on the purpose of the search, the appropriate journal subset could be chosen. For example, if a clinician is searching MEDLINE to find an answer to a patient care question the search could be restricted to a journal subset derived to find high-quality content (those studies that are ready for clinical application) in the disease area in question. On other hand, if a researcher is conducting a systematic review the search could be restricted to a journal subset derived to find all content for a given content area. Thus, both journal subsets serve a purpose.

Regardless of the journal subset chosen searching in MEDLINE, using a "virtual journal subset" will improve the precision of the search in terms of absolute numbers. Rather than searching through the entire MEDLINE database that contains references from over 5,000 journals, the search will be conducted using only 466 journals (in the case of the nephrology example). This will substantively decrease the number of articles that will need to be sorted through in order to find those that are on target, and the concentration of these articles will be much higher than in the entire database, resulting in increased search precision.

Conclusion

The bibliographies of systematic reviews can be used to define a journal subset for a clinical discipline area. The journal titles can be used to create a "virtual journal subset" that can be stored on-line and used when searching the large biomedical databases such as MEDLINE.

Abstract

Interoperability is a common understanding of the meaning of data between a sending and receiving computer system [1]. The level of interoperability required varies with application needs. The specification of data in enough detail to create a common shared meaning between organizations is a complex task as systems work within organizational and human factors contexts as well as having specific technical requirements. Aequus communis sententia translates from Latin to the "level of common meaning." In this manuscript, we define an Ontology of Interoperability. The scale asks reviewers of a specification to define it's level in terms of Syntactic, Semantic and Pragmatic Interoperability. We tested the scale by having five medical Informaticians rate a set of ANSI standard specifications and we report the inter-rater variability of the interoperability rating scheme. We learned that some elements of the scale presented more difficulty for our reviewers and based on our findings we present a final version of the interoperability scale in our discussion. Our interoperability rating ontology has high inter-rater reliability and is a relatively simple mechanism for comparing the levels of interoperability afforded by different specifications or the same specification over multiple versions.

Keywords:

interoperability, standards

Introduction

Interoperability is one of the main goals of standardization for health information technology (IT) [2]. Although many Informaticians appreciate what would define an ideal state where we have perfect interoperability such that the receiver appreciates the information in the same context and meaning as the sender of the data. Levels of interoperability that fall short of this ideal have to date been only minimally defined. We believe that there are occasions when standards have been touted as supplying interoperability without actually accomplishing this lofty goal [3]. We contend that it would be useful to reviewers and users of standard specifications to know what level of interoperability is afforded by the specification.

Users of specifications, we believe, should be informed of what level of interoperability is afforded by any particular specification. Implementers of specifications could compare the functional requirements for interoperability for their applications with the level of interoperability afforded by any specification that they are contemplating implementing to ensure that their needs are well served by their choice of which standard to implement. This is implementation protective if the standard being considered would if implemented fall short of providing the level of interoperability needed by the functional requirements of their application. This method is cost protective if the standard contains significant unnecessary machinery to ensure a level of interoperability well beyond the functional requirements of the application in question.

As new versions of specifications are developed or released standards development organizations (SDOs) and implementers of specifications could be informed regarding how the changes in the new version of the standard effects the level of interoperability provided by each version of the standard.

Syntax, semantics and pragmatics

In 1938, Charles Morris published his seminal work dividing interoperability into three components [4]. Syntactic Interoperability deals with interoperable structures. Semantic Interoperability deals with the interoperability of a common shared meaning. Pragmatic Interoperability deals with the external constraints on the system. This last category takes into account the level of granularity needed for common understanding and the complexity or difficulty required to achieve a certain level of interoperability. Although Morris was referring to the Pragmatic Philosophers, we have extended this in our scale to address the practical side of standards development and implementation.

Levels of Interoperability

Many authors have discussed the benefits of Interoperability. Some like Hammond et al in 1998, have differentiated partial from full or true interoperability [5].

Interoperability		
	Syntactic Interoperability	
	a	Headings (e.g. Section of the clinical record)
	b	Select Fields Are Delimited, but relationships between fields are not specified
	c	4 plus data types are fixed and reliable
	d	5 plus numbers are broken out along with values (e.g. Blood pressure and values are diastolic and systolic values)
	e	6 plus Hierarchical structure of data without non hierarchical relationships between fields (e.g. XML structures)
	f	7 plus non-hierarchical relationships can be specified
	Semantic Interoperability	
	1	Free Text
	2	Free Text with fixed data types
	3	Codification of data by local codes
	4	Codification of data by nationally standard aggregate codes
	5	Codification of data by nationally standard detailed coding system allowing only pre-coordinated concepts
	6	Codification of data by nationally standard detailed coding system allowing both atomic and pre-coordinated concepts
	7	Codification of data by nationally standard detailed coding system allowing post-coordination (based on formal logic)
	8	Model based knowledge representation with local codes
	9	Model based knowledge representation with nationally standard aggregate codes
	10	Model based knowledge representation with nationally standard granular pre-coordinated codes
	11	Model based knowledge representation with nationally standard detailed coding system allowing both atomic and pre-coordinated concepts
	12	Model based knowledge representation coordinated semantically nationally standard detailed coding system allowing post-coordination (based on formal first order logic)
	13	Model based knowledge representation coordinated semantically nationally standard detailed coding system allowing post-coordination with support for context (based on formal higher order logic)
	Pragmatic Interoperability	
	α	Currently available and easily implemented
	β	Currently available but with barriers to implementation
	γ	Could be built and implemented within one year without barriers to implementation
		Could be built and implemented within one year with barriers to implementation
	ϵ	Could be built and implemented within three years without barriers to implementation
		Could be built and implemented within three years with barriers to implementation
	$\hat{\epsilon}$	Could be built and implemented within ten years
	λ	Would take longer than ten years to achieve
	μ	Not practically achievable
		Not possibly achievable

Table 1: Interoperability scale

The scale has three components. Syntactic interoperability ranges from simple headings to fixed and formatted hierarchically organized fields with possible structural links indicating non-hierarchical relationships between concepts. Semantic interoperability has as its simplest incarnation, free text, to the formal representation of knowledge using higher order logics which can fully support context. The authors believe that context is integral to how clinicians process information and will be important to achieving adequate computer based clinical decision support, which is one of the important goals of standards that deliver interoperable data. Pragmatic Interoperability speaks to the practical application of the standard. Here the levels go from currently available and easily implementable to impossible to achieve, advancing using a combination of how difficult it is to achieve and how long it is estimated to take to reach the goal of being practically implemented.

Methods

In order to evaluate the inter-rater reliability of the scale we had five Informatics professionals independently evaluate three standard specifications. The specifications chosen were Health Level 7 (HL7) v2.5, HL7 v3.0 [6] and the American Society of Testing and Materials (ASTM) Continuity of Care Record (CCR) specification [7]. These standards were chosen as they represent important national and international efforts that have taken somewhat different approaches to similar clinical problems (i.e. the representation of clinical laboratory data). Each Informatician rated each of these three standards by the three components of the interoperability scale.

For each scale, we simulated 50,000 "deals" of 15 cards into 3 hands of 5 each. The 15 cards dealt out were determined by the overall distribution of each scale. We then had the computer count the number of "pairs" in each hand and summed this over the 3 hands (3 of a kind counts as 3 pairs, 4 of a kind counts as 6 pairs, and 2 of a kind is obviously just 1 pair). In doing so we generated for each "deck", what the expected total pair count from a random deal would be. In addition to calculating where our observed pair count fell in the tail of the distribution (this is a one-sided testing situation), we also calculated the mean and SD of the pair count.

Results

The five reviewers showed excellent inter-rater agreement. The agreement with respect to Syntax and Pragmatics was greater than with Semantics. The agreement in the semantic category could be improved by conflating categories 5 and 6 and also conflating categories 10 and 11, as reviewers had particular difficulty making this distinction.

Although not directly studied, comments from the reviewers recommended simplification of the Pragmatic scale leading to the final recommended scale given below

HL7 v2.5	R1	R2	R3	R4	R5
Semantics	5	5	3	5	6
Syntax	d	d	d	d	d
Pragmatics	alpha	alpha	beta	alpha	alpha

Table 2 - Review data for HL7 v2.5

HL7 v3.0	R1	R2	R3	R4	R5
Semantics	11	11	4	10	11
Syntax	e	e	e	e	e
Pragmatics	delta	delta	beta	beta	beta

Table 3 - Review data for HL7 v3.0

ASTM CCR	R1	R2	R3	R4	R5
Semantics	6	6	3	5	6
Syntax	e	e	d	e	e
Pragmatics	beta	beta	beta	alpha	beta

Table 4 - Review data for the ASTM CCR.

Statistical analysis:

The agreement among the reviewers was analyzed as follows. For each scale the overall distribution of 15 responses was assumed fixed, and a probabilistic calculation was performed for how likely these 15 responses, when grouped by chance into 3 subsets (1 for each test case) would contain as many or more reviewers agreeing in a pairwise fashion. For each scale, the maximum number of pairwise agreements over the 3 cases was 10*3 = 30.

Case 1: Semantics, no grouping; Distribution of scale:

3	4	5	6	10	11
2	1	4	4	1	3

Number of pairwise matches = 9 (3 for each case).

The probability of at least 9 pairwise matches occurring in all, given this distribution, assuming ***random*** clustering of

responses, was p = 0.026. The expected number of pairwise matches was 4.6 with an SD of 1.7.

Case 2: Semantics, grouping 5/6, 10/11; Distribution of scale:

3	4	5/6	10/11
2	1	8	4

In this case, there were 18 pairwise matches in all (6 in each case). The chance of at least 18 pairwise matches occurring under random clustering, was P = 0.0042. The expected number of matches under random assortment was 10 with an SD of 1.9.

Case 3: Syntax; Distribution of scale:

d	e
6	9

The number of pairwise matches was 26 (out of a possible maximum of 30).

The chance of this good an agreement occurring by chance was p = 0.006. The expected number of pairwise matches in this case was 14.6 with an SD of 2.4

Case 4: Pragmatics; Distribution of scale:

Alpha	Beta	Epsilon
5	8	2

Number of pairwise agreements was 16 (6+4+6)

The probability by chance of obtaining at least 16 pairwise agreements was 0.054. The expected number of agreements was 11.2 with an SD of 2.2. Thus in this case only, we cannot rule out chance as accounting for the amount of agreement, if we use the 0.05 significance level.

Discussion

Here we present a revised (Table #5, below) scale for indicating the level of interoperability provided by any health informatics standard. The authors hope that ratings using this scale will help consumers of health informatics standard to better understand the level of interoperability provided by any particular specification. Further we believe that the use of this scale will help these same consumers, who are faced with the choice of which standards to implement, to compare the relative levels of syntactic, semantic and pragmatic interoperability provided by each of the specifications under review

Interoperability		**Table #5**
	Syntactic Interoperability	
	a	Headings (e.g. Section of the clinical record)
	b	Select Fields Are Delimited
	c	b plus data types are fixed and reliable
	d	c plus numbers are broken out along with values (e.g. Blood pressure and values are diastolic and systolic values)
	e	d plus Hierarchical structure of data without non hierarchical relationships between fields (e.g. XML structures)
	f	e plus non-hierarchical relationships can be specified
	Semantic Interoperability	
	1	Free Text
	2	Free Text with fixed data types
	3	Codification of data by local codes
	4	Codification of data by nationally standard aggregate codes
	5	Codification of data by nationally standard detailed coding system allowing both atomic and pre-coordinated concepts
	6	Codification of data by nationally standard detailed coding system allowing post-coordination (based on formal logic)
	7	Model based knowledge representation with local codes
	8	Model based knowledge representation with nationally standard aggregate codes
	9	Model based knowledge representation with nationally standard detailed coding system allowing both atomic and pre-coordinated concepts
	10	Model based knowledge representation coordinated semantically nationally standard detailed coding system allowing post-coordination (based on formal first order logic)

	11	Model based knowledge representation coordinated semantically nationally standard detailed coding system allowing post-coordination with support for context (based on formal higher order logic)
	Pragmatic Interoperability	
	α	Currently available and easily implemented
	β	Currently available but with barriers to implementation
	γ	Barriers could be overcome within one year
		Barriers could be overcome within three years
	ε	Barriers could be overcome within ten years
	ζ	Would take longer than ten years to achieve
	μ	Not practically achievable
		Not possibly achievable

Conclusions

Interoperability is essential for information about patients to be shipped from one computer to another in a reliable and computable manner. The information once transferred should be adequate to drive the local clinical decision support software, thereby helping to improve patient safety and optimize patient outcomes. We have presented a scale with good inter-rater agreement which can help implementers of healthcare standards to better understand the level of interoperability provided by standard specifications that they are considering implementing. This transparency, we believe, will help mitigate the risk of choosing a healthcare standard and in that regard will fuel adoption of standards in health IT solutions.

What's in a code?
Towards a Formal Account of the Relation of Ontologies and Coding Systems

Alan L Rector MD PhD

School of Computer Science, University of Manchester, Manchester, England M13 9PL

Abstract

Terminologies are increasingly based on "ontologies" developed in description logics and related languages such as the new Web Ontology Language, OWL. The use of description logic has been expected to reduce ambiguity and make it easier determine logical equivalence, deal with negation, and specify EHRs. However, this promise has not been fully realised: in part because early description logics were relatively inexpressive, in part, because the relation between coding systems, EHRs, and ontologies expressed in description logics has not been fully understood. This paper presents a unifying approach using the expressive formalisms available in the latest version of OWL, OWL 1.1.

Keywords:

knowledge representation, terminology, ontology, electronic health records, OWL

Introduction

Coding systems, such as SNOMED-CT [1] and the NCI Thesaurus [2] are increasingly being developed using "ontologies" represented in description logics or languages based on them such as OWL. Other groups, such as the Open Biomedical Ontologies (OBO) consortium in the basic biological sciences, are developing what they overtly describe as "ontologies" [1], many of which are implemented in OWL.

A major benefit of using description logics and ontologies to represent coding systems is purported to be the ability to infer logical equivalence between sets of codes and to classify codes automatically. However, that promise is still far from being realised routinely in practice. We suggest here that one reasons for the difficulty is that the relationship between "ontologies" and coding systems has not been clarified. We put forward here a procedure that clearly distinguishes between the ontology as a logical representation about the world and the code as a data structure, and show how different questions can be answered by each.

Throughout this paper we shall use OWL 1.1[2] as our representation language in the simplified Manchester syntax described in [3]. Exemplar ontologies are available on the Web.[3]

1 http://obo.sourceforge.net/

2 http://owl1_1.cs.manchester.ac.uk/

Requirements

The first question for this paper is: "What should a code represent?" Our basic requirements are to be able to express:

1. Individual "pre-coordinated" codes – *e.g.* the code for "head injury".
2. Clinical complexes common in many coding systems such as "head injury with/without intracranial bleed"[4].
3. Syndromes in two senses: a) well defined invariant combinations of conditions – *e.g.* tetralogy of Fallot – and ill defined variable combinations of symptoms – *e.g.* chronic fatigue syndrome.
4. Composite "post-coordinated" code expressions (what HL7 refers to as "code phrases").
5. The logical equivalence, or not, of alternative combinations of codes – *e.g.* tof identify "intracranial bleed" whether it occurs singly or as part of the complex "head injury with intracranial bleed".
6. Negation – definitely not having a condition and "absence" in the sense of negative findings such as an absent pedal pulse.
7. Formation of arbitrary "value sets" – sets of codes for use in particular situations.
8. The clinical dialogue.

Finally, we require that these requirements be met within a uniform logical framework for what constitutes a code, so that an inference engine or "classifier" can infer the subsumption hierarchy according to well specified semantics.

Framework: Data structures and ontologies

In a separate paper [4] we have argued that we need to consider information models at two levels:

- *Representations of the world* (or our conceptualisation of it) – "ontologies" and formal logical statements about patients, their disease and treatments, etc. The criteria for correctness is prediction of observations of the world.

3 http://www.cs.man.ac.uk/~rector/ontologies/whats-in-a-code/

4 In this paper we have sometimes substituted "bleed" for "haemorrhage" to conserve space in figures and formal expressions.

- *Models of data structures* – "information models" – which we use to specify which data structures are valid. The criteria for adequacy is that it sufficiently constrains data structures that those produced by one system can be correctly processed by another.

We argue that the task for information systems is: a) to begin with a representation of our understanding of the patient's situation in the world – the level of the ontology, b) to transform it into valid data structures – messages or EHR fragments – for storage and/or transfer to other systems, and then c) to re-interpret these data structures to derive representations of statements about the world – again at the level of the ontology Furthermore, we wish to perform these transformations with no, or only well defined, loss of information. These transformations are shown diagrammatically in Figure 1.

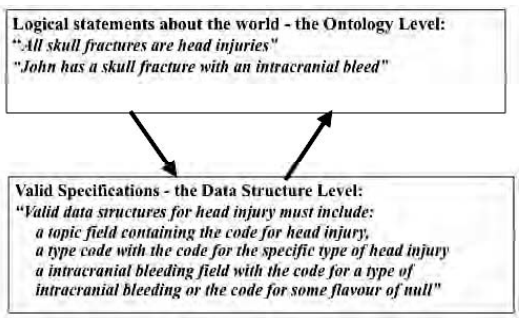

Figure 1 – Relation of ontology about the world and specification of valid data structures

Codes, data structures, and ontologies.

We argue that, although they may be derived from ontologies, "codes" are themselves data structures. An important reason to develop ontologies is to support coding systems, but the ontologies and the coding systems are distinct. Coding systems derived from ontologies may be thought of as "meta-models" of the underlying ontology – *i.e.* as models of the representation of the ontology in which each individual in the coding system represents the representation of a class in a particular formalisation of an ontology.[5] In hierarchical coding systems, the hierarchical relation – which we will here term "has_sub/is_sub_of" – reflects that subsumption (superclass-subclass) relationship in the underlying ontology.

The relationship between the ontology and the coding system derived from it is shown in Figure 2: each individual (dot) in the coding system represents a class (oval) in the ontology from which it is derived. The individuals (dots) in the ontology represent cases of the condition, or more precisely patient situations including those conditions.

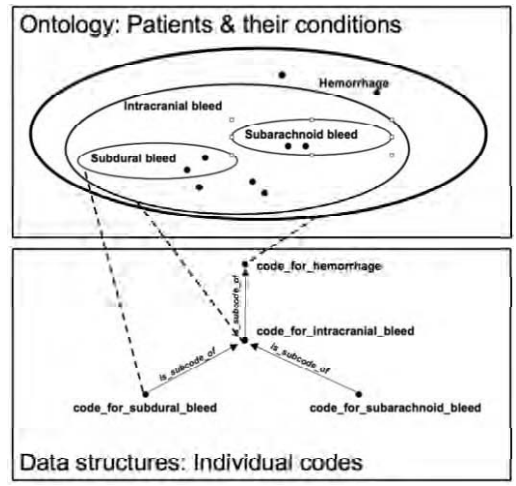

Figure 2 – Relation of ontology to codes. Each class in ontology corresponds to an individual code.

Note that the classes in the ontology and the codes in the coding system have very different characteristics. The ontology is "open". There are an indefinite number of possible subclasses of cases in the ontology – and an indefinite number of different ways of classifying the world. By contrast, the coding system is "closed". It consists of enumerated lists of codes, in some cases with enumerated lists of possible qualifiers. For example, in the above schema, there might be many descriptions for intracranial bleeds expressible in the ontology, but the only two for which we have codes in this limited coding system are "subarachnoid bleed" and "subdural bleed".

Ontological interpretation of codes

In discussing the ontological interpretation of codes, it is useful to deal with two cases which, following SNOMED, we shall term "findings" and "observables". "Findings" are things that apply to only some patients – *e.g.* diseases, injuries, symptoms etc. The existence of a "finding" is significant information, regardless of its detailed description. "Observables" are characteristics of all patients but with different values or states – values measured by laboratory tests, examinations, or other means. For example, only some patients have head injuries. The presence of a head injury is information. By contrast, all patients have a serum potassium concentration; the information is in the *value* of that concentration.

Case 1: Findings and clinical situations

An "ontology" in the narrow sense, represents the fundamental entities in a domain and the relations between them. In clinical medicine, these entities include anatomical structures, pathophysiological processes, organisms, cells, cognitive processes, etc. Authors such as Smith [5] advocate confining the word "ontology" to this narrow scope.

However, a major function of clinical knowledge is how these basic phenomena are organised into more complex entities with clinical significance – "macrocytic anaemia", "head injury without intracranial bleeding", "grade II stage

5 This is very roughly the relation of the SNOMED-CT "distribution form" to the underlying description logic form

1 carcinoma of the breast", etc. Clinical coding systems typically reflect this higher level of organisation. To ascribe a code to a patient is to say that the patient has (or in some cases does not have) the complex conditions indicated.

OpenGALEN used the term "ClinicalSituation" to define classes of such complexes [6] . They correspond roughly to what SNOMED-CT has termed "Context Dependent Entities" and it has recently rechristened "situations"[6] and are related to what Smith terms "Spans" [5].

Figure 3 gives examples of a simple representation of pathophysiological entities and classes of clinical situations in OWL. Note that many of the classes of clinical situation contain only a single condition. "Wrapping" single conditions in "Situations" in this way may seem redundant. However, it provides the uniform structure needed to support uniform automatic classification as required. To each of these classes of situations there corresponds a code, hi_s_code, sfx_s_code, etc. organised in a hierarchy that mirrors the subsumption hierarchy for the classes of situations as indicated in Figure 2.

HI_S = Situation THAT includes SOME Head_injury.
SFx_S = Situation THAT includes some Skull_fracture.
…
ICB_S = Situation THAT includes SOME Intracranial_bleed.
SDB_S = Situation THAT includes SOME Subdural_bleed.
HI_ICB_S = Situation THAT includes SOME Head_injury
AND
includes SOME Intracranial_bleed
…
Not_ICB_S =
Situation THAT not (includes SOME Intracranial_bleed).
HI_Not_ICB_S =
Situation THAT includes SOME Head_injury AND
NOT (includes SOME Intracranial_bleed).
…

Figure 3 – Example definitions of "situations" in OWL (Abbreviated names correspond to labels in Fig 5)

Case 2: Observables, codes and values

"Observables" are qualities of patients that are present in all patients and whose values or states are determined by observation – often by means of laboratory tests or physical examination. Typically, observables are represented by a "code-value pair". However, as often noted, an observable plus its value – *e.g.* "<Serum potassium, elevated>" – can be equivalent to a finding – "elevated serum potassium". We therefore propose an interpretation in the ontology that makes this equivalence apparent following the example in Figure 4:

Whereas for findings a single code is interpreted in the ontology as a "Situation", for observables, it is usually a code-value pair, *e.g.* "<serum_potassium_code, elevated_code>", that is interpreted as a "Situation". However, not uncommonly there is also a code assigned to the entire Situation, especially when a qualitative symbolic value such as "elevated" is involved, *e.g.* in Figure 4, the class of situations involving elevated serum potassium, ESP_S, and the corresponding code esp_s_code. To determine if the code-value pair and single code are equivalent merely requires interpreting each according to their meanings in the ontology and then using the reasoner to determine if the two meanings are equivalent.

Ontological Level:
ESP_S = Situation THAT includes SOME
(Serum_potassium THAT has_state VALUE elevated)
PQ5_S = Situation THAT includes SOME
(Serum_potassium THAT has_quantity VALUE
[5.1 mMolPerL]
Corresponding coded representation:
For code-value pairs: <serum_potassium_code, elevated_code>
For Situations: pq5_s_code, esp_s_code

Figure 4 – Ontological representation and corresponding codes for example observable

Consequences: Addressing the requirements

Of the requirements in the introduction, the proposed framework meets requirements 1-3 directly. As indicated in the examples in Figure 3, pre-coordinated codes, complexes, and syndromes are treated uniformly. The extension to qualifiers and post-coordinated codes (requirement 4) is straightforward and omitted for reasons of space. Requirements 5-8 are more subtle and are discussed below.

Classification and equivalence (requirement 5)

Is a patient who is assigned the code-value pair "<serum_potassium_code, elevated_code>" the same as a patient assigned the single finding code "esp_s_code"? Is a patient who is assigned separately the codes for "Situation THAT includes SOME Head_injury" (hi_s_code) and "Situation THAT includes SOME Intracranial_bleed" (icb_s_code) separately equivalent to a patient that has assigned the single code for "Situation that includes some Head_injury AND includes SOME Intracranial_bleed" (hi_icb_s_code)?

In the proposed framework, all such questions are answered by re-interpreting the codes as representations in the ontology and then comparing these representations, using an appropriate classifier where necessary. In the case of the equivalence of a code value pair and the corresponding finding code, the answer is obvious, since the interpretations as expressions in the ontology are identical – see Figure 4.

In the case of comparing several separate findings of single conditions with a single finding of those conditions combined, the answer follows naturally from the notion of a "clinical situation". If each patient can have only one "situation" at any one time (perhaps as observed by a given observer), then we need only form the conjunction of the criteria and compare the result. This can be done manually for simple lists, or the inference engine can be used for more complicated cases.

6 Kent Spackman, Personal communication, 2006.

For example, to determine if patients with "head injury" and "no intracranial bleed" coded separately are equivalent to patients with the single code for "head injury without intracranial bleed", first interpret the codes to describe a patient or class of patients at a particular time:

(Patient THAT at_time SOME Time_point)
has SOME
(Situation THAT includes SOME Head_injury) AND
has SOME
(Situation THAT NOT (includes SOME Intracranial_bleed).

Because a patient can have only one situation at one time, the classifier will recognise that the second Situation is redundant and find that this is logically equivalent to:

Patient at_time SOME Time_point)
has SOME
(Situation THAT includes SOME Head_injury AND
NOT includes SOME Intracranial_bleed).

The axiom that each patient at a given time can have only one situation is captured by the generic axiom in OWL:

(Patient at_time SOME Time_point) has MAX 1
Situation

Note that this axiom holds at the level of the ontology but not at the level of codes. It is not true that a patient can be ascribed only a single code in an EHR or message. It is true that there can be only one clinical situation for a given patient at a given time (as determined by a single observer).

Dealing with negation (requirement 6)

Negation of a finding – "not any"

Many codes represent classes of situations that involve a patient *not* have certain findings. Examples in Figure 3 include "No intracranial bleed" (Not_ICB_S) or "Head injury without intracranial bleed" (HI_Not_ICB_S). The classes of findings in these cases would best be defined by analogy with "patients who do not have *any* intracranial bleed".

Correct classification of negation manually without formal inference is difficult. The result of applying the classifier to an extended set of definitions based on Figure 3 is shown in Figure 4. This achieves the correct results automatically. For example, "No intracranial bleed" (Not_ICB_S) is a kind of "No subdural bleed" (Not_SDB_S) rather than vice versa. This is an example of the rule that negation inverts the kind-of hierarchy. If "B is a kind of A" – *i.e.* "all Bs are As" – then "NOT A is a kind of NOT B" – *i.e.* "all non-As are non-Bs".

However, note that the negation in Figure 3 applies to the entire criterion "includes SOME Intracranial_bleed" rather than to "Intracranial_bleed" itself. To say "Situation THAT not includes SOME Intracranial_bleed" means "the situation does not include *any* intracranial bleed", as intended. By contrast, to say "Situation THAT includes SOME NOT Intracranial_bleed" is to say that "the situation includes *something that is not* an intracranial bleed" – a different statement altogether.

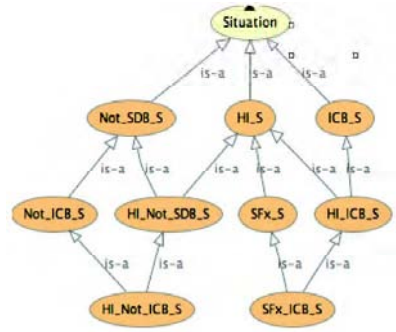

Figure 5 – Fragment of logical classification of complexes in Figure 3as determined by the OWL classifier (abbreviations follow pattern of Fig 3).

Negative findings and negative observables – "some not"

In most cases negation follows the example of intracranial bleeding above. However, there is a group of what are often referred to as "negative findings" that cause confusion.

The classic example is "absence of pedal pulse". Such rubrics are fundamentally ambiguous. Does it mean "Absence of any pedal pulse" or "Absence of some pedal pulse". In the first case, we would expect it to imply the absence of all pedal pulses – *e.g.* "absence of dorsalis pedis pulse", "absence of posterior tibial pulse", etc. We would therefore expect the hierarchy to be inverted as for types of intracranial bleeding. "Absence of any pedis pulse" would therefore fall under "absence of dorsalis pedis pulse" in the hierarchy.

However, in the second case, if we mean "Absence of some pedal pulse", we would expect the reverse. The "absence of the dorsalis pedis pulse" is certainly an example of the "absence of *some* pedal pulse", so we would expect "absence of dorsalis pedis pulse" to fall under "absence of some pedal pulse". The hierarchy would not be inverted.

The cleanest way to deal with this case is to use the ontological interpretations as shown in Figure 6. The first, for the absence of *any pedal pulse,* is analogous to the usual negation of situations in Figure 5. The second, for the absence of *some* pedal pulse, deals with the special case of "negative findings".

Absence_of_any_pedal_pulse = Situation THAT NOT (includes SOME Pedal_pulse).
Absence_of_some_pedal_pulse = Situation THAT excludes SOME Pedal_pulse
Preferred property axiom: excludes = NOT includes
OWL 1.1 property axiom: DISJOINT excludes includes

Figure 6 – Absence of any vs Absence of some

The scope of the negation in the second case is critical. In the definition of "Absence_of_some_pedal_pulse" the negation is included in the definition of the property, "excludes" and affects just that property, whereas in the definition of "Absence_of_any_pedal_pulse" it negates the entire restriction "includes SOME Pedal_pulse".[7]

Unfortunately, no current description logic implements the constructor for negating properties, although it is known to be tractable [7]. OWL 1.1 implements a slightly weaker construct, disjoint properties, as shown in the "*OWL 1.1 property axiom*", which gives the same results in except in cases involving double negation.[8]

Theoretically, the OWL 1.1 solution is the best approximation that can be implemented currently, but because it has just become available, there is little experience with it in practice. An alternative construct, available in most formalisms with which there is more experience, is to regard "having a pedal pulse", "having a dorsalis pedis pulse" etc. as "observables" with possible values "detectable" and "NOT detectable" as shown in Figure 7. This leads to correct classification but is arguably less faithful to the intended meaning.

```
Absence_of_some_pedal_pulse =
 Situation THAT includes SOME
  (Having_pedal_pulse THAT has_state SOME (NOT
Detectable))
```

Figure 7 – Alternative representation for negative findings

Value sets and faithfulness to the clinical dialogue (requirements 7 and 8)

Whereas equivalence of meaning can only be addressed by re-interpreting the information structures, including codes, into the ontology, specifying valid value sets and a faithful representation of the actual clinical statements made can only be made in terms data structures and codes themselves.

Value sets are closed lists of codes or tightly specified code phrases. While we can talk about requiring "only the code for head injury and none of its subcodes", at the ontological level, we cannot talk about the "all cases of head injury" without including all cases of all kinds of head injury. The process of specifying code sets and binding code sets to health records is discussed in detail in a separate paper [4].

Similarly, on the one hand, we want the *meaning* for a patient of the two statements – "This patient has a head injury" and "this patient has an intracranial bleed" – to be the same as the meaning for a patient of a single statement combining the two conditions. On the other hand, for purposes of clinical responsibility and documenting the clinical dialogue, we want to keep track separately of each statement made about the patient in the form in which it was made. For example we may want to record who made which statement, when, why, etc. This can only be done at the level of the codes and data structures where the statements are distinct, not at the level of the ontology where their meanings are indistinguishable.

7 In standard predicate logic notation, the difference is between ∃y. PP(y) & includes(s,y) and ∃y . PP(y) & includes(s,y).

8 The difference between "includes = NOT excludes" and "DISJOINT includes, excludes" is that in the case of true negation, we can infer that something not included is excluded, where in the case of mere disjointness we cannot.

Conclusion

This paper presents two key ideas: a) That codes should be regarded as individual data structures which can be interpreted in terms of meanings in a separate ontology about patients and their conditions, and b) that the ontology should be structured in two layers: a layer of kernel concepts – conditions, anatomy, etc – and a layer of "clinical situations" which describe classes of patient states at a particular times as viewed by particular observers. It suggests that both codes for "findings" and code-value pairs for "observables" should be interpreted as representing classes of situations in the ontology. It shows how these notions can be used to provide a unified framework for dealing with the questions of equivalence of the meaning of negation. An account of patients' situations, the conditions for validity of data structures conveying information on those situations, and the dialogue about those patients' care requires taking account of both the level of the ontology and the level of data structures and codes.

Abstract

There is an increasing need for updated and harmonised health care classifications and coding systems to allow international comparisons and cooperation for instance for population based WHO indicators, Electronic Health Record safety, trans border migration of population, case mix and procedure payment. It is not feasible to propose a standardisation of the linguistic expressiveness of different health care professionals and of the citizens. Natural language expressions show inconsistencies and ambiguities as assessed by biomedical ontology driven tools. In order to build a road towards standardisation the European Standard Body CEN has stated that it was not possible to convince the different European member states using different national languages to agree on a reference clinical terminology as Snomed-CT or to standardise a detailed language independent biomedical ontology. It has developed since 1990 an approach named categorial structure as a step standardising only the terminologies model structure. The categorial structure for terminologies of human anatomy currently in the phase of final approval is presented as a methodology for bridging between classifications and coding systems and biomedical ontology on the way to semantic interoperability between different languages, legacies and goals.

Keywords:

classification, coding system, terminology, ontology, standards, categorial structure, anatomy

Introduction

Interoperability – the fact that data produced in one Information and Communication Technology (ICT) system is readily useable in another ICT system – has by now matured to provide reliable operational platforms for technical and functional aspects. In healthcare or for e-Health, content interoperability now emerges as a top challenge under the name of semantic interoperability.

If we defined semantic interoperability as ìthe ability for information shared by systems to be understood at the level of formally defined entities, so that the receiving system can process the information effectively and safelyî [1] it is easy to understand that it is a major issue for most health care organisations and countries.

There is an increasing need to address national and international comparisons and cooperation across the most advanced and less developed organizations or countries for instance for population based WHO indicators, Electronic Health Record safety , trans border migration of population, case mix and procedure payment et.

Unfortunately, clinical terminological systems, classifications and coding systems have been developed by independent, divergent and uncoordinated approaches which have produced non reusable systems on overlapping fields for different needs. For some decades several broad pre-coordinated or compositional systems have been proposed to users targeting different goals. The most well known are the UMLS (Unified Medical Language System) [2], SNOMED international [3], Read Clinical Classification Version 3 [4], LOINC [5] for clinical laboratories, DICOM SDM [6] for imaging, SNOMED CT [7] and Convergent Medical Terminology (CMT) [8].

On the other hand, most of developed countries have kept on maintaining, updating and modifying their own coding systems for procedures, as well as national adaptations of ICD, in order to manage and to fund their health care delivery. The most significant efforts were done in Australia with ACHI (Australian Classification of Health Interventions) or ICD10-AM [9], in Canada with the Canadian Classification of Health Interventions (CCI) [10] developed by the Canadian Institute for Health Information (CIHI) and in France with CCAM (Classification Commune des Actes Médicaux) [11][12].

Natural language expressions show inconsistencies and ambiguities as it can be assessed by biomedical ontology driven tools [13] which have been enabled by advances in computer science, artificial intelligence, linguistics and philosophy. These are based on terminology server architecture making available knowledge bases representing multi-hierarchies of concepts associated by semantics subsuming the logical meaning of their relations and automated language generation. These knowledge repre-

sentations are called *biomedical ontologies* [14] [15], – a term coming from metaphysics – but are in fact formal logic using mathematical expressions.

These representations have been supported by specific software tools and natural language processing techniques, including the linkage of lexicons from different national languages [16] to the knowledge representation. The most important achievements are GALEN (Generalised Architecture for Languages, Encyclopaedias and Nomenclatures in Medicine) [17], FMA (Foundational Model of Anatomy) [18] [19]. For biomedical terminologies and OBO (Open Biomedical Ontology) which provides an interesting training process [20].

On the other hand, the standardisation in health informatics started in the US with the HL7 user group and was formalised by 1990 in Europe with CEN (ComitÈ EuropÈen de Normalisation) TC 251 and internationally in 1998 with ISO (International Standard Organisation) TC 215. The process aimed to the electronic health record of the patients (EHR) has opened the way to divergent initiatives encompassing information models (HL7 Reference Information Model RIM, CEN Continuity of care, et.) messages, architecture (HL7 Common Document Architecture CDA, CEN EHRcom, et.), security, context (Templates or Archetypes, et.) and the forest of ìpragmaticî or ìreenceî clinical terminologies. Finally WHO has initiated the revision of ICD which will take advantage of such achievements to enhance the interoperability of products of the family of international classifications (ICD, ICF and classification of procedures) by the year 2011.fer

We address the standard approach for biomedical terminology elaborated and developed by the European Standard Body CEN TC 251 WG2 (Comité Européen de Normalisation Technical Committee 251 Working Group 2) named categorial structure in part 2 and the last standard in the state of final approval on terminologies of human anatomy [21] in part 3 .We finally discuss the role of this standard approach on the road from bridging between classifications and coding systems of biomedical terminology to a more complete semantic interoperability based on a shared biomedical ontology.

CEN Categorial Structure Standard approach

Rationale

As a prerequisite it was clearly stated at the beginning of the CEN standard process that it was not realistic to impose within Europe a standard terminology to health care professionals even when saying it is a reference terminology or a pragmatic terminology. The 2 top arguments supporting this point were that European countries are speaking different natural languages and that different health care professionals within the same natural language are not using the same meanings for the same terminology statements. The increasing role of citizens in health care has hampered this point for they currently use natural language different statements to mean the same things.

The CEN categorial structure standard approach was based on advances in computer sciences, artificial intelligence, linguistic and philosophy allowing to define a new approach to support unambiguous exchanges of meaning through computers named biomedical ontology [14-15].

We have proposed in a FP 6 European Union seminar [22] to define biomedical ontology as: a representation of some pre-existing domain of reality which

1. reflects the properties of the entities within its domain in such a way that it obtains a systematic or according to rule correlation between reality and the representation itself and the non ambiguous comparison between different formal representations of the reality
2. is intelligible to a health care domain expert,
3. is formalised in a way that allows it to support automatic information processing.

CEN has considered not possible to standardise the clinical knowledge in an only one biomedical ontology which could support one reference clinical terminology or different types of clinical terminology due to the volume of terms ,the quickly evolving size and the international and not only European production and use of clinical terminologies.

Definition

As a consequence the CEN categorial structure was defined within some linguistic variations [23-25], as a minimal set of health care domain constraints to represent a biomedical terminology in a precise health care domain with a precise goal to communicate safely.

It is a definition of a minimal semantic structure describing the main properties of the different artefacts used as terminology (controlled vocabularies, nomenclatures, coding systems and classifications), a model of knowledge restricted to:

1. a list of semantic categories
2. the goal of the categorial structure
3. the list of semantic links between semantic categories authorised with their associated semantic categories and
4. the minimal constraints allowing the generation and the validation of well formed terminological phrases.

This methodology has been applied by CEN for the coding systems and classifications of surgical procedures [24], clinical laboratory [26] and by ISO for nursing diagnostics and procedures [27]. The standardisation processes are on going for medical devices, medicinal products, continuity of care and anatomy.

The categorial structure for terminologies of human anatomy: Catanat

To conform with the CEN standard terminologies of human anatomy we shall describe the 4 elements of an anatomical categorial structure.

The Anatomical Categories

The anatomical categories are defined as types of anatomical entity shared by all the individual instances in existence in the present, past and future.

For example, the anatomical category liver is instantiated by this liver and all individual livers in existence in the present, past and future.

Anatomical categories may be more or less general. Where one anatomical category is subsumed by another, the "is_a" relation is asserted to obtain between the more specific and the general anatomical entity [21].

To conform with the CEN standard terminologies of human anatomy we shall use as root one of the 19 anatomical categories defined in [21] and adapted from the FMA [18-19] and the hierarchy defined in [21] and adapted from the FMA [18-19] as well.

The following 19 anatomical categories are defined within their hierarchy in [21]: Physical anatomical entity, Immaterial physical anatomical entity, Anatomical space, Anatomical surface, Anatomical line, Anatomical point, Material physical anatomical entity, Body substance, Anatomical structure, Cell, Organ, Cardinal organ part, Portion of tissue, Cardinal body part, Body region, Organ systems, Anatomical cluster, Anatomical set, and Anatomical junction.

We give here some examples from [21].

Physical anatomical entity:

anatomical entity which has a spatial dimension e.g. organ, surface, apex of the orbit.

Immaterial physical anatomical entity:

a physical anatomical entity which has no mass e.g. diaphragmatic surface of left ventricle.

Anatomical space:

immaterial physical anatomical entity which has spatial dimension of value 3 e.g. thoracic cavity.

Anatomical line:

immaterial physical anatomical entity which has spatial dimension of value 1 e.g. inferior margin of liver.

Anatomical point:

immaterial physical anatomical entity which has spatial dimension of value 0 .Apex of heart.

Material physical anatomical entity:

physical anatomical entity which has a mass e.g. liver, cell nucleus.

Body substance:

material physical anatomical entity which has no inherent shape e.g. portion of blood.

Anatomical structure:

material physical anatomical entity which has inherent shape and is generated by coordinated expression of the organism's own structural genes e.g. thorax, tibia.

Organ

anatomical structure, which consists of a maximal collection of cardinal organ parts so connected to one another that together they constitute a self-contained unit of macroscopic anatomy, morphologically distinct from other such units e.g. heart, urinary bladder.

Cardinal organ part

anatomical structure, which consists of two or more portions of tissue, spatially related to one another in patterns determined by coordinated gene expression; together with other contiguous cardinal organ parts it constitutes an organ e.g. upper lobe of right lung, shaft of humerus.

Cardinal body part

anatomical structure, which has as its parts the most complete set of diverse subclasses of organ and cardinal_organ part spatially associated with either the skull, a segment of the vertebral column or a complete set of bones of the appendicular skeleton; it is partially surrounded by skin and forms a distinct morphological subdivision of the body; together all cardinal body parts constitute the body e.g. head, neck, trunk, upper limb.

Body region

sub volume of a cardinal body part demarcated by at least one fiat boundary e.g. femoral triangle, epigastrium.

Organ systems

anatomical structure which consists of organs predominantly of the same anatomical category, which are interconnected by zones of continuity e.g. alimentary system musculoskeletal system. Organ systems shall be distinguished from body systems based on function as endocrine or immune system.

Anatomical cluster:

anatomical structure which consists of a heterogeneous set of organ parts grouped together in a predetermined manner, but which do not constitute the whole or a subdivision of either a body part or an organ system e.g. joint, adnexa of uterus, renal pedicle..

Anatomical set

material anatomical entity which consist of the maximum number of discontinuous members of the same class e.g. set of cranial nerves, thoracic viscera.

Anatomical junction

anatomical structure in which two or more anatomical structures are in physical continuity with one another or intermingle their component parts.

Precise goal of the anatomical categorial structure

The goal of each anatomical terminology used in the terminology systems of health care and biomedical science shall be defined by the users to explicit the scope and the content of the categorial structure. This point must at least mention the situations and applications for which the categorial structure is intended and a statement on the limits of use, for example controlled vocabulary production for clinicians or comparison with another terminological system for coding centres.

List of the representations of anatomical relations between anatomical categories authorised by anatomical domain constraints

The representations of anatomical relations which shall be used when necessary to be conformant with the CEN standard are the 8 following anatomical relations plus the Is_a

anatomical relation defined in [21] and adapted from the FMA [18] [19].

has_part

Anatomical relation which holds between each anatomical entity of one to three dimensions in category A and some anatomical entity of the same dimension in category B such that if A has_part B there is a complement C which together with B accounts for the whole of A; for example, Stomach has_part fundus. Together with body and pyloric antrum, fundus accounts for the whole of Stomach.

A contained_in B

Anatomical relation which holds between each anatomical entity in category A contained in some anatomical entity in category B. The former is a body substance or an anatomical structure; the latter is an anatomical space. For example Urinary bladder contained_in pelvic cavity. Contained_in does not imply part_of. Although cavity of urinary bladder is part_of urinary bladder, urine part_of urinary bladder is an invalid assertion.

A adjacent_to B

Anatomical relation which holds between each anatomical entity in category A is adjacent to some entity in category B. Two anatomical entities of the same dimension are adjacent when they are spatially proximate, share no boundary or parts, and are separated by no further anatomical entities of the same dimension. For example Spleen adjacent_to stomach, Posterior surface of kidney adjacent_to anterior surface of quadratus lumborum

Adjacent_to which is adirectional may be qualified with the aid of qualitative anatomical coordinates such as anterior_to, posterior_to, superior_to, inferior_to, medial_to, lateral_to depending upon the value of the trajectory relationship; These qualifiers are directional and asymmetric.

A continuous_with B

Anatomical relation which holds between each anatomical entity in category A and some entity in category B when there is no bona fide boundary (real physical discontinuity) between the related entities and their parts. For example Arterial trunk continuous_with branch of arterial trunk

A attached_to B

Anatomical relation which holds between each anatomical entity in category A and some entity in category B when some of the parts of the entity in category A are continuous with some entity in category B across a portion of their maximal boundary which the related entities share. For example each patellar ligament is attached_to the patella at a narrow area along the lower margin of the latter and also to the tuberosity of the tibia, or the circumference of the tympanic membrane is attached_to bones of the skull forming the external auditory meatus.

has_dimension

Anatomical relation which relates an anatomical entity to the number of its spatial dimension; for example wall of stomach has_dimension 3

has_shape

Anatomical relation which relates an anatomical entity to its three dimensional shape. For example oesophagus has_shape hollow cylinder

has_boundary

Anatomical relation which relates categories of anatomical entities of one to three dimensions to categories of immaterial physical anatomical entities of one dimension lower, called bounding anatomical entities. Such bounding entities delimit anatomical entities of one, two or three dimensions from one another. A boundary may be bona fide or fiat. A bona fide boundary of an anatomical structure is a real physical discontinuity. A fiat boundary is a virtual plane or line such as those that demarcate the oesophagus from the stomach. For example cavity of stomach has_boundary internal surface of stomach.

The practical application of boundary information is critical for example to processes of automatic image segmentation and to the analysis of volumetric datasets.

List of minimal anatomical domain constraints

The list shall contain the different anatomical relations and the different related anatomical categories which are valid and necessary for the precise goal of an anatomical categorial structure.

As a summary to be conformant to the CEN standard any biomedical terminology using a terminology of human anatomy shall explicit its anatomical categorial structure which shall provide the information described in 1, 2, and 3 within part **22** and shall be conformant to the following three rules:

1. An anatomical categorial structure shall have as root node any anatomical entity from one anatomical category listed in this CEN European standard [21].
2. An anatomical categorial structure shall make precise the level of granularity of the classes of anatomical categories used as described in this CEN European standard [21].
3. An anatomical categorial structure shall use when necessary the anatomical relations only as described in this CEN European standard [21].

Discussion

- The first issue to address on the road from divergent initiatives on health care classifications and coding systems to semantic interoperability is the role of standard.

There are at least 3 different ways to address the standard issues.

The first way can be called the way of the Family of classifications used since the nineteenth century by the International Classification of Diseases (ICD) and now by the WHO Family of International Classifications (FIC). This is the rationale behind the ICD eleventh revision and the International Health Terminology (IHT) Standard Development Organisation (SDO) [28] currently under creation and based on Snomed CT.

Unfortunately this model faces a lot of drawbacks Let us stress the most important ones.

First the size of knowledge is increasing so quickly with biomedical research and technology developments that maintenance and updating is huge and never quality assured. It is a bottomless permanent work based on divergent individual and time related expert opinions when there is no open and transparent access to a commonly agreed and shared knowledge representation.

On the other hand the multilingualism is a major constraint and multi-translation a very important effort not only across national languages but as well across different specialists and researchers using one type or another of biomedical terminology for different situations.

The second way can be called the biomedical formal ontology and the biomedical ontology tools coordinated with natural language processing and web based tools[17,19-20]. This way provides a new perspective to semantic interoperability by de-multiplying the workload organised by disseminated social computing.

Unfortunately this perspective is at its beginning and can only fulfil the needs step by step in specific areas [13,20].

Between these 2 trends the international standardisation organisations have the responsibility to support or to build the road to increase semantic interoperability as defined in [1].

This has been the choice of the CEN European standard body within Technical Committee 251 and ISO Technical Committee 215 for information model, network infrastructure, architecture and messages, security and terminology. For terminology CEN has proposed a third way between the Family of classifications and the biomedical formal ontology named the Categorial Structure:

The Categorial structures as presented in part 2 cannot be considered separately from the other standards of this framework.

- The second issue is how this type of standard can work.

The categorial structure CEN standard for terminologies of human anatomy shall be used for any biomedical terminology using anatomical terms under the framework of interoperable communications between different ICT or e-Health systems including an Electronic Health Record (EHR).

It must be communicated by the e-Health sender system to the e-Health receiver system. The template sent shall contain the 4 parts of the categorial structure as developed earlier and more precisely in [21].

The intention is not to insure a full semantic interoperability defined in [1] as if Users of System B are able to use information acquired automatically from System A with equivalent meaning to its local data.

The intention is to reach an intermediate interoperability defined in [1] as if System A is able to send information automatically to system B, but System B (and Users B) can only interpret the meaning from the perspective of users A and System A.

As a consequence any biomedical terminology using the FMA (model and terms) is conformant to the CEN standard but any biomedical terminology based on a categorial structure defined as in [21] by a subset of FMA will be as well. This choice faces the criticism that the anatomical relation representations are not exhaustive and that a biomedical terminology may need to use additional relations not part of the standard.

Of course the alternative should be to use the whole FMA (model and terms) as the standard.

The Foundational Model of Anatomy (FMA), initially developed as an enhancement of the anatomical content of UMLS, is the biomedical domain ontology of the concepts and relationships that pertain to the structural organization of the human body. It encompasses the material objects from the molecular to the macroscopic levels that constitute the body and associates with them non-material entities (spaces, surfaces, lines, and points) required for describing structural relationships. The disciplined modelling approach employed for the development of the FMA relies on a set of declared principles, high level schemes, Aristotelian definitions and a frame-based authoring environment. The FMA is applied as the reference ontology in biomedical informatics for correlating different views of anatomy, aligning existing and emerging ontologies in bioinformatics and providing a structure-based template for representing biological functions.

On one hand CEN is not considering to be entitled by its charter of multinational and multilingual European organisation to dictate the terms to be used by health care professionals, administrators and citizens within Europe. On the other hand this new categorial structure is more detailed, precise and prescriptive than the previous ones [23-27] and for the first period of the standard (5 years) it has been decided that the incentive to share the same anatomical terminology by an increase use of at least a part of FMA was sufficient for the time being.

- The third issue is the relation between the CEN standard categorial structures and a biomedical ontology as defined in [22].

They fulfil the point 2 and partly the point 1 of the biomedical ontology definition by giving the categories and the relations between the categories as we have shown earlier for Anatomy but they do not allow a systematic (i.e. according to the precise rules of description logic) correlation between representations and between the representation and the reality. Finally they are not formalised enough to support automatic information processing. For these reasons they must be considered as a milestone on the road to more complete semantic interoperability.

- The last issue is how this categorial structure approach can facilitate the road towards formal ontology developments and applications.

The first categorial structures were defined for surgical interventions and clinical laboratory measurements which are occurrent events

The principles, anatomical categories, part relations and other structural relations adopted for the construction of the categorial structure for terminologies of human anatomy have been largely derived from the Foundational Model of Anatomy (FMA) [18]. This categorial structure [21] is a sensible move for it is a continuant present in most of biomedical and clinical terminologies for instance in surgical procedures terminologies [13]. It is intended to train more and more people to base their biomedical terminologies on a well formed biomedical ontology for Anatomy to decrease inconsistencies and ambiguity.

On the other hand this minimal structure separated from terminology artefacts gives a common framework to analyse them, their comparison, alignment, their gaps and inconsistencies. It is proposed as a methodology to demonstrate the need of a common worldwide full set of biomedical ontologies necessary to achieve a full semantic interoperability.

Acknowledgements

We wish to thank our partners in the CEN TC251 WG2 and terminology and biomedical ontology experts who commented and proposed useful modifications to Catanat and namely Alan Rector from University of Manchester and Barry Smith from the University at Buffalo.

Abstract

Knowledge management is one of the significant issues in this century. In medical informatics, the concept of ontology is an important current topic. In addition, there is great interest in knowledge acquisition from clinical data. When doctors use clinical information systems (CIS), their operation implicitly represents, to some extent, their thinking processes with clear reasons and goals according to their intent. If we can capture such resources in an appropriate representation, considerable empirical knowledge could be utilized in various research fields. With this prospect, the authors built an experimental CIS and a nodes-focusing tool for abstracting a summary of the clinical course being examined. The information model is based on a thinking process model, and data are represented in the ontological framework CSX. Then we showed the knowledge-abstracting procedures with this tool. Some domain experts and intern students showed great interest. The authors thereby concluded that such an empirical knowledge acquisition environment is useful for research, education, and so on.

Keywords:

intention, decision-making, clinical course, visualization, knowledge acquisition and representation, ontology

Introduction

As clinical information systems (CIS) extend their functionalities to support the practices of physicians and nurses in a more comprehensive and direct manner, the systems should be designed based on a profound understanding of clinical workflows. We think well-designed CIS can play a considerable part in the clinical practitioners' thinking process behind these workflows, and therefore CIS can provide a significant resource for empirical knowledge about clinical thinking process, by recording the *reasons, goals and intentions of medical interventions* in a semantically cohered data structure during clinical courses.

Knowledge can be represented in a net or hypergraph structure. Each node corresponds to each concept or piece of information, and each edge shows the meaning of the inter-relationship between nodes. As a clinical process ontology, this hypergraph must have enough capability to represent the facts or facets of the facts at point-of-care to acquire clinical empirical knowledge.

In general, a CIS requires several information models: at least one for a transaction and another for clinical document representation, and they may be formulated as health IT standards [1, 2]. Now we propose another model for the thinking process. Those three refer to the same data in the same repository in a CIS to contain them in a semantically related structure of each model. In this sense, the structure of the information model is expressed as semantic inter-relationships among semantically defined data containers according to its model perspective. The differences of models depend on their perspectives, which then leads to different structures.

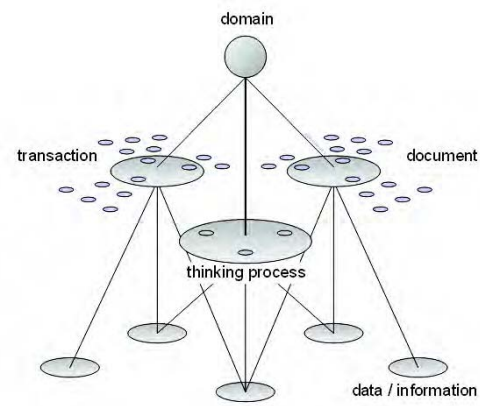

Figure 1 – Perspective variations in a domain

Of course a container may contain other containers when a structure is complex and the hierarchy is deep. An element in a container may be identified with a code of other terminology systems.

Smith et al. have asserted the significance of perspective in methodology axes, and the possibility of the representation of in a single framework that holds plural ontologies [3]. We agree because of our design policy that was based on 'perspective' in the sense of oriental philosophy [4], and because of our experience in research supported by grants from the Research on Health Technology Assessment,

Ministry of Health, Labor and Welfare, Japan from 2000 [5, 6].

To support plural ontologies in one system, we decided to utilize an ontological framework called CSX that we originally developed as a metamodeling environment [7]. Then we developed an experimental CIS based on the model of the clinical thinking process to capture clinical empirical knowledge. We also developed a node-focusing tool for abstracting a kind of partial graph of the clinical course being examined.

Methods and designs

The clinical thinking process model

Model outline

A clinical course model should have two aspects: the clinical course itself and the health care provider's thinking process at point-of-care. We had already developed the latter, as a *decision* process model, along with the problem-transition model known as a problem-oriented system (POS) or the problem-oriented medical record (POMR) [8]. Generally speaking, this model is an *intention* realizing process model; therefore, each *reason* in the thinking process and the *goals* of interventions are clearly delimited. One cycle of the thinking process in a clinical session (i.e., encounter) is illustrated in the following:

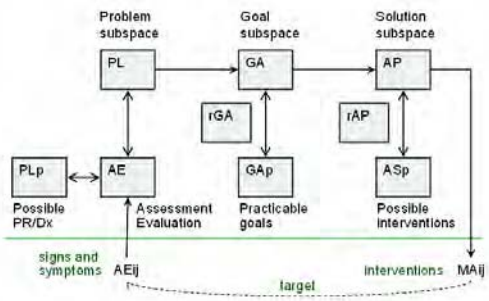

Figure 2 – The clinical thinking process model

The decision process is placed in three spaces: problem, goal and solution. Each space contains elements that represent an 'assorted step' in the thinking process. Each is a container that holds child objects (e.g., each problem or disease (PRi) in 'ProblemList' (PL), and each assessment and evaluation (AEi) in 'AssessmentEvaluation' (AE)). AEi may contain a physician's inference and/or reasoning for diagnoses, with referring atomic data of signs and symptoms. These are called S/O in SOAP in POMR. The Goal (GA) is decided due to PRi or PL with reasons of each goal item (GAi), and those reasons are held in reason of GA (rGA). The action plan (AP) consists of some protocols and/or particles of interventions (ASi/MAi). They are adopted to gain GA with reasons held in reason in rAP.

Then, any clinical course is composed of a series of clinical sessions, where each phase connects to another with a screw structure or spiral binding through PL as an axis.

In this research, we carried out the implementation by focusing mainly on problem list and problem transitions, and on the problem-intervention relation.

Some requirements for a representation framework

The representation framework should have the capability (i) to represent the hypergraph structure and to support n-arity, (ii) to discriminate between semantic roles and semantic relations', and (iii) to represent perspective for handling plural ontologies. At the same time, these are the reasons for adopting the ontological framework CSX.

Those three are coupled to each other in knowledge operation and system functions. A complicated semantic graph becomes more complicated because there are multiple interrelationships among nodes with plural perspectives of plural ontologies. Consequently, the usual semantic link does not work well when finding an appropriate path to a target node.

One has to take a notice of the degree or valence of the node, i.e., number of arcs of a node, with respect to data processing, because they may become too much tasking to control a 'path walk in a knowledge graph. Simply stated, one needs a strategy to find out correct 'semantically grouped links' within an appropriate processing time. This is not clearly known as yet because, in some sense, each application module in CIS knows' all arcs and their target information objects. However, it is quite another story to find out the exact path to the target node from the starting node that has many arcs, and some arcs may belong to a different 'semantic group' i.e., semantic relation.

For example, there are elements in AE or PL or 'signs and symptoms' referred to and semantic roles of semantic relations among them: [cardiac silhouette size in thorax] (reason) conclude (object) [cardiac hypertrophy], [decreased ejection fraction] (reason) [oliguria] (reason) conclude (object) [dysfunctional pump], [[cardiac hypertrophy], [dysfunctional pump]] (reason) define (object) [cardiac failure]. Here, [] is a node, () is an arc, and the underlined is the meaning or scope of the 'semantic relation. In this sample, a relation represents predicate and an arc represents a 'semantic role as a deep case that is required in each predicate.

Therefore, one solution is that the separation of 'semantic link into semantic relation and semantic role. The ontological framework CSX provides this capacity.

The ontological framework CSX

The outline of this framework is as follows:

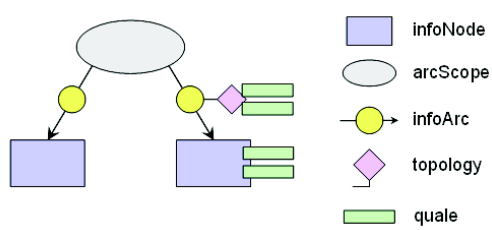

Figure 3 – The ontological framework CSX

O=<P, S, N, vr>, P{dm, sg}, S=<A..A, sg, id>, A=<N, N, T, sg>, N{C, Q, sg, id}(t), C{cs, ci, vr}, T{dr, cd, Q}, Q{dn, ms, ut, eq}, where O:ontology, P:perspective, dm:domain, sg:designation, id:identifier, S(arcScope):semantic relation that integrates A and represents the predicate or copula, A(infoArc):rhetorical role or semantic role in a semantic relation, N(infoNode):information object that represents thing or event, C:code that identifies what a element is, T(topology):represents the topological relationship between N, Q(quale):represents quantity/quality, vr:version, t:timestamp, cs:code system that defines the combination of code/content /designation, ci:identifier in cs, dr:direction, cd:coordinate, dn:dimensionality, ms: measure, ut:unit, and eq:equivalence.

S, A and N have the attributes of category and family. Those two attributes hold the value that represents the position of meaning in the ontological category. Please refer to Figure 1 and the preliminary works [5, 9].

Here, ontology means 'a framework or methodology that manifests concepts/entities and relationships between/ among them in the target world'; and, the representation of relationship is weighted in this research. On the other hand, building a vocabulary/concept repository is beyond the scope of this paper; thus, positively referring vocabularies are defined in terminologies, especially in C held in N.

Implementation scope in this paper

System environment

To evaluate our approach, we implemented an experimental CIS with two edit/browse windows (Disease/Problem Transition and Clinical Chart) and four supporting entry tools (problem/diagnosis, prescription order, laboratory order, and operation and procedure). Edit/browse windows were designed to imitate Japanese unique regulated forms of No.1 and No.2 respectively. In this system, controlled vocabularies and identifiers in following code systems are used: ICD-10 based disease code system, JLAC10 (resembles LOINC) based laboratory code system, HOT based drug code system, and operation/procedure code system for reimbursement. The history of the clinical course is output as xml defined for CSX, which is used as an input file for the nodes-focusing tool.

Visualization of clinical course and focusing

This tool is designed to facilitate the browsing of the whole image of a graph that illustrates a clinical course, then to abstract the nodes and arcs that are focused on according to the end users purpose. With this tool, the model of a clinical course or empirical knowledge from a certain case might be clarified, although it has large numbers of encounters in a very long course; for example, only four essential PLs and its transition illustrated in Figure 4. Such a summary would be found through the trial and error process of comparing, masking and tracking.

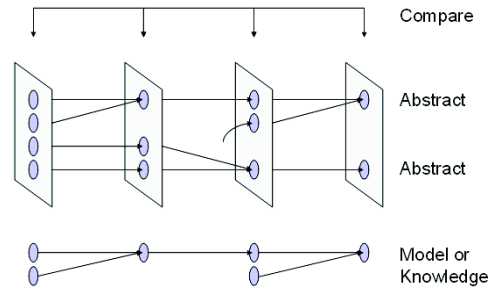

Figure 4 – Abstraction with nodes-focusing tool

Extracted data (or knowledge or pre-knowledge) is output as xml defined for CSX. The image of graph can also be output in JPG format.

Results

Disease/problem transition and relevant care information

The Disease/Problem transition window has a maximum of three panes. One pane view is for a usual Dx/PRi list, and the three-pane view (Figure 5) is for editing and browsing disease/problem transitions. In the three panes, an end-user can control the pane linking which one is connected or unconnected. The latter provides end-users with the capability to look discretely at problem lists.

The kinds of semantic roles in each PRi is automatically determined due to a partial graph between the PRi in the former PL and PRi in the latter PL: proceeded, diverged, converged, promoted, demoted, and terminated in semantic role A in CSX and transition or transmute in a semantic relation S in CSX.

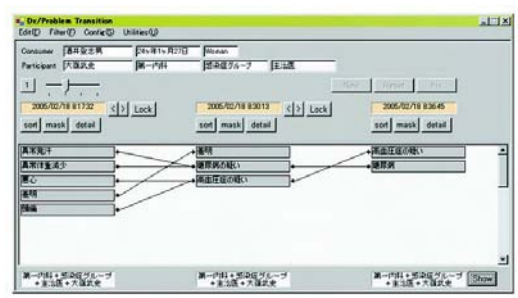

Figure 5 – Sample of the disease/problem transition window

Each PRi is selected in the problem/diagnosis entry tool by the end-user operation, often to be compiled with prefix and/or suffix. Then the PRi is inserted into the Disease/ Problem transition window when the problem/diagnosis selecting operation is fixed. Therefore, the PRi node has three codes in C held in N: main, prefix and suffix.

Each problem (again, including diagnosis) has the attributes ofpriority, activity and Basso Continuo. They are also editable in this window. Basso Continuo means the problem with the attribute influences other problems and their course, including the available interventions for those problems.

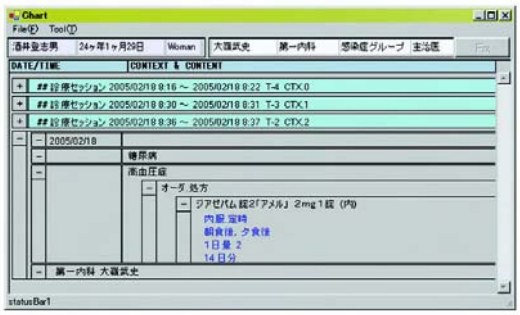

Figure 6 – Sample of the chart window

In the Chart window, interventions are semantically linked to a problem, as a 'reason or object in a sense of deep case in A; a 'cure or intervene in a semantic relation S. Of course, one can list various patterns in such a relation; for example, a single problem holds many interventions, a group of problems is linked to a set of interventions, and different problems hold the same intervention. All of them are implemented in the system, and the latter one is realized as an *alias* in the GUI. The application runs appropriate responses.

Highlighting significant clinical course

Figure 7 shows a sample of a bird's eye view of a clinical course in expressed in a graph.

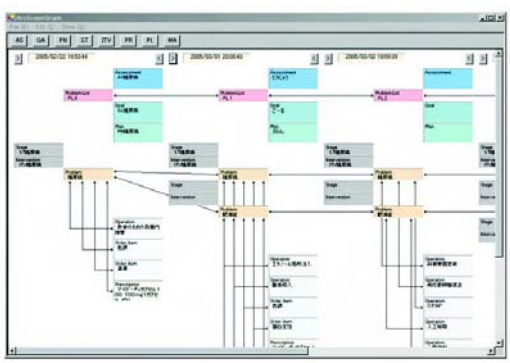

Figure 7 – Sample of a whole graph

The number of panes for each encounter is unlimited (or depends on the system environment). An end-user can control the pane linking in the same way as the Disease/ Problem transition window.

It is worth noting that the path tracking function is available. An end-user selects a start node, then selects the path walk policy, then clicks the extract button, and finally gets to the situation shown in Figure 8, for example.

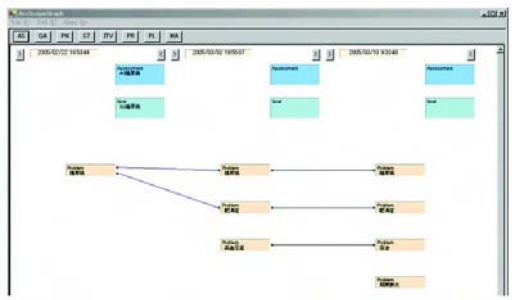

Figure 8 – Sample of a focused and abstracted

In this experimental implementation of the node-focusing tool, four kinds of tactics are independently available: start and end date, tracking direction (backward, forward, or both), code matching in problem (main code, whole codes, or any when linked), and selectable divergence walk (track whole path, track if targeted on Basso Continuo, or no track).

Discussion

Visualization and knowledge acquisition

This tool provides the visualization capability of a clinical course by focusing nodes and arcs on the various purposes of end-users. As it is enabled to trace the focused nodes and arcs through the crowd, it is obviously useful for case review, clinical research, clinical education, the creation of a new clinical path or the consideration of the revision of it, and variance analysis for financial management in a hospital. Using the visual tracing function, inexperienced residents or medical students could refer to experienced doctors' successful processes, which contributes to appropriate decision-making and therefore better outcomes. Hence, we believe this tool will help health care providers in certain cases, especially for the compromised patient.

Such advantages follow the output from the POMR system, a file is in xml format defined for CSX, and data represent the clinical course according to the ontological framework CSX.

Some functions might be insufficient but others can be added to this tool.

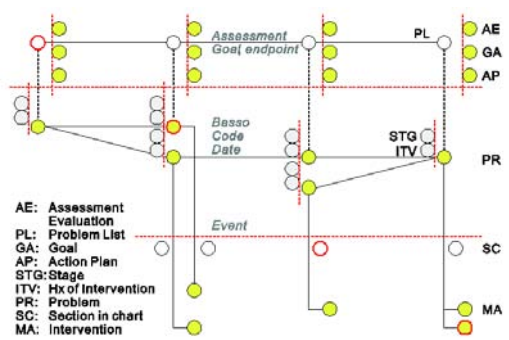

Figure 9 – Graph of clinical course data

In this framework, we used designations for entities and semantic relations that resemble or parallel ISO/CD TS 22789 in the implemented model, given the need for this experimental implementation.

Evaluation of the experimental implementation

Six domain experts (all were physicians and their subject was clinical trials) and a hundred of intern students showed great interest. When the authors showed medical students this tool, most immediately understood its idea. They also stated that they wanted to use this tool at clinical conferences, especially for complicated cases. Therefore, we believe that such an empirical knowledge acquisition tool is useful for clinical research and education.

Conclusion

We developed the experimental POMR based on the clinical thinking process model with the ontological representation framework CSX, which has the capability of handling plural ontologies, and the nodes-focusing tool for clinical course data in a hypergraph structure to capture and acquire or mine some portion of health care providers empirical knowledge at point-of-care, including their intent. Then some domain experts and intern students showed great interest. Therefore, the authors concluded that such empirical knowledge acquisition environment is useful for research, education and so on.

Abstract

To coordinate themselves, home care (HC) professionals use artifacts to keep a mutual understanding on their common activity: lightly structured charts written in natural language. Instead of trying to define a record to capture them, we want to focus on efficient indexing of this information. The use of a Domain Ontology was proposed. This paper explains how we built and implemented it. Three complementary aspects of the HC charts were analyzed (i) functional aspects performed with precise analyses of actual charts; (ii) interoperability aspects with the use of some HL7-RIM standardized descriptions; and (iii) cooperative aspects, with the integration of a cooperation model. We proposed a Domain Ontology to represent the concepts and the relations used in the charts. The implementation was done with Protégé; the ontology was built in OWL-DL. The IAnnotate application helps us to index the HC chart with the domain ontology. The next step of the work will use the ontology to reason about the different items of information contained in the charts so that contextual use of them should be envisaged.

Keywords:

medical informatics, cooperation, quality of care, ontology

Introduction

- Health professionals, who work together in order to care their patients, very often have to coordinate themselves asynchronously. They use some artifacts in order to keep a mutual understanding of the situation such as the knowledge of the patient's state or the knowledge of the performed medical tasks. In particular, documents such as Home Care Charts or Annotations are shared. They are readable by different individuals at different times, and they allow the elaboration of an awareness of the different activities performed by the caring team. These documents are highly complex: information is often given in natural language, they are not very structured or even not structured at all, they mix all kinds of information (medical, legal, logistic and so on) and they are consulted by different people assuming different roles for the care (nurse, practitioner, family, patient, physiotherapist and so on). Moreover, this information has a double status for the cooperation: (i) it is used at an operational level (coordination of actions); (ii) it is used at a more abstract level of planning (synchronization of the knowledge that everyone has on the current care process). It also builds the common ground indispensable for efficiency, good cooperation and coordination. The medical domain is highly concerned with the computerization of the information. The use of electronic records helps people to store, retrieve, display and exchange many items of complex information. Such electronics records have shown their strength and are actually used in everyday situations of care, but they have also shown some weaknesses [1].

In the context of our studies of Home Care Situations, one of our purposes is to understand how to represent and how to use the information contained in the Home Care Charts. Instead of trying to define an efficient record for such information, we thought it could be interesting to treat this information according to the "Semantic Web" paradigm and to focus on efficient indexing of the information. The items of knowledge contained in the Home Care Chart should:

- be displayed in an efficient and "business oriented" way;
- support the cooperation of the health care professionals by improving the mutual awareness they have on the care; and
- develop new exchanges between Home Care organization and other medical Information Systems.

These three dimensions should be captured by three interconnected descriptions of the complementary aspects of the domain: functional, interoperability-oriented and cooperation-oriented.

The following definition of ontology is proposed by Sowa [2]: "The subject of *ontology* is the study of the *categories* of things that exist or may exist in some domain. The product of such a study, called *ontology*, is a catalog of the types of things that are assumed to exist in a domain of interest ***D*** from the perspective of a person who uses a language ***L*** for the purpose of talking about ***D***. The types in the ontology represent the *predicates, word senses*, or *concept and relation types* of the language ***L*** when used to discuss topics in the domain ***D***."

Indexing the Home Care Charts items by using domain ontology, as proposed in other areas of research [3], could improve the understanding of the written home care charts while keeping a flexible way of expression for the health care professionals.

If the long-term perspective of this work is to propose an efficient way of indexing the home care charts in order to focus on useful information according to the context of use or to the user's identity, the first steps of this work are to build a domain ontology able to answer the problem of indexation of the home care charts as well as to validate the idea that this ontology could help to reason on the items to focus on.

The objective of this paper is to relate the work we have done to analyze the home care charts and to explain the ontology we have then proposed to support such indexation. A brief description of the use of the ontology will also be presented.

Materials and methods

Materials

The study was performed:

- From raw and real information: we used 16 home care charts as a corpus, each one containing all the information exchanged between nurses throughout the entire care period (from 1 month to 6 months). These charts come from the SANTELYS association that is a rather big association (200 employees), with an active and well-organized branch dedicated to Home Care. Patient's anonymity has been preserved. Home care charts have been analyzed by a psychologist involved in this project, and then described. These descriptions have been confronted with the opinion of some of the nurses involved in such a care.
- From medical standards: in the medical field, a lot of work has been done to define standards in order to increase the interoperability of the health care information systems. In particular, HL7 was created "to provide (global) standards for the exchange, management and integration of data that supports clinical patient care and the management, delivery and evaluation of healthcare services."[4]. Moreover, a formal model, the Reference Information Model (RIM) "specifies the grammar of HL7 messages and, pecifically, the basic building blocks of the language and their permitted relationships" [5].

These materials will help us improve our understanding and representation of: (i) functional aspects of the charts, (ii) interoperability and (iii) cooperation.

Functional aspects of the Home Care Chart

Thanks to the activity analysis performed by the psychologists working on this project [6, 7]; we had rich information about how to combine meaningful units in the domain of the home care. A typology of the home care information, according to a functional point of view, has been performed.

Interoperability

As one of our purposes was to assume interoperability between the Home Care System and other Medical Information Systems, it was then really interesting to integrate the RIM standardized description to our model for Home Care Charts indexation. We used the pre-existing RIM ontologies made by Bhavna Orgun [8] and Samson Tu [9] to propose an ontology answering to the reference ontology of the Health care domain aspects.

Cooperation

Hoc's architecture of collaboration [10] which proposes three levels of collaboration (action, plan and meta-collaboration) can anchor a conceptual framework for an ontology of cooperation. Two levels of synchronization can be identified: (i) cognitive synchronization (plan and metacooperation), which aims to build a mutual knowledge context, to elaborate and maintain a shared representation structure; (ii) temporal and operative synchronization (action level) which facilitates the coordination by the implementation of two functions: it ensures the task allocation between partners and it ensures the train of actions, their simultaneity, their starting or their stopping. Such refined descriptions actually allow the psychologists to perform their study of the asynchronous cooperation with the home care chart. We decided to integrate such knowledge in our work.

Methods

Smith and Ceusters [11] criticizes HL7/RIM that presents some weakness while mixing different aspects in the same standard. These authors recommend to distinguish between the 'Reference Ontology of the Healthcare Domain' (needed to provide a compact and coherent high-level framework in terms of which the lower-level types captured in vocabularies like SNOMED CT could be coherently organized) and the 'Model of Healthcare Information' (needed to specify how information about the entities that instantiate the mentioned types can be combined into meaningful units and used for further processing). In [12] Thieu et al. suggest a way to combine two different ontologies to represent both morphological and diagnostic concepts to define one cell, in [4] Isaac combines ontologies to describe audiovisual documents.

Our hypothesis was then that it could be possible to combine the functional, the descriptive and the cooperative aspects of the Home Care Charts and to propose a useful ontology for indexing them.

Healthcare professionals' cooperation context study and frameworks' elaboration:

A systemic approach [13] which proposed the following steps: systemic exploration, qualitative representation, dynamic representation and treatment of the created framework, revealed helpful to elaborate our frameworks. Each step was discussed with the psychologists:

- *Systemic exploration; representing the objects of the world of the homecare process.* Taxonomy of the home care charts was proposed so that any observations contained in one of the 16 despoiled home care charts

could be classifiable in one of the elements of the taxonomy.

- *Qualitative representation; representing the taxonomy of the home care charts in terms of flows and hierarchical organization*. Based on the previous mapping, a model was refined to visualize the interactions between the main components of the ystem, and the different information flows between different levels of organization.
- *Dynamic representation; superposition of the HL7/ RIM and of the qualitative representation.* During this step we determined how the elements found in the taxonomy of the home care charts could match the entities of HL7/RIM: obviously, some fundamentals belong to these different representations.
- *Treatment of the created framework; domain ontology building.* To propose an ontology for indexing the home care charts, the model of HL7's RIM does not appear to be sufficient enough to describe the home-care process from a functional viewpoint as only the subclasses of the qualitative representation were visible. Truncating the representation of the home care charts' taxonomy to integrate it into the RIM could generate some problems too. For example, one could find it incomprehensible that a person is considered as an "Entity", such as a place or a material. To merge the two models, we represented the home healthcare process from a descriptive sight (according to the HL7's RIM model), from a functional sight and a cooperation sight (according to the qualitative representation, the latest including the home care information model and the home care cooperation model).

Results

The qualitative model

Home Care was described through 6 main functional parts which are: Initial Prescription; General Evaluations and Actions; Organization of Care, Therapeutics; Non-Action; Patient Information. These parts can be refined with "is-A" relations, or can be linked with "isConsequenceOf" relations.

If the higher-level classes have no RIM correspondences, some subclasses of the qualitative model match some RIM classes. Some choices have been made in order to build the complete classification. For example, the class "Indication for care follow-up" in the functional model could match the "To-do List" in RIM representation. In fact, "To-do List" is a subclass of "Working List", defined by HL7 workers as: "A dynamic list of individual instances of Act which reflects the needs of an individual worker, team of workers, or an organization to view groups of Acts for clinical or administrative reasons. (…). – as: problem lists, goal lists, allergy lists, to-do lists, etc." Another example is "Visit stopping," which is considered as a "Control Act," defined as: "An act representing a change to the state of another class, a user event (e.g. query), or a system event (e.g. time-based occurrences). – *as:* Discharging a patient (Encounter from Active to Completed); Stopping a medication (Substance Administration from Active to Aborted); Sending an end-of-day summary (time-based event)."

The Home Care Domain Ontology

To represent the concepts and the links of our qualitative model, we decided to build Home Care Domain Ontology. Three sub-ontologies were used to represent the different aspects of the homecare process.

1. The descriptive ontology of the domain (Ontodescriptive).
   This ontology was adapted from existing RIM ontologies. [8][9]. It allows to characterize the home-care documents according to HL7/RIM concepts.
2. The functional ontology of the domain (Ontofonctionnelle).
   Drawn from the functional representation of the home care charts, it should give the professional a way to index communication units in a business oriented way.
3. The cooperative ontology (Ontocooperative).
   It introduces the concepts of the cooperation and supports a new way to characterize the activities according to a cooperative point of view.

To build the global ontology of the homecare process domain, we described the relationships between fundamentals in the different sub-ontologies.

- An object property called "hasRimDefinition" served to link some instances of the functional domain to their RIM equivalent so that: "Instance.functional_ontology" hasRimDefinition "Instance.descriptive_ontology". The cause-consequence and class-subclasses relationships have been kept, respectively thanks to the object properties "hasConsequence" and "isA".
- In the same way, we could see the superposition of the functional and the cooperative models: a property "hasCooperationType" will connect some instances of the functional ontology to the matching instances of the cooperative ontology:

For example, a "realisation of a physical or a behavioural evaluation" is linked with the "management of a common ground". A "demand for therapeutics change" is linked to a "creation of interference".

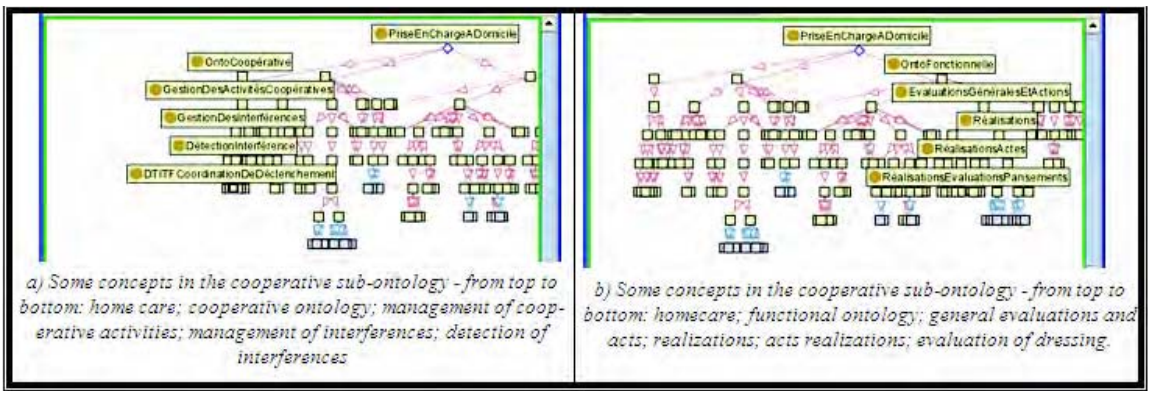

Figure 1 - Examples of the concepts used in the ontologies built from the communication unit analyses

The Indexation of the Home Care Charts

The coordination ontology as well as the functional ontology has been used to index the medical events. For example, when it is written on the chart "nurse care, morning and evening, every days including Sundays and public holidays:"

- it can be marked as an "initial prescription" in a functional representation;
- it deals with temporal and operative synchronisation and can be marked as a "creation of planning" in a cooperative point of view.

A sentence like "constipation since 3 days:"

- is a "reported event" in the functional representation;
- can be marked as "an elaboration of shared representation structure" in a cooperative representation.

Moreover, as the indexation is supported by ontology, we can use the subsumption links to increase the knowledge we have on the marked sentence; for example, "reported event" is an "evaluation".

We can have very flexible views on the information as we can choose to underline the information according to some of the descriptions we have on it.

Implementation

The ontology was built in OWL-DL, under the 3.1 version of the Protégé ontology editor [14]. Protégé plugins were used o have graphic representations such as in fig. 1,2. So as to make reasoning on the ontology, the RACER [15] inference engine, based on description logics was installed. This Reasoner was used to automatically classify the instances of the classes on regard to their properties, to compute the inferred ontology class hierarchy and to check for inconsistencies.

To perform the annotation of the home care chart, we chose to start from the iAannotate [16] application that uses an ontology to index content (file or web pages). It allows choosing a concept of the ontology to select part of the text and to index it with the selected concept. Once part of the text is annotated with an ontology concept, it is highlighted in a colour associated to this concept. Moreover, the indexations are shown or hidden by checking or not the checkboxes associated to each concept. (Cf figure 2).

IAnnotate can be used as a plug-in in Protégé. Some modifications have been applied to the iAnnotate program so that it could support multiple indexing for one text entity.

Figure 2 - Example of an annotated Home Care Chart where the underlined items are those that are underlined with cooperative concepts (here, the ticked checkboxes are those that describe cooperative concepts)

Discussion and conclusion

The production of Communication Notes (informal written sentences, annotations, and so on) is important to manage all the informal and unforeseeable information produced by the Health Care Professionals during care delivery [17]. Being able to use information for different purposes, according to different points of view or different contexts is one of the challenges we have to face in our information society. Thanks to free content, in the homecare setting, we want to keep the flexibility of the notes and to allow people to express all the information that is needed to support efficient collaboration. At the same time, we want to use some descriptions to highlight relevant information according to the collaborative nature of the activity. It could be interesting to apply the Semantic Web paradigm to the homecare chart and to perform efficient indexing of the information. But just how to build such indexing is less than obvious.

We have made different deep analyses of home care charts to feed our work and we are able to describe the main concepts and their relations in a functional or a cooperative approach. The RIM concepts can also feed our work. The first step of work was then to build a domain ontology that reorganises all the concepts associated to the homecare charts. Now, we have rich material to use as a basis for more extensive studies.

The second step of the work is then to have a tool that uses the ontology to index the homecare charts. At this stage of work, it was not realistic to perform the indexing automatically, so we decided to implement software with a user interface that allows selection of a concept from the ontology and to use it to index some text. By slightly modifying iAnnotate, we now have such a tool to index the charts.

A further step of the work will explore the use of the indexing.

A direct application is that the psychologists would use it to index the home care chart in a convenient way for their next studies. But obviously, the strength of this domain ontology representation is that we will now be able to reason on the knowledge we have. The functional descriptions we have on these charts, increased with the relationships between functional descriptions and cooperative descriptions, should help us to suggest cooperative views on the written items. For example, is it possible and useful to highlight all the items focusing on the planning concepts, when people organize their work? In the same way, we wanted to know how far we could use our system to provide automatically information from the home care chart to a homecare information system, using the relationships between functional and descriptive ontologies.

Acknowledgments

This work has been supported by the Region Nord - Pas de Calais in France (CPER).

Abstract

To ease and speed up the translation of the ICNP version 1 into the German language a web service was developed to support the collaborative work of all Austrian, Swiss, and German translators and subsequently of the evaluators of the resultant translation. The web service does help to support a modified Delphi technique. Since the web service is multilingual by design it can facilitate the translation of the ICNP into other languages as well. The process chosen can be adopted by other projects involved in translating terminologies.

Keywords:

ICNP, nursing terminology, translation, internet, web services, collaboration.

Introduction

The International Classification for Nursing Practice (ICNP) is a terminology system of the International Council of Nurses. It defines itself as "a unified nursing language system. It is a compositional terminology for nursing practice that facilitates the development of and the cross-mapping among local terms and existing terminologies" [1]. The current version 1 has been published in English in 2005 [2].

In order to be usable and as an important prerequisite to being an accepted nursing language it has to be translated. Building on the experience of the previous translation of the beta-version, which took almost three years to be translated and published [3], a different approach was sought to speed up the process.

As the ICNP version 1 is published in its original form in English it must be observed that the content has been collected internationally and the use of the English language reflects a more international style than just American or British English. A different problem arises as the ICNP version 1 has to be translated into the German language which is used not quite congruently also in Austria and Switzerland. Even if the translation is targeting high German, it also has to take into account the different uses of the German language. This makes the use of synonyms a necessity to accommodate for regional or national variations.

Translation efforts of the previous versions relied highly on documents being send around by email to the different translators, and also on moderators collecting and consolidating the different translations. This is a very time consuming process involving a large amount of work especially for the moderators putting out consolidated versions in each translation step.

For the translation of the ICNP version 1 a web-based service was designed to speed up this work. An additional challenge to be considered is that all work is performed by volunteers. So the different time frames each volunteer can donated have to be taken into account.

Methods

Concept

The basic idea of the concept is that at any time all ICNP terms and all their translations are visible to all translators. Any terms not yet translated can be seen by all translators at any time thus indicating areas still in need to be worked upon.

Since all existing translations of all translators are visible once they are made this offers a way to eliminate redundant work. If a translator agrees with an already existing translation by another person he does not have to translate the term again. Only if he wants to suggest a different translation it has to be entered into the system and is stored along with all other translations. It then will be available immediately for all other translators. Items hard to translate or with regional differences will show up by having multiple translations. Additionally it should be possible to have simple discussion threads for each translation in order to annotate them.

Because their is only one body of ICNP terms and their translations at any time the consolidating work of the moderator is not needed at that stage, resulting in a reduction of workload.

Once the translations of an ICNP term stabilizes, e. g. no new translations are offered, the term will be closed for transla-

tions and be made available for evaluation. Each evaluator will use a questionnaire to evaluate the quality of the translation. The evaluations are collected and analyzed centrally

Realization

Since the translation and evaluation work has to be performed by volunteers from home or from the office a web-based solution was proposed. The solution should require as little as possible on the user's side. There are two components to the complete system: a wiki to publish and discuss translation and evaluation issues as they arise, and to look up translation guidelines and a newly developed browser and translation tool for the ICNP (BaT). The wiki is based on the open source project PhpWiki realized using PHP as scripting language and a MySQL database. Both are usually available on a standard web server running under the Windows or Linux operat

ing system. The browser and translation tool was developed using the same tools.

In order to keep the requirements to just a browser on the user's side JavaScipt was not used. Only cookies have to be enabled for the authentication methods to work.

The BaT can handle several translation languages simultaneously. Each user is allowed to offer only translations in one language but he can view all the other languages. One example of the user interface is depicted in fig. 1. The original English version is on the left side, the corresponding German translation on the right. As shown on the very top of the window the user can select the languages of the interface and the translation displayed. Navigation to and through the ICNP terms is realized using a linear list with several options for filtering and sorting, a direct link to a specific code, and a text search option. The linear list can be easily printed and the printout be used as basis for the translation. Translations can then be easily entered by going directly to the term using its code.

Additionally, the ICNP terms can be browsed according to the hierarchical structures of the ICNP. Here each term is displayed with its parent, child, and sibling terms. To be able to see each term in its context is important for the correct translation of it. This way of navigation also favors users who prefer to translate specific topics like everything concerned with the term 'mobility'.

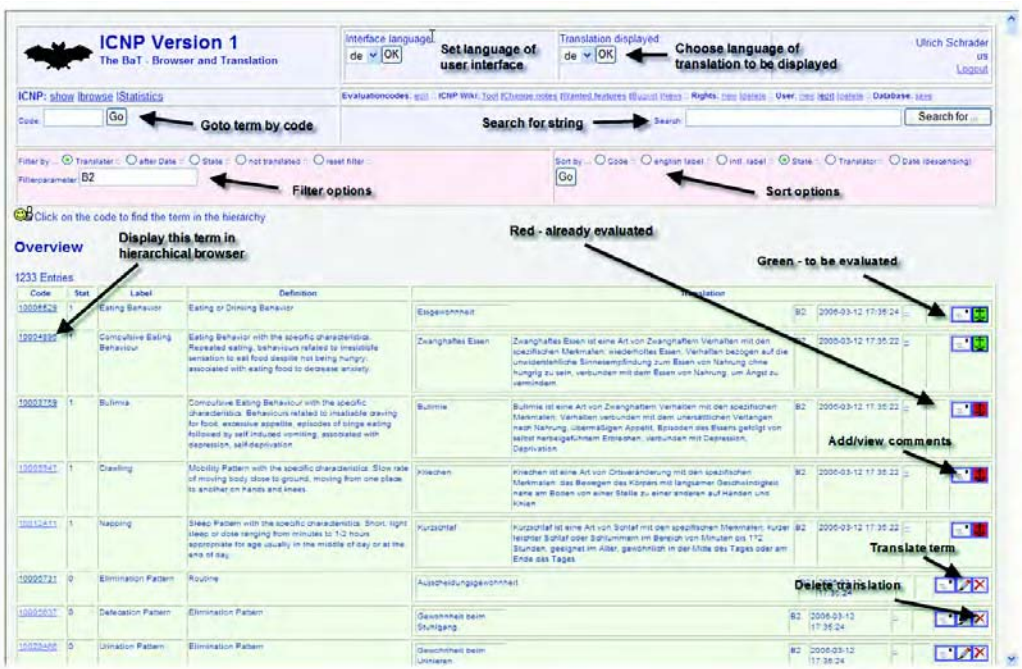

Figure 1 - Example of the user interface

Rights management

The management of access rights of the BaT is function based. Each function of the BaT has a specific right attached to it. When the functionality is invoked or made accessible, e.g. as a link or icon, it is checked whether the right is also assigned to the user. All rights can be assigned individually to each user, thus making it possible to create individual profiles.

Since the translation process is done collaborative and multilingual, care must be taken, that no one does undo the work of another translator. So if a user has the right to translate, he can translate only to one language assigned to him. All other languages are read only for this user. He can either add his own translation, or create a new translation building on an existing translation by another person. A regular user can only edit or delete his own translations as long as the ICNP term is open for translation. Only a user

with moderation rights can edit or delete the translations of others. Once the evaluation phase has started for an ICNP term it will be closed for translation meaning no translations of this term can be added, edited, or deleted.

Due to the multilingual design there are two types of user administrators necessary:

- The 'super' administrator can create regular user administrators responsible for each language.
- The regular user administrator can only create and administer users translating into the same language as is assigned to the regular user administrator. The same restriction applies to the creation of evaluators.

Guidelines of the translation process

The quality of the translation is dependent of the process chosen. The process again is a compromise between what could ideally be done and what is realizable considering limited resources. Given limited resources the web-based tools are used to make the most of them. A guideline for the translation into the German language has been defined and can be accessed by each translator in the wiki. The guidelines are based on the recommendations of the WHO used in the revision process of the ICF [4].

In 2005 the ICN announced the development of a guideline for the translation process. Once it will be available it will be incorporated into the guideline for the translation into the German language.

For the German translation there are currently four main points to consider:

1. Translation of the meaning of the term
2. Identification of a preferred term. A translator can suggest a translation to be a preferred term. The evaluation committee will make the final decision.
3. Optional translations. If a translator is uncertain about a possible translation this can be declared as an 'optional translation'. The BaT allows for multiple optional translations per ICNP term.
4. Synonyms. If there is more than one translation possible preserving the original meaning, the BaT permits the declaration of multiple synonyms per ICNP term. A translator can suggest a translation to be a synonym. Again the evaluation committee will make the final decision.

Since the status of each ICNP term can be set individually it is possible that the translation phase and the evaluation phase are organized to run in parallel.

Rules for the translation phase of each term

Every person translating a term should also do a first self-evaluation of his translation. Along with the translation he should rate his translation as being a:

1. Preferred term,
2. Synonym,
3. Optional translation,
4. or undefined.

Also each translation should be self-evaluated by the translator according to the following criteria:

1. Translation has the same meaning as the original ICNP-term.
2. Translation has a narrower meaning as the original ICNP-term.
3. Translation has a broader meaning as the original ICNP-term.
4. Translating requires more than one translation due to regional differences.
5. Differences between the meaning of two or more original ICNP-terms are lost during the translation process.
6. ICNP-term can be translated, but the meaning is different in the target language.
7. ICNP-term can not be translated. The target language does not have such a concept.

Rules for the evaluation phase of each term

It is planned to nominate seven experts to the evaluation committee. Once the translation of an ICNP-term seems to stabilize it will be closed for translation in the BaT tool. The experts then are evaluating each translation using the BaT tool. For each translation they have to fill out a form to evaluate whether the translation:

1. is a preferred term,
2. is a synomym,
3. requires further translation work,
4. should be considered to be deleted,
5. or the ICNP-term can not be translated.

All translations with an at least 66% vote for preferred term are declared preferred term and finalized. The same applies for the synonyms.

The experts also evaluate each translation according to the same seven criteria of the self-evaluation. This evaluation is used in the processing of the translations requiring further work.

After evaluation of the translations of an ICNP term the results will be made public using the BaT by highlighting preferred terms, synonyms, and translations to be deleted. The ICNP terms with preferred terms and synonyms will be finalized. No further translation or evaluation work will be possible in this stage.

All translations considered for deletion will be open for comments for a while. If there is no reason given for keeping, they will be deleted.

All terms needing further translation work to be done will be opened for translation again and the circle begins. ICNP terms that are impossible to translate will be sent to the ICN to be considered in further releases of the ICNP.

A web-based two-phase Delphi technique

Taking a closer look at the defined process for getting consensus in the translation and evaluation phases similarities to a Delphi technique are appearing. There are actually two teams of experts at work in the different phases. The ques-

tionnaires used in the Delphi technique are generated by the web server.

In the first phase - the translation phase - the experts are the translators. The initial questionnaire is the list of all ICNP terms to translate. But instead of having several rounds of distinct questionnaires that are summed, analyzed, and send back as feed back to the translators, they get a dynamic instrument e.g. a list of translations each time they log into the BaT. They reach consensus once the translations are stabilizing. This means no translator finds it necessary to add another or modify an existing translation. Since at this phase the feedback offered to the translators consists of all the translations for a given ICNP term, this list (questionnaire) is generated automatically by the web server. During this phase there is not need for a moderator to consolidate the translations as they are collected by the application.

In the second phase – the evaluation phase – the experts are the evaluators. Because the form (questionnaire) generated by the BaT tool when evaluating a translation does not contain any open questions, it again can be automatically summed, analyzed and fed back to the evaluators as statistics of the current state of evaluation of a translation. Again the application is doing most of the work.

The first and second phase continue repeatedly until consensus is found for most translations.

The time consuming and expensive procedure of a Delphi technique can be sped up by using a web server to generate and distribute the questionnaires and feedbacks to the experts. The only intervention that has to be done is located at the interface between the two phases in order to decide if the translation of a specific ICNP term has stabilized enough so that the evaluation phase for this term can follow.

Results/experiences

The translation of the ICNP into the German language started in May 2006. About two dozen nurses from Austria, Switzerland, and Germany are working on the translation. A first preliminary translation will be available at the end of December 2006.

The translation is done completely using the BaT tool and the wiki. Both systems have been running without any problems and seem to be well accepted for the process. There seems to be very little discussion necessary outside of the tools. The instructions to use the system are restricted to a few pages in the wiki, but it seems that the tools used are quite self-explanatory.

There seems to be interest in using the system for the translation of the ICNP into other languages as well.

Discussion

So far the system has been used for only one target language. Although it is designed and tested for a multilingual use supporting several translations at the same time this still has to be proven in routine work. But there has been some interest to integrate other languages as well so that might happen in the near future. Up to today the wiki is not really integrated with the BaT. While there are links used to navigate from one application to the other, both are still using a separate user administration requiring each user to login twice which should not be necessary.

Up to today demand for user support has been minimal, although the system is used currently by about two dozen nurses for translation purposes. This could be an indicator that the philosophy of following standard web browsing techniques might pay off in terms of ease of use and low support requirements.

The evaluation module of the BaT has not yet been tested in routine application. This will start in the beginning of January 2007 after the preliminary translation into German is completed at the end of December. Depending on the upcoming guidelines for translation by the ICN some changes might have to be applied to the evaluation module.

Conclusion

Translation of any terminology is time and resource consuming. This can be eased by using a web-based approach. While the process of translating and evaluating being chosen is a good compromise between what should be done ideally and what can be realized given limited resources, principles like back translation should still be considered as a follow up if resources might be made available in the future. Since the BaT tool is already multilingual it can be used for other translations of the ICNP. The already existing infrastructure can be made available free of cost. The source code of the BaT will be made licensed under an open source license.

Acknowledgments

The coordination of the translation is supported by administrative and financial resources of the nursing associations DBfK, SPK and ÖGKV. But without the voluntary efforts donated by the members of the German-speaking ICNP Users group such a translation would be unfeasible.

Abstract

Computer-based simulation of influenza outbreaks in local communities can help researchers, epidemiologists, and decision makers better understand the impact of the community structure on the reproduction rate of disease, and the relative benefits of different types of prevention and interventions. The goal of scenario modeling is to develop a description of scenario components, such as the disease, the community, and interventions. An ontology-based representation of the scenario model together with a modeling tool, which is based on an extension to Protégé, assist scenario developers in formulating simulation specifications. This approach allows the exploration of new ideas by rapidly formulating and reconstructing scenarios from novel components.

Keywords:

epidemiological simulations, ontologies, public health informatics, influenza

Introduction

The recent outbreaks of avian influenza (H5N1) have put renewed emphasis on preparing for a human influenza pandemic. Of particular concern in this planning is the allocation of resources, such as vaccine and antiviral medications, which will likely become scarce during a pandemic. One component of pandemic preparedness is surveillance and disease monitoring. Currently, there are operational systems that allow the global monitoring of influenza [1]. A second component of preparedness is simulation and forecasting epidemiological outcomes. In such simulations, networks and the epidemiology of infectious diseases are fundamentally linked. The basis for early epidemiological models is population-wide random-mixing. In practice, however, each individual has a finite set of contacts to which they can pass infection, described as a *mixing network*. Knowledge of the structure of such networks allows models to be created that compute the epidemic dynamics at the population level from the individual-level behavior of infections [2]. Therefore, representation of mixing networks, and how these deviate from the random-mixing norm, can enhance the understanding and prediction of epidemic patterns and intervention measures. Another central problem with forecasting in the context of influenza pandemics is the ecological fallacy; that is, that results obtained at regional or national levels may not necessarily be congruent with local levels, because regional averages may mask diversity between smaller areas. [3,4].

Simulation environments for the prediction of influenza pandemics must support rapid development, must display limited complexity, and allow for flexibility in the underlying models. However, nontrivial changes in software environments currently used for epidemiological simulations often require reprogramming of the simulator, which is time-consuming and potentially error prone. Furthermore, it is interesting to simulate multiple scenarios, such as scenarios adapted to local contexts and variations of scenarios for sensitivity analysis and alternative interventions. Thus, the management of different scenarios and scenario versions, and their implementation in the simulator is an important task for simulator developers. Finally, it is important to perform simulations during an ongoing outbreak as more information about the disease and how it is spread becomes available, which requires fast turnaround times for modeling and simulation.

Our approach is to develop a framework for separating simulation modeling and execution that maintains simulator run-time performance while allowing flexible high-level modeling [5]. Modeling and implementation of models in simulators are different areas of expertise that should be reflected in the architecture. Ontology-based models allow the scenario developer to define the relevant concepts and relationships for the major parts of the model, such as the community, the disease, and interventions. We use an extension of the Protégé ontology editor [6] to model scenarios and their components, such as household and school structures of communities. Furthermore, we use a custom-developed simulation engine that takes input scenario specifications from the modeling tool and produces the simulation report. This approach combines the benefit of an advanced modeling tool with the performance of simulation engines designed for efficient execution.

Background

Mixing with a group of people increases the probability of infection from exposure to an infectious individual in the group. Because people are part of several *mixing groups*, their total probability of becoming infected is the combination of the risks contributed by each of the mixing groups. Figure 1 illustrates sample mixing groups common in most communities.

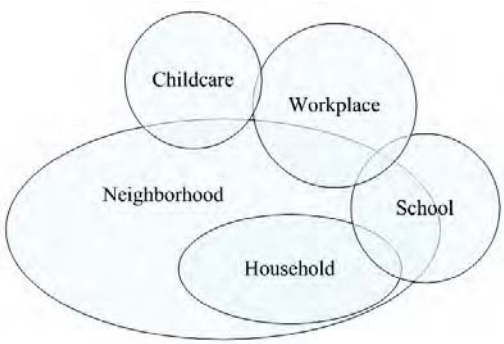

Figure 1 – Sample mixing groups

It is possible to simulate the interaction of people in mixing groups. Several researchers have used stochastic discrete-event simulation models to study outbreaks in simulated populations [7,8,9]. Typically, these approaches use mixing groups with defined transmission probabilities and contact rates, and they simulate the probability of transmission for every individual for the duration they are part of the group. The simulator maintains the dynamic state of each person with respect to infection and mixes people with others in their mixing groups based on the social context. Infectious persons in a mixing group contribute to the total probability that a susceptible person becomes infected.

The advantage of this type of simulation is that it allows us to study the outcome of different scenarios by varying the underlying model. Although the core of this simulation approach is relatively straightforward, there are several modeling issues that scenario developers must address. For example, the community model must reflect the age distribution of the population used to assign children and adults to schools and workplaces, respectively. In addition, the model must define the mixing groups used in the simulation and their properties.

Methods

The requirements of the modeling environment were formulated in terms of flexibility and turn-around-time for the modeling-and-simulation cycle. These requirements resulted in an architecture separating the modeling tool and the simulator engine, and the use of ontologies for modeling. Furthermore, the basis for the structure of the ontology model is the generalization of a previous version of the simulator using hard-coded models founded on relevant literature.

Results

The resulting modeling and simulation architecture approach comprises an ontology for scenario modeling, model formulation tools, and a simulation engine.

Scenario model

The purpose of the scenario model is to define a virtual situation to simulate, such as the spread of a disease in a certain community. Performing a simulator-based study usually involves creating multiple scenarios that alter the variable or variables under study. The scenario developer can prepare a series of scenarios that define the study by reusing (keeping constant) parts of the model while adjusting (varying) other parts. For example, a series of scenarios could simulate the impact of different countermeasures on the basic reproductive number, R_0. Alternatively, it would be possible to study the impact of differences in communities.

A scenario consists primarily of a community model and a disease model. In addition, a scenario can contain references to a model of the intervention policy and a model for mapping the community model to basic mixing groups.

Community model

Our approach is to inform models for simulation of pandemics by social geography by transforming Hägerstrand's concept of *pockets of local order* [10] to homogenous localized population mixing groups. A network structure is used to represent the mixing groups as nodes with contact frequencies between individuals within the nodes, as well as other properties of social pockets. Instead of a fixed arbitrary hierarchy of household groups and regions, we use a system of meeting place centered, floating, overlapping reference areas. As part of the modeling framework, we have implemented a generator that produces a randomized population that fits the household size and household member age distribution specified in the community model. The simulator engine uses this generated population to form the mixing groups during initialization.

Basically, there are two ways in which we can use detailed population data. One approach is to use as much of the detailed data as possible in the simulation; that is, to use information about households, such as residence location, workplace locations, and age of household members, and form mixing groups for the simulator from these data. An alternative approach is to extract the relevant features for the population in question, such as age distribution and household size distribution, and then generate a synthetic population with the same key distributions as the factual population for the simulation.

Disease model

The basic disease model, the susceptible-infectious-recovered (SIR) model, describes the number of individuals (or proportion of the population) that are susceptible to, infected with, and recovered from an infectious disease. Many of the details of infection progression are therefore neglected, as are differences in response among individuals. The SIR model is appropriate for infectious diseases

that confer lifelong immunity, such as influenza. Biomedically motivated modifications can be made to this basic model, such as involving the inclusion of more heterogeneities by further subdividing the SIR classification to reflect either more complex pathogen biology or greater structure within the host population. However, the number of contacts each individual has may be considerably smaller than the population size, and, in such circumstances, random mixing does not occur. Models that incorporate network structure avoid the random-mixing assumption by assigning to each individual a finite set of permanent contacts to whom they can transmit infection, and from whom they can be infected. Although in network and random-mixing models, individuals may have the same number of effective contacts per unit time and within a network, this set of contacts is fixed, whereas in random-mixing models, it is continually changing. Networks thus capture the permanence of interactions. The present disease model has therefore been customized to accommodate also network components in future developments of the SIR disease model.

Scenario modeling

Figure 2 shows the general workflow for scenario modeling. The scenario developer starts with a problem formulation and proceeds with conceptualization and definition of the concepts, properties, and relationships in the scenario ontology. Typically, the developer extends a basic ontology with scenario-specific concepts and instances. This basic ontology provides guidance for the developer. Moreover, the basic ontology can restrict relationships in the extended ontology. Because the scenario ontology is partitioned into community, disease, and intervention models, the developer can modularize the work and, perhaps, use different data sources for different parts, e.g. population databases for the community model, when extending the basic ontology. Once the modeling is completed, the developer can generate the intermediate specification format for use in the simulator engine. Because scenario ontologies extend the basic ontology, the subsequent generation and simulation steps can make assumptions about the concepts in the basic ontology, such as the base concept of mixing group.

Scenario reuse

An important aspect of simulation modeling is the potential to reuse models and model parts. For example, simulator users may want to keep the community and disease models constant while varying the intervention model. Alternatively, simulator users may want to vary the community models while keeping other models constant, for instance to simulate the impact of different community structures and community-oriented interventions on R_0.

Scenario developers can use this approach to build a library of scenarios and scenario components. The advantage of using this type of library approach is that it makes it easier to work with several types of local communities, which could correspond to actual cities, municipalities, and villages, in multiple scenarios. The library could contain past scenarios, i.e. previously simulated scenarios, and scenario components suitable for reuse. Furthermore, it is advantageous to archive scenarios from previous simulation runs together with results for future reference.

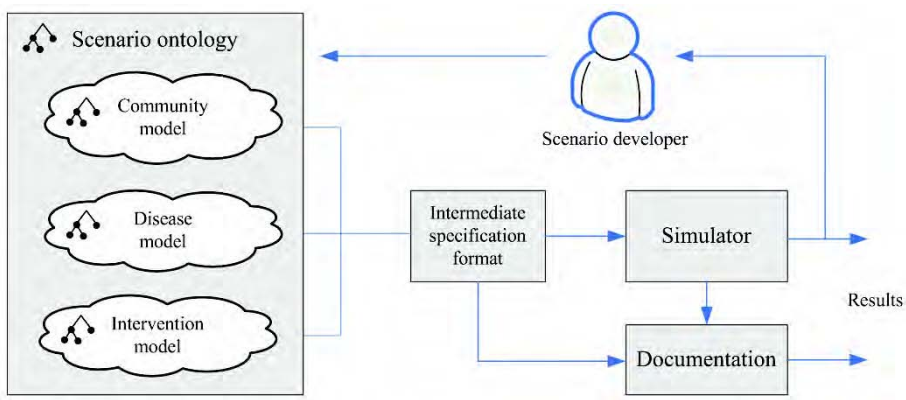

Figure 2 – General workflow for scenario modeling and simulation

Modeling support

Protégé is a widely-used ontology-development environment that provides several graphical tools for creating and editing ontologies [6]. We have extended Protégé with a plug-in for managing scenarios, and for generating specifications for the simulator engine. This extension adds a tab to the Protégé user interface, which allows users to create and define scenarios (see Figure 3). Using the scenario editor, developers can link models to the scenario, such as a community model representing the population used in the scenario.

Figure 5 shows the editing of a community specification in Protégé. This sample community instance consists mainly of the population, a household model with household size distribution, and a school structure model with the number of schools of each type (ranging from daycare centers to high schools).

The community model in Figure 4 corresponds to the city of Linköping, Sweden. It is possible to reuse this model in several scenarios as it represents the standard model for this city. Furthermore, is possible to construct a new scenario by replacing the standard Linköping model with another population, such as the household structure of

Washington DC, which has a high proportion of single-person households, or Utah, which has a low proportion of single-person households.

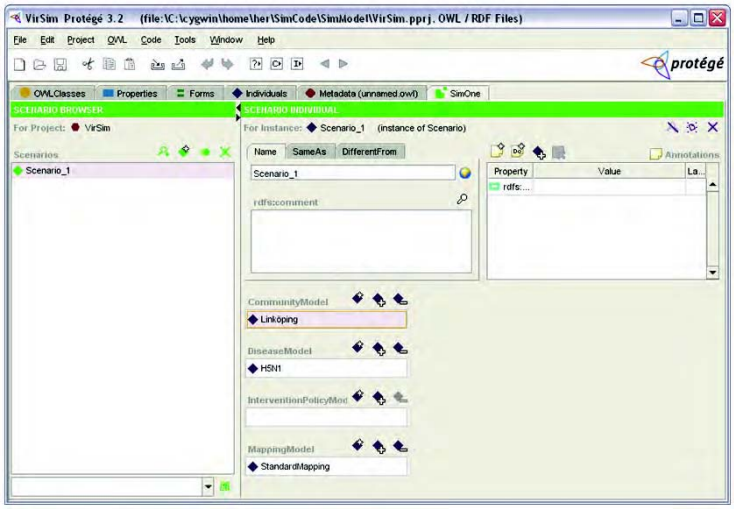

Figure 3 – Protégé tab extension for scenario editing

Figure 4 – Editing of community definition in Protégé

Architecture

Figure 5 shows a summary of the architecture for the modeling and simulation system. Protégé manages the ontology with the community, disease, and intervention models. The population generator, which is implemented as a Protégé extension in Java, expands the abstract community model to a set of generic mixing groups for use in the simulator engine. The intermediate specification format, which is XML-based, defines the mixing groups and their members as well as the disease and intervention model parts. The simulator then parses this intermediate format and instantiates the simulation. One of the advantages of the XML-based specification is that it makes it possible to transfer the specification to alternate simulation-execution architectures, such as an array of processors performing parallel simulations.

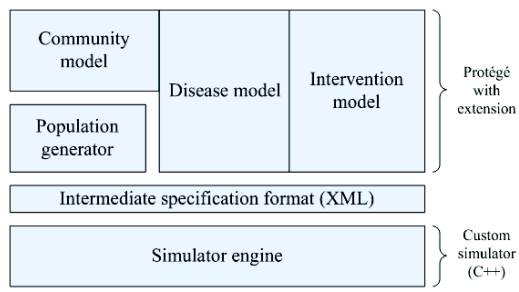

Figure 5 – Architectural layers

Discussion

Scenario modeling is an important part of the scientific process. In particular, modeling assists hypothesis formulation and simulation documentation. However, epidemiological simulation is limited by a modeling bottleneck in that it is difficult to develop and modify models for simulators. Additionally, epidemiological simulation often requires simulation experts and programmers to perform the modeling task. An important goal of our work is adaptation to local contexts to support simulation of local outbreaks. Ultimately, we want to enable local epidemiologists and decision makers to use simulation. Thus, the modeling approach must allow developers to construct models that reflect the structure of neighborhoods and interventions at the local level, informing decisions such as closing schools and workplaces. The systematic development of scenarios from components helps developers to construct case models rapidly, and to run them in the simulation engine.

In our modeling of H5N1 influenza outbreaks in local communities, we found that the ontological modeling helped structure the problem, reuse model components, and organize different scenarios and their corresponding simulation results. Furthermore, the use of a spatially explicit community model allows us to employ several alternative community structures for sensitivity analysis and for experimenting with moving an alternative population, such as one with a different household structure, into a community. In our continued work, we plan to extend the ontology to support the aggregation of scenario descriptions in larger simulation jobs that specify simulation series. In addition, we plan to generate documents, e.g. PDF documents that summarize the simulation model used and describe simulation results.

Summary and conclusions

Simulation of influenza outbreaks benefits from a clear separation of modeling and implementation. Ontologies provide a suitable representation scheme for such epidemiological models. It is useful to divide the scenario model into subparts for communities, diseases, and interventions and to support construction of new scenarios from these components. Protégé, combined with the scenario extension, provides a modeling environment that uses ontologies to define scenarios and scenario modules. Moreover, such ontologies, when populated, make up a scenario library with a collection of instances representing the scenarios. The modeling result is a specification for efficient execution in the simulation engine.

An Ontology-based Model of Clinical Information

Thomas Beale[†a], Sam Heard MD[‡ab]

[†] *CTO,* [‡] *CEO Ocean Informatics Pty, Ltd*
[a] *Visiting Senior Research Fellow, University College London*
[b] *Adjunct Professor, University Central Queensland*

Abstract

In this paper we describe a model of clinical information designed to make health information systems properly interoperable and safely computable. The model is a response to a number of categories of requirements, ranging from the semantic to the performance of software at runtime. We argue that the starting point of a successful model must be an ontological analysis of the process of clinical care delivery, seen as a scientific problem-solving process. From this approach we develop a classification of types of clinical information called the Clinical Investigator Record (CIR) ontology.

Keywords:

EHR, health records, clinical process, information models, information systems, archetypes, problem-solving.

Introduction

Interoperability and computability of information in the healthcare sector promise a great deal in the global effort for better quality and more efficient healthcare, yet remain largely unachieved. Models of clinical information, including models of the Electronic Health Record (EHR) and variants (EMR, EPR, CPR etc), do not currently have a theoretical basis sufficiently strong to guarantee interoperability and computability. Any information model developed must also satisfy a myriad of other requirements when actually implemented including: computational efficiency and performance; economically viable implementation; maintainability; system scalability and extensibility; and the considerable privacy and security requirements of the health domain. A successful model of health information is thus like any other good model; it is an expression not only of the semantics of the domain, but also a response to the needs of economics of system construction and runtime performance.

Methods

Our methodological approach to developing a model of health information consisted of four steps. Firstly a conceptual model for understanding the creation and recording of information during the healthcare process was developed. This was used to develop an ontology of recorded health information. An information model suitable for software development was developed based on the process model and ontology as well as other requirements - this became the *open*EHR Entry model. Finally we validated the model in a number of ways, including testing it with real clinical statements and queries and showing how it works in implemented systems. This paper describes the first two steps.

Background

Systems and models whose design ignores the real world in which they operate will fail to work well (see e.g. [1], [2]). The challenge is to find a way of basing a system design on the reality in which it is intended to function. An ontological approach provides a formal basis. An 'ontology' can be understood as a 'description of reality' and may be subdivided into a description of *process* (e.g what occurs, what is done) anda description of *information* (e.g. what is thought, said, communicated, remembered).

Sowa [3] provides a top-level and very general classification of the world, which is a useful reference point for any ontology, while more health-specific ontologies include the Ontology of Biomedical Reality (OBR) [4] and the SNOMED-CT clinical terminology [5]. The CIR ontology describes information created in the process of healthcare delivery.

A model of clinical information that will perform at all levels must meet three broad categories of requirement:

- *semantic requirements*: accurately represent and convey intended meaning of its users;
- *functional requirements*: provide the functions required by its users when deployed; and
- *economic requirements*: enable economically viable software construction and maintenance into the future.

A process model for clinical healthcare

It is important that any model used as a basis for software be based on a generic and high-level conceptualisation of the care delivery process. Various attempts to do this have been made in the past. Weed's problem-oriented medical record (POMR) methodology [6] formally linked a particular model of the process of care (relying heavily on testing) to the information gathered during that care (leading to the well-known "SOAP" headings). Elstein's

'hypothetico-deductive' model of clinical reasoning [7] mainly accounts for the cognitive aspects of clinical care (cue recognition and evaluation) during diagnosis. The model makes a good case for clinical healthcare to be seen as an iterative, scientific problem-solving process. The model originally developed by Rector, Nolan and Kay in the PEN&PAD system [8] is not so much based on problem-solving, rather a faithful yet flexible ability to *record* clinical action, thinking and dialogue. They propose only a limited ontology of information, namely 'direct observations' and 'meta-observations', thus distinguishing 'facts' from 'opinions'.

The Danish 'general electronic patient journal' (G-EPJ) [9], shown in Figure 1, includes a conceptual model of the iterative problem-solving process and categories of information generated. This model represents the clinical investigative process in the form of the cycle with process steps (circles) and information arising (blocks). While it has proved too rigid in practice, it formalises both process and information based on a paradigm of rational problem-solving.

Various clinical modelling efforts dating from the RICHE [10] project to the present HL7 version 3 standard [11] have based their models on an 'act management' paradigm in which all aspects of clinical care are represented as Acts. This approach enables 'everything that is done' to be recorded, which has clear attractions for business process tracking and cost-recovery (based on costs associated with fine-grained acts). It also has applications in messaging, where most notifications are to do with acts being requested, or being carried out.

Useful principles

A proper understanding of the notion of 'recording' is required. The point of view taken here is that what is recorded in the health record is likely to be a small, selective choice of notes about real events, situations etc, intended for interpretation by other professionals. The implication is that any model of health information must capture the *cognitive* communication processes of health professionals wherein very partial information may be recorded, rather than some more general notion of 'comprehensive fact representation'.

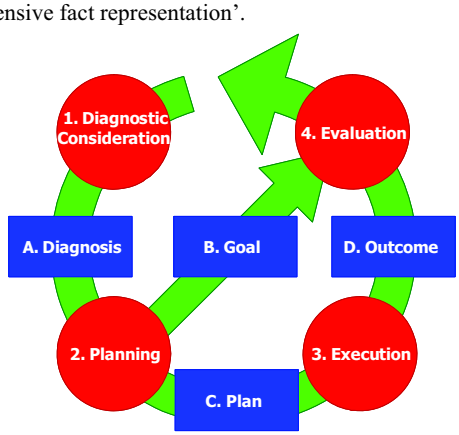

Figure 1 Danish G-EPJ Conceptual Model

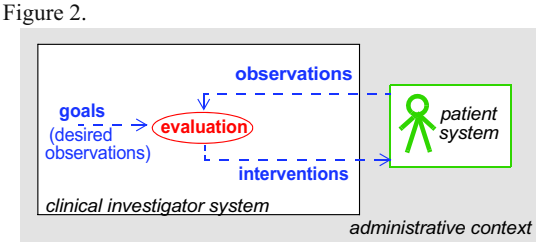
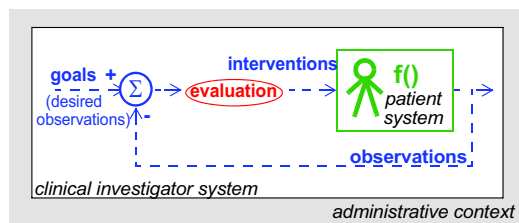
It is also important to avoid the danger of confusion of linguistic entities with real entities and phenomena. This often manifests in models that define types with names like 'problem', 'observation', 'plan' and 'result', without properly defining the meaning of these categories.

The clinical investigator model

The theory we describe in this paper was originally conceived during the GeHR (Australia) [13] (pp29-32) and *open*EHR [14] projects, and built on some of the earlier work described above. We model health care delivery as two kinds of process: a *clinical process,* corresponding to the interaction between a 'clinical investigator system' and a 'patient system', situated within a *business process*, which is owned by an 'administrative context'. The model can be illustrated in two equivalent ways, as shown in Figure 2.



a) problem-solving metaphor



b) control system metaphor

Figure 2 - The Clinical Investigator Model

In part a) of this figure, the clinical process is shown as a two-entity system: a subject of investigation - the 'patient system', and the investigating entity - the 'investigator system'. The former is defined as the subject of care (typically one person, but may be more) seen essentially as a biological or social system (depending on the perspective of the investigator), while the latter is defined as the totality of healthcare professionals and other agents who perform actions to do with care of the patient; this includes the patient in the role of self-carer or self-medicator, as well as any family members or other people. The investigator system's purpose is to use *observations* as a basis for *evaluation*, leading to *interventions*. The investigator system is driven by *goals*.

Part b) of the diagram shows exactly the same elements, but redrawn in a manner familiar to control system engineers and those familiar with systems theory. In this schema, goals (desired observations) are seen as the controlling input signal, with observations being the output, and the patient the filter, or 'transfer function'. The difference between the actual and desired observations is used

by the controller (the evaluation activity) to determine the actual (corrective) input signal to the patient, in the form of interventions. In acute care, the external control system realised by the clinical investigator(s) is attempting to perform the same kind of homeostatic function that the body itself does, and in some cases, it is performing *exactly* the same function, such as in the case of patients using substances such as insulin. The fact that the clinical process can be mapped directly onto the standard model of negative feedback is not only intellectually satisfying, but indicative that this particular conceptualisation of the process is likely to be correct.

An ontology of clinical information

Since our main goal here is to understand how to support healthcare delivery using information systems, we initially need to know what kinds of information might be created by the processes described above *for recording and use in the information system*. We can redraw the investigator system in order to more clearly show the types of information created during the care process, as shown in Figure 3. Five types of information are identified, as follows:

- *observation*: information created by an act of observation, measurement, questioning, or testing of the patient or related substance (tissue, urine etc.), including by the patient himself (e.g. taking own blood glucose measurement), in short, *the entire stream of information captured by the investigator, used to characterise the patient system*;
- *opinion*: inferences of the investigator using the personal and published knowledge base about what the observations mean, and what to do about them; includes all diagnoses, assessments, plans, goals;
- *instruction*: opinion-based instructions sufficiently detailed so as to be directly executable by investigator agents (people or machines), in order to effect a desired intervention (including obtaining a sample for further investigation, as in a biopsy);
- *action*: a record of intervention actions that have occurred, due to instructions or otherwise;
- *administrative event*: a record of a business event occurring within the administrative context, such as admission, booking, referral, discharge etc.

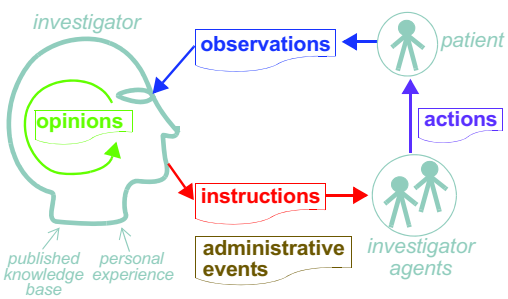


Figure 3 - Information Created by the Investigator

From these categories we construct an initial ontology, shown in Figure 4, the main purpose of which is to introduce the abstract categories 'recorded information' and 'care information', and to situate the five information types with respect to these.

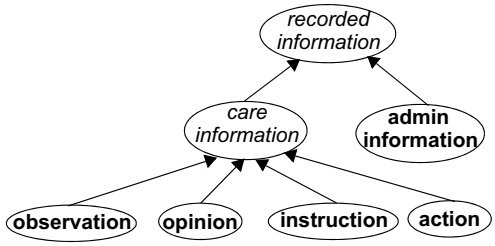

Figure 4 - Initial Clinical Information Ontology

Historical information: observation and action

We have already defined 'observations' as any information received by the clinical investigator used to characterise the patient state. It is axiomatic that observation information is 'in the past', since it expresses states or events that have already occurred. Observations are therefore *historical* in nature.

The Action information category is also historical in nature: a record of actions taken cannot be written until the actions have been completed (the documentation of actions 'to be done' is another category we call Instruction). Clinical actions such as administration of a medication or discontinuing a medication can all create Action instances. We can conclude, therefore, that the Observation and Action categories are subsumed by a category which we will simply call Historical (following Sowa's top-level categories). These categories can now be understood respectively as: a historical record of natural phenomena to do with the patient, and a historical record of things done to or for the patient.

Information in the cognitive 'present': opinions

Within the cognitive investigation process, clinical thinking, including any analysis, assessment or planning, is always 'in the present'. This is true of any analytical or decision-making activity: temporally it comes between evidence about the subject of study and actions to be performed in the future. When specific examples of clinical opinion are examined, the relationship with time may not always seem so clear. Consider a diagnosis; to properly characterise the problem, it will include time-related information such as the following:

- date of initial onset
- date clinically recognised
- for each occurrence or exacerbation:
  - date of last onset of occurrence
  - date of resolution
- date of resolution

Timings like this represent the 'continuant' or persistent relevance of this information and as such the Opinion category includes the idea of summary or review. As such the diagnosis is not itself an *observational* record of onset, exacerbation, resolution etc. (these events may have been documented as Observations when they occurred), but a

structured *summary* of dates and other items seen as important by the physician. The Opinion category of information is thoughts and analysis *about* previously recorded facts, not a historical record of the facts themselves. This is the same as items reported in the "news" section of a newspaper, and later analytical pieces, such as editorials and current affairs TV shows - the latter cannot help mentioning facts and dates from the former, but is not itself the contemporary record of the events in question. The Opinion category corresponds to Sowa's Description category.

Information about the future: instructions

We denote the last major category of information coming from the clinical care process as Instruction. Information in this category is in the form of orders, requests, and other directions to be performed by clinical investigator agents, so as to effect desired changes in the patient system, or else to gather new evidence for further consideration. Instruction time is therefore in the future, since the information speaks of events that have not yet occurred or are not completed. The Instruction category corresponds to Sowa's Script category.

We can describe two sub-categories of Instruction, distinguished on the basis of being for the purpose of investigation (to make further observations) or for intervention (aimed at changing the state of the patient system). We will call these categories Investigation-request and Intervention-request. As with the other categories, these names are to be understood as contractions for 'record of instruction for investigation' and 'record of instruction for intervention'. These may overlap when investigations have some treatment aspect; for example, removal of fluid around the lung will aid in the diagnosis as well as alleviate symptoms.

One of the key clarifications provided in the types described so far is between Instruction and Action. The former is a specification of what to do, while the latter is a record of what was done. A medication order may say to take 1 or 2 tablets every 4 hours, whereas an administration action will record the actual number taken. Models that are not clear about this distinction are likely to be problematic when connected to workflow systems. In simple terms, a series of Actions always represents a particular path taken through the set of possibilities described by an Instruction.

Accordingly, we arrive at an improved form of the ontology in which the three categories History, Opinion and Instruction are distinguished on the basis of the temporal relationship between the recorded information and the investigation process.

Observation and intervention sub-categories

We can make further improvements by analysing the categories so far in terms of their relationship to the two sides of the investigation process, i.e. 'observation' (characterising the patient system) and 'intervention' (changing it). We have included two subclassifications on this basis, namely Observation/Action and History and Investigation-request with Intervention-request below Instruction level.

Types of opinion

The top-level category *opinion* corresponds to inferences about observations, as well as about interventions, such as goals, and plans. Types of opinion have historically posed the most difficulties for models of health information, because they are so variable. The Opinion category corresponds to the notion of 'hypothesis' in general science. In health informatics, it corresponds to Weed's 'assessment' and (partially) 'plan' categories, to Van de Velde & Degoulet's [12] 'abstraction' category, and to Rector *et al's* [8] 'meta-observations'.

Here we propose two sub-categories, more directly related to the systems view of healthcare proposed above: *assessments*, i.e. opinions about what is happening in the Patient System, and *proposals*, i.e. opinions about what should be done by the Investigator system. Under this approach, we can say that the first category relates to *current* or *projected* states of affairs, and the second to a *desired* state of affairs.

The primary example of an Assessment in clinical medicine is the diagnosis. A diagnosis is the attachment of a label to a group of observed signs and symptoms, which designates it in the understanding of the Investigator as being a particular known phenomenon. A differential diagnosis, another category of assessment, allows for multiple possibilities, due to the lack of sufficient information or understanding to discount all but one.

Assessments include *quantification of risk* providing the basis for prevention or investigation. Such a notion includes the idea of *family history* being a risk arising from an unusual prevalence of a condition amongst relatives. *Prognosis*, the likely outcome corresponding to a current diagnosis, is a further example. In general science, risk assessment and prognosis correspond to *prediction*.

The second major sub-category of Opinion corresponds to opinions about the *desired* state of the patient system, and includes much of the creative thinking of the clinical investigator. Once a diagnosis, risk assessment or other evaluation about the patient's condition has been formulated, the clinical investigator determines what to do about it. Three key types of clinical thought at this point are *scenarios* (or what-if statements, *goals* and *plans*. A goal, such as weightloss and a target weight of 85kg, is a statement about *what* the desired state of the patient system should be, while a plan is a statement about *how* to get there.

In summary, the Opinion category is distinguished from the Observation category by representing inferences from evidence, rather than representing the evidence. Two investigators can form different interpretations of the same set of observations, but the observations themselves remain an objective picture of some aspect of the patient's situation, within the limits of the observational method itself. Similarly, two investigators can formulate different goals and plans based on the same observations, and even the same diagnosis.

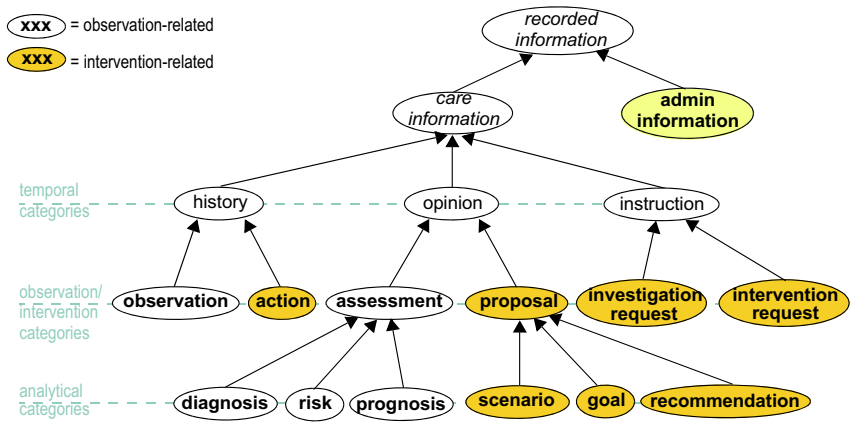

Figure 5 - The Clinical Investigator Record (CIR) Ontology

The clinical investigator record ontology

The ontology thus described is illustrated in Figure 5. Categories which correspond to the describing the patient system are shown using plain bubbles, while categories corresponding to interventions intended to change the system are shown using filled bubbles. We call this ontology the Clinical Investigator Record (CIR) ontology. The CIR ontology does not yet include any detailed subcategories beneath Admin information. Far less work has been done on this subject from an ontological point of view in health to date.

Conclusion

The Clinical Investigator Record Ontology provides the basis for the Entry classes in the *open*EHR reference model. The latter has proved to be semantically robust and a successful basis for defining clinical content models (known as 'archetypes') used in various kinds of health computing, as well as for EHR systems. The archetyping methodology has been used to create over 250 archetypes based on the *open*EHR Entry classes during the last few years, including in recent work (early 2007) in the UK NHS Connecting for Health programme.

Abstract

This paper describes the steps followed in the creation of a local Interface Terminology to SNOMED CT (as reference terminology) with a strong focus on user acceptability. The resulting list of terms is used for clinical data input by physicians and nurses at the Hospital Italiano in Buenos Aires, Argentina. Description includes data model, mappings to SNOMED CT and classifications, subsets definitions and extensibility mechanisms. The Interface Terminology is currently used in the recording of diagnosis and procedures in inpatient discharge summaries and its coverage is improving from user feedback. Its current size is 24,800 concepts, 67% of them needed post-coordination for appropriate semantic representation, due to a very flexible policy that allows the use of any number of modifiers on concepts.

Keywords:

interface terminology, terminology services

Introduction

Interface terminologies (IfT) had been used for a long time in electronic medical records, and consisting in a list of local terms, familiar to the user, that are used for clinical data entry[1]. The name "interface" comes from its role as a link between user's vocabulary and a stricter, standardized, list of terms used to describe clinical data. Each term in the IfT is mapped to a term in any standard terminology used as a "reference". This strategy isolates the user from the complexity of standard classifications or nomenclatures used as reference terminologies, whose terms may not be appropriate for the setting, may have an arbitrary level of detail or may have too many rules for code selection.

SNOMED CT®[2] is currently regarded as the most advanced terminology system for storing clinical information, and is a government mandated standard in many countries[3-8]. SNOMED CT includes mappings to several standard classifications as ICD-9CM and ICD-10. In this paper we will review the approach of the Hospital Italiano of Buenos Aires for implementing an Interface Terminology mapped to SNOMED CT in a hospital wide Health Information System.

Background

The need of a local interface terminology for SNOMED CT

SNOMED CT includes IfT capabilities, with a list of different terms applied to each concept. The advantage of using a local IfT is to provide easier adaptation to local content and to create a permanent, list of terms, isolated from periodic SNOMED CT changes.

Localization involves two basic functions: hiding not desired content of SNOMED CT and including new terms and concepts needed in the local setting but not present in the standard terminology. These objectives can be achieved using two SNOMED CT functions, the "subsets" for restricting content and the "extensions" for adding new content.

Defining subsets for content restriction can define different scopes, using large subsets for extensive topics like "Problems List" and smaller ones for specific purposes like data input from templates, etc. The local IfT consists in all the subsets created for local use, including a mix of standard terms and local terms, created in an extension of SNOMED CT.

The main drawback of creating a local IfT is the additional work required for its development and maintenance. In our case, conforming to usability demands from our user base was a key point in our implementation, so the extra effort in creating and maintaining an IfT was deemed acceptable.

Setting

The Hospital Italiano of Buenos Aires is a 650-bed non-profit university hospital located in Buenos Aires, Argentina. More than 150,000 outpatient visits and 3,000 hospitalizations are registered every month. It is affiliated with a Health Maintenance Organization (Plan de Salud) that takes care of a population of 140,000 patients.

Since 1998, a full scale HIS has been gradually implemented, including ambulatory Electronic Medical Record (EMR), inpatient discharge summary, administrative systems, scheduling systems, inpatient tracking systems, pharmacy systems and complementary studies report and visualization. Several health informatics standards had been implemented, including HL7, CDA Version 2, ICD-9CM, DRG, ICD10, and ICPC.

Existing experiences

Several health systems created local IfTs for their electronic medical records, mapped to necessary billing classifications like ICD-9CM and other standard terminologies, some examples are shown in Table 1. Sometimes, IfTs were created from scratch and others were based on previously existing standards.

Table 1 - Examples of interface terminologies

Interface Terminology	Site
MED (Medical Entities Dictionary)[9]	Columbia University and the New York Presbyterian Hospital
VA terminology Lexicon[10]	U.S. Department of Veterans Affairs
Convergent Medical Terminology[11]	Kaiser Permanente
UNMC Lexicon[12]	University of Nebraska Medical Center
ICPC Plus[13]	Australia, General Practice
Mayo Master Sheet Index[3]	Mayo Clinic in Rochester, Minn.

Terminology Services had been described as a way to implement centralized terminology access in enterprise wide electronic health information systems[14, 15]. HL7 Common Terminology Services (CTS) specification proposes a full set of features that a terminology server should provide.

Recently, Rosenbloom et al. published a review about IfT features and challenges[1], which we used to adjust and rethink some parts of our project, and we are now applying some of these concepts to structure this paper.

Objectives

The key objective of our project was to build a local Interface Terminology that allows users to record clinical data choosing options from a list of familiar terms but storing information SNOMED CT -compatible.

The IfT should provide adequate coverage for our reality. Users should have the ability to refine terms, choosing a more specific option of a given term, and propose new terms to improve coverage. The system should provide the equivalence of a given local term in standard classifications.

A "Terminology Team" would be in charge of the maintenance of the IfT, the system should also provide the tools required by this team.

System description

Concepts are unique cognitive representations of objects or situations in the reality in people's minds. Concepts are represented in textual form by terms, also called descriptions in this setting. Terms included in an IfT are arranged in concepts, expressing synonymy, and concepts are linked to other semantically related concepts in hierarchies.

Scope of the local IfT covers most aspects of medicine in a setting like ours. For the purposes of this paper, we will describe the development of the "Diagnosis Subset", 'Procedures Subset", "Drugs Subset" and a very specific "Causes of liver failure Subset" as an example.

The creation of the local IfT included the steps described in the following sections using the "Diagnosis Subset" as the main example.

Definition of IfT data structure

Our IfT was designed to take full advantage of SNOMED CT semantic structure and description logics, so our data structure is also tied to the standard SNOMED CT structure. SNOMED CT provides a data structure[16] (Figure 1) that allows storing local data following simple guidelines; local data can be differentiated from original SNOMED CT standard data by a "namespace" identifier included as part of each concept, term or description identifier.

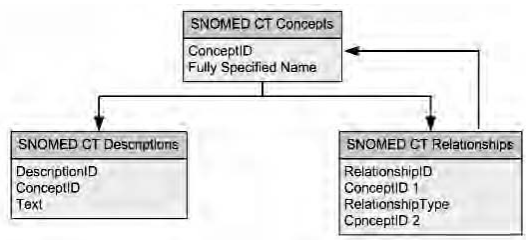

Figure 1 - Overview of SNOMED CT core data structure

This strategy is appropriate for small additions to SNOMED CT. In our case, we aimed to create an extensive local IfT, as independent as possible from the reference terminology. We decided to duplicate SNOMED CT data structure, and fill the empty model with our local data. The concept and description tables will contain our local concepts and descriptions, regardless if they are also present in standard SNOMED CT data or not. The relationship table will work as the link between the two models, linking from each local concept to standard SNOMED CT concepts (Figure 2).

Concepts that exist in both terminologies are linked with a "same as" relationship. New concepts in the local IfT are linked with a "is-a" relationship with the appropriate supertypes in SNOMED CT structure. The defining characteristics of the new concept, those that make it different from its super-type or father concept, are represented using other "attribute" relationships to standard SNOMED CT concepts, following official SNOMED CT modeling guidelines. The definition process using additional attributes is called post-coordination, which is done by experts from the Terminology Team based on user request of new terms. In this way, our local relationship table always links from local concepts to standard SNOMED CT concepts, providing semantic information to the local model.

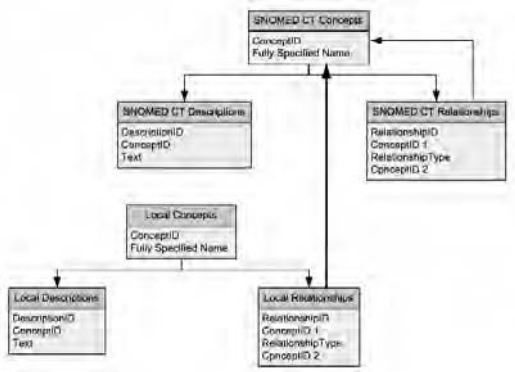

Figure 2 - Relationship between local IfT data structure and SNOMED CT core data structure

All concepts will be unique and each will have a unique "Fully Specified" description that fully describes the concept meaning, a preferred term for displaying to the user and a list of synonyms (descriptions).

Unique identifiers for concepts, descriptions and relationships are independent numbers, conforming to the SNOMED CT concept ID specification, using a local namespace. Applications use these identifiers to store data in the clinical repository and to retrieve subsets for structured entry in user interfaces.

Applications will code clinical data using the identifier for the description selected by the user, not the concept identifier. In this way, whenever the terminology team changes the relationship between a concept and some of its terms, pointing to another concept, there is no need to recode previously stored data in the clinical data repository.

We also decided that terms would be unique in our IfT, so each term is a synonym of only one concept. Ambiguous terms, defined as terms that possibly would relate to more than one concept were treated separately, as will be described later.

Subsets are implemented using SNOMED CT subset mechanism for enumeration of members (Figure 3).

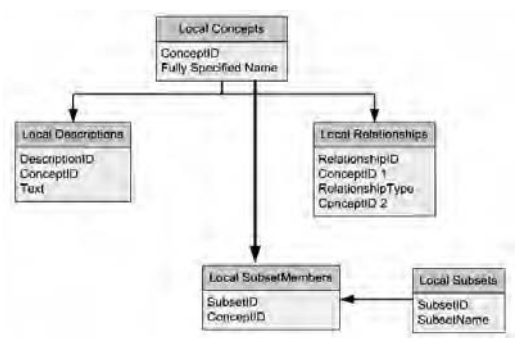

Figure 3 - Local Subsets data structure

Local terms collection and vonceptual aggregation

Some IfT's domains are expected to have more local variation and need to be more adjusted to our setting, such as terms for the diagnosis subset. On the other hand, some smaller issues, like drugs, have a much more limited number of textual variations and any standard list can be presented to the user as the IfT.

The Hospital Italiano previous vocabulary control system for the problems list consisted in physicians entering free text descriptions in the electronic medical record, which were later assigned classification codes by a group of coders. This process generated a backlog of more than 2 million free text phrases describing medical problems, entered by the professionals of the institution. We used this data for creating the terms included in the "diagnosis" subset of our IfT.

After applying a normalization process to these data, a list of more than 250,000 different short text phrases was created; about 110,000 descriptions appeared with 10 repetitions or more, accounting for more than 90% of the free text expressiveness variation of our setting. These 110,000 terms were manually revised, and synonyms were grouped together. We adopted the definition that synonyms are a group of terms that describe the same unique concept. After this process, the 110,000 terms were arranged in 24,800 concepts. We included these concept and synonym data into the "diagnosis" subset of our Interface Terminology. Only 33% of these concepts are direct links to SNOMED CT, a number of additional attributes where needed to represent the remaining 67%.

Terms for "Drugs" subset were imported from our Computer Physician Order Entry (CPOE) software databases.

For specific data-entry subsets like the "Cause of liver failure Subset" content was provided by specialists, describing the possible valid inputs.

Defining invalid terms, refinement and disambiguation rules

During manual revision of the free text entries, several terms where flagged as "Invalid" when their use was not appropriate in each sub-domain. Examples of invalid terms are uncompressible strings of text or terms of concepts not considered valid entries in the sub-domain, like entering procedures in a diagnosis field. In the implementation of the IfT, user interfaces should not allow terms included in this list to be added to the clinical record.

Some concepts were flagged as "Mandatory Refinement", when represented too general concepts and its clinical use would be improved with more detail. An example of that is the term "Diabetes Mellitus", which would be much more useful if refined to "Diabetes Type I", "Diabetes Type II", etc. In the implementation of the IfT, if the user selects one of these concepts he/she should be enforced to select a more specific concept, and a set of appropriate options should be presented, according to the semantic relationships in the local IfT.

Physicians were found to record data using less detail than they actually have obtained during a consultation or examination. Therefore, it must be possible to refine every concept to its more detailed sub-types, and these options should be presented to the user as non-mandatory alternatives.

Ambiguous terms cannot be assigned as valid descriptions of any concept and should be manually disambiguated by the users. These terms were stored separately and were related to the possible concepts in the Interface Terminology, so user interfaces should present the options to the users and force them to specify the concept they wish to use.

Adding semantic definitions through SNOMED CT mapping

Each local concept was modeled either as a direct equivalence to SNOMED CT or its meaning was described with a set of attribute relationships following SNOMED CT guidelines. The resulting relationships were also used for detecting synonymy, as there is a good chance that two terms that share the same definition refer to the same concept.

At this point, our Interface Terminology consisted only in a list of unrelated concepts in each subset, each of them with one or more textual descriptions. In our model all semantic information is derived from SNOMED CT. That means that it would be possible to understand the relationship between two terms in the Interface Terminology by following SNOMED CT semantic structure as can be interpreted from our data structure (Figure 2). This is equally possible for our post-coordinated terms, as they share the same semantic structure with original SNOMED CT concepts.

Definition of cross-maps to standard classifications

Mapping from our local IfT to standard classifications like ICD-9CM, ICD-10 or ICPC2 is provided through the SNOMED CT standard cross-maps mechanism.

Concepts included in the local IfT that are not present in the original SNOMED CT distribution, are mapped through its super-types, the more general, standard concepts used for represent their meaning.

This strategy was preferred instead of a direct linking in order to provide a full access to available standard cross-maps sets from SNOMED CT to classifications.

Defining strategies to mMaintain domain coverage

The coverage of the Interface Terminology can be described at two levels, conceptual level, and term level. The conceptual level refers to the proportion of the locally used medical concepts that are included in the terminology. Term level coverage refers to the proportion of the different text descriptions or terms used to describe those concepts which are included in the Interface Terminology.

The coverage is originally determined by the accuracy of the initial process of data recollection for inclusion in the Interface Terminology. Later, this coverage is maintained and adjusted by the expansion of the terminology, based on user experience.

According to its definition, the expansion process had to be based on direct user suggestions that would be manually evaluated by the Terminology Teams prior to its formal incorporation in the interface terminology. Software user interfaces would enforce user participation with suggestions and commentaries.

Definition of strategies for updating to new versions of SNOMED CT

The IfT should provide an adequate solution to the management of new SNOMED CT versions. New versions may carry ambiguity, including new standard concepts that were previously included in the local extension. In this case, the local IfT concept should map directly to the new SNOMED CT concept instead of the super type and the attributes used to model its meaning. Classification algorithms can automatically detect these cases and remap the concepts maintaining consistency.

Another problem is SNOMED retiring concepts or terms in new versions, in order to correct problems in its representation .When those concepts were used in the representation of the local IfT, concepts would be pointing to inactive codes in the standard. Current SNOMED CT mechanisms do not support automatic selection of new, valid, codes to replace retired ones. The IfT should provide a local valid list of concepts and terms whose representation is affected by changes in the new version of SNOMED CT to manually correct its representation.

Current status

Implementation of the local IfT

The local IfT was implemented in our health information system on June 2006 using a set of Terminology Services. The first area was the inpatient structured discharge summary input. Subsets for Diagnosis and Procedures are used in a user interface that allows text input and search of related terms. The user interface uses the rules for dealing with invalid, ambiguous and refinement rules.

During the initial 6-month deployment, the user proposal of terms is enforced and free-text input is an alternative available to the users. These inputs are redirected as new terms proposals.

The IfT administration software provides tools to support all the design objectives described before.

Coverage

Coverage is estimated by subset, the incidence of “new terms” proposal issued by users. We measured this during a week after 3 month of implementation; using the Diagnosis input interface new terms were proposed in 12% of the interactions by users, meaning than in 86% of the cases a good option was selected from the IfT. Using the Procedures input interface, proposal rate was 30% of the cases.

New terms proposals were evaluated by the terminology team, and accepted as new terms in the IfT in less than 40% of the cases for Diagnosis and 80% for Procedures. Reasons for rejections were the proposal of invalid terms or already existing terms.

Discussion

Our model performance was very satisfactory for our extensibility needs and the creation of local subsets. The duplication of data models with SNOMED CT adds complexity to data access, but once the basic mechanisms were created and tuned they did not impact on system performance or software development speed.

Our aim is to gradually enforce the user to only use terms included in the IfT, allowing suggestions but in a different process outside the data entry workflow. From the results is clear that the Diagnosis domain has achieved a much more mature status than Procedures. New improvements in search algorithms and contents are still needed until final implementation of a more restrictive interface.

The desired level of user expression freedom we wanted to support included describing laterality in findings and procedures. This lead to a combinatory "explosion" of thousands of new concepts to model outside SNOMED CT and an important increase in manual work by the terminology team. This is the cause of the 67% of post-coordination, which puts us on the need of a very strict quality assurance process over those more than 16,000 post-coordinated concepts. This will be the focus of a future paper.

Additionally, body parts are not always represented as lateralized concepts in SNOMED CT, for example different codes exist in SNOMED CT (1-2006) for left and right hand or breast, but not for great toe. We used a non-official "Laterality" attribute applied to the finding or procedure instead of modeling new concepts for body parts in SNOMED CT. In order to provide interoperability this can be easily solved at the moment of sharing data.

The procedures subset proved to be a much more complex domain than findings (diagnosis). Surgeons in our setting used a complex language, often combining different procedures in the same sentence, or adding details on the intention or result of the procedure. The rate of proposals of new terms by the user remains high in this domain; perhaps a structured, compositional approach to the user interface would be useful.

Analysis of user proposals was very important for introducing changes in the search algorithms, as in many cases the term already existed and was not found by the user.

In this experience we implemented post-coordination to SNOMED CT by expert authors of the Terminology Team. We are testing end-user interfaces to post-coordinate new concepts in specific settings, like the "Family History" subset. In this way, any user can create a new term in the IfT expressing that is a "Family History" of a given existing local concept, and selecting in which family member occurs. The proposed model is compared to existing "Family History" concepts. In case it has not previously appeared, a new concept is created, as well as the automatic creation of relationships to the corresponding standard SNOMED CT concepts.

A test of interoperability sharing post-coordinated data with other institutions with a similar SNOMED CT-based IfT is being tested and will be the subject of a future paper.

We are also testing a model for dynamic subset definitions, a set of rules that allows the definition of a subset in terms of their relationships with SNOMED CT concepts. In this way we can define in the local IfT a "Diabetes Subset" with all the terms related to the concept "Diabetes Mellitus" in SNOMED CT or any of its subtypes. Dynamic subsets are updated nightly in order to include recently added local concepts, and are the way to select data from the data repository with a clinical focus, including a wide range of terms, from the standard concept "Diabetes Mellitus Type II" to the very specific, post coordinated, local concept "Diabetes Mellitus Type II with mild diabetic neuropathy".

Future implementation of the system in the outpatient ambulatory setting and general restriction of free text input will prove how much work is required to maintain good domain coverage of the local IfT.

Abstract

There is growing interest in the development of standards which structure information round discrete clinical concepts, in a way that supports system development and interoperability. Most notable are the openEHR Archetypes and Templates, and HL7 Templates.

A project is described which explored the potential for these to engage and support clinical practitioners in developing clinical information standards in an open and accessible way.

The project followed three phases: professional development, including networking for content development; library implementation, including modelling and processes for managing content and relating to information standards; and implementation in working systems in a manner that is professionally acceptable.

The project findings are encouraging although there remain some important issues to be explored in further work. The topic has now emerged as an important area of standards development, and a useful focus for international cooperation.

Keywords:

archetypes, clinical templates, nursing informatics

Introduction

At the heart of systems development is formalisation [1]: the process by which we describe objects in the world and actions that change them in ways that allow us to develop systems to help us achieve our goals. As our systems become more complex, interoperability becomes a key requirement and is dependant on shared formalisations.

This is the main driver behind current standardisation efforts: the goal of consistency and predictability across our data and our system processes, with the added goal of saving effort through re-use, and more controversially, raising quality.

Background to relevant standards development in NHS Scotland

During the 1990s, in the UK there was a large investment in terminology as an essential clinical information standard. There may be many reasons why this did not give the anticipated return on investment, but one explanation is that standardised terminology systems do not give enough support to developers and users who do not want to interact with terminology browsers, but with data items structured in ways that fit well with the context of the user at a particular point in time. [2]

The NHS Clinical Terms Project subsequently became part of SNOMED-CT, and NHS Scotland has adopted this as a national standard for clinical terminology. Other standards work has included the National Data Dictionary, and the National Clinical Datasets Development Programme. [3] However, none of this work meets the need identified above: context-specific domain models as the basis for standard components for building clinical information systems.

In the absence of standards in this area, there has been widespread ad hoc development within end-user applications such as GP systems, and, for example, in the national Scottish SCI XML messaging standards used for structured clinical communication. [4] Although the terminology concepts used are standardised, the contextual 'wrappers' around the terms are idiosyncratic.

A recent NHS Scotland project, the Generic Clinical System (GCS), has anticipated the issue of standard domain models applied to the user interface, and has done design work for a National Forms Library.

Archetypes and templates as international standards

The issues outlined above have motivated standards work in both openEHR and HL7.

An openEHR archetype is "*a computable expression of a domain content model in the form of structured constraint statements, based on some reference model.*" [5]

Archetypes are seen as a means of defining clinical knowledge in an explicit way, separating it out from the system

Selected for best paper award.

software that uses it. This has dual benefits of enhancing clinical ownership and making system development and maintenance easier.

An openEHR template is "*a directly, locally usable definition which composes archetypes into a larger structure logically corresponding to a screen form*." [5]

Templates have an important role in grouping and refining archetypes for specific local applications.

A HL7 Template is "*... an expression of a set of constraints on the RIM which is used to apply additional constraints to a portion of an instance of data which is expressed in terms of some other Static Model. Templates are used to further define and refine these existing models within a narrower and more focused scope*." [6]

The most obvious difference between the two approaches is that HL7 starts with a highly abstracted pattern, the Reference Information Model (RIM) that is then constrained by templates that define the local content of the model. In contrast, openEHR uses a small, generic and granular information model. Archetypes specify instances based on and built up from objects in the model. It is argued that this latter approach is closer to development methods such as object-oriented techniques where generic objects are specialised until they are fit for purpose.

HL7 was primarily intended to support the modelling of messaging between clinical systems whereas openEHR's design focus is on the clinical record itself, but both models intrude on the other's natural territory. The HL7 Clinical Document Architecture (CDA) [7] is designed to model elements of the clinical record, whilst the openEHR EHR Extract provides the basis for constructing clinical messages.

There have been interesting 'frank and open' exchanges on email discussion lists as some proponents point out differences, while those interested in solutions search for the similarities. [8, 9]

The feasibility study

As interest in this topic has grown in recent years, a project was commissioned by the Scottish Executive Health Department, funded by the Primary Care Division, and sponsored by the Community Nursing Network and the Chief Nurse for Scotland. The project started in November 2005, running until May 2007. The project was delivered by Glasgow Caledonian University and titled *'a National Library of Clinical Templates for Community Nursing in Scotland: a Feasibility Study'*.

Study aims

The project aimed to describe the options for developing and implementing a National Library of electronic Clinical Templates for Nursing in the Community in Scotland and evaluate the benefits to clinical care and secondary information users.

The objectives were to:

- identify the extent of commonality in the structure and content of community nursing records in Scotland;
- prototype and test a method of collecting record content, evidence-based, and other expert sources to develop and maintain templates;
- evaluate options for template types;
- prototype and evaluate an option for publication of templates, including information on sources and levels of authority of content;
- examine the use of template-driven data entry for community nurses to identify models of integration with clinical practice; and
- evaluate the implications of these models to produce implementation guidance.

The desired outcomes were to have:

- a clinically-owned reliable methodology for getting nationally standardised templates that support care delivery processes into electronic records and updating them; and
- a sustainable mechanism, the national library, for maintaining the templates.

This emphasis on clinical involvement was key in shaping the approach taken by the project.

Method

The project comprised three phases: *professional development, library management,* and *implementation*.

The *professional development* phase explored options for supporting clinical involvement in the process of development and maintenance of national standard clinical information tools.

Existing national groups of Tissue Viability Nurses, Continence Advisors and a Health and Well-being Network (concerning the physical health of people with serious mental health problems) were approached and cooperated over the development of national standard templates. In addition some standardised tools have been modelled, and content from the Dutch Care Information Model [10] included. A third source is template content from existing community information systems, included as example material.

The project has developed and tested on-line collaboration for working groups, using an approach based on the Open Source movement [11] at a public web site. [12] Working groups have been open for anyone to join. Joining means that members are notified by email of news or discussion items posted in the group. Anyone can visit the group page and view resources or templates, and comment on the work. Comments can be entered against individual template items to make the process easier.

Changes to templates are controlled by a group of *core developers*, and membership is restricted to those approved by the group itself.

The *library management* phase explored the development outputs to produce clinical domain models, candidate templates/archetypes, and prototype tools and architectures for maintenance and electronic publishing.

One use case explored collaboration and re-use. The Health and Wellbeing working group wanted to work on a general physical health screening tool. Their examples included content that would be commonly used in other primary care settings, including sections on smoking and alcohol use. The project invited experts on these topics to set up their own working groups, which would produce the component templates that the Health and Wellbeing group would re-use.

Owing to uncertainty over standards for archetypes, the project used simple XML mark-up, with a schema that supported metadata, individual items, and groups, which could be nested to an arbitrary level.

The *implementation* phase included evaluation of user experience with form-based systems at existing sites, for 'professional' acceptability. It also considered issues around importing schema from the library and issues of localised form development and updating.

A survey of expert practitioners is to be completed between January and May 2007, and results will be available for presentation at Medinfo 2007.

Emerging model

It seems that the more our user groups were able to engage in developing tools that were close to what they would use in their work, the easier they found their task. Very few users expressed any interest in the underlying technical detail of archetype definition and management.

The project experience therefore suggests that there is a line of demarcation between the clinical domain with forms and templates, and the technical domain of archetypes and other information standards that underpin them.

The project has therefore proposed that template development be continued with strong clinical ownership, while archetypes (or whatever approach is taken to defining standardised components) are best developed and managed by NHS national information standards bodies. This should also help with implementation of SNOMED-CT in a consistent way.

Discussion

By focussing on processes and methods to support clinical ownership and development of templates, these benefits are anticipated:

- immediate needs of national and local systems development for standardized forms will be met;
- a larger corpus of clinically acceptable templates will be available for 'technical' standards development;
- professional issues around clinical standards can be better addressed and awareness raised through clinical communities;
- re-use of templates will be increased if local developers know of a national source; and
- once the underlying standards work (archetypes etc) is sufficiently mature, there will already be a means for this to be used as the basis for further template development.

Given this emerging model, the openEHR model was a good fit, distinguishing as it does between templates and archetypes. However, given the developmental nature of the standards at the time, it was too early to select one over the other. The project therefore made an effort to include content developed using HL7 Templates, from the Netherlands.

The project was limited in its exploration of issues round *local customisation*. Attempts to promote reuse in software engineering, notably in object oriented programming, have resulted in a raft of techniques to enable reusable objects to behave in a slightly modified way. [13] Templates will require the application of similar techniques.

While national standard templates can carry identifiers when implanted on local systems, there are many 'soft' organisational issues around change control. Should local changes be fed back, as requests for change? A refactoring approach to local changes might be the best approach, i.e. an approach that contains the mechanisms for local changes to be 'pushed up' to achieve more national visibility if it is agreed that the local change should be used by others.

There is clearly a requirement for national knowledge of 'who is using what, and which version' and this could be done either by a nominated change control group, or collaboratively using a similar approach to the one used in this project.

The NHS already has a content management system, the technology that underpins the National Data Dictionary, and this would be suitable for containing templates to be used nationally.

The project did not investigate the effects on clinician/patient interaction due to structured data entry becoming part of the encounter. This is a major issue in clinical domains like nursing, where this will be new to many practitioners. However, we do have a large body of experience to draw on from General Practice medicine, where it has been well-researched [14, 15, 16] and guidance is available. [17] General practitioner training now specifically addresses the issues raised but the integration of decision support into the clinical setting remains problematic due to the competing cognitive demands on the practitioner. [18]

Mention was made earlier of the over-expectation in the 1990s that clinical terminology systems would 'enable' clinical system improvements, an expectation that was largely unrealised. It is important not to 'over-sell' the potential benefits of clinical templates. They do not remove the requirement for careful requirements analysis, and imaginative and sensitive system design. There is a doomsday scenario where a national *library* with a large number of forms would result in *systems* with large num-

bers of forms, which only increase the burden of data entry on clinical practitioners.

Successful implementation of a large national library would depend on template management. In common with openEHR archetypes, the project found that while templates may be simple in conception, we should not underestimate their complexity in representation. As templates are essentially combinatorial in nature it is important that template fragments can easily be reused across templates. Thus effective indexing becomes key, i.e. the ability easily to locate relevant templates or template fragments within a large repository.

A variety of approaches to representation and indexing were trialled in the pilot project including: an openEHR approach using the Ocean Informatics Archetype Editor [19]; and full representation in the Web Ontology Language (OWL) [20] using the Protégé ontology modelling environment. [21]

Each approach brought its own merits, for example the ability within OWL to specify and enforce the basic form of templates. However, no one approach emerged as a standard. Indeed, much simpler XML mark-up and metadata (as described previously) met the needs of this project. This represents a shift in emphasis but is consistent with the Open Source movement in providing relatively simple solutions to global problems (rather than vice versa). However, it is not yet known how such a simple approach might scale up.

Conclusion

The project has attracted strong interest from key stakeholders:

- *clinical groups* who see national templates as a means of supporting best practice;
- *clinical informatics staff*, who see the benefits of reuse, rapid development, and interoperability; and
- *national information standards bodies*, who require clinically acceptable standardized content, consistency for national information requirements, and a means of supporting implementation of SNOMED-CT.

Given the encouraging findings of the project, next steps should increase and widen clinical engagement and template development, most likely by involving Allied Health Professionals and Primary Care teams.

Finally, contact has been established with international colleagues working in this area, in particular the Netherlands [10], Australia [22] and developers in the USA, and there is agreement between interested parties to cooperate.

Acknowledgments

The authors acknowledge the support of the Scottish Executive Health Department Primary Care Division, the Community Nursing Network, NHS Scotland Information Services Division, and Dr William Goossen of the Dutch Care Information Model Project.

Keeping Up with Changing Source System Terms in a Local Health Information Infrastructure: Running to Stand Still

Daniel J. Vreeman, PT, DPT[a]

[a] *Regenstrief Institute, Inc and Indiana University, United States*

Abstract

Keeping up with changes in source system terms in a local health information infrastructure requires substantial effort. I developed a program to assist us that returns candidate mappings based on string similarities between newly encountered source test names, existing source test names, and our master dictionary term names. I evaluated this program's performance in identifying correct mappings through a retrospective study of term mappings to our master dictionary from four radiology systems. For source terms created after the initial system integration, the semi-automated mapping program identified correct mappings for 76.3% of terms from all systems. Overall, the program correctly identified mappings for 45.6% of all terms by exact string match to an existing term. The program identified correct mappings for 36.9% of the terms without an exact string match by string comparison to existing source terms, and for 54.4% of the remaining unmapped terms by string comparison directly to master dictionary terms. Because managing vocabulary mappings is resource-intensive, accurate automated tools can help reduce the effort required for ongoing health information exchange among disparate systems.

Keywords:

terminology; medical record systems, computerized; interinstitutional relations

Introduction

Interoperable health information exchange is hindered by the myriad internal, idiosyncratic conventions for identifying identical data in separate electronic systems. A comprehensive health information exchange must coalesce all of the various sources that produce health data in order to provide clinicians with information when and where they need it. The Indiana Network for Patient Care (INPC) [1] is an early example of a local health information infrastructure (LHII) that has been operating in central Indiana for more than eight years.

The INPC includes data from all five major hospital systems (fifteen different hospitals and more than a hundred clinics), the state and county public health departments, Indiana Medicaid, and RxHub. The federated INPC repository now contains more than a billion clinical observations, including laboratory results, text reports, radiology images, and EKG tracings. As a neutral, third party convener and data "Switzerland", the Regenstrief Institute receives all of the clinical message streams from participating systems. Last year approximately one hundred source systems sent HL7 clinical result messages to us in this collaboration. We accomplish the task of integrating data elements from all of these contributing systems by mapping the internal codes from the source systems to a common master dictionary that is based on vocabulary standards such as LOINC®.[2]

Mapping the local observation codes from all of these source systems requires substantial manual effort, domain expertise, and may be inconsistent because of the variability inherent in human review. Our centralized approach is effective at consolidating the expertise and tools needed for the task. Although the mapping effort for a given system is typically largest during the initial system integration, each source system continues to evolve after that initial period. INPC participants retain control over their institution's naming conventions and local term dictionaries, adding, deleting, and changing terms to meet their needs. Ideally, everyone would follow good terminology principles to allow "graceful evolution" [3] and would give the terminologists who manage the common dictionary advanced notice of upcoming changes. In practice, we have found the work of surveillance for and managing these source system changes to be a challenging aspect of operating an LHII.

To help address these challenges, we develop automated tools to assist us wherever possible. A recent focus in the INPC has been on integrating reports from six radiology centers throughout the network. By integrating these systems and distributing their content throughout the network, we hope to combat the common problem of radiology reports being unavailable when and where they are needed.[4] We previously developed and evaluated [5,6] programs to help map local radiology terms to LOINC®. While these tools are valuable in the initial mapping period, we have observed that many of the term changes occurring after this initial phase are the result of inventing new terms for the same test that are intended to distinguish among the various facilities performing that test. Because these new terms are often variants of an existing test term, their string names are often the same as (or very similar to) a term we have already mapped, but their test codes are different.

Approximate string comparators compute a measure of similarity between two strings. Although approximate string comparators have long been used in record linkage,[7-10] there is a paucity of literature about their performance in term mapping. I previously conducted a short term pilot study [11] of one institution's codes, which suggested that approximate string comparators could be valuable in managing these maintenance mappings. Based on these initial findings, I developed a revised program to help semi-automatically map new observation codes from our message processor exception logs to the INPC's master dictionary. Here I present a retrospective analysis of its performance in maintenance mapping test terms from four radiology centers in the INPC.

Materials and methods

Data sources

To evaluate the performance of the mapping program, I extracted local radiology terms from four systems participating in the INPC. The goal of my analysis was to simulate performance with maintenance mapping using the historical data contained in the INPC master dictionary. For each institution, I extracted local terms that were created after the initial system mapping. System A was initially mapped in March 2001, system B in October 2003, and system C and D were both mapped in December 2005.

In practice, as terms from each system are mapped to the master dictionary, we encounter some tests for which no suitable master dictionary term exists and therefore a new master dictionary term must be created. To simulate this retrospectively, I excluded local terms that were mapped to a master dictionary term created after the record of the local term was created. This process excluded 561 terms from system A, 318 terms from system B, and no terms from either system C or D. The extract thus included a total of 3,243 terms, of which 1,100 were from system A, 1,552 terms were from system B, 243 terms were from system C, and 348 terms were from system D. Because all of these terms have already been mapped into the master dictionary, the existing mappings served as the reference standard.

Maintenance mapping process

I developed a maintenance mapping program in Perl that is designed to semi-automate the process of finding master dictionary matches for unmapped local codes. In practice, these codes are caught by our HL7 message exception processor because they are not present in our dictionary mapping tables, and then stored in an exception log table. For this study, I modified the program to operate on the file of extracted terms rather than the log table. Because of the common feature of radiology systems inventing multiple codes for one test to distinguish among facilities, I designed the program to leverage the existing term mappings assigned during the initial system integration. The program identifies potential master dictionary matches in three phases.

Phase 1 - Exact string matches

For radiology tests from the same institution, we assume that if the string names are identical, there is a very low likelihood that the tests are actually different. Thus, we feel relatively confident in automatically assigning a master dictionary mapping based on identical strings. Therefore, the mapping program first looks for existing local terms from the same system that are mapped to the master dictionary and whose name ***exactly matches*** the string name of the unmapped code.

Phases 2 and 3 - Approximate string comparators

In the second phase, the program identifies candidate matches for all of the terms without an exact string match to an existing local term. It does this by calculating approximate string comparator scores between the new term name and existing local term names that have already been mapped to the master dictionary. The comparators we employed all generate a score between 0 and 1, with 0 being little similarity and 1 being an exact match between the strings. Because different string comparators exhibit varying sensitivity and specificity [7] related to the kinds of mismatches between strings, the program returns candidates based on the root mean square (RMS) of three different comparators.

The ***longest common substring*** algorithm generates its score by iteratively locating and deleting the longest common substring between the two strings.[12] The ***Levenshtein edit distance*** [13] between two strings is given by the minimum number of insertions, deletions, or single character substitutions needed to transform one string into the other. In this implementation, the program transforms the edit distance metric into the 0 to 1 range using a previously described method.[7] The third string comparator used is the ***Ukkonen similarity function*** [14], which is similar to the Levenshtein edit distance, but includes the operation of allowing arbitrary length substitutions. The program implements the Ukkonen function with the freely available Perl module String::Similarity (http://cpan.org) written by Marc Lehmann.

The mapping program generates its list of candidates from existing local terms with an RMS similarity score of 0.75 or greater. Candidates are ranked by descending RMS score, and the top three candidates are returned for human review.

In the third and final phase of the mapping process, the program returns candidate mappings directly to master dictionary terms for local codes that could not be mapped based on exact string matches or string similarity scores with existing local terms. Because of differences in naming conventions, master dictionary terms are much more likely to be dissimilar to local term names than are terms from the same system. Therefore, the candidate mappings in this phase are based on the less stringent RMS similarity score of 0.65 or greater. The program returns the top three candidates for human review. Figure 1 shows a Microsoft Access form for reviewing candidate maps and their similarity scores.

Table 1 – Mapping program identification of correct matches by phase and radiology system

	Correct Matches by System				
Mapping Phase	**A** n=1100	**B** n=1552	**C** n=243	**D** n=348	**Overall** n=3243
Exact string match to an existing local term % (n)	12.5 (137)	68 (1054)	0 (0)	82.5 (287)	45.6 (1478)
Match to a top 3 candidate local term by string comparator score % (n)	14.6 (141)	76.8 (380)	41.2 (100)	49.2 (30)	36.9 (651)
Match to a top 3 candidate master dictionary term by string comparator score % (n)	34.3 (282)	18.5 (22)	23.1 (33)	25.8 (8)	54.4 (345)
Total of all phases % (n)	50.9 (560)	93.8 (1456)	54.7 (133)	93.4 (325)	76.3 (2474)

Measures

To assess the performance of the mapping program, I recorded the number of correct matches that could be identified in each sequential phase: exact match to an existing local term, match to a local term returned by the string comparators, and match to a master dictionary term by the string comparators. Correct matches were ascertained by comparing the program's results with the reference standard.

Results

Overall, the three steps of the mapping program identified correct matches for 76.3% (2474/3243) of terms from all systems. The mapping performance at each step in the process for the four radiology systems is given in Table 1. Correct matches were identified by exact string match to an existing mapped local term for 45.6% (1478/3243) of the terms. These matches represent the subset of terms that we felt could be automatically assigned a master dictionary mapping.

Of the terms that did not have an exact match to an existing mapped local term, the program returned at least one candidate mapped local term for 47.5% (839/1765) based on RMS string comparator scores exceeding the threshold. A local term with the correct master dictionary mapping was present in the top three ranking for 77.6% (651/839) of the terms with candidates. The top ranked existing local term had the correct master dictionary mapping in 84.0% (547/651) of the terms for which the correct mapping was present in the list of candidates. In summary, the string comparator-generated candidate list contained the local term with the correct mapping for 36.9% (651/1765) of the terms that did not have an exact match to an existing local term.

Of the terms without an exact match or a string comparator candidate match to an existing mapped local term, the mapping program returned at least one candidate master dictionary term for 56.9% (634/1115). The correct master dictionary term was present in the top three ranking for 54.4% (345/634) of the terms with candidates. The top ranked master dictionary term was the correct term in 81.7% (282/345) of the terms for which the correct master dictionary term was present in the list of candidates. In summary, the string comparator-generated list of master dictionary terms contained the correct mapping for 30.9% (345/1115) of the terms that did not have a match from the first two phases.

Discussion

The semi-automated process of the mapping program identified the correct master dictionary term mapping for two-thirds of the terms in this extract from four radiology

systems. Nearly half of the terms encountered since the initial system mappings could be automatically assigned a master dictionary code because of an exact string match with an existing term from that source system. More than half of the remaining terms could be assigned a map by a human reviewer examining at most six ranked candidate terms based on approximate string similarity scores (three existing mapped local terms and three master dictionary terms). For terms that could be assigned a map in this way, the likelihood of the correct mapping coming from the top ranked code is very high (82-84%).

This study was designed to evaluate the performance of the mapping program's unique, tiered approach to identifying candidate matches. Using the first phase of exact string matches to automatically assign a map without human review could greatly reduce the manual effort of maintenance mapping. Likewise, human review of a short, high probability, ranked candidate list is more efficient than our current term-by-term searching mechanism, even with database searching tools. Anecdotally, a domain expert can review these candidates and determine if a correct mapping exists in less than a minute per term. Because the volume of maintenance mapping is relatively low and there are relatively few pair-wise comparisons, the computational costs of using approximate string comparators is not prohibitive of this approach.

The method of bootstrapping existing term mappings from the initial system integration may not be as successful in domains other than radiology, because test naming conventions differ across domains. Although automatically assigning a master dictionary mapping based on an exact string match is defensible and pragmatic, it is not without error. Comparing the mappings that could be assigned by exact string match with actual historical mappings assigned by our largely manual process identified discrepancies in 4.7% (70/1478) of the terms. These discrepancies may indicate errors in either the initial system mapping or our current manual maintenance mapping procedures. Nevertheless, it highlights how fully automating this phase of the mapping process could propagate errors over time.

The success in identifying correct master dictionary matches varied widely among the four institutions examined in this study, both in total, and by phase. For example, 82.5% of the new terms from system D could be mapped based on exact string matches with existing terms, whereas none of the new terms from system C could be mapped in this manner. This variable success highlights the non-uniformity in naming conventions and terminology practices among radiology systems. Internal variation within a system's term names as well as that system's likelihood of assigning multiple codes for the same test both influence mapping success in phases 1 and 2. Mapping success in phase 3 is linked to the similarity of local system naming conventions to the master dictionary conventions. For example, some systems tended to use very few abbreviations, e.g. "CT Upper Extremity Angiography Without then W Contrast". In comparison, abbreviations and acronyms are commonly employed in master dictionary term names, e.g. "Extremity Up CTA WWO Contr". These discrepancies hinder identification by string comparison.

The maintenance mapping program evaluated in this study used three different approximate string comparators to assess string similarity, but inclusion in the candidate rankings was based only on the RMS combined metric. It is possible that the individual comparators have meaningfully different characteristics that were masked by aggregating them into one score. I intend to evaluate the relative individual performance of these comparators in future work. Furthermore, our RMS thresholds for phases 2 and 3 were arbitrarily set rather than by comprehensive empiric analysis. Moreover, it is possible that other string comparator functions[8], phonetic compression algorithms[15,16], alone or in combination with blocking schemes[17] or probabilistic methods of obtaining an overall agreement score[18] may perform better at the task of term mapping than the current approach. Other terminology mapping approaches, such as ontology-based integration techniques [19] may also be valuable in maintenance mapping from source systems.

Conclusion

This study demonstrates the utility of a simple program in maintaining the mappings from radiology source systems in an LHII. By leveraging the mappings generated during the initial system implementation and employing approximate string comparators to identify high likelihood candidate matches for focused human review, the program can reduce the manual effort of managing these changes. Nearly half of the terms encountered in this retrospective analysis could be automatically mapped with high accuracy. Half of the remaining terms could be mapped by human review of a short list of ranked candidates. Because the program so often includes the correct match first in its rankings, domain experts can review the candidates and choose the correct mapping more quickly than our current term-by-term searching methods. Because vocabulary mapping is a resource-intensive step in managing an LHII, automated tools that help us keep up with changes in source terminologies will reduce the effort required for ongoing health information exchange among disparate systems.

Acknowledgments

The author thanks Shaun Grannis, MD for providing Perl implementations of the longest common substring and Levenshtein edit distance algorithms, and the Regenstrief Institute for supporting this work.

Abstract

Despite decades of work, there is no universally accepted standard medical terminology and no generally usable terminological tools have yet emerged. The local dictionary of concepts of the Georges Pompidou European Hospital (HEGP) is a Terminological System (TS) designed to support clinical data entry. It covers 93 data entry forms and contains definitions and synonyms of more than 5000 concepts, sometimes linked to reference terminologies such as ICD-10.In this article, we evaluate to which extend SNOMED CT could fully replace or rather be mapped to the local terminology system. We first describe the local dictionary of concepts of HEGP according to some published TS characterization framework. Then we discuss the specific role that a local terminology system plays with regards to reference terminologies.

Keywords:

terminology; controlled vocabulary; medical records systems, computerized

Introduction

The need for terminological systems (TS) to support clinical statements in Electronic Health Records (EHR) has been widely recognized [1]. A terminology system can range from simple code-name-hierarchies, e.g. ICD and MeSH to knowledge-based ontologies such as FMA [2], SNOMED-CT [3] or Gene Ontology [4]. Beside this, terminology browsers, editors and servers have been developed to facilitate creation, maintenance and use of terminological systems [5]. Nowadays, no universally accepted standard medical terminology and no generally usable tools have yet emerged.

By contrast, consensus on requirements for terminological systems and servers to be useful in EHR is emerging [6]. Evaluation methodologies are already available to describe and compare TS in an objective and reproducible manner [7-9]. For Cornet et al., a TS has to be characterized as a terminology (providing a list of terms) and possibly also as one or more among: a thesaurus (alphabetically ordered terms with synonyms), a classification (arrangement of concepts using is-a relationships), a vocabulary (providing free-text or formal definitions of concepts), a nomenclature (providing composition rules) and a coding system. Cornet *et al.* have applied their evaluation framework to SNOMED CT used in combination with the CLUE browser [8].

In the Georges Pompidou European Hospital (HEGP), a local dictionary of concepts was designed to support structured data entry and to provide decision support based on the recorded clinical information. The local dictionary of concepts was populated with the concepts derived from the items of data entry forms. In the next future, we plan to use SNOMED as a reference terminology in order to ensure semantic interoperability. Our main concern is to investigate if SNOMED should fully replace or rather be mapped to the local terminology system.

We first describe the local dictionary of concepts of HEGP and the evaluation framework proposed by Cornet et al. Then we characterize the local dictionary of concepts according to this framework and compare it to SNOMED CT. We further discuss the specific role that a local terminology system may play with regard to reference terminologies.

Material and methods

Local dictionary of concepts of HEGP

The component-based hospital information system of the HEGP is provided by a consortium driven by Thales©. This company develops generic components and middleware tools for the integration of healthcare components into a multilayered architecture. A generic component stores reference terminologies used by various other components. These terminologies are: international reference terminologies (e.g. ICD-10), national reference terminologies (e.g. CCAM, the French national procedures nomenclature) and local reference terminologies (e.g. list of HEGP care units or healthcare professionals, list of pharmaceutical drugs available in the hospital, etc.).

One of the healthcare components provides EHR components including patient order entry. Clinical information can be entered as free text in Word® documents or as semi-structured documents using entry forms called "questionnaires".

A module allows users developing their own local dictionary of concepts. Another module allows users to create questionnaires. Local concepts directly derive from the items (attribute-value pairs) of questionnaires. In practice,

each question (attribute) is expressed in colloquial terms in the questionnaire and linked to one and only one concept of the local dictionary of concepts. If no matching concept is found in the dictionary, then a new concept is created by the user. For checklist questions, with a predefined list of possible values, each answer (value) is also linked to one and only one concept, preexisting in the dictionary or newly defined. It is also possible to link these predefined answers to concepts selected in one of the reference terminologies rather than to concepts of the local dictionary.

Since 2003, HEGP users derived the local dictionary of concepts from clinical items of 93 questionnaires. Among these questionnaires, 58 were created for physicians, 33 for other healthcare professionals and 2 questionnaires about past medical history and allergy were common to all healthcare professionals.

Characterization of the HEGP local dictionary of concepts

We analyzed the local dictionary of concepts of the HEGP (LDC-HEGP) according to the TS characterization framework proposed by Cornet *et al* [8]. This framework distinguishes between application-dependant features and application-independent features.

The only application-dependant feature is content coverage of the TS according to predefined purpose and scope.

Application-independent features are categorized along two axes. Along the first axis, features are categorized as being related to one of the six main types of TS: list of terms management for "basic" terminologies, indexes and synonyms management for thesauri, free-text or formal concept definitions for vocabularies, classification principles for classifications, composition rules for nomenclatures and coding process for coding systems. Along the second axis, features are categorized as being formalism-related characteristics, function-related characteristics and content-related characteristics.

This two-axial evaluation framework was applied by Cornet *et al.* to the July 2003 English version of SNOMED CT used in combination with the CLUE browser 5.5 [8]. We applied the same framework to the HEGP local dictionary of concept and its browser. Although the HEGP dictionary of concepts should mainly be seen as a thesaurus and a vocabulary, we applied the full set of criteria found in Cornet's evaluation framework in order to expand our view on the system. Content coverage of the local dictionary of concept was analyzed according to its predefined purpose and scope – i.e. enhancing structured data entry and decision support.

Results

Application-independent evaluation

Table 1 - Criteria related to "Management of a list of terms" (Terminology)

List of terms management		LDC HEGP	*SNOMED CT [5]*
Formalism	· Concepts and terms distinguished	· Yes	· *Yes*
	· Term length restriction	· Yes	· *None*
	· Character encoding	· n/a	· *UTF-8*
	· Concept obsoletion mechanism	· Yes, concept status flag and author tracked	· *Yes, concept status flag, with motivations*
Content Tool	· Convert code to text	· No	· *For concept and description IDs*
	· Lookup phrases for a string	· Yes	· *Yes*
	· Lookup phrases with wildcards	· No	· *Yes*
	· Inexact match	· No	· *No*
	· Code refinement	· No	· *No*
	· Keyword matching	· No	· *n/a*
	· Case-insensitive	· Yes	
	· Total nb of concepts	· 5426	· *352662*
	· Total nb of terms	· 7693	· *939705*
	· Covered areas	· See below	· *Cf [5]*

The local dictionary of concepts comprises 5426 concepts among which 2087 are from the questions (attributes) of the questionnaires and 3339 are from the predefined answers (values) of checklist questions (table 1). Concepts were organized according to SNOMED covered areas. Concepts distribution is the following: procedures: 44% (medical procedures (including lab and radiology): 27%, social procedures: 15%, nursing procedure: 1%, physiotherapy procedure: 1%), social context: 26%, subjective symptoms and findings: 11%, care management: 7%, diseases: 4%, healthcare providers: 2%, anatomy: 1%, other areas: 5%.

Table 1 shows that changes in name, synonyms or description of concepts are tracked but not their motivation.

Table 2 - Criteria related to "Indexing and synonyms" (Thesaurus)

Indexing and synonyms		LDC HEGP	*SNOMED CT [8]*
Formalism	• Terms indexed	• Yes	• *None*
	• Supports synonyms	• Yes	• *Yes*
	• Synonym representation	• Yes	• *Yes*
	• Multilingual representation	• No	• *Yes, language code*
	• Synonyms for fragments	• No	• *No*
	• Description obsoletion mechanism	• No	• *Yes, status flag, with motivations*
Tool	• Translation to other languages	• No	• *No*
Content	• Nb of synonyms by concepts (average)	• 0.61	• *2.66*
	• Langages	• French	• *UK&US English, German, Spanish*

As shown in table 2, each concept of the dictionary is characterized by a preferred term or expression. A term can be preferred for no more than one concept, since the system recognizes redundancy. Meaningless local identifiers are associated to concepts. The identifier assigned to a concept is not inextricably bound to a hierarchy position in the terminology, so that there is no need to change the code as we update our understanding. Some synonyms can optionally be stated for each concept. At the present time, there are only French terms and descriptions in the HEGP dictionary of concepts.

Table 3 - Criteria related to "Concept definition" (Vocabulary)

Concept definition	LDC HEGP	*SNOMED CT [8]*
• Free-text concept definition	• Yes	• *None*
• Formal concept definition	• No	• *Yes, Description Logics*
• Atomic concepts	• No	• *No*
• Explicitly defined relationships	• No	• *Yes*
• Retrieve definitions (properties of a concept)	• Yes (if available)	• *Yes*
• Subsumption testing	• No	• *No*
• Instance checking	• No	• *No*
• Detection of equivalent definition	• No	• *No*
• Query for concepts matching structural criteria	• No	• *n/a*
• Nb of vague concepts	• n/a	• *13151 (3,7%)*[1]
• Nb of ambiguous/ redundant concepts	• n/a	• *n/a*
• Relationships used	• no typed relationships in the hierarchy	• *993 attributes defined, 42 used*

As shown in table 3, each concept of the dictionary of concepts can be defined by a free text description but there is no formal representation of concepts and no explicit relationships between concepts.

Table 4 - Criteria related to "Classification" (Classification)

Classification		LDC HEGP	*SNOMED CT [8]*
Formalism	• Hierarchical relationships	• Yes	• *Yes*
	• Properties inheritance	• No	• *Yes*
	• Polyhierarchies	• Not used	• *Yes*
	• Hierarchical depth restriction	• None	• *None*
	• Hierarchical breadth restriction	• None	• *None*
	• Classification inferred according to concept definitions	• No	• *Yes, since DL based*[2]
T	• Retrieve descendants	• Yes	• *Yes*
C	• Nb of parents per concepts (average)	• One	• *1.3*

To ease the navigation within the dictionary of concepts, concepts are organized into a taxonomic hierarchy. As previously said, the first level of the hierarchy consists in twenty-two categories defined according to the SNOMED top-level classes. For the "Body structure", "Finding", "Disease" and "Procedure" categories, the second level of the hierarchy consists in a partition based on anatomy. For the "procedure" category, the third level of the hierarchy consists in a partition based on the techniques defined in French national procedures nomenclature (CCAM, e.g. computed radiography, computed tomography, etc).

Concepts related to clinical information about someone else than the patient (relatives or others (like organ donors)) are prefixed by 'NP-'standing for 'NonPatient' and categorized in a separate hierarchy. We don't use multiple inheritances for the local dictionary of concepts.

Table 5 - Criteria related "Composition rules" (Nomenclature)

Composition rules		LDC HEGP	*SNOMED CT [8]*
Formalism	• Composition	• Only pre-coordination	• *Yes*[3]
	• Composition formalism	• Not used	• *Refinability*[4]
	• Detection of equivalent definitions	• Not used	• *Yes (DL reasoners)*[5]
	• Composition change meaning or only specify more detail	• Not used	• *More detail only*
Tool	• Support in concept composition	• Not used	• *No*
	• Retrieve refinable relations	• Not used	• *Yes*
C	• Nb of refinable concepts	• n/a	• *153080 (43%)*

Pre-coordinated concepts of the local dictionary of concepts are not linked to the two or more atomic concepts they derive from. Concepts can not be post-coordinated during data entry through questionnaires.

Table 6 - Criteria related to "Codes" (Coding system)

Codes	LDC HEGP	*SNOMED CT [8]*
· Codes assigned	· Only for concepts related to values	· Yes
· Code generation mechanism	· Manual	· Number +partition id+ check digit
· Code length restriction	· n/a	· 18 positions
· Meaning of identifiers	· No	· No
· Limitation of taxonomic placements	· No	· No
· Cross coding	· No	· No
· All concepts coded	· No	· Yes
· Cross mappings	· No	· Yes[6]

Concepts related to values (checklist predefined answers) can optionally be associated either to one local code or linked to a coded concept of an external codification system. There is no complete cross mapping between the local dictionary of concepts and the reference terminologies.

Application-dependant evaluation

The domain coverage is evaluated in relation to the main purpose and scope of the HEGP dictionary of concepts: supporting structured data entry by health care providers. Due to the building process of the dictionary of concepts, its coverage for structured data entry is necessarily good. Furthermore 22,6% of the concepts are "reused", i.e. linked with questions in at least two different questionnaires. Reusing concepts make it possible to report values/answers from one questionnaire to another, even if the wordings of the questions are different. For example, if the question "Hypertension?" in one questionnaire and the question "Does the patient suffer from high blood pressure?" in another questionnaire are linked to the same concept, and if the answer was "Yes" in the first questionnaire, then it is possible to take this answer as default value for the second questionnaire. This process makes data entry easier and faster.

Another purpose of the local dictionary of concepts was to use clinical information to perform alerts for patient order entry. Due to the building process of the dictionary of concepts, its coverage is not sufficient. Only clinical information recorded through questionnaire is linked to concepts. Then, data not recorded through questionnaire (i.e. from inpatient and outpatient reports and other documents) cannot be processed by the rules engine based on medical concepts. Moreover, automatic process can only rely on clinical data entered as answers to checklist questions since data entered as answers to free text or numeric questions are not linked to concepts.

Discussion

We have characterized the LDC-HEGP according to the evaluation framework proposed by Cornet *et al.* in order to identify precisely the main differences between such a local terminology and reference terminologies like SNOMED CT that includes 120 times more concepts than the LDC. The results show that the reference terminology provides many features that are lacking in the LDC.

Evaluated as a vocabulary, LDC-HEGP provides only optional free-text description of the concepts while SNOMED CT provides formal definition of concepts based on Description Logic. In SNOMED CT, atomic concepts are distinguished and explicit relationships are defined.

With regards to the criteria related to classification, we haven't define strict "is-a" relationships within the hierarchy of concepts and we don't make use of multiple inheritance. The hierarchical organization of LDC-HEGP was mainly meant to ease the navigation process within the dictionary and not to perform aggregation of data.

Criteria related to "Composition rules" underline that concepts of the LDC cannot be further post-coordinated. This ensures that coordinated concepts have a valid medical meaning. However, searching in long lists of fully defined pre-coordinated concepts is tedious as well as the creation of numerous pre-coordinated concepts (for refinability, temporal duration, uncertainty or context information, etc). For example, for clinical information about someone else than the patient, we chose to duplicate and prefix the corresponding concepts. In SNOMED CT, concepts may be defined by composition and/or modified by a qualifier. Refinability can be optional or mandatory. Description Logic provides semantic normalization insuring automatic comparability of composite expression (e.g. of "Stenosis of coronary artery" and "Coronary artery stenosis" or of "Cholecystectomy" and "Excision of Gallbladder"). This could allow detection of equivalent definitions although no SNOMED browser actually has this functionality [8].

At last, even though the local dictionary of concepts could be used as a coding system, automation of Disease Related Group (DRG) coding relies on reference terminologies. Today, when DRG coding is intended predefined values of checklist questions are linked to ICD-10 or CCAM instead of being linked to a concept of the local dictionary.

The evaluation framework proposed by Cornet *et al.* increases the understanding of specific properties of any TS and allows comparison between TS according to prominent features. We noted that some criteria could be added to the evaluation framework., for example authorship and motivation as a criteria for "basic" terminologies (who did introduce the concept and on which grounds?); mapping to other TS as a quality criteria for thesauri; detection of vague or ambiguous concepts and the rate of concepts with formal and/or free-text definition as criteria for vocabularies.

We found it useful to combine in a single evaluation framework both intrinsic features (formalism related-characteristics and content-related characteristics), directly related to the terminology itself, and extrinsic features (function-related characteristics), more related to the terminology browser.

Terminology developers historically have focused on reference terminologies designed to provide sound representation of a given domain (entities and their relationships) and to support the storage, retrieval, and

classification of clinical data. Ongoing efforts aim to define the binding processes between reference terminologies and information model of EHR. But other types of terminologies may complement reference terminologies since they are not easily and directly usable by health care providers during routine clinical tasks [10]. Rector has suggested that TS should conform to conflicting requirements: being usable and flexible for humans and providing formal representation for computer programs [11].

Spackman *et al.* distinguished three different types of terminologies: interface terminologies supporting data entry, processing terminologies optimizing natural language processing and finally reference terminologies for computer storage, retrieval and analysis of clinical data [12]. Rosenbloom *et al.* reviewed existing definitions of interface terminologies, which have also been called colloquial terminologies, application terminologies or entry terminologies [13]. The LCD-HEGP may be considered as an interface terminology primarily intended to support data entry. It interfaces clinicians' own colloquial conceptualizations and more structured elements that can be shared or used by computers.

According to Rosenbloom, existing evaluation frameworks for medical terminologies, such as the one proposed by Cornet *et al.* may not be applicable to interface terminologies. He defines prominent features of interface terminologies: representation of relevant assertional medical knowledge, adequate support of synonymy, balance between pre- and post-coordination and mapping to terminologies having formal concept representation [13].

With regard to this last point, we think that a local terminology may be useful not only as an interface terminology but also as an integration locus for multiple terminologies into a thesaurus. Indeed, it is doubtful that single TS will ever support as diverse needs as clinical care, billing, and research. Therefore, terminologies mapping and integration is an unavoidable challenge.

Our perspectives are first to characterize the local dictionary of concepts focusing on criteria specific to interface terminologies and to improve this local terminology in order to efficiently "interface" SNOMED CT to support data entry for structured documentation. We plan to use automated methods for mapping the local interface terminology to large scale reference terminologies.

Ontology-based Knowledge Base Model Construction-OntoKBCF

Xia Jing, Stephen Kay, Nicholas Hardiker, Tom Marley

SHIRE, IHSCR, University of Salford, UK

Abstract

Semantic web technologies are used in the construction of a bio-health knowledge base model, which, when coupled with an Electronic Health Record (EHR), is to be used by clinicians. Specifically, this ontology provides the basis for a domain knowledge resource that attempts to bridge biological and clinical information. The prototype is focused on a Cystic Fibrosis exemplar, and the content of the model includes: Cochrane reviews; a time-oriented description; gene therapy; and the most common cystic fibrosis gene mutations. The facts within the model range from nucleobase mutation and amino acid change to clinical phenotype. The knowledge is represented by layers from the micro level to the macro level. Here, emphasis is placed upon the details between levels (i.e., the vertical axis) and these are made available to bridge the knowledge from different levels. The description of gender, age, mutation and clinical manifestations are clues for matching points within an EHR system. OWL is the ontology representation language used and the output from Protégé-OWL is a XML-based file format, which facilitates further application and communication.

Keywords:

knowledge representation; OWL; cystic fibrosis; OntoKBCF

Introduction

The ultimate goal is to provide relevant bio-health information to doctors in a clinical environment. To move towards this goal, we construct an ontology-based knowledge base (KB) model (called OntoKBCF) to provide the required domain knowledge and then consider how to make it available to an electronic health record (EHR) system as a plug-in. Figure 1 provides a schematic overview of the layered knowledge base exploiting the metaphor of an EHR as a container drawing from clinical and bio-information.

The content produced for the model, depicted by the horizontal levels in figure 1, is merely sufficient to organize the relationships between the vertical levels for this research. This paper introduces the OntoKBCF construction and the results obtained thus far.

Semantic web technology is the major technology used in the OntoKBCF construction, recognising that this is the next evolution of the current World Wide Web. Simply put, the semantic web provides more "labels" for data so that machines can process the data more precisely and in more meaningful ways. The semantic web requires common formats and language; the former are useful for data sharing, reuse and exchange; the latter is used for expressing data meaningfully and relating it with real objects[1].

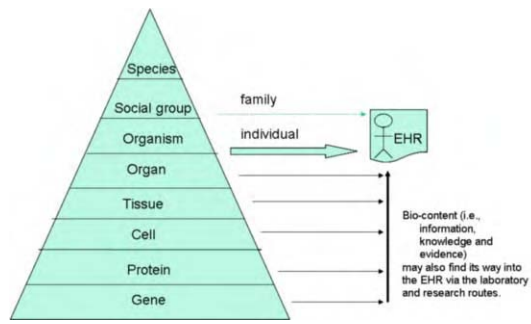

Figure 1 - The EHR as container of diverse and complex data

An ontology is an important part of the infrastructure for semantic web applications and shares similar characteristics with it. However, it is particularly useful for providing a "common understanding of a domain" and provides opportunity to improve knowledge management[2](p5). Considering these characteristics i.e., universal format (URI, uniform resource identifiers), expression capability (to represent data related with real objects), extensibility and standardization, we select the ontology-based KB to construct the applications knowledge source. Cystic Fibrosis is chosen as an exemplar.

Procedures, technology and tool

General procedures

The general procedures for OntoKBCF construction are outlined: (A): To understand doctors information needs; (B): To define OntoKBCFs border, axes and granularity; (C): To dissect knowledge resources into basic concepts; (D): To list relevant vocabularies; (E): To extract target concepts from UMLS (Unified Medical Language System)[3] or GO(Gene Ontology)[4]; (F): To organize and arrange concepts; (G): To create terms necessary for OntoKBCF ; (H): To discuss with colleagues and to iterate all the procedures until the concepts are stable. The OntoKBCF is constructed bottom-up. Most of the hierar-

chy of the basic concepts in OntoKBCF follow UMLS and GO when appropriate, and so do the semantic types in UMLS. However, we also add, adjust relationships and vocabularies if there are no appropriate choices. For example, we use "Gender_group" to connect "Population_group" and "Female"; but "Gender-group" is not an independent concept in UMLS. Likewise we create "Patient_CF" and all its subclasses and adjust the concept "CFTR gene" (cystic fibrosis transmembrane regulator) in UMLS to "Human CFTR gene". We justify these changes with respect to the OntoKBCF border, which is discussed in more detail in the "model construction" section of this paper.

Technologies and tool: OWL and Protégé-OWL

OWL (web ontology language) is used to explicitly represent vocabularies and their relationships in an ontology and this representation is directly usable by machine[5]. OWL has more semantic representation ability than XML (extensible markup language), RDF, and RDFS (resource description framework schema)[5] and OWL facilitate greater machine interoperability. OWL ontology can be encoded in different syntactic forms including RDF/XML, which is defined by XML syntax for RDF[6].

OWL Lite is an ontology language supporting a subset of the OWL language , specially designed to develop OWL tools; OWL DL (description logic) and the complete OWL language (OWL Full) support the same set of OWL language, however the former has desirable functions for reasoning system with more restrict constraints. We choose OWL Full as the ontology language in the OntoKBCF construction, as it provides the maximal RDF compatibility. OWL Full ontologies contain all the RDF content in a consistent manner, and OWL Full also assigns more meaning for certain RDF triples[7]. The OWL ontology uses the Protégé-OWL 3.2 platform and is encoded in XML. OWL statements make the OntoKBCF consistent, extensible and computer-readable.

OntoKBCF construction

OntoKBCFs border, main axes and granularity

The first thing in order to construct a KB model is to define its scope or border[8]. The research assumes that the OntoKBCF will be a plug-in to an EHR system, with the target end-users being clinicians (more specifically doctors). Initial scoping must therefore include the doctors information need.

There are several ways to obtain details of information need: e.g., survey, questionnaire, interview, observation, system log files analysis and so on. We utilized the published literature to set the initial scope. According to references [9-11], the most common clinical question is about treatment. Since we are trying to construct a knowledge base prototype to show proof of concept rather than produce a full commercial product, pragmatically we limited our search to a few reputable sources. In particular, we chose the Cochrane review topics as our starting clinical requirements.

There content of OntoKBCF comprises four parts: cystic fibrosis related Cochrane reviews [12]; time related cystic fibrosis description [13]; gene therapy of cystic fibrosis [14, 15]; the most common CFTR mutations and their characteristics [16, 17]. All the detailed content is available on request.

The two main axes developed in the OntoKBCF are time and problem orientation. With respect to Time the interest is in how cystic fibrosis may announce itself at different ages; with respect to problem-orientation the emphasis is from the Cochrane review on treatment, gene therapy and the most common CFTR mutations and their characteristics. We did not include the entire Cochrane reviews conclusions about cystic fibrosis, only some definite positive conclusions. Negative and uncertainty conclusions were excluded.

We only represent the definite knowledge facts about cystic fibrosis in the OntoKBCF-content i.e., the "what", without disease mechanism and reasons explanation i.e., "how" and "why". In the OntoKBCF the granularity of genetic level starts from nucleobase, which is the important component for the elementary unit (nucleotide) of RNA and DNA; the most of representation granularity in phenotype level starts from those concepts, such as diarrhea, nausea and coughing; other part of representation granularity in phenotype level depends on the border of the OntoKBCF, if the subclasses of the concepts are out of the border, we will not split the concepts any more. In OntoKBCF construction, the border and granularity are also the major criteria in considering an upper class concepts inclusion or exclusion.

Construction

We will explain construction of the OntoKBCF in detail by using the example knowledge fact (1) and biological concepts organization (2). The example given is from the time-oriented cystic fibrosis description. We organize the biological concepts since we have been unable to find an agreed reference hierarchy, and therefore we explicitly introduce what we include and how we have done it. Space determines we only give examples rather than provide every statement.

The following font conventions are used in this section: the class name is in **bold**, and the class defined by us is in **bold** and underline; the property we defined is in *italic* and underlined; description from "Asserted Conditions" panel in "OWL Classes" tab on the Protégé-OWL interface is in *italic*. We connect the sub class with super class by symbol "<" and super class with sub class by symbol ">". The general procedures, mentioned earlier, are given here (e.g., C, E etc).

1. ***In female adolescent cystic fibrosis patient: infertile with scanty cervical mucus, bronchiectasis***

- C) To analyze and dissect knowledge fact into basic concepts

  In female adolescent cystic fibrosis patient group, the clinical manifestations include infertile, scanty cervical mucus and bronchiectasis. Basic concepts include:

gender: female; different age groups: adolescent; diseases: cystic fibrosis and infertility; human being group: patient; quantitative concept: scanty; body substances: cervical mucus; respiratory tract diseases: bronchiectasis.

- E) To select proper terms and upper class terms used in UMLS according to their definitions

  We choose the corresponding terms from UMLS according to the concepts acquired from step (C) and their super classes. Examples include in figure 2.

Conceptual_entity	Phenomenon_or_process
Group	Pathologic_function
Population_group	Disease_or_syndrome
Female	Diseases
Age_group	Cystic_fibrosis
Adolescent_age_group	Infertility

Figure 2 - Example terms & hierarchy from UMLS

Patient - there is no proper terms in UMLS for patients in different diseases categories.

- F) To organize, create and arrange the terms with original identities and alternative vocabularies

In this case the original identity is a concept unique identifier (CUI) from UMLS, which can be used to track the concept over time and also can be used like a "primary key" in further application or communication. Alternative vocabularies are synonyms. Both of CUI and synonyms are recorded in the "Annotations" panel in the "OWL Classes" tab.

The exact terms found in UMLS and their upper class terms can be organized hierarchically from bottom up. We create the new term **"Patient_CF**" as a subclass of **"Human_being"** to represent patient diagnosed with cystic fibrosis. Because the cystic fibrosis patients have different properties, such as different age groups, different mutations and different therapies, and they are the subjects for representation as knowledge facts, we split the concept **"Patient_CF"** further. An example hierarchy for this concept is:

Patient_CF>Patient_CF_with_age_group>Adolescent_CF>

Adolescent_female_CF

We define the **"Patient_CF"** as intersection of *(1) Human_being; (2) has_diagnosis some Cystic_fibrosis*.

"has_diagnosis" is a property used to connect human being with diseases or syndrome.

"Patient_CF_with_age_group": this class is only an abstract and interim concept used for keeping its subclasses tidy.

"Adolescent_female_CF" is an intersection of *(1) Adolescent_CF; (2) occur_in_gender_group some Female*.

"occur_in_gender_group" is a sub property of *"occur"* to describe human being in male or female group.

- G) To represent the knowledge fact by combination of the terms and properties with logic symbols

The final representation of this fact is under the **"Adolescent_female_CF"** concept as a necessary condition: *has_manifestation some (Infertility and Scanty_cervix_mucus)*. There are also some inherited descriptions from upper classes. The final representation of this knowledge fact showed in figure 3.

"has_manifestation" is a property to describe human beings manifestation specifically related with diseases or syndromes.

We define **"Scanty_cervix_mucus"** as in intersection of *(1) Cervix_mucus; (2) has_quantitative_property some Scanty.*

Figure 3 - Representation of example 1

2. *Introduce the hierarchy of the bio concepts in the model*

We explain the construction idea top down. There are two major parts: **"Nucleobase_mutation**, **Translation_change"**, both are subclasses of **"Phenomenon_or_process"** for mutation related concepts; **"Amino_acid_peptide_or _protein"**, **"Nucleic_acid_nucleoside_or_nucleotide"**, both are sub classes of **"Chemical"**. We will introduce them separately.

- Hierarchy of **"Nucleobase_mutation"** and **"Translation_change"**(Figure 4, 5)

Nucleobase_mutation	Translation_change
Nucleobase_deletion	Amino_acid_deletion
Nucleobase_insertion	Amino_acid_insertion
Nucleobase_transition	Amino_acid_substitution
Nucleobase_transversion	

*Figure 4 - Hierarchy of **Nucleobase_mutation** and*

Translation_change

Nucleobase_transversion	Nucleobase_deletion
A_transversion_C	Del_A
A_transversion_T	Del_C
C_transversion_A	Del_G
C_transversion_G	Del_T
G_transversion_C	Del394_TT
G_transversion_T	Del_U
T_transversion_A	
T_transversion_G	

*Figure 5- Hierarchy of **Nucleobase_transversion** and **Nucleobase_deletion***

"Nucleobase_insertion" is similar with **"Nucleobase_deletion"**, and Ins_A, C, G, T, U are its subclasses.

There are four possible nucleobase transitions, **"A_transition_G"** , **"C_transition_T"** , **G_transition_A**, and **T_transition_C"**.

Hierarchy of **"Translation_change"** is shown in figure 6.

Hierarchy of **"Amino_acid_peptide_or_protein"** and **"Nucleic_acid_nucleoside_or_nucleotide"**

The subclasses of **"Amino_acid_peptide_or_protein"** are: **"Amino_acids"** and **"Human_CFTR_protein"**. Under **Amino_acids** we list all the three letters abbreviation names. Hierarchy of **"Nucleic_acid_nucleoside_or_nucleotide"** is shown in figure 7.

We choose **"Nucleobase"** as subclass of **"Nucleic_acid_nucleoside_or_nucleotide"** and super class of all the nitrogenous bases abbreviation name. We also classified the nucleobases into **"Purines_and_derivatives"** or **"Pyrimidines_and_derivatives"** correspondingly.

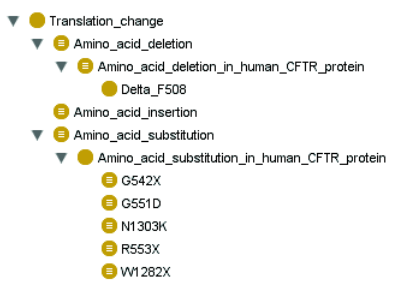

Figure 6 - Hierarchy of Translation_change

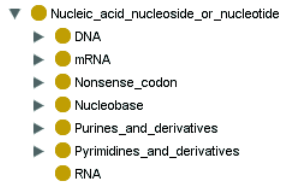

Figure 7 - Hierarchy of Nucleic acid

Discussion

The complete OntoKBCF is a subset of cystic fibrosis clinical and biological knowledge facts. These are appropriate to our model border so as to support our applications aim. We have provided some comments about the construction, its limitations, and the upper ontology.

Explanation of the construction approach

The construction idea starts from the top-down analysis of the knowledge facts and for the dissection from general to specific; construction work starts from basic concepts, from bottom to top and from specific to general-to modify step by step until the basic concept is turned into complex one with more meaning or restrictions. For example we may need to represent patient with the G542X mutation, and need several steps to achieve it. Thus: we define **"G542"** as an amino acid location in the human CFTR protein; we define **"G542X"** as an amino acid substitution in human CFTR protein; finally we define **"Patient_CF_with_G542X"** as a cystic fibrosis patient group with amino acid change G542X.

Nucleotides are units of nucleic acid[18] (p47). According to its chemical structure, nucleotides can be broken into nucleosides and phosphate. The nucleosides can be broken down further into nitrogenous bases and ribose (RNA) or deoxyribose (DNA). It is the nitrogenous base (A, T, C, G, or U) decides the nucleotide type. The one letter abbreviation can be used for either the bases alone or for the nucleotides containing them[18] (p185). So when mutation occurs in DNA or RNA chain, it is mutation in nitrogenous base, also named nucleobase. We choose Nucleobase in the classes naming for description of bases and their mutations.

There are 22 types of amino acids, so there are many more possibilities for amino acid changes; we only list those involved in our border or scope. There are 5 types of nucleobases, so there is less possibility for nucleobase mutations; we list the entire possible point mutation types.

The amino acid three letters names are listed and the single letter names and full names are recorded in the Annotation panel as reference. The nomenclature follows the IUPAC recommendation. For description of amino acid changes we use single letter abbreviation name (such as **"G551D"**) and three letters abbreviation name (**"Gly_551_Asp"**) is recorded in the Annotation panel as well. The single abbreviation letter name also is used for amino acid change location, such as: **"G542"**, which is shorter and simpler.

Single letter abbreviation of amino acid can be confused with nucleobase: A, C, G, T have different meanings. In the OntoKBCF amino acids change with three letter abbreviation names and full names in the Annotation panel. Those nucleobase mutation location name with minus or plus, or start from Ins or Del, all are labels for nucleobase mutation location (such as **"G621_plus_1"** or **"Ins3905"**); it is not easy to distinct the location between nucleobase mutation and amino acid change if they dont carry the labels, although we did not encounter an example in construction.

There is a dilemma: according to IUPAC recommendation X can refer to any amino acid; according to recommendation of protein sequence variants[19] X is used to designate a translation termination codon. In the OntoKBCF we use X to represent stop codon. Because we list all the 22 amino acids, we can use the specific name if required.

Protégé-OWL can not accept the class name start from number, and also can not accept ">" or "+" symbols in the class name, which is the necessary symbols for nomenclature of mutation[19], so we adjust the way it represented. We use **"Del_A"** and **"Ins_A"** to represent nucleobase deletion or insertion. Specific name like **"Ins3905_T"** means insertion in nucleotides 3905 (position) with thymine. For nucleobase substitutions name, we use minus or plus to replace the symbol and start from the replaced nucleobase and end with the new nucleobase (avoid to use ">"): such as **"G1717_minus_1_A"**, which means at nucleotides 1717-1(means the end of the intron, in this case it is intron 10, 1717 is the first nucleotide for exon 11) guanine change to adenine. To name amino acid substitution is in the similar way, such as **"Gly_551_Asp"**, amino acid 551- glycine changes to aspartate .

Although we didnt follow strictly the nomenclature recommendation[19] about mutation, we believe it is acceptable considering our aim for the model, which attempts to explain explicitly the meaning of mutation, instead of a reference dictionary to map all the possible mutations. We hold to the principle of the "recommendation" and adjust it according to the naming rules of Protégé-OWL.

In OntoKBCF and its further application within an EHR system, we only consider the human being as the subject of care, not other species. So we narrow down the classes into human being type, such as: under **"Gene_or_genome"** , we list **"Human_CFTR_gene"**; under **"Exon"** we list **"Human_CFTR_gene_exon"**. At this stage all the basic concepts or combined concepts are treated as class. We only consider individual if it belongs to a specific person, but this can be revised later if required.

Scope: border, granularity and axes

It is important to decide the border and granularity of the OnKBCF as knowledge itself is endless; here we only construct the OntoKBCF within the defined scope to complete our goal. Indeed, construction of the OntoKBCF is only part of our research and we need use it in the next stage. We prefer to extend the properties and constraints in future according to the application scenario rather than complete all properties, some of which will never be used. Without establishing clear granularity, it would also be an endless process to split the knowledge into subunits. The main axes are helpful in deciding the position of terms and will provide clarity and keep the knowledge unit organization consistent.

Upper ontology

There are some higher level formal ontologies which can be followed: Medical Ontology, SnapBFO (snapshot ontologies, indexed by times) and SpanBFO (videoscopic ontology) [20].

However at this stage it is difficult to say if the upper ontology view from SnapBFO and SpanBFO can make sense in this application. The OntoKBCF tests with the EHR system may provide more practical evidence for upper ontology mapping.

Representation limitation

An attempt was made to represent all the selected content fully in the OntoKBCF, but there are some precise details that cannot be represented. For example, "nasal polyps, especially if recurrent", is a highly suspected evidence for cystic fibrosis for older children. But it is difficult to represent especially within OWL. And it is also difficult to represent the difference between "very common" and "sometimes", both of which are quite common in bio and clinical knowledge description.

Conclusion

The OntoKBCF includes knowledge facts from nucleobase mutation, amino acid change to clinical phenotype. Although the horizontal layers of knowledge in the model are far from complete, the vertical relationships and structures partially succeed in bridging the knowledge from different levels. The link to a record system as modelled by openEHR will be the next stage of our work.

Integrating Biological Pathways in Disease Ontologies

Julie Chabalier[a], Jean Mosser[b], Anita Burgun[a]

Abstract

Anatomy, clinical features, etiology, and morphology are the major organizing principles in existing disease ontologies. Assuming that biological pathways (including protein physical interactions, metabolic reactions, regulatory networks) will be in the near future key components in classifications of diseases, we have analyzed how information about pathways can be integrated into disease ontologies. We designed a disease ontology in OWL. SNOMED CT was used to provide the initial disease descriptions. In a second step, we integrated information from the KEGG PATHWAY and the GO annotation databases into the disease ontology. In the last step, we analyzed the classification of diseases. For example glioma of brain shares 30 pathways with other cancers, and 19 pathways with Alzheimer's disease. As our knowledge about biological pathways is constantly evolving, this approach can be used for integrating automatically this knowledge in existing ontologies. Thanks to the automatic classification associated with formal ontologies, this approach helps identify physio-pathological classes and taxonomic relations in diseases ontologies. It can therefore be used to create new partitions, focusing on pathways, in biomedical ontologies.

Keywords:

ontology, biomedical domain, knowledge representation, knowledge base, KEGG

Introduction

In most disease ontologies, the major organizing principles relate to clinical features, etiology, location and morphology. Etiology of diseases, when present, is mainly represented by extrinsic agents such as micro-organisms, while the genetic etiology and the metabolic pathways behind diseases remain absent. For example, in SNOMED Clinical Terms® (SNOMED CT®)[1], the characterization of diseases is based on roles such as *definitional manifestation,* which relates disorders to clinical findings, *causative agent*, which relates disorders to organisms, *finding site*, which relates disorders to anatomical entities, and *associated morphology*, which relates disorders to morphologic abnormalities.

Nowadays, associations between classes of genes and diseases as well as associations between pathways and diseases are key components in the characterization of diseases. Different phenotypes may share common pathways and different biological processes may explain the different grades of a given disease. Therefore, we assume that knowledge about pathways will become a major organizing principle in the next versions of disease ontologies.

The Kyoto Encyclopedia of Genes and Genomes (KEGG) PATHWAY database is a collection of pathways maps representing our knowledge on the molecular interaction and reaction networks for metabolism and cellular processes [1]. As the Gene Ontology (GO) [2] does not provide direct association with pathways, Mao et al have proposed to use the KEGG Orthology (KO) as a controlled vocabulary for automated gene annotation and pathway identification [3]. Recently, information about the pathways involved in human diseases has been added to KEGG. The Nov 26th, 2006 release of KEGG contains pathway information for six neurodegenerative disorders (including Alzheimer's disease), three infectious diseases, three metabolic disorders, and four malignant diseases (including glioma and chronic myeloid leukemia).

The objective of this study is to investigate how information about *pathways* can be integrated into disease ontologies. In this paper, we will use the term 'pathway' for metabolic pathways, regulatory pathways and biological processes. We have evaluated the degree to which, the knowledge provided by KEGG and GO annotation can be used to populate the *hasPathway* role in disease ontologies. We selected SNOMED CT as the reference for disease definitions because it is the most comprehensive biomedical terminology recently developed in native description logics formalism, which enables automated classification. To illustrate our results, we selected glioma, because the KEGG PATHWAY database contains information about the pathways involved in glioma. Glioma is the most common primary brain tumor. To investigate how information about pathways can serve disease classification purposes, we compared glioma to other neurological diseases, including Alzheimer's disease, and other cancers, including chronic myeloid leukemia.

Selected for best paper award.

Materials and methods

The methods of this study can be summarized as follows. First, we identify the diseases present in the KEGG PATHWAY database and create a disease ontology in OWL[2] (Web Ontology Language). Disease descriptions are based on SNOMED CT. A *hasPathway* role is added to the ontology. We then use the KEGG PATHWAY database to (i) extract the relations between a given disease and the biological pathways which are related to it, and (ii) populate the *hasPathway* role. Using the *hasPathway* property, we identify the associations among the diseases in the ontology and evaluate them. An overview of the method is given in figure 1.

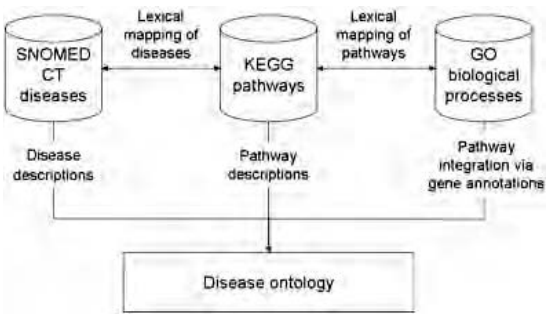

Figure 1 - Conception of the disease ontology

Designing the ontology

We described the ontology in OWL, a description logics language designed specifically to provide a common way to process the content of web information. The SNOMED concepts and roles needed to describe the diseases present in the KEGG PATHWAY database as well as their ascendants were turned into, respectively, OWL classes and properties. We added a *hasPathway* property and its inverse, *isPathwayOf,* in the disease ontology.

The KEGG PATHWAY database was used as the reference database for biochemical pathways. It contains most of the known metabolic pathways and some regulatory pathways. KEGG pathways are structured according to a four-level hierarchy with five major root classes: *Metabolism, Genetic Information Processing, Environmental Information Processing, Cellular Processes,* and *Human Diseases*. The third level corresponds directly to the pathway maps, and the fourth level consists of the leaf nodes, which represent the genes involved in the pathways. The first three levels of this hierarchy were integrated in the disease ontology.

In order to obtain a disease ontology consistent with the KEGG hierarchy and GO, the KEGG pathways were aligned with the concepts of SNOMED CT and GO terms using lexical mapping. As the KEGG pathways often correspond to composite terms, e.g. *Fructose and mannose metabolism*, we segmented and reconstructed these terms according to the coordination conjunctions in order to improve the mapping. For example, *Fructose and mannose metabolism* is present as such neither in GO nor in SNOMED CT. The segmentation-reconstruction operation results in two terms, *Fructose metabolism* and *Glucose metabolism*, which are both present in GO.

We used the MetaMap Transfer program (version 2.4.B) [4] which is part of the UMLS Knowledge Sources [5]. The MetaMap program maps a list of terms to UMLS concepts with the possibility to restrict the output to selected sources (*restrict_to_sources* option). As SNOMED CT and GO are part of the UMLS source vocabularies, we used this option to restrict the mappings to respectively SNOMED CT and GO. Once the mapping was done, we extracted all the ascendants of these concepts.

Populating the *hasPathway* role in the ontology

Diseases and pathways were linked through the *hasPathway* properties. We used the KEGG PATHWAY database and the Gene Ontology Annotation files (GOA) [6] to retrieve these relations.

First, for each disease present in KEGG, we extracted the relations between the genes and the disease pathways from the fourth level of the KEGG hierarchy. We retrieved the biological pathways where these genes are involved by mining the KEGG hierarchy and the GOA files. We have considered that a pathway is related to a disease if a gene is involved in both the disease and the pathway according to KEGG and GOA. The question is then to quantify the strength of this association. For a given disease D, we assume that the more genes are associated with D and involved in a same pathway, the more this pathway is likely to be related to D. The relationships and the gene-dependent distance between diseases and pathways were described in the DOT language which is a plain text graph description language. We used Graphviz[3], a graphical layout package, for visualization of the resulting graphs (especially the NEATO module). Each graph is centered on a disease node, which is linked to all the pathways that are related to it. The length of each edge is inverse-proportional to the number of genes that are shared by the disease and the pathway. For a given disease, the pathways that are graphically close to it are considered related to this disease very strongly.

Reasoning with the disease ontology

Once the disease ontology was modeled and populated, we used Pellet, an open-source OWL-DL reasoner to infer new knowledge on the diseases [7]. We focused on the classification of diseases according to their shared pathways.

Results

Of the 16 disease entities modeled in the KEGG hierarchy (third-level subclasses of the *Human Disease* class), 15 disease terms were successfully mapped to SNOMED CT concepts through MetaMap. The remaining disease, *Epithelial cell signaling in Helicobacter pylori infection*, was partially mapped to the concept *Helicobacter pylori infection (Helicobacter Infections)*.

2 http://www.w3.org/TR/owl-features/

3 http://www.graphviz.org

Of the 213 KEGG pathways (third-level subclasses not derived from *Human Disease* class), 112 have an exact correspondence in GO. This relative low number is due to the complexity of the KEGG classes which are often represented by composite terms. The segmentation-reconstruction operation resulted in 17 supplementary classes strictly mapped to GO terms. Finally, 61% of the classes were successfully mapped to GO.

Figure 2 shows the pathways associated with glioma. 25 pathways involve at least two genes that are associated with glioma. The four pathways in the first circle around the glioma node, *i.e.* those that are closely associated with this disease, correspond to cell proliferation and signal transduction mechanisms. Those mechanisms are well-known for their implication in cancers. On the second circle, two pathways, *Cell motility and insulin receptor pathway*, illustrate the invasive aspect of glioma which is one of the most deadly tumors, with median survival of about one year [8].

Through the reasoner, we proposed an automatic classification of the diseases modeled in the ontology according to the pathways that they shared. First, we compared two neurological disorders, namely glioma and Alzheimer's disease. 19 pathways involved in glioma were also associated to Alzheimer's disease (see figure 3). Then we compared two cancers, namely glioma and chronic myeloid leukemia; 30 pathways were shared by these two cancers, including the four pathways previously introduced as closely related to glioma (see figure 4).

Discussion

Integration of genotype and phenotype information is crucial for biomedical research *e.g.* [9]. This paper presents a study about the integration of information on biological pathways in disease ontologies. To address this issue, we modeled a disease ontology based on SNOMED CT. Each disease class was enriched with the pathway information contained in GO and KEGG, which enables automated classification based on pathways.

Generalization

This study has focused on KEGG, GO and classification of diseases with respect to pathways. In this paper, we present results that are limited to a few diseases. This limitation is due to the limited coverage of the KEGG database in terms of disease pathways -- the Nov 26th, 2006 release of KEGG contains pathway information for 16 diseases. As more information about disease pathways becomes available, this approach can be applied to larger sets of diseases. This approach can be used to classify diseases with respect to the pathways involved. Given an ontology of biological pathways, a database providing relations between genes and diseases, and a database providing functional annotation of genes, these resources can help identify new relations between the diseases. Knowing that a disease D is related to a pathway P, it is possible to infer that D may be classified with other diseases sharing the same pathway. Moreover, since the whole process of integrating pathways in the ontology is automated, the classification of diseases evolves as the KEGG knowledge base is updated.

Disease classification

In our approach, the relation between a disease and a pathway is based on the number of genes involved in both. These relative distances are visualized as a set of undirected graphs which are centered on the disease. However, in order to illustrate how information about pathways can be integrated in disease ontologies, we decided to model the relations in the ontology independently of these distances. Therefore, the resulting model is made of two complementary representations. First, in the ontology, all the relations between pathways and diseases that can be extracted from KEGG are represented. Second, by the means of graph-based representations the strength of the associations between diseases and pathways is taken into account and pathways are organized according to the distances between the pathways and the diseases.

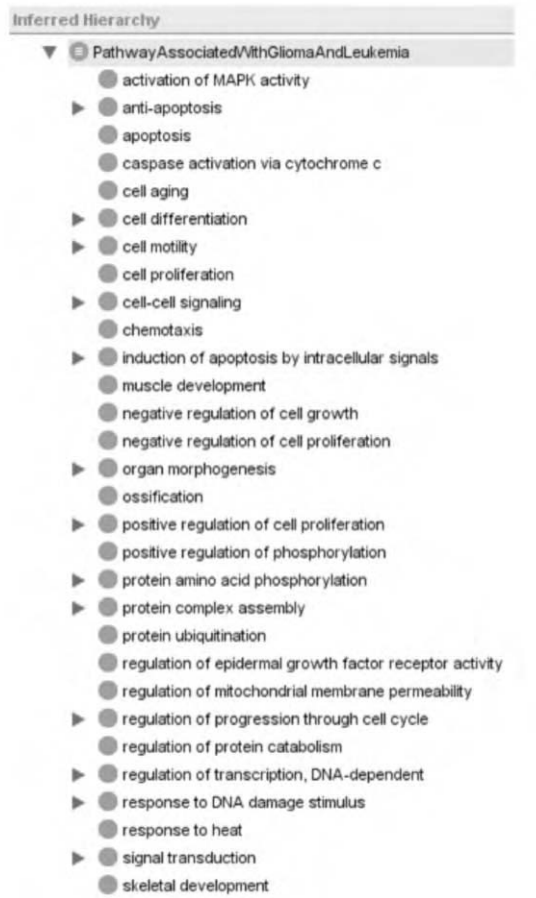

Figure 4 - Pathways shared by two cancer disorders

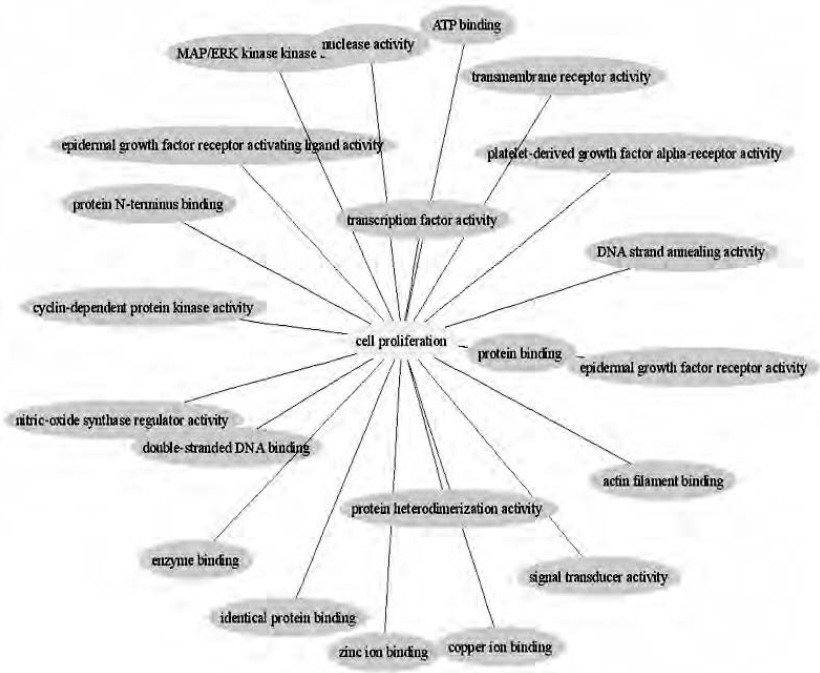

Figure 5 - Molecular functions related to the cell proliferation pathway

Molecular function integration

This study focused on the integration of the biological pathways in disease ontologies. Currently, we work to integrate the molecular functions related to the pathways in these ontologies. For instance, we have studied the pathway-function relationships based on the number of shared genes (see figure 5). However, to extend our approach to molecular functions, we have to first address some issues in reasoning in large, complex, nested ontologies with the current classifiers.

Conclusion

Biological processes and pathways related to gene expression are underlying mechanisms for diseases (phenotypes). Beyond the traditional classificatory principles employed in the construction of disease ontologies, we have represented the relation between pathways and diseases and we have used KEGG to populate this ontology. Thanks to the automatic classification associated with formal ontologies, this approach helps identify relations between diseases based on their underlying physio-pathological mechanisms

Abstract

Objectives: *To discuss the relationships between ontologies, terminologies and language in the context of Natural Language Processing (NLP) applications in order to show the negative consequences of confusing them.*

Methods: *The viewpoints of the terminologist and (computational) linguist are developed separately, and then compared, leading to the presentation of reconciliation among these points of view, with consideration of the role of the ontologist.*

Results: *In order to encourage appropriate usage of terminologies, guidelines are presented advocating the simultaneous publication of pragmatic vocabularies supported by terminological material based on adequate ontological analysis.*

Conclusions: *Ontologies, terminologies and natural languages each have their own purpose. Ontologies support machine understanding, natural languages support human communication, and terminologies should form the bridge between them. Therefore, future terminology standards should be based on sound ontology and do justice to the diversities in natural languages. Moreover, they should support local vocabularies, in order to be easily adaptable to local needs and practices.*

Keywords:

terminology, ontology, natural language processing

Introduction

Recently, Cimino expressed 12 new desiderata for controlled vocabularies in the twenty-first century [1]. The second desideratum says that for each object of a domain, there should be one and only one representative term, which is unique and non ambiguous. Such a term is often call the *preferred term* and the collection of all such terms is a *controlled terminology* (formerly named a *controlled vocabulary*). A revision paper adds 6 new desiderata [2], in response to the recent trend in favor of more formal ontological foundations for terminologies in which terms refer to entities in reality, rather than to concepts in the mind of domain experts [3]. Although controlled terminologies based on preferred terms may contribute to semantic interoperability amongst applications, they are also the source of a modern myth according to which the world could do without the freedom of expressivity that is possible in natural language [4]. Clearly, natural languages are not controllable. Human beings use natural language not only for professional reasons, but also for cultural and social reasons. The patient record, for example, whether paper- or computer based, is usually dictated or written directly in the care provider's natural language so that direct local expressiveness of the language and not conformity to academic desiderata or controlled terminologies is given priority.

This is not to say that Cimino is wrong, but that his paper is written from the perspective of a terminologist: the primary goal is to make data annotated by means of terminologies computer understandable and to enable interoperability between different systems. The desiderata he proposes thus encode these constraints. Despite his expertise in terminology-based lexicon development such as the MED [5], the clothes that Cimino wears in his papers are not those of the linguist. Nevertheless, he also asserts that *'synonymy is a type of redundancy which is desirable'* (desideratum 12). This statement, so we argue, supports the conclusion of this paper.

If a terminology is intended to be disseminated widely and to facilitate communication between human agents and computer systems, then it should take the modus operandi of both these players into account. Thus in order to accommodate the needs imposed by computer systems, terminologies should be based on adequate ontologies. To service human agents, terminologies should be linked to lexicons containing multiple synonyms, eponyms, acronyms, and local jargon. Perhaps, they should even come equipped with facilities to deal with common spelling errors.

This paper deals primarily with the design issues of terminologies related to human agents, and more specifically with the following paradox: on one side, the terminologists recommend unique preferred terms for referring to the entities in a domain and on the other side the linguists and the majority of users are in favor for a full diversification of natural languages, including all kinds of synonyms. To overcome this paradox this paper will first consider the two points of view (that of the terminologist and that of the linguist/end-user) and their supporting arguments. Acknowledging that each expert is guided by specific con-

straints and is accordingly acting coherently, the constraints are made explicit. In a second step, conflicting constraints are examined and an enlarged perspective able to accommodate both points of view is developed. Finally, guidelines based on this enlarged perspective are formulated.

State of the art

Numerous terminologies have been found to suffer from major inconsistencies, examples being SNOMED CT [6], the Terminologia Anatomica (TA) [7] and the NCI Thesaurus [8]. Rector, who raised the question "Clinical terminology: Why is it so hard?" [9], argues that *'clinical terminology concerns the meaning, expression and use of concepts in statements in the medical record'* and assumes the reason for the inconsistencies in terminologies to be the result of a failure in *'separating language and concept representation'* (#4 of 10 difficulties). He describes it as the *'confusion of concepts and words used to express those concepts.'*

However, others argue that the inconsistencies are introduced by the lack of a sound ontological basis for these terminologies, misled as their authors are by the concept orientation advocated by Rector [3] thereby confusing ontology with epistemology [10]. Therefore, in order to avoid such inconsistencies and to coordinate the efforts of several groups by means of commitment to an agreed upon set of principles for best ontology practices, the Open Biomedical Ontology (OBO) Foundry - a new paradigm for biomedical ontology development - has been created [11]. Currently, a set of 10 principles is published and all OBO members are committed to follow them. This initiative is clearly a collaborative experiment in the quest for discovery of best practices in ontology and terminology development. It rests on the principle that high quality representations should be built out of representational units that refer exclusively to three sorts of entities that exist in reality - universals (e.g. person, disease), defined classes (e.g. employee of a hospital, patient under treatment) and particulars (this tumor, the World Health Organization) – and that are connected by means of relationships that mirror ontological relationships [12]. In this context, a terminology is defined as a representational artifact consisting of representational units which are the general terms of some natural language used to refer to entities in some domain. As a result of this effort, quality ontologies in the biomedical domain start to exist. The Gene Ontology (GO) [13] is in constant development, following the evolution of genetic sciences and the provisions of the OBO Foundry [11]. On the side of clinical practice, the Foundational Model of Anatomy (FMA) [14], supporting the TA [15], is an example of a high quality ontology following the OBO principles.

This is in contrast with mainstream work on terminology during the last 20 years which was dominated by a linguistic and normative perspective, primarily driven by the English speaking community. This has had (at least) two inconveniences. First, language itself is not able to make predictions about what exists: although the term "king" might refer to the universal *king*, and "France" to the particular *France*, language rules allow us to create terms such as "the king of France", even though no such entity currently exists. Second, emphasis on English language terminologies hampered creating translations and this for many reasons: 1) human translation is resource dependant and time consuming; 2) the terminology is in principle subject to major revision; 3) questions arise about the role and quality of terms; 4) sets of useful synonyms are not often available and difficult to collect.

The terminology line

The most widely prevailing view on terminology holds that *'terms are the linguistic representation of the concepts in a particular subject field and are characterized by special reference'* as opposed to words that *'function in general reference over a variety of codes'* [16]. According to Lauriston, a term is *'the intersection between a conceptual realm (a defined semantic content) and a linguistic realm'* [17].

In order to ensure that terms are used with the correct meaning, the terminologist may provide definitions which allow the terms to be organized in a hierarchy. However, because this task is difficult, long and expensive, he may not be able to provide explicit definitions for all entities. Therefore, he uses the entity's name as subsidiary definition. But at the same time he is constrained to limit the names to short terms (say up to 5 words) for pragmatic reasons. Using terms alone as implicit definitions is a design error, leading to severe problems[1].

Most terminologies have also adopted usage of what is called *preferred terms*, although SNOMED CT, GO and FMA have added non significant numeric identifiers. Preferred terms are subject to desideratum 2 (one and only one meaning) and terminologists try to respect this constraint.

However, in our view, the primary goal of the terminologist is not to relate the terms in a domain of discourse to 'concepts', but to organize them in such a way that it is clear which terms refer to what entities in reality, and which do not. Furthermore, for the purpose of communication he has to identify the relevant entities that are not yet properly named. This means that the terminologist must play partly the role of the ontologist, or rely on services offered by ontologists. However, he must be aware that the ontology underlying any terminology is universal and language independent. There is a significant risk of mixing the ontologist's role with the terminologist's role, which is mainly language dependent. As an example, it is not because medicine identified the two distinct diseases formerly named "diabetes type 1" and "diabetes type 2", that there exists a universal referred to by the term "diabetes".

The terminologist should also be aware that in contrast to definitions in ontologies that describe the necessary and sufficient conditions for an entity to be what it is, termino-

1 In TA the code a05.6.02.010 is for *hidden part of duodenum*. Not every physician knows about this object and the term is non existent in most atlas of anatomy!

logical definitions should focus on the conditions under which a term may appropriately be used.

This in turn puts a different perspective on the notion of preferred terms the effectiveness of which has been questioned:

- preferred terms have been selected according to the needs of the experts, not the casual users,
- they may not be adequate in specific contexts,
- they contradict local habits and usages,
- they are not easily accessed by non expert users,
- they vary from one language to another,
- human beings fancy to be different and are reluctant to standardize their language.

In his paper [4], Ceusters gives a voice to the users. He demonstrates that less than 50% of them are using the defined preferred terms in practice, this trend being augmented by usage of speech recognition tools. He says that *'clinicians do not face major problems in understanding terms derived from clinical narratives generated by peers'*. He also suggests that *'preferred terms are merely an academic artifact rather than a reality'*. Moreover, Ceusters shows that the mean number of variants for any term is superior to 5 in practice, in concordance with another study showing even higher figures [18]. In order to do justice to the users, it should be recognized that they *'want (and get) back the freedom of expression with all delicate yet important nuances that are required for individual patient care'* [4].

In theory, the need for preferred terms is artificial: with only numeric identifiers and explicit definitions of entities, the design and publication of a source terminology is feasible. From a pragmatic point of view, the usage of unique text identifiers (the *knowledge names* in Galen) is possibly a good choice, but their usage should be limited to the experts and discouraged to the end-users!

The language line

The primary goal of the computational linguist is to build applications that can analyze and understand medical texts. A first requirement for an application of this type is that it is able to recognize which terms or phrases in a text, including any linguistic variants or forms, refer to domain entities [19]. There is a practically unlimited number of variants for any given term, as shown in [18], thus the construction of an explicit list is not feasible. Therefore, the linguist tries to design intelligent algorithms that can take a short list as input, and deduce other variants based on it.

Variants come in many flavors and for various reasons, as witnessed by the TA [20]: 1) different sources for naming an entity (for a02.1.05.053 *pterigoid canal*, there is also *recurrent canal*); 2) use of Latin terms (for a02.1.06.022, there are two terms: the Latin *tegmen tympani* or simply *roof of tympanum*); 3) usage of eponyms (*Eustachian tube* for a15.3.02.073 in place of *pharyngotympanic tube*); 4) representation by different part of speech (for a15.2.07.024 *eyelids*, there is also an adjective *palpebral* and a prefix root *blepharo*); 5) use of old or layman terms (for a02.4.01.001 *scapula* there is also *shoulder blade*); 6) difficulties with orthography and/or usage of keyboard (for a11.3.00.001 *tyroid gland* in place of *thyroid gland*); 7) usage of local expressions; 8) differences between professionals, typically surgeons and anatomists; 9) order of word segments (for a03.1.02.006 both *frontosphenoid suture* and *sphenofrontal suture* are correct!); 10) morphological changes and usage of plural (terminology should avoid plural terms, but not the medical texts: a02.2.05.001 *sacral vertebrae* should preferably be *sacral vertebra*); etc.

In free text, rather than terminologies, for instance in the context of data registration in electronic health records, there are even more degrees of freedom such as the use of local idioms, non-academic sentences or orthographic errors. If NLP applications aim for total understanding of the content, these lexical aspects must be taken into account in a way that fortunately has become almost feasible today.

A second requirement for NLP applications is to identify to what domain entity a specific term refers. This often requires the resolution of ambiguities. One type of ambiguity is that the same term may refer to two or more distinct domain entities. Another type is brought about by the use of more generic terms when previously a more specific term has been used. Furthermore, algorithms that generate lexical variants to obtain better recall typically sacrifice on precision, thereby introducing more ambiguity. This calls for taking context into account. If the author of the text is willing to be non ambiguous, he could apply ambiguity free paradigms such as Referent Tracking [21], but this requires considerable future developments and fine tuning of computer applications. This is the cost for an improved situation.

Conjunction of the needs

In [3], Smith introduced a formal definition of a terminology based on philosophical realism. Taking into account the follow-up work reported on in [12], this definition may be rewritten as:

A **terminology** T is a triple <N, L, v>

where:

- N is a set of triples <p, S_p, d>, called *nodes*, with p a unique *label*, S_p a set of *synonyms* and d a *definition* of a node,
- L is a set of ordered pairs <r, L_r>. called *links*, consisting of a relation designation r (*is_a, part_of,* etc), together with a set L_r of ordered pairs <s, s'> of those terms for which srs' represents a consensus assertion of biomedical science about corresponding universals and defined classes at the time the given terminology is prepared,
- v is a *version* number, which encodes the time.

But in order to harmonize the terminology line and the language line, an extension of the definition of synonym is necessary[2]:

This approach involves a shift from the preferred term paradigm to the *bag of terms* paradigm, a bag of terms being by definition an unordered set of terms, each being qualified by different properties governing its usage. No term is above the others and the terminology does not favor any language. Nevertheless, the parameter k below may include a tag indicating whether a string is to be considered appropriate for use in text generation applications. This will avoid that such an application would introduce terms with typographic errors or layman terms in a professional document. But from a pragmatic point of view, any implementation is free to select any term from the set according to local preferences, for the sake of designing user friendly interfaces.

S_p is a set of synonyms, where each **synonym** is a five-tuple <s, k, p, l, t>

where:

- s is a string of characters in some regimented language l,
- k specifies the sort of string (perferred term, acronym, eponym, local idiom, old term, common orthographic error, etc), governing its usage,
- p is the *part of speech* argument of the term t (noun, adjective, verb, etc, augmented by information on gender, number, and so forth)
- l is the language,
- t is the time (or time period) when the string is (or was) considered appropriate to refer to the corresponding entity.

This is in line with, Rector's *'principle of separability between clinical linguistics and clinical pragmatics'* [9]: building appropriate bags of terms is a matter of clinical pragmatics, preferred terms a matter of clinical linguistics.

The bag of term principle is not new and has been advocated by UMLS (Unified Medical Language System), where each CUI (Concept Unique Identifier) may be considered as acting as a recipient or identifier for several variant terms. But UMLS is not a terminology in itself; it is rather a collection of terminologies. The paradigm shift presented here remains a valid recommendation for any individual terminology. Wordnet [22] presents a similar approach with the synsets.

2 The above definition of terminology is borrowed from Smith in [3]; the definition of synonyms' set below is original, in complement.

Guidelines

Based on the above arguments, we propose the following guidelines for future terminologies (emphasizing the language point of view):

- let the label p for a node N in terminology T be a meaningless unique identifier,
- let definition d for node N be such that it reflects the necessary and sufficient conditions for a particular to be an instance of the universal, or a member of the defined class, referred to by N,
- prepare an open bag of terms S_p able to contain any number of strings, preserving the principle of an unordered set (this is the main complement to the initial Smith proposal in [3]),
- qualify any string in S_p for its usage, in particular specify any preferred terms depending on the contexts (be aware that terms do not strictly need to be unique),
- fill in the bag of terms for any language, corresponding to the locations where the terminology is to be disseminated,
- add for any string its parts of speech,
- develop the links of the terminology (this includes the taxonomy) in total independence of the bag of terms, in a language independent way, and on the basis of sound ontological principles,
- consider the maintenance aspect of the terminology, including free addition of new terms and their attributes at any time,
- consider quality assessment tests for the terminology, including validation of the completeness of the set of synonyms.

Discussion

Although ontology is by definition language independent, terminology is not. We argue that terminologies should be made available for each language by using an underlying ontology as a reference, rather than by relying on a structured organization of preferred terms in a specific language.

We believe however that the ontology, terminology and language points of view can be reconciliated through a simple move: the renunciation of preferred terms and the replacing of them with a bag of representative terms, together with qualifiers defining their usage. In addition, the availability of explicit definitions is recommended. This should lead to a win-win situation: the terminology line is totally preserved and the language line is adequately presented. The multilingual aspect underlying any universal terminology is now explicitly mentioned. But of course, there is a cost: the guidelines proposed here will certainly be labor intensive if adhered to. However, we believe that the approach will help save efforts in the long run, which will be necessary anyway before widespread usage of the best terminologies will be possible. Further-

more, the open bag of terms may remain partially empty for a long time, without direct inconvenience for most of the users. The main point is that the bag remains open and is progressively filled in. Natural language generation of compound terms might be helpful here: if the ontology is expressed in some form of logic, then the ontology itself can be used to generate parts of the terminology automatically, and this in many languages. This approach should progressively become the rule for terminologies, because numerous entities are composed from more atomic entities referred to by means of single words.

In order to show how this works, consider the SNOMED CT code SN 285344007, whose preferred term in English is *viral gastritis*. A graph representation of this entity could be the following (square brackets are for objects, round brackets are for relations):

[InflammationProcess]

- (hasLocation) - [Stomach]

- (hasAgent)-[Virus]

The generator program may find in its English lexicon the following words: for [Stomach]: { gastr-, stomach, stomachal}, for [InflammationProcess]: {-ite, inflammation, inflammatory}, for [Virus]: {virus, viral}. In any other language the lexicon may be more or less extensive and the generator will have to cope with this. The generator may use any combination of words, one of them coming from each subset. However, some rules specific to the language will give more weight to some combinations and others will be excluded. Each word will be selected according to its own specificity, computed from its frequency in a large corpus of representative medical texts. At the end of the process, the generator is left with 2 combinations (the first being considered as the best if the strategy is to prefer the short terms): *viral gastritis, inflammation of stomach caused by a virus*. Other terms are theoretically possible, they are correct but they are discarded because they are unusual: *viral stomachal inflammation, gastritis by virus*.

A successful generation experiment has already been conducted for surgical procedures [23, 24]. The same approach is considered by WHO for preparing ICD-11.

Conclusion

Terminologies should not be developed by reference to a system of preferred terms, rather they should be developed in such a way that their individual nodes and relations amongst these nodes are modeled on an underlying formal ontology, where the linguistic content of these nodes will be filled in based on a system of terms and synonyms (from many different languages) that is associated with each node based on the intended ontological interpretation of that node. The idea is that this will give terminologies the rigor of scientific theories, while also making them understandable in natural language.

Acknowlegments

Abstract

After a critical review of the present architecture of SNOMED CT, addressing both logical and ontological issues, we present a roadmap towards an overall improvement of this terminology. In particular, we recommend the following actions: Upper level categories should be rearranged according to a standard upper level ontology. Meta-class like concepts should be identified and removed from the taxonomy. SNOMED concepts denoting (non instantiable) individual entities (e.g. geographical regions) should be kept separate from those concepts that denote (instantiable) types. SNOMED binary relations should be reduced to a set of canonical ones, following existing recommendations. Taxonomies should be cleansed and split into disjoint partitions. The number of full definitions should be increased. Finally, we propose a new approach to modeling part-whole hierarchies, as well as the integration of qualifier relations into the description logic framework.

Keywords:

SNOMED CT, ontologies, description logic

Introduction

The globalization of SNOMED CT offers a unique opportunity to bring together the following tendencies:

- The urgent need for a global standardized terminology for medicine and life sciences, suitable to cope with an immense flood of clinical and scientific information;
- An impressive legacy of systematized terminology;
- Ongoing efforts toward an ontological foundation of the basic kinds of entities in the biomedical domain;
- The increasing availability of logic-based reasoning artifacts suited for large terminological knowledge bases.

After a long-lasting embryonic and fetal period, the Standardized Nomenclature of Medicine, SNOMED, has seen the light of day as SNOMED CT (Clinical Terms). Since then, it has grown rapidly, in spite of some congenital and infancy problems which have raised the attention not only of domain experts, medical terminologists and software engineers but also of computer scientists and ontologists. Concerned about the conditions under which SNOMED CT is now reaching its adolescence, we recommend an in-depth health check.

Clinical advice will be required from specialists of Ontology and Logic. A careful follow-up of their counseling will be crucial for making SNOMED CT fit for the next decades.

According to the present status of its growth chart [1], SNOMED CT counts 300,000 concepts, about 770,000 English language descriptions, and 900,000 defining relationships. Each SNOMED concept is assigned to one of 19 top-level categories and each relation to one of 49 attribute types.

Methodology

The ontologists' investigation

Amongst the multiple definitions of what an ontology is [2], we narrow the scope to *formal* ontologies. We consider a formal ontology a formal theory that accurately describes a domain in light of the kinds of entities it contains. Ontologists evaluate a terminology system by its agreement with ontological principles, such as the use of well-defined, unambiguous, and non-idiosyncratic types and relations, in accordance with existing standards.

The logicians' investigation

When dealing with ontologies or terminological systems, logicians are primarily interested in formal description languages in which the whole content of the terminology can be expressed. Such languages need to have sufficient expressivity for describing the domain entities. It must be suited for supporting truth-maintenance in the terminology design and maintenance process. It should be sufficiently intuitive for being used in a proper way by the curators of the terminology.

In the style of a clinical problem list, we will present first a thorough analysis of SNOMED CT's current status, under both ontological and logical perspectives. After that we will present a plan for adequate therapeutic measures which will be as little as invasive as possible, cost-effective, and with little impact on the patient's working capacity.

Selected for best paper award.

SNOMED CT's problem list

Dystrophic upper level

Ontologically oriented terminology systems should be grounded upon an upper level that introduces fundamental distinctions such as between endurants and perdurants. Endurants are those entities that exist in their entirety at any point in time, perdurants, however, are never completely present at one single moment. Examples for endurants are objects and spaces, such as organs, cells, spaces, molecules, body fluids etc. Perdurants are traumatic events, courses of diseases, surgical interventions. Functions, dysfunctions, states, and processes, are frequently classified as non-material endurants. SNOMED CT's 19 top level categories preserve the legacy of the former SNOMED axes which do not easily agree with any formal upper level ontology.

Concept borderline disorder

The Biomedical Informatics community has used the term "concept" to an extent that "Concept Systems" became a synonym of any ontology or knowledge engineering artifact. In the last years there has been a strive toward more terminological clarity which has challenged this tradition, arguing that the term "concept" is too ambiguous and obscures the representation of real-world entities [3,4] by ontologies.

We use the term "concept" as a synonym for the nodes in SNOMED CT – as SNOMED CT does, but we normally refine it by talking about "classes", "meta-classes" and "individuals", which is – in our opinion – the most neutral parlance. Problematic under ontology scrutiny is that the wording of numerous SNOMED CT concepts suggests a meta-class interpretation, i.e. classes which classify classes, not individual entities of the world. Examples are *"SNOMED CT concept"*, *"Navigational concept", and "Additional values"*. This causes strange conclusions such as that *London* is an *Additional value*; my particular *Adverse reaction to premedication* is a *Navigational concept*; and my particular *Heartburn* is a *SNOMED CT concept*. Unfortunately – for lack of documentation – it remains open, whether these examples should be interpreted as normal classes (which are identified by rather sloppy and misleading labels), or indeed as meta-classes.

Infestation by individuals

There is no principle objection to why an ontology should not represent individuals, well distinguished from classes. There is, however, a broad consensus that the subsumption relation between two kinds, types or classes (*subtype-of* or *is-a*) is completely different from the instantiation relation between an individual and its type or class (*instance-of*). There are numerous SNOMED CT concepts that stand for individual entities (such as *Europe*, *Greater London*, *Binge eating scale*), most of them being instances of the class *Geographic Location*. However, an *instance-of* relation in missing in SNOMED CT.

Relation idiosyncrasy

Relations should be consistent and unambiguous in order to assist ontology developers and users in avoiding errors [5]. SNOMED CT does not formally define its relations, and by their names they can rarely be mapped to other ontologies. Some relations such as *Finding Site/Procedure Site* or *Specimen Substance* obviously specialize standard relations (e.g. *has-location, has-part*) which, on their part, are missing in SNOMED CT. Finally, there are a number of utterly fuzzy relations such as *Subject Relationship Context*. The problem here is that the more relations exist, the less one can expect agreement among users. Last but not least, there is the ontologically obscure *Relationship group* which was found to correspond to *has-part* between perdurants in most cases but which can also have other hidden meanings [6].

Taxonomic dystrophy

Subclass hierarchies (taxonomies) should obey certain principles such as described in [7]. Accordingly, it must be criticized that numerous non-terminal SNOMED CT classes have one subclass only and that the number of classes with multiple parents is higher than necessary. Another kind of taxonomic dystrophy is the so-called *"is-a overloading",* i.e., the use of taxonomic subsumption in order to express roles rather than generic properties, as already analyzed by [8], using the OntoClean methodology [9]. Sadly, this and other problems found nearly three years ago have not been fixed since then. An example for this is that *Bacterium* is subsumed by *Infectious Agent:* Not every individual bacterium is an infective agent, this is rather a role that can be played by bacteria under certain circumstances. Finally, as pointed out by [10], epistemological aspects should be kept apart from a clinical terminology. In SNOMED CT, there are numerous cases for "epistemology intrusion" such as *Newly diagnosed diabetes*. The point here is that the diabetes as such is no way of a different type by the fact that is has recently been diagnosed.

SEP implants

The so-called SEP triplets [11] are modeling artifacts which expand taxonomies by reified relations. For instance, $Femur_P$ is defined as the class of everything that is part of a *Femur*. $Femur_S$ is introduced as a common taxonomic parent of $Femur_P$ and *Femur*. Together, *Femur*, $Femur_P$ and $Femur_S$ form an SEP triplet. Such structures allow one to express part-whole relationships without explicitly using partitive relations. The main reason why SNOMED CT uses such structures is to enable the propagation of attributes along the aggregation hierarchy (part-whole relationships) in a parsimonious way. E.g., *Femur fracture* defined as a *Fracture* located at some $Femur_S$. Since $Femur_S$ subsumes *Neck of femur*, *Fracture of the neck of femur* is classified as a *Femur fracture*. SNOMED CT is replete of such reified classes, yet in an unsystematic and incomplete way. They are undefined and the terms assigned to them are often misleading. More precisely, we can consider taxonomic A_S-B_S links as kind of prostheses for missing *part-of* relations in the anatomy branch. However, they serve the needs of attribute propagation which is seen as an important asset in medical terminological reasoning.

Partition agenesis

Partitioning means that sibling classes are declared mutually disjoint, as it can be assumed with the 19 SNOMED CT top-level categories. On lower levels, sibling overlap is a general phenomenon that gives rise to complex taxonomic graphs, making the maintenance of the ontology difficult.

Description asthenia

As advocated by [12, 13] for biomedical ontologies, taxonomies should be founded upon the Aristotelian principle of *genus* (the common properties of members in the subsuming class) and *differentiae* (the properties that distinguish each instance of the subsumed class from the genus). According to [7], half of the classes are primitive ones, i.e. they have no criterion which distinguishes them from their super-classes. Besides cases in which Aristotelian definitions are difficult or impossible (e.g. in anatomy), other ones are obviously defined as primitive in order to obviate undesired inferences, such as classifying *amputation of the foot* as a kind of *amputation of the lower limb.* In other cases, there is no obvious reason for primitive definitions: For instance, *severe asthma* could be fully defined as *asthma* (genus), characterized by the value *severe* of the attribute *severity* (differentia).

The qualifier syndrome

SNOMED CT qualifiers, such as *laterality, severity, onset* and *course* are relations used for constraining post-coordination for a further refinement of a class [14]. For example, *asthma* allows 12 different values for the qualifier *course* and six for the qualifier *severity.* Only a small subset of all SNOMED CT relations are used as qualifiers, and it seems that these relations are never used for different purposes. On the other hand, those relations which are used in definitions never feature as qualifiers. So we have the strange situation in which the qualifier *severity* is allowed for the class *asthma*, but is not used for defining its subclass *severe asthma*. For the latter one, *severity* is allowed with its whole range of values, so that the formation of a post-coordinated class *severe asthma* with *severity = mild* is possible. There are innumerous examples that show that the value ranges of the qualifiers are not well adapted to the characteristics of the class they belong to.

SNOMED CT's treatment plan

The assessment of SNOMED CT's health status by both specialties has revealed the following trade-off: Ontologists strive for a comprehensive account of reality, they want to use the whole inventory of logics for describing it with the precision and expressiveness they deem adequate. In contrast, logicians point at the computational properties of full logics, which are prohibitive for any large scale implementation, let alone the issues of modeling and maintenance expenses. A good compromise is given by description logics (DLs), a family of decidable fragments of the first-order logic, which have a clean and intuitive syntax (without the need for free variables), cf. [15]. The description logics implementations available now as well as in future only cover part of this expressiveness. This results in an only partial ability of the system to perform the inferences which should ideally be expected. It is therefore not desirable (and not even feasible from a practical point of view) to use the whole logical machinery for describing entities in a large terminology system. As a result of these underspecifications, one has to be aware of unintended models, but this is unavoidable. However, description logics are relatively well studied, and computationally cheap dialects can be tailored to the actual needs of the ontology under scrutiny. We here sketch the specification of a logic which seems to be well suited to support most modeling and reasoning requirements of SNOMED CT.

It is the *computationally tractable* Description Logic $\mathcal{EL}^{++}$ [16], which is the underlying DL $\mathcal{EL}$ (conjunction and existential quantification) of SNOMED CT enhanced by general class inclusions (GCIs), complex role inclusions (CRIs), the empty class $\bot$, nominals (individuals as classes), restricted concrete domains, and ABox (extensional knowledge about individuals). To give an example, the $\mathcal{EL}$ class expression $Inflammation \sqcap \exists has\text{-}location.Appendix$ denotes the set of all individuals belonging to the class *Inflammation* and relating via the relation *has-location* to some individual of the class *Appendix.* The example constitutes both necessary and sufficient conditions for the class *Appendicitis* and thus can be used as its definition. Not only can GCIs be used to add supplement constraints that are beyond capacity of definitions, together with $\bot$, class disjointness can also be expressed ($BodyPart \sqcap ClinicalFinding \sqsubseteq \bot$). Briefly speaking, CRIs make feasible several ontologically important constraints on roles, including role hierarchy ($proper\text{-}part\text{-}of \sqsubseteq part\text{-}of$), role reflexivity ($\varepsilon \sqsubseteq part\text{-}of$), role transitivity ($part\text{-}of \circ part\text{-}of \sqsubseteq part\text{-}of$), and right identity on role ($has\text{-}location \circ part\text{-}of \sqsubseteq has\text{-}location$). Concrete domains help connect classes in the medical domain to values in concrete domains such as numbers and strings. A simple example is $Minor \equiv Person \sqcap <_{18year}(age)$, i.e., a minor is defined to be a person with less than 18 years of age. Considering the scale of SNOMED CT, it is inevitable to pay attention to the complexity of the logic employed. It has been shown both theoretically [16] and empirically [17] that the $\mathcal{EL}$ DL family is computationally cheap and adequate in terms of ontological expressive power.

Rectification of the upper level

There are several proposals of upper level ontologies, such as BFO, DOLCE, GFO, and SUMO, which roughly coincide in their upper level categories. The ontologists' recommendation is to refer as much as possible to a commonly accepted upper ontology. From the logicians' point of view, the choice is of minor importance. A major preoccupation is, however, that the upper level be expressible in terms of the logics supported. Note that with regard to upper-level organization there are still several controversial points, first of all the ontological account for disease (delimited from *courses of disease*, but also from *sign* and *symptom*). This is currently subject to ontological inquiry, and SNOMED CT could be a good testbed for this.

Isolation of meta-classes

The mentioned borderline problems derive from the fact that most SNOMED CT concepts coincide with classes, describing real-world entities, whereas a minor part corresponds to meta-classes, defining and describing the proper SNOMED CT terminology. These two aspects must be kept apart. However, the proposed logic does not properly support a meta-class level for reasoning. This is not really a problem because we see the necessity of meta-classes more as a kind of housekeeping feature for which annotation functions such as in Protegé and OWL can be used and in which additional *rdf* attributes can be introduced.

Increasing tolerance of individuals

Geographic locations, scales, etc., which are individual entities, should be related as individuals to the corresponding classes and could be related via a certain relation to other individuals. As mentioned, $\mathcal{EL}^{++}$ supports nominals and ABoxes. Both are closely related and are helpful when information about individuals is to be included. For instance, the Siamese cat could be specified to have been originated in Thailand, with Thailand a nominal, not a class ($SiameseCat \subseteq \exists country\text{-}of\text{-}origin.\{Thailand\}$). An ABox comprises assertions about individuals by means of *instance-of* (concept assertions) or *related-by* (role assertions) relations, e.g., $London \in GeographicLocation$ and $(London, England) \in has\text{-}location$, respectively. To keep it simpler without the need of introducing individuals, we could limit ourselves to the reference to geographical entities in terms of location classes. In this case, reifications of the type $A_L \sqsubseteq \exists has\text{-}location.A$ with $A \sqsubseteq GeographicLocation$ may be discussed for the sake of parsimony. Then, for instance, the fact that London is located in England could be indirectly expressed by $London_L \sqsubseteq England_L$.

Reconstruction of relations

SNOMED CT relations should be reduced to a minimum of canonical ones, starting with the OBO relations [5]. Relationship groups should be substituted by the corresponding relation, most likely *has-part*. One should also give a clear account of the algebraic features of each relation in terms of reflexivity, symmetry, and transitivity. Furthermore, relations should be further defined in terms of domain ($\exists r.\top \sqsubseteq D$) and range ($\top \sqsubseteq \forall r.R$)[1] restrictions.

Cleansing of taxonomies

All classes should have at least one sibling, otherwise they should be merged with their super-class. Multiple inheritance should be reduced to a minimum. Wherever an *is-a* link is inferable from defined classes it should be omitted for the sake of brevity and clarity. For instance, *Acute type B viral hepatitis* is fully defined as *Type B viral hepatitis* which is *acute.* By the definitions of *Type B viral hepatitis, Hepatitis,* and *Acute hepatitis* a DL classifier can compute the subsumption between *Acute type B viral hepatitis* and *Acute hepatitis,* so that this *is-a* link does not have to be included.

SEP explanation and substitution

The extra nodes should be fully defined. Although irrelevant under ontological scrutiny, they may be preserved for reasons of backward compatibility. A full definition of S and P nodes, however, requires distinguishing between *proper-part-of* which is transitive and irreflexive, and the broader relation *part-of* which is transitive and reflexive.

So we can fully define $A_P \equiv \exists proper\text{-}part\text{-}of.A,$ together with $A_S \equiv \exists part\text{-}of.A$. However, our language does not allow to enforce irreflexivity of a relation, so that the following GCI might be added where required: $\exists proper\text{-}part\text{-}of.A \sqsubseteq A \sqsubseteq \bot$. With the right identity rule $has\text{-}location \circ part\text{-}of \sqsubseteq has\text{-}location$ we then get the right inference in the femur example. False inferences, such as the classification of an *amputation of the foot* as an *amputation of the lower limb*, can then be prevented by introducing a subrelation of *has-location, viz. has-exact-location* for which the right identity rule dos not apply.

Taxonomy partitioning operation

Although we do not advocate pure single hierarchies as an ontological engineering dogma, we nevertheless recommend the use of one classifying principle for all subclasses of every class as far as possible. This will yield clear partitions at each level, which helps maintain and better understand the terminology. Partitioning a taxonomy generally requires negation statements of the form $A \sqsubseteq \neg B$. Such a restricted negation statement is in fact equivalent to a disjointness axiom of the form $A \sqcap B \sqsubseteq \bot$ which is available in our DL dialect.

Revitalization of full definitions

We suggest the revision of primitive SNOMED CT classes, especially the elimination of misspecifications that are, obviously, the reasons that SNOMED CT classes which could be fully defined, are still kept as primitive ones. Where possible, full definitions should be introduced. The introduction of full definitions generally brings to light hidden misspecifications as soon as the ontology is classified. The use of a terminological classifier is therefore of utmost heuristic importance in the process of building and maintaining SNOMED CT. This requires, however, that SNOMED CT moves to the DL format as the primary format in which all editing is performed.

Qualifier transplant

The realm of qualifiers which is kept somewhat apart from the rest of SNOMED CT sheds light on an intricate problem which complicates the move from a database of frame-like view towards description logics. Whereas the former systems assume a closed world, description logics assume an open world. As a practical consequence, this means that once there are relation types and classes, any relation may be asserted between any individuals unless this is explicitly precluded. SNOMED CT's approach of providing qualifiers with well-defined value restrictions for controlling the building of post-coordinated classes in

1 A controlled use of the universal quantifier $\forall$ in these cases has no negative impact on the computational properties.

description logics extends the capabilities of the logics we use. Strictly spoken, the job of description logics is to define classes by logic descriptions but not to provide constraints for the definition of new classes or the handling of individuals. There are in principle two different ways we can deal with this problem. Firstly, we can handle the constraints as provided by the qualifiers outside description logics. This would mean that we abandon the goal of proposing that the whole content of SNOMED CT be expressed in description logics. The second way is to resort to a more expressive DL dialect, at the price of performance of the implementations. As a possible way out of this dilemma we suggest the following. On the one hand, we maintain the $\mathcal{EL}$ specification for SNOMED CT class definitions, but on the other hand we add an additional layer using DL value constraints. This second layer would then be invisible for the DL reasoner, but it can be used as a resource for those applications in which this information is needed, e.g., to constrain data entry by adaptive pick lists etc., which had been the main rationale for the SNOMED CT qualifiers. Similar to what for meta-classes, this kind of housekeeping information can be realized with the help of annotation functions.

Conclusion

We have subjected the current version of SNOMED CT to an in-depth diagnostic examination under the aspects of ontology and logic. SNOMED CT's clinical picture exhibits mostly chronic problems most of which can be treated in a conservative but yet determined fashion. Some of the problems require a more invasive intervention. We recommend the elaboration of a treatment plan, the definition of priorities, and the allocation of resources. Altogether, the cost of this treatment will be considerable, and it requires specialists from the field of ontology and description logics; nonetheless, it is a good investment for assuring the SNOMED CT's long lasting fitness and its increasing ability to stand the upcoming challenges of medical documentation and standardization.

Abstract

Representing clinical guidelines is a very complex knowledge-representation task, requiring a lot of expertise and efforts. Nevertheless, guideline representations often contain several kinds of errors. Therefore, checking the well-formedness and correctness of a guideline representation is an important task, which can be drastically improved with the adoption of computer programs. In this paper, we discuss the advanced facilities provided by the GLARE system to assist physicians to produce correct representations of clinical guidelines.

Keywords:

artificial intelligence, clinical guidelines, syntactic and semantic correctness

Introduction

Clinical guidelines are a means for specifying the "best" clinical procedures and for standardizing them. Despite the fact that they are usually produced as a result of long-term cooperative efforts of large teams of experts, clinical guidelines representations can nevertheless contain different forms of errors and/or inconsistencies. This fact seems to us a natural consequence of the intrinsic difficulty of organizing and representing huge amount of both explicit and implicit knowledge. The dimension of guidelines usually makes it infeasible to conduct an extensive human check for correctness. On the other hand, advanced Artificial Intelligence techniques can be used to automate large parts of such a check. In the rest of the paper we describe the advanced facilities provided by GLARE (Guideline Acquisition, Representation and Execution), a domain-independent prototypical system for acquiring, representing and executing clinical guidelines, to check the correctness of guidelines being represented.

Background

In recent years, the medical community has started to recognize that computer-based systems dealing with clinical guidelines provide relevant advantages, since, for example, they can be used to support physicians in the diagnosis and treatment of diseases, or for education, critical review and evaluation aims [5]. Thus, many different approaches and projects have been developed in recent years to create domain-independent computer-assisted tools for managing clinical guidelines (see e.g., Asbru [13], EON [9], GEM [14], GLIF [10, 11], GUIDE [12], PROforma [3], and also [5, 7, 8, 16]). Besides the above-mentioned advantages, we believe that computer-based tool might also play a crucial role in assisting experts in the extremely difficult task of producing correct guideline representations. In the following, we first sketch the main features of our system, and then we show how it has been extended in order to provide several forms of automatic checks, to enhance the production of terminologically, syntactically and semantically correct representations of guidelines.

The GLARE system

GLARE (Guideline Acquisition, Representation and Execution) is a domain-independent tool for acquiring, representing and executing clinical guidelines [4, 15]. It has been built, starting from 1997, in a long-term cooperation between Dipartimento di Informatica of Università del Piemonte Orientale, Alessandria, Italy, and Azienda Ospedaliera S. Giovanni Battista, Torino, Italy, one of the largest hospitals in Italy. In the rest of this section, we sketch some of the more interesting general features of the GLARE's approach, while in the following section we focus on GLARE's advanced approach to check the correctness of guideline representations.

Representation formalism

In order to guarantee usability of the program to physicians not expert in Computer Science, in GLARE we aimed at defining a *limited set* of clear representation primitives, covering most of the relevant aspects of a guideline [15]. We distinguish between *atomic* and *composite actions* (*plans*), where *atomic actions* represent simple steps in a guideline, and *plans* represent actions which can be defined in terms of their components via the *has-part* relation. The *has-part* relation supports top-down refinement: a guideline itself can be seen as a composite action. *Control relations* establish which actions can be executed next, and in what order. We distinguish between four different control relations: *sequence, controlled, alternative* and *repetition*.

Four different types of *atomic actions* have been defined as well: *work actions* (actions to be performed at a certain step of the guideline), *query actions* (requests for information), *decisions* (selections among alternatives) and

conclusions (explicit output of a decision process). Actions are described in terms of their attributes.

Acquisition and execution tools

As in most approaches in the literature, GLARE distinguishes between the *acquisition* phase (when a guideline is introduced into the system –e.g., by a committee of expert physicians) and the *execution* phase (when a guideline is applied to a specific patient). Therefore, the system is composed by two main modules, the *acquisition tool* and the *execution tool*. The tools strictly interact with a set of databases, including the terminological database (during acquisition) and the patient database (during execution).

The acquisition tool provides a graphical interface to acquire atomic actions, *has-part* relations and control relations between the components of plans. The guideline is depicted as a graph, where each action is represented by a node (different forms and colours are used to distinguish among different types of actions), while control relations are represented by arcs. By clicking on the nodes in the graph, the user can trigger other windows to acquire the internal descriptions (attributes) of the nodes. The interface also shows the hierarchical structure of the guideline in the form of a tree, where plans can be seen as parents of their components (see figure 1).

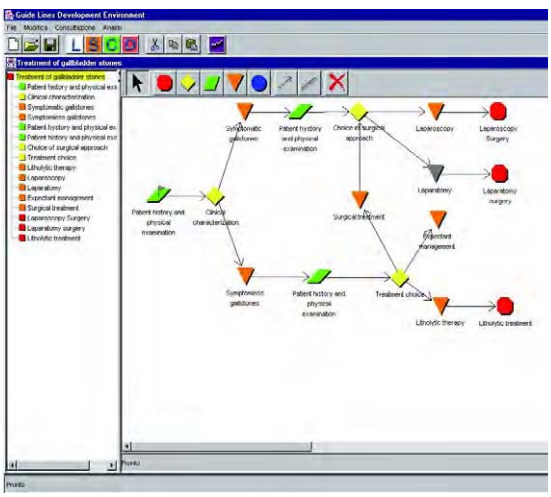

Figure 1 - A window of GLARE's acquisition tool graphical interface (concerning part of the gallbladder stones treatment guideline): on the left, the hierarchical structure of the guideline is displayed; on the right, the representation of control relations is shown in form of a graph

The execution tool is typically used "on-line": a user physician applies a guideline with reference to a specific patient. This method is used for integrating guidelines into clinical practice. Moreover, GLARE is available for "off-line" execution, i.e. for education, critical review and evaluation purposes. The execution tool also provides a decision support facility, which allows physicians navigate through the guideline to see and compare alternative paths (stemming from decision actions).

Testing

We have already tested our representation formalism and acquisition tool prototype. Several groups of expert physicians, following a few-hour training session, used GLARE to acquire algorithms concerning different clinical domains (e.g., bladder cancer, reflux esophagitis, and heart failure), with the help of a knowledge engineer. In all the tests, our representation formalism and acquisition tool proved expressive enough to cover the clinical algorithms, and the acquisition of a clinical guideline was reasonably fast (e.g., the acquisition of the guideline on heart failure, starting from a non-structured textual representation, required only 3 days).

Methods

Our acquisition module provides an "intelligent" interface to expert-physicians, in the sense that it helps them in the task of acquiring a consistent guideline. In order to achieve this goal, our acquisition module supports different types of consistency checking, which automatically operate whenever the expert-physician modifies (typically, with the addition of new nodes —actions—, arcs —control relations— or descriptions of the attributes of a node) a guideline. Other checks can be applied afterwards, when an entire guideline has been acquired, to verify its semantic consistency.

Checking terminological correctness

This first type of consistency checking is automatically triggered whenever the expert physician introduces a new term or value within the description of an action in a guideline. The acquisition module strictly interacts with the clinical vocabulary Database in order to provide expert-physicians with a standard terminology, and with a standard range of values for clinical findings. We currently support two modalities for the execution of the acquisition tool: the "safe" and the "advanced" modalities. In the "safe" mode, the expert physician is only allowed to introduce in the guideline terms/values that have already been defined within the clinical vocabulary Database. In order to make this task easier, the acquisition tool provides a means of browsing the clinical vocabulary Database, on the basis of the hierarchical organization of the data it contains. For instance, in the decision "GERD differential diagnosis" one criterion regards duration of heartburn. This datum can be found by browsing the database as follows: patient history (section) → subjective symptoms (class) → specific complaints (category) → heartburn (datum) → duration (attribute). The possible values of this attribute, as stored in the Clinical Database, are "null", "less than 3 months", "more than 3 months".

Thus, in the "safe" mode, the acquisition tool enforces all data and values to be consistent with the dictionary provided by the Clinical Database.

In the "advanced" mode is we also allow expert physicians to introduce new terms/values, that are not already contained within the Clinical Database. In such a case, a warning is shown to the expert physician. If s/he decides to

go on, s/he is directly responsible for the correctness of the new term/value.

Checking syntactic consistency

The second type of consistency checking is automatically triggered whenever the expert physician introduces a node or arc within a guideline. The acquisition module checks whether the new element being introduced is consistent with several "logical design criteria" of guidelines we want to enforce with our tool. For example, the acquisition module:

i) checks that each alternative is preceded by a decision; whenever alternative arcs exit a node, the acquisition module checks that such a node is a decisional one. This check allows for the fact that whenever alternative ways of achieving goals are considered in the guideline, the guideline also contains an explicit way of discriminating between them. This property is important especially at execution time, since, in such a way, the execution tool can provide specific support to the user physicians whenever they have to choose from alternatives;

ii) checks that decision actions are preceded by query actions specifying all the data involved in the decision criteria. Thus, at execution time, a decision action is executable only after all necessary data for that decision are available.

Checking semantic consistency: temporal constraints

In most therapies, actions have to be performed according to a set of temporal constraints concerning their relative order, their duration, and the delays between them. Additionally, in many cases, actions must be repeated at regular (i.e., periodic) times. Furthermore, it is also necessary to carefully take into account the (implicit) temporal constraints derived from the hierarchical decomposition of actions into their components and from the control-flow of actions in the guideline. Checking the consistency of such a set of implicit and explicit constraints is a very hard task, which cannot be performed manually by any expert. On the other hand, within the Artificial Intelligence community, several approaches to perform automatically the propagation of temporal constraints and to check their consistency have been developed [17].

Despite the large amount of valuable works, there still seems to be a gap between the range of phenomena covered by current AI temporal reasoning approaches and the needs arising from clinical guidelines management. In particular, in clinical guidelines,

1. qualitative and quantitative constraints, as well as repeated/periodic events need to be considered at the same time; all types of constraints may be *imprecise and/or partially defined*;
2. a structured representation of complex events (in terms of part-of relations) must be supported, to deal with structured descriptions of the domain knowledge;
3. the distinction between *classes* of actions (e.g. an action in a general guideline) and *instances* of such actions (e.g., the specific execution of an action in a guideline) has to be supported;

Obviously, the interplay between issues (1)-(3) needs to be dealt with, too. For example, the interaction between composite and periodic events might be complex to represent and manage. In fact, in the case of a composite periodic event, the temporal pattern regards the components, which may, recursively, be composite and/or periodic events. For instance, consider Ex.1.

(Ex. 1) *The therapy for multiple mieloma is made by six cycles of 5-day treatment, each one followed by a delay of 23 days (for a total time of 24 weeks). Within each cycle of 5 days, 2 inner cycles can be distinguished: the melphalan treatment, to be provided twice a day, for each of the 5 days, and the prednisone treatment, to be provided once a day, for each of the 5 days. These two treatments must be performed in parallel.*

In Ex. 1, e.g., the instances of the melphalan treatment must be repeated "twice a day, for 5 days". However, since the melphalan treatment is part of the general therapy for multiple mieloma, such a repetition pattern must be repeated for six cycles, each one followed by a delay of 23 days.

Unfortunately, no current approach in the AI and in the guideline literature proposes a comprehensive approach in which all the above phenomena can be represented, and correct, complete and tractable temporal reasoning can be performed. In GLARE, we define an approach addressing all the above-mentioned issues [1].

A complete automatic treatment of temporal constraints involves, besides the design of an expressive representation formalism, also the development of suitable temporal reasoning algorithms operating on them, to be applied both at acquisition and at execution time. However, subtle issues such as the trade-off between the expressiveness of the representation formalism and the tractability of correct and complete temporal reasoning algorithms have to be faced in order to deal with temporal constraints in a principled and well-founded way; few works in the area of computerized guidelines have deeply analyzed this topic so far.

As a starting point, we have chosen to rely as much as possible on STP (Simple Temporal Problem) [2], a well known and consolidated Artificial Intelligence approach coping with different types of temporal constraints. However, we had to extend it, in order to cope with the beforementioned additional temporal issues. Specifically, We have chosen to model the constraints regarding repeated actions into separate STPs, one for each repeated action. Thus, in our approach, the overall set of constraints between actions in the guideline is represented by a tree of STPs (STP-tree henceforth). The root of the tree (node N1 in the example in Fig. 2) is the STP which homogeneously represents the constraints (including the ones derived from the control-flow of actions in the guideline) between all the actions in the guideline (e.g., in N1, the fact that the duration of the chemotherapy is 168 days), except repeated actions. Each node in the tree is an STP, and has as many

children as the number of repeated actions it contains. Each edge in the tree connects a pair of endpoints in an STP (the starting and ending point of a repeated action) to the STP containing the constraints between its subactions, and is labeled with the list of properties describing the temporal constraints on the repetitions. For example, in Fig. 2, we show the STP-tree representing the temporal constraints involved by the example Ex. 1.

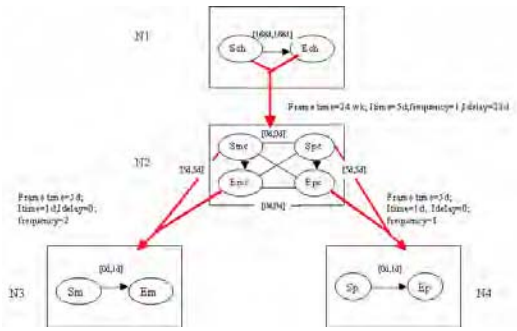

Figure 2 - STP-tree for the multiple mieloma chemotherapy guideline. Thiny lines and arcs between nodes in a STP represent bound on differences constraints. Arcs from a pair of nodes to a child STP represent repetitions. Arcs between any two nodes X and Y in a STP of the STP-tree are labeled by a pair [n,m] representing the minimum and maximum distance between X and Y

In order to check the consistency of the STP-tree, it is not sufficient to check the consistency of each node separately. In such a case, in fact, we would neglect the repetition/ periodicity information. Temporal consistency checking, thus, proceeds in a top-down fashion, starting from the root of the STP-tree. Basically, the root contains a "standard" STP, so that the Floyd-Warshall's algorithm can be applied to check its consistency (as shown in [2]). Thereafter, we proceed top down towards the leaves of the tree. For each node in the tree, we first check that the constraints on the arcs, considered alone, are consistent. If so, we then merge such constraints with the constraints in the son node, and propagate the resulting constraints to verify the joint consistence. We also formally proved the following.

Property 1. Our algorithm to check the consistency of STP-trees is *correct, complete,* and operate in *polynomial time* with respect to the number of actions in the guideline.

Property 1 grants that all and only the correct inferences are drawn by our temporal reasoning algorithm, and that such inferences are performed in tractable time.

Checking semantic "logical" consistency

Besides the property of being temporally consistent, several other semantic properties (e.g., logical consistency, safeness) should be checked on clinical guidelines. Specifically, we have identified four different classes of properties relevant in the clinical guideline context, and we have proposed a general and task-independent approach to check all of them.

i) **Properties concerning a guideline "per se"**. One can check if the guideline contains a path of actions satisfying a given set of conditions (e.g., a path including actions X, Y and Z, or a path in which no action of type X is executed, or a path nor requiring a given laboratory test, or a path requiring only a given set of resources, and so on);

ii) **Properties of a guideline in a given context.** Specific contexts of execution may impose several limitations on the executable actions of guidelines, related, e.g., to the lack of certain resources (e.g., laboratory instruments). The consequences of such limitations may be automatically investigated. For instance, one can check whether there is or not a therapy for a patient affected by a given disease, in the case a specific set of resources is available (not available).

iii) **Properties of a guideline when applied to a specific patient.** For instance, the feasibility of a given action or path of actions on the specific patient can be checked.

iv) **Integrated proofs.** Any combination of the above types of checks can be performed. For instance, one may ask whether, given a patient with a specific disease and set of symptoms, and given an hospital with a specific set of resources, there is a path in the guideline which applies to the patient and satisfies a given set of properties.

In our approach, we provide a general way of proving all the above properties by loosely coupling GLARE with the model checker SPIN [6]. Roughly speaking, we have devised a tool to map clinical guidelines acquired by the GLARE system into the Promela language, which is the language used by the SPIN model-checker. Promela allows a high level model of a distributed system to be defined by modelling each agent in an extended pseudo-C code, including synchronization primitives and message exchange primitives. Specifically, GLARE's guidelines are translated into a set of agents (e.g., the agents representing the guideline actions, the agent representing the physician executing the guideline, and so on). Once we have the translation of GLARE's guidelines in Promela code, we can use SPIN as a general-purpose engine to prove any property that can be expressed in the temporal logic LTL. In fact, SPIN translates each process (each agent) into a finite automaton, and the global behaviour of the system is obtained by computing an asynchronous interleaving product of automata. The resulting automaton represents the global state space of the system and can built on-the-fly during the verification process. The property which has to be verified on the system is passed to the verifier through an interface, which maps it into a temporal formula, as required by SPIN. SPIN converts the negation of the temporal formula into a Büchi automaton and computes its synchronous product with the system global state space. If the language of the resulting Büchi automaton is empty then the property is true on all the possible execution of the system, otherwise the verifier provides a

counterexample for the property (an execution path on which it is false).

In such a way, we provide a general-purpose approach to automatically check all the types of properties discussed above.

Results

GLARE provides a set of facilities to help physician during the acquisition of clinical guidelines, and to verify a-posteriori the correctness of guidelines being represented. To the best of our knowledge, no other guideline system in the literature provides such a large set of facilities. GLARE's facilities have proven to be quite effective in our testing activities. In particular, in the cases in which a textually written guideline had to be entered into the GLARE systems, the adoption of GLARE facilities allowed us to detect different kinds of errors in the original guidelines. In certain cases, these errors were simply due to omissions (e.g., lack of a decision action to discriminate between alternative paths of actions). In other cases, they were due to the human impossibility to propagate constraints (and, in particular, temporal constraints) along long paths of actions. In all cases the physician experts agreed that the errors detected by the GLARE systems were "genuine" errors in the original guidelines, and agreed to correct them.

Acknowledgments

We acknowledge Prof Gianpaolo Molino and Dr. Mauro Torchio of Azienda Ospedaliera S. Giovanni Battista, Turin, Italy for their cooperation in defining and testing the GLARE system. The research reported in this paper has been partially supported by a grant from Koine Sistemi, Torino, and by PRIN'06.

Knowledge Zone: A Public Repository of Peer-Reviewed Biomedical Ontologies

Kaustubh Supekar, Daniel Rubin, Natasha Noy, Mark Musen

Stanford Medical Informatics, Stanford University School of Medicine

Abstract

Reuse of ontologies is important for achieving better interoperability among health systems and relieving knowledge engineers from the burden of developing ontologies from scratch. Most of the work that aims to facilitate ontology reuse has focused on building ontology libraries that are simple repositories of ontologies or has led to keyword-based search tools that search among ontologies. To our knowledge, there are no operational methodologies that allow users to evaluate ontologies and to compare them in order to choose the most appropriate ontology for their task. In this paper, we present, Knowledge Zone – a Web-based portal that allows users to submit their ontologies, to associate metadata with their ontologies, to search for existing ontologies, to find ontology rankings based on user reviews, to post their own reviews, and to rate reviews

Keywords:

biomedical ontologies, ontology search, ontology ranking, knowledge management

Introduction

The medical community has seen widespread application and use of ontologies. With the ever-increasing amount of competing knowledge available for computation, workers in the medical domain who wish to reuse this computational knowledge find it difficult to assess and keep track of all available ontologies. Consequently, more often than not, institutions expend their valuable time and resources to develop their own ontologies, thus creating an assortment of ontologies of varying degree of quality that are not interoperable. In the healthcare system, this translates to the creation of solutions that are not interoperable, thereby hampering the information flow between these solutions, which is critical to the operation and long-term sustainability of the system.

There have been some efforts to develop Web-based libraries of ontologies: Table 1 provides a listing of some of the popular systems. These efforts have served varying purposes, from developing repositories specific to a knowledge representation (DAML Ontology Repository, Protégé-OWL Library) to supporting collaborative development of ontologies (Ontolingua). Most of these resources are mere listings of ontology resources and use different logical and structural organization to present the information relevant to the ontology. A survey [1] of these systems has rightly identified their key inadequacies, and also has suggested important requirements for structuring an ontology library system to enhance ontology management, adaptation, and standardization. Furthermore, with the limited search facility available in these resources, finding the desired ontology requires manual perusal of these Web resources, a cumbersome and a time-consuming process.

Table - Ontology libraries

DAML Ontology Library	http://www.daml.org/ontologies
WebOnto	http://kmi.open.ac.uk/project/Webonto
Ontolingua	http://www.ksl.stanford.edu/software/ontolingua
Protégé-OWL Library	http://protege.stanford.edu/plugins/owl/owl-library
OntoWeb	http://www.ontoWeb.org
OBO	http://obo.sourceforge.net

Researchers at the University of Maryland have developed Swoogle [2] - a Web based tool that provides a keyword based query facility to search and access ontologies. Through its basic and advanced query interfaces, users can search across a large collection of knowledge resources (1,898,651 Semantic Web documents, ~10,000 ontologies)[1] that exists in the cyberspace. This tool is noteworthy in its ability to search a large collection of ontologies, and to present the user with a list of relevant ontologies that match his query.

We argue that simply listing relevant ontologies is not sufficient for users who need to select the most appropriate ontology for their task. Users need a facility to help them evaluate ontologies and to compare them. Users need to ascertain how well an ontology or a part of an ontology covers the domain of interest, what is the maturity of ontology content, and how the content is related to stan-

1 Statistics obtained from http://swoogle.umbc.edu/ as of November 28, 2006

dard ontologies such as CYC, GO, and UMLS. Most of this information, if available, is provided by the creators of the ontology or by the institution that hosts the ontology, and is usually made available to the public through their Website. For evaluating an ontology, it is also valuable for a user to find out what were the experiences of other users with that ontology. Unfortunately, most of this important metadata is usually not included as part of the ontology content. This problem can be attributed to the limitations of the underlying knowledge representation language to specify such support information and the lack of tool support to associate metadata with an ontology.

To facilitate ontology reuse, we have developed Knowledge Zone, a resource where users can submit their ontologies, associate metadata with their ontologies and search for existing ontologies that satisfy their requirements. Unlike existing libraries, our system allows users to create and view peer reviews, ratings, experience reports and to find out rankings of an ontology. In Knowledge Zone, we have implemented an Open Rating System model [3] that uses reviews and ratings to compute a Web of Trust, which is then used to compute ranking of an ontology and to filter reviews.

Methods

Ontology submission: associating metadata with an ontology

The Knowledge Zone portal provides a Web interface (figure 1) that allows users to associate metadata with their ontologies. We have developed a comprehensive ontology of features (metadata) that characterize an ontology. Some of the categories included in the metadata ontology are:

- Domain of the ontology (using controlled terminology, when possible); informal description of the content; intended use of the ontology;
- Version number; contact and author information; supporting institutions; availability and licenses; citations and references;
- Verification tools used and development methodology;
- Naming policy; reliance on other ontologies
- Peer reviews; experience reports; usage data; ratings along different axes, such as correctness; coverage; degree of formality.

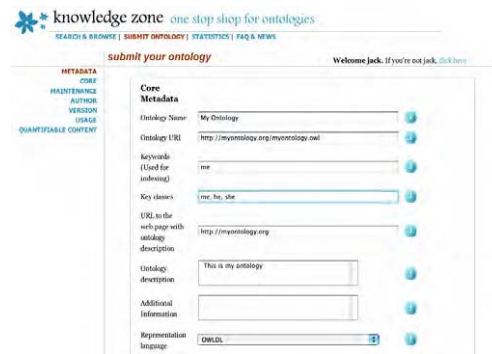

*Figure 1 - **Knowledge Zone - Ontology submission interface.** Users can enter textual information such as name and URL of the ontology, and specific information about the ontology, such as its representation language.*

These metadata features are principally categorized along two axis (1) source metadata, which include metadata provided by the ontology authors, and (2) third-party metadata, which are provided by the ontology users.

The Knowledge Zone portal employs a dynamically generated UI mechanism that leverages the semantics encoded in the Metadata ontology to provide a contextual interface based on the representation format of the ontology being submitted, level of expertise of the user, type of user (author vs. third-party user), and importance of a particular metadata element. Accordingly, the ontology submission interface is dynamically constructed to generate a Web form that will solicit the user to enter all the metadata information that has been categorized as "source metadata". This process of ontology-driven dynamic UI generation, which is used to generate every page in the Knowledge Zone portal, is depicted in figure 2. Through the dynamically generated ontology submission interface, users can enter, among other things, textual information such as the name of the author and a description of the ontology, as well as controlled information such as intended use, conceptual representation {e.g. Directed Acyclic Graph, Logic based, Frames} and the representation language {e.g. XML, Text, RDF, OWL} can be entered through the drop down boxes, which are populated from the metadata ontology.

The ontology development community in the medical domain comprises of a wide range of researchers, from those who have little or no formal training in logic, to expert knowledge engineers. To accommodate these diverse users, it is imperative to develop a solution that would not overwhelm the naïve user, while at the same time enabling capture of detailed information from the expert user. The dynamic UI generation process employed by Knowledge Zone, and the semantics encoded in our comprehensive metadata ontology allows us provide this flexible behavior in the user interface. For example, based on the axioms in the metadata ontology, an expert user who wishes to annotate description-logic ontology is presented with a different set of metadata information than would be a novice user.

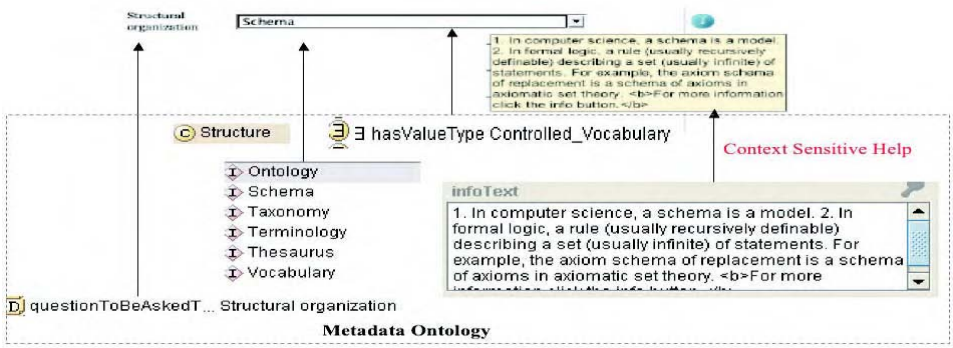

*Figure 2 - **Dynamic UI Generation in Knowledge Zone**: Process of generating a drop-down form element to capture information about a "Controlled_Vocabulary" metadata element - structural organization of ontology is shown. The label of the form element, tool tip text, and the drop-down box elements, is retrieved from the "questionToBeAskedToAuthor", "infoText", and the "Structure" properties associated with the "Structural_Organization" class in the metadata ontology.*

The metadata ontology employed in Knowledge Zone is comprehensive, and has undergone several revisions through a rigorous ontology development process. However, the inclusion and exclusion of metadata features from our ontology could, potentially, evolve; similarly, users might have different opinions about the features attributed to the novice users, controlled terms for a metadata feature, and so on. To accommodate these diverse user opinions and to ensure wide usability of Knowledge Zone, we allow the user to extend the metadata ontology. Currently, these extensions can be made on one or more of the following sections of our ontology: Ontology features (metadata), Controlled Vocabulary, and Tool Tip.

If users extend the metadata ontology, Knowledge Zone can be configured to use their extended ontology (by simply specifying its location). The metadata information that we collect is stored as instances of the metadata ontology.

Ontology search

Most of the current ontology repositories provide a simple keyword search facility. Even though keyword searches are preferred by many users, and work partially for searching Web pages, they are not desirable for searching ontologies, which have an inherent structure. Also, keyword-based searches suffer from poor precision. For example, a search for "anatomy" in Swoogle yields 59 "hits". It is then up to the user to scour through these XML files to look for the ontology that suits his requirements. Also, keyword-based searches are likely to miss out on ontologies that do not have those keywords. For example, the GALEN ontology, one of the popular anatomy ontologies, which, even though crawled by Swoogle, does not appear in the search results when users enter "anatomy" into Swoogle.

Knowledge Zone provides not only a simple keyword-based search interface, but also a structured query interface. For example, through the structured query interface, users can query for anatomy ontologies, which have been encoded in OWL, have been used for data integration, have a GNU license, and have heart, lung, and kidney among its classes. The search engine executes this query by looking up the values of the associated metadata terms across ontologies stored in our repository, and returns all the ontologies that satisfy the search criteria.

Ontology evaluation

Peer-review of ontologies

As more ontologies become available, even when users make structured and specific queries, they will obtain multiple "hits". These results will include ontologies that are developed by different institutions, and that are of varying quality. Currently, there are no operational methodologies to compare and evaluate quality of ontologies to select the best ontology for the purpose. We argue that deciding whether some ontology is "best" for a particular purpose is a purely subjective matter.

In Knowledge Zone, users can enter their subjective evaluations and reviews of an ontology. Our idea is akin to that employed by Epinions and Amazon to collect user reviews and ratings on products so that users can subjectively evaluate which "book" or "MP3 player" is best suited for their needs. This peer-review approach is well suited to ontologies, as, like "books" or "mp3 players", ontologies lack universally agreed upon criteria to denote "goodness", and thus users have to rely on other user evaluations and opinions to select a good one.

To evaluate ontologies, it is not only useful to have user evaluations of the ontology itself, but also it is particularly useful if users can comment on particular aspects of an ontology. For example, it is valuable to know what other users think about the "correctness" of a particular ontology. In Knowledge Zone, currently, users can provide numeric ratings and a free text review along the following dimensions: Syntactic Correctness of the ontology, Maturity of the ontology content, Expressibility, Semantic Consistency, Degree of Formality, Availability of documentation, and Usability of the Ontology.

Open rating systems and computing ontology rank

A user review of ontologies is a time consuming process and to have its maximum utility it is desirable to keep the review process "open". However, opening the review process to everyone causes the problem of trust. Furthermore, users have varying degree of expertise: biologists are more likely to comment better on the "domain coverage" of the ontology compared to a logician, who is likely to review better on the "semantic correctness" of the ontology. Consequently, we are bound to get some reviews that are of poor quality. To have a "usable" system, it is imperative to be able to filter them.

In Knowledge Zone, we have used the Open Rating System model [3] to accomplish this and to be able to rank ontologies. Users of our system can not only rate the ontology content, but also can rate the reviews as well as the reviewers. We use these reviews and "trust" statements made by the users to compute a "Web of Trust" (WOT), which is then used to compute rank of ontologies. The Web of Trust model [3] has been successfully used and implemented in systems such as Epinions and Amazon to rank products and to filter reviews.

The Web of Trust model as adapted and implemented in Knowledge Zone has six major components and can be summarized as follows:

- Set of Ontologies O: {O1, O2…On) that are being rated.
- Set of Users U: {U1, U2…Un} that either participate in reviewing the Ontology or providing ratings on other users.
- Set of possible ratings on an Ontology D: {0,1,2,3,4,5}
- Set of possible ratings by a user on another user T: {useful (positive), not-useful (negative)}
- Function that stores the ontology ratings provided by the user R: $O \times U \rightarrow D$
- Function that stores the ratings of users provided by other users: W: $U \times U \rightarrow T$

As mentioned earlier, a structured query by a user might return more than one ontology. We define "ranking" as a problem of being able to rank these ontologies in the descending order of their importance for a particular user. This is equivalent to finding top N ontologies, given all the six major components of our Web of Trust model. Similarly, reviews can be filtered by finding the top N reviews that are relevant to the user.

Given the WOT model; there are many approaches [4] to compute the top N objects. In our case, due to the relatively small size of the user set as compared to that available for systems such as Amazon and Epinions, we envision that functions R and W would be relatively sparse, consequently, most of the users will not have a WOT. To tackle this issue, in Knowledge Zone, we have implemented a TrustRank [5], an approach that is well suited to scenarios where most of the people do not have a WOT. However, TrustRank is limited by its applicability to compute rankings based on reviews and ratings on ontology as a whole. To accommodate for reviews that are collected on specific aspects of an ontology (for example: maturity, correctness) we augmented the TrustRank with a topic-specific trust model. This augmented approach is used to compute ontology rankings and to rank reviews associated with an ontology. Space limitations prohibit us from providing details of this approach; interested reader is encouraged to read the supplementary paper [6].

Results and implementation

Knowledge Zone is a java-based Web portal that is hosted on an Apache Tomcat server, and is publicly available. The portal uses AJAX, DHTML, and XSLT for dynamic UI generation, and MySQL database to store the user information. User reviews and ontology annotations are stored as instances of the Metadata Ontology in OWL format; Protégé-OWL API is used to access, query, and retrieve and store these instances.

From its inception, Knowledge Zone has consistently attracted a sizeable number of hits (Total hits: 12,456) from the user community, with a large portion of it being unique hits. At the time of this writing, Knowledge Zone is host to a total of twenty eight ontologies, with some notable submissions like BioPAX, Foundational Model of Anatomy, OBO Relationship Ontology and GALEN, and a total of eleven user reviews. Most of the current ontologies in our repository cover different domains. Finding the ontology rank in that case is trivial because a keyword-search or a structured query will at the most return one or two ontologies as the search result. For e.g. a structured query made in Knowledge Zone that represents the user query "Find all the anatomy ontologies" returns two ontologies – the Foundational model of Anatomy and GALEN. The number of ontologies and the number of reviews in Knowledge Zone are a limiting factor in doing a real-world evaluation of our Web of trust model to rank ontologies. However, the Web of trust model, implemented in Knowledge Zone has been successfully tested on non-ontological data, which in terms of our model has similar properties compared to the ontological data.

In future, we envision Knowledge Zone to be host to a sizeable number of ontologies and their reviews. To facilitate this process, we investigated factors that may hamper the growth of Knowledge Zone as a system. From informal interviews with the curators of biomedical ontologies, we postulate that the following may be the rate-limiting factors,

Associating metadata with ontologies is a time consuming process. To tackle this issue we are working on methods to automatically compute the quantifiable metadata. Another approach is to hire curators to enter information about ontologies on behalf of the ontology authors, and get it verified from them. We have used this approach to seed Knowledge Zone with ontologies from the Protégé-OWL library. For these ontologies we obtained metadata information through manual perusal of relevant publications and Web sites. Even though we were able to capture most of the metadata information, such an approach is not scalable, and we would miss out on critical

mass of ontologies, which we are not aware-of or are not hosted on one of the existing ontology repositories. We found that there are approximately 500 ontologies in the popular ontology libraries (see Table 1); on the other hand, the number of ontologies crawled by Swoogle is 10K.

Social issues. There are a number of social issues involved, predominantly in the biomedical domain, which hampers information sharing among researchers. These issues are widely studied and solutions involve making the user aware of the benefits of sharing information, ontologies in our case.

Peer-pressure. Currently, the biomedical ontology development community is small and comprises of closely knitted group of researchers. Our approach results in exposing their work (ontologies) for critiquing from colleagues, an approach to which they are receptive to in a private setting such as through email conversations rather than in a public forum. Having anonymous ontology submissions and reviews could possibly alleviate this concern. However, having large number of anonymous users would need substantial modifications to the current Web of Trust model.

In order to overcome these issues, work is in progress to automatically compute the metadata information associated with an ontology, and in future we plan to disseminate information in the ontology community about incentives of sharing ontologies.

Discussion and conclusion

We have developed Knowledge Zone – a Web-based portal that allows users to submit their ontologies, associate metadata with their ontologies, to search for existing ontologies, to find out their rankings based on user reviews, to post their own reviews, and to rate reviews. Our hypothesis is that having a substantial number of ontologies and a large number of reviews provided by the user community would support the user in selecting the suitable ontology for his purpose, which, consequently, would facilitate ontology reuse.

The infrastructure developed as part of Knowledge Zone: metadata ontology, ontology search and indexing mechanisms, and peer-review approach for ontology evaluation, is currently being ported for similar purposes in the Bioportal application [7], which is maintained and developed by the National Center for Biomedical Ontology. With the migration of Knowledge Zone functionality and implementation to Bioportal, planned activity by our Center to disseminate information in the ontology community about "incentives" of sharing ontologies, and current efforts to seed the Bioportal with all the ontologies from the Open Biomedical Ontology (OBO) repository, we believe that there would an increase in the number of ontology submissions, and consequently number of reviews collected in, thereby increasing the utility of our system to facilitate ontology reuse and consequently enabling the building of sustainable, interoperable health systems.

Acknowledgments

This work was supported by the National Center for Biomedical Ontology, under roadmap-initiative grant U54 HG004028 from the National Institutes of Health.

Abstract

PICO Linguist and BabelMeSH are multilanguage search tools intended for users whose native language is not English. A database of medical terms was created using concept identification equivalents of English terms to other languages. The primary sources of vocabularies were UMLS, MeSH, WHO EMRO and UMLF. The search interface changes according to the language selected which allows search terms to be entered in the native language. The user can limit the search output according to the language of publication but citations retrieved are in English only. Links may be provided to journals if published online. Evaluation of the French and Spanish versions using journal key words and a list of common diseases showed 77.5% and 86.5% accuracy respectively. User feedback was positive. PICO Linguist and BabelMeSH could be useful and convenient tools in finding current evidence sources in the medical literature especially for non-English medical terms that may be difficult to express in English.

Keywords:

evidence-based medicine, multilanguage search, MeSH, MEDLINE/PubMed, PICO, UMLS

Introduction

*ask*MEDLINE was developed as a free-text search tool for MEDLINE/PubMed.[1] We noticed that about 8% of queries early in its development were non-English terms. This is not unexpected because when searching the medical literature, it is often easier to use the language in which one is most accustomed to.[2] This observation motivated us to design search tools for MEDLINE/PubMed. PICO Linguist and BabelMeSH are the results of these efforts. Using their own native language could help find certain concepts that are difficult to translate into English. MeSH translations could be useful to healthcare providers and researchers who are not too comfortable with English in locating journal articles in MEDLINE/PubMed.

The PICO (Patient, Intervention, Comparison, Outcome) format is a method of searching medical literature that promotes the use of a focused, structured question. This search strategy leads to more precise searches[3] and facilitates the practice of evidence-based medicine using the well-built clinical question.[4] There are reports[5,6] in the literature of cross-language or multi-language projects for medical information retrieval but not many active Web sites. We propose PICO Linguist and BabelMeSH, concept-based search tools, for healthcare personnel and researchers who are not too familiar with English.

Materials and methods

BabelMeSH is designed as a transparent multilanguage and cross-language interface. Users can submit medical terms in their native language (currently, Arabic, Chinese, English, French, German, Italian, Japanese, Portuguese, Russian and Spanish) then a parser translates the query into English using a multi-language MySQL database. BabelMeSH then sends the query to PubMed through E-Utilities and returns English citations to the user.

PICO Linguist includes all the features that BabelMeSH have but instead of a single input box, PICO Linguist provides users with the structured PICO format consisting of Patient/Problem (P), Intervention (I), Comparison (C) and Outcome (O) input forms. The interface changes according to the input language selected.

Multi-language database

The major source for most translation records in the databases is the UMLS Metathesaurus, which contains MeSH translations in French, German, Italian, Japanese, Portuguese, Russian and Spanish. Permissions were obtained from the contributing organizations. In addition, Dr. Stephan Darmoni and Dr. Patrick Ruch provided French MeSH translations and the unified medical lexicon for French (UMLF). Dr. Najeeb Al-Shorbaji, Regional Office for the Eastern Mediterranean, World Health Organization, kindly provided Arabic translations of MeSH and the Unified Medical Dictionary. Chinese terms were collected from multiple open source web sites.

The concept unique identifier (CUI) and its concept source were used to find translations from UMLS. Briefly, all the concepts in one non-English language and corresponding CUIs in UMLS were identified. If the English concept in UMLS from MeSH links to the same CUI, the English concept and the foreign language concept were paired.

Otherwise, the English concept from another vocabulary was selected.

A hierarchal scheme was devised in order to create separate translation tables for each foreign language using MySQL. The priority of source vocabulary from high to low in our system is: MeSH, UMLS-Meta, SNOMED and any other vocabulary. Table 1 illustrates the structure of each table, which includes CUI, English term, non-English term, and accented non-English term (if available).

Table 1 – Translation table structure (French)

CUI	English	French	Accented French
C0702166	Acne	Acne	Acné
C0019686	HIV Antigens	Antigenes VIH	Antig_nes VIH

For translation pairs that are not from UMLS where the foreign term and English term do not map to the same CUI, an internally generated concept ID is created by the system. An example is shown in Table 2 (P-45-52.)

Character-based language processing

Character-based languages require special handling for string processing in Web applications and in the database. First, we unified character settings by encoding in UTF-8 (Unicode). The default character set in MySQL configuration file is UTF-8. Next, we installed the Multi-byte String Extension package for PHP because each letter or character in these languages may be represented by more than one byte in storage. Multi-byte String Extension can perform string processing for all of these languages. The character setting for internal encoding, HTML input and output in this extension is also in UTF-8.

Parsing algorithm

The parser identifies terms found in the translation database and deletes all others not in the database. The corresponding English translations are sent to PubMed through E-utilities. For terms entered in the search form with accents, the parser searches the accented terms column in the database (Table 1.) If no matches are found, it will transform the accented input to the unaccented form, then search the database again and return the unaccented term. If no exact matches for some terms are found, BabelMeSH will suggest records that contain part of the non-English query. The user may modify the suggestions before sending to PubMed.

An algorithm was developed for complex searches such as combined MeSH terms or concepts. In order to compel the parser to find the optimal translation, the algorithm browses the input by two pointers, recursively (Figure 1.) First, translations of PubMed "stop words" are ignored. A multi-word input is then split into an array where each array element stores an input word. Two pointers (Pointer 1 and Pointer 2) are inserted at the beginning and the end of the array. Comparing them with the database identifies individual elements between the two pointers in the array. If no match is found, Pointer 2 moves towards the front of the array one element at a time, until a match is found, or Pointer 1 meets Pointer 2. Once a translation match for the multi-word term or phrase is found, these elements are removed from the array and Pointer 1 will move towards the end to the next unmatched element in the array. If two pointers meet before the translation processing finishes, Pointer 2 will reposition to the end of the array, and Pointer 1 will again move to the end, one element at a time. The translation search will repeat until Pointer 1 and 2 meets at the end of the array. Table 2 shows the records in the database related to the search illustrated in Figure 1.

Table 2 – Records involved for translating the example query

CUI	English	Spanish
C0004916	bed	cama
C0231290	after	despues
C0442022	lumbar	lumbar
C0033119	puncture wound	puncion
C0553794	spinal tap	puncion lumbar
C0004910	bed rest	reposo en cama
P-42-52	rest	reposo

User interface

An auto-complete feature (Figure 2, in Chinese) using XMLHttp object request JavaScript, provides suggestions as the query is entered. Suggestions can be selected from the drop down list.

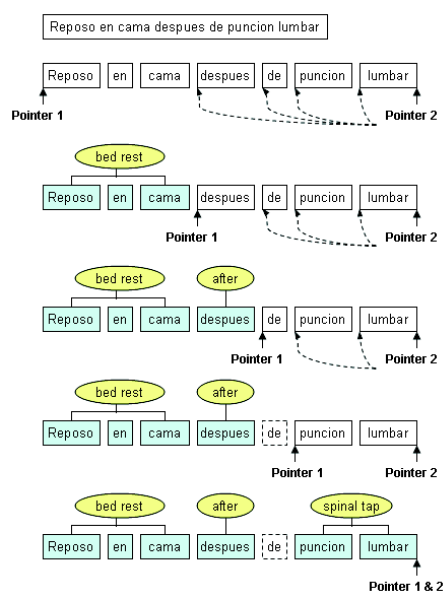

Figure 1 – How the parser works

Figure 2 – BabelMeSH (Chinese) with autosuggestion

In PICO Linguist, the embedded JavaScript code makes the Web interface change dynamically with the input language choices, shown in Figure 3. The JavaScript code changes the text orientation to right to left when Arabic is selected (Figure 4.)

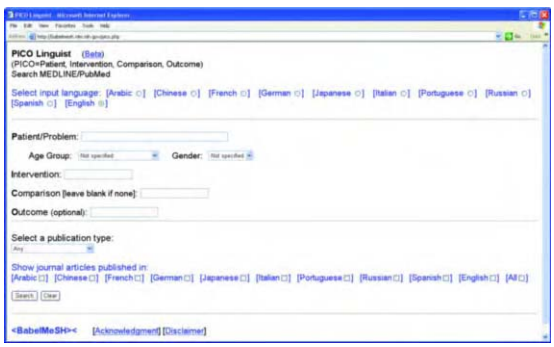

Figure 3 – PICO Linguist English search page

Figure 4 – PICO Linguist interface in Arabic

Citation result filter

The user can select to view the titles of citations by language of publication. An output filter can display the results in one or more publication languages. The default is for articles published in all languages in PubMed journals. If a filter of publication language other than English is selected, the title of citation results will be shown in both English and the original language. However, this feature will only work for Latin languages. PubMed does not record original titles in character-based language, such as Arabic, Chinese, Japanese, and Russian.

BabelMeSH and PICO Linguist transmit the translated query to PubMed through E-Utilities. Retrieved citations are shown in English only because citations of foreign language journals indexed in MEDLINE are in English only. Links are provided to the foreign journal if published online. Journals may require subscription for full-text access. Search terms in the result's page are highlighted for the user's easy identification. Figure 5 demonstrates the result page of a query in Arabic.

Evaluation

The full list of *BMJ Clinical Evidence* systematic reviews[7] was translated into Spanish by one of the authors (SL). These terms were searched in BabelMeSH then compared to the Spanish translations. The accuracy of BabelMeSH's English translation was compared to the original list. User opinion was obtained through a Web form. The evaluation of the French version consisted of three parts: (1) comparison of the author's own translation of keywords to English in journal articles published in French and the translations of the same terms to English by BabelMeSH; (2) actual user search terms from the our Web server's log files; (3) online user feedback questionnaire using a 5-point Likert scale to evaluate user opinion on the usefulness of BabelMeSH.

Results

The search strategy in Figure 4 retrieved results shown below in Figure 5.

Figure 5 – Retrieval of a PICO Linguist search in Arabic

Table 3 shows the evaluation results of the French and Spanish versions of BabelMeSH and PICO Linguist. The two test sets used for evaluating the French version journal keywords and user query terms from server logs showed an accuracy of 75% and 79.9% respectively (mean=77.5%). Partial matches were obtained in 13.2% and 7.3% respectively. Full term matches and partial term matches equal to 88.2% and 87.2% of the test sets respectively. There were no matches in approximately 12% for both sets.

Table 3 – Evaluation of the French and Spanish versions

	French		Spanish
	Journal keywords	**User query from server log**	
Total number of terms	**174**	**179**	**221**
Exact or suggestions match	130	143	191
% Total	**75%**	**79.9%**	**86.4%**
Partial match	23	13	20
% Total	**13.2%**	**7.3%**	**9.0%**
Incorrect translation	21	23	10
% Total	**12%**	**12.8**	**4.5%**

One hundred ninety one of the 221 terms from the disease list had exact matches for the Spanish version or 86.4% accuracy. For 20 terms (9%) partial matching was found but some translations missed one or two key words that could negatively affect a search. No translations were found for 10 (4.5%) search terms. We analyzed the complexity of search term or phrase as a measure of the parsing algorithm. The results (Table 4) show that accuracy is inversely related to the number of terms used.

Of the six responses received from the French feedback form, the average ratings (5=agree, 1=disagree) for the following statements were: 1) that BabelMeSH was useful 4.3/5; 2) the overall quality of citations retrieved was excellent 4.3/5; and 3) that they would continue to use BabelMeSH 4.6/5. All stated that they had previously searched MEDLINE in English and all except one declared that they would recommend it to others.

Table 4 – Effect of search term count on translation accuracy

Number of terms	Total	Translated	% Total
1	104	85	81.7
2	150	69	46
3	67	11	16.4
4	24	2	8.3
5	6	1	1.7
6	2	0	0

Comments from the Spanish users were mostly positive. Figure 6 shows the results of the two questions asked: (1) is searching MEDLINE/PubMed in your native language useful? and (2) how would you rate the results obtained? The mean responses were 4.3 and 3.9 respectively in a 5-point Likert scale.

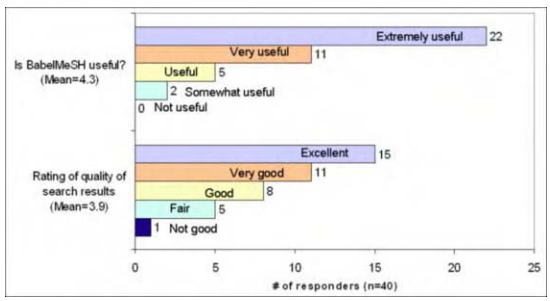

Figure 6 - User feedback on Spanish version

Discussion

The aim of this project, as in most medical translations is to bring out the same cognitive "equivalent effect"[8] that an individual might be searching for in MEDLINE/PubMed. This is challenging in one language, even more when dealing with many languages as we have attempted here. The quality of sources is also a major determinant of success, one that we have no control over.

The evaluation of PICO Linguist and BabelMeSH demonstrates the usual challenges of medical translation due to the highly technical and scientific nature of medical language. The parsing algorithm is an attempt to overcome Newmark's "transparent collocation" phenomenon[8] as well as grammar. This is quite a challenge as shown in Table 4 where translation success drastically plummets as the complexity of the search term increases.

During development, we also found that the simple change in use of singular or plural nouns adversely affected the result of a query. This was common among all language versions. This is related to the MeSH translation in other languages, some translations only include descriptors but not all the valid entries. For example, the MeSH heading, "heart diseases", has 8 valid records, such as "heart disease" and "cardiac disease". For this medical concept, our database has differences among languages: six records in French, five in German, two in Japanese and one record each in Italian and Russian. If "heart disease", instead of "heart diseases", in Italian or Russian is entered, there will be no translation result. We have done some machine-normalization work on plural and non-plural words in those foreign languages, but it could also bring errors. MeSH contains more than 22,000 descriptors, but it also has greater than 130,000 additional valid entries that can help find the appropriate MeSH heading.

Table 3 shows the results of the evaluation of the French and Spanish versions. Using two different test sets, the results in French are comparable. Contrasted with the Spanish version the accuracy of translation was higher in Spanish, although this is really not a one-on-one comparison since they use entirely different databases. This is also

likely related to the size of the database, the Spanish database contains 788,835 entries while the French only 190,330.

We were unable to compare translation accuracy with other medical translation studies. Cross-language reports such as the one done by Volk,[9] evaluated their algorithms using precision and recall from MEDLINE searches. In this project we opted to use keywords and disease list to maximize the number of terms tested. It would be difficult to use precision and recall studies. We chose user satisfaction questionnaires to evaluate real-world searches.

Usability approval was encouraging. Thirty-eight responders in Spanish said that BabelMeSH was 'useful' to 'extremely useful' while only two found it 'somewhat useful' and none responded that it was not useful. The high rating on the quality of search results directly supports the cognitive equivalent effect of translations. This would have been possible only with accurate translations. Almost all of the 40 responders submitted comments that were even more enthusiastic like, "I've been waiting for it" and "There's nothing like mother language." There were also comments that expressed a preference to be able to read the citations and abstracts in their native language. The French evaluators were equally enthusiastic about these resources.

The highly positive feedback obtained from French and Spanish users showed us that there is need for multilanguage resources and the medical community may be eager to adopt utilities like PICO Linguist and BabelMeSH in their daily activities. We suspect the same type of response from users in other languages not tested in this phase of the project. Medical translation in not a simple matter, nevertheless, it is very important to have tools available for immediate use at the point-of-care when the healthcare professional is looking for current evidence in the field.

Future challenges and developments

This resource is only as good as its database. It is a product of international collaboration and we invite collaborative research to make it even better. We also invite evaluation studies especially languages that are not covered by this report. The databases will be updated yearly as new editions of UMLS are released. Non-English translations of the abstract would be desirable. We will explore possible solution to this goal.

Conclusion

PICO Linguist (http://babelmesh.nlm.nih.gov) and BabelMeSH (http://babelmesh.nlm.nih.gov/pico.php) provide templates for multilanguage search tools including character-based languages. They can be alternative search resources for healthcare personnel searching for current evidence in the medical literature for whom English is not their primary language. We invite collaborative research especially in improving its multilanguage database and evaluating its potential.

Acknowledgments

We gratefully acknowledge colleagues[10] who provided advice, content and translation assistance for this project especially Dr. Najeeb Al-Shorbaji, EMRO, WHO.

Lessons Learned from Cross-Validating Alignments between Large Anatomical Ontologies

Songmao Zhang[1] and Olivier Bodenreider[2]

[1]Institute of Mathematics, Academy of Mathematics and Systems Science
Chinese Academy of Sciences, Beijing, P. R. China
[2]U.S. National Library of Medicine, NIH, Bethesda, Maryland, USA

Abstract

Objectives: To compare the alignments of two large anatomical ontologies (the Foundational Model of Anatomy and GALEN) produced by three ontology alignment systems (AOAS, FALCON and PRIOR) in the framework of the Ontology Alignment Evaluation Initiative during its 2006 campaign. Materials: Number of mappings identified by AOAS: 3,132, FALCON: 2,518 and PRIOR: 2,589. Methods: Three approaches to analyzing and comparing the results were utilized: computing the overlap among result files, manual review of some 2,000 mappings and structural validation. Conclusions: The generic systems FALCON and PRIOR identify many false positives and false negatives. With a stricter and domain-specific lexical similarity model, AOAS has a better precision, but is more sensitive to missing synonyms and misspellings.

Keywords:

anatomy, ontology alignment, collaborative evaluation, cross-validation

Introduction

A given domain is often represented by multiple ontologies, providing overlapping, yet different coverage of the domain knowledge. Anatomy, for example, is represented in ontologies such as the Foundational Model of Anatomy (FMA) and GALEN. There is a need for creating mappings among such ontologies in order to facilitate the integration of data annotated with these ontologies and reasoning across ontologies. Ontology alignment is the identification of correspondences among entities (i.e., concepts and relationships) across ontologies with overlapping content. Ontology alignment is an active field of research and many approaches to aligning ontologies have been developed in the past decade [1].

Like other research communities, such as information retrieval (TREC[1]) and information extraction (BioCreAtIvE[2]), ontology alignment researchers have set up a competitive evaluation: the Ontology Alignment Evaluation Initiative (OAEI[3]), with the goal of comparing systems and algorithms and gaining insights from the best matching strategies [2].

Evaluating ontology alignment is generally challenging. Except for ontologies of limited size (and significance), no reference alignment ("gold standard") is usually available for most ontologies, particularly in specialized domains such as anatomy. In the absence of a gold standard, the traditional framework of recall and precision cannot be used as the basis for the evaluation. Instead, the organizers used cross-validation as a surrogate. The assumption here is that mappings identified by several teams have a better chance of being valid.

At the 2006 edition of OAEI, five teams – including ours – presented the results of their alignment of the FMA and GALEN. The objective of this study is to review some of the results of the 2006 OAEI campaign for anatomy and to analyze the strengths and weaknesses of the various approaches.

Background

Anatomical ontologies

The two anatomical ontologies under investigation in the 2006 OAEI campaign are the Foundational Model of Anatomy (FMA) and GALEN.

The **Foundational Model of Anatomy**[4] (FMA) is an evolving ontology that has been under development at the University of Washington since 1994 [3]. Its objective is to conceptualize the physical objects and spaces that constitute the human body. The underlying data model for the FMA is a frame-based structure implemented with Protégé[5]. Over 70,000 concepts cover the entire range of macroscopic, microscopic and subcellular canonical anatomy. In addition to preferred terms (one per concept), some 50,000 synonyms are provided (up to 6 per concept). For example, there is a concept named *Uterine tube*, which has two synonyms: *Oviduct* and *Fallopian tube*. Because single inheritance is one of the modeling principles used in the FMA, every concept (except for the root) stands in a

5 http://protege.stanford.edu/

unique *is-a* relation to other concepts. Additionally, seven kinds of partitive relationships are used to connect anatomical concepts (e.g., *part of, constitutional part of*, *regional part of*, and their inverses *part, constitutional part, regional part*). Beside hierarchical relationships, there are 81 kinds of associative relationships between concepts in the FMA. While most of them have inverses (e.g., *branch of* and *branch*), a few do not (e.g., *input from*).

The Generalized Architecture for Languages, Encyclopedias and Nomenclatures in medicine[6] (**GALEN**) has been developed as a European Union AIM project led by the University of Manchester since 1991 [4]. The GALEN common reference model is a clinical terminology based on description logics. GALEN contains some 25,000 concepts and intends to represent the biomedical domain, of which canonical anatomy is only one part. Only one name is provided for each non-anonymous concept (e.g., *Lobe of thyroid gland*). There are over 3,000 anonymous concepts (e.g., *SolidStructure which <isPairedOrUnpaired leftRightPaired>*). GALEN supports multiple inheritance and every concept in GALEN (except for the root) stands in at least one *IS-A* relation – and often several – to other concepts. Relationships in GALEN are generally finer-grained than in the FMA. There are 41 kinds of *PART-OF* relationships (e.g., *isStructuralComponentOf, IsDivisionOf)*, and 536 associative relationships (e.g., *isBranchOf*, *isServedBy*). All relationships have inverses (e.g., *hasStructuralComponent*, *HasDivision*, *hasBranch*, *serves*).

OWL Full representation. As mentioned earlier, the FMA and GALEN were created using different knowledge representation formalisms: frames for the FMA and description logics for GALEN. In order to facilitate the alignment, the organizers converted the FMA and the anatomy subset of GALEN into OWL Full, the most expressive version of the Web Ontology Language. The resulting representation includes the class hierarchy and relations between classes for both ontologies. Additionally, concept names (including synonyms) and textual definitions for classes are represented for the FMA. The datasets provided by the organizers contain 72,560 concepts for the FMA (with 44,597 synonyms), and 9,566 concepts for GALEN (anatomy subset), of which 1,035 are anonymous.

Alignment systems

The three alignment systems analyzed in this study are the Anatomical Ontology Alignment System (AOAS), the Propagation and InfOrmation Retrieval based ontology mapping system (PRIOR) and Falcon-AO (FALCON). Two other systems participating in the 2006 OAEI campaign are not included in this review for the following reasons. Almost all mappings identified by COMA++ were specific to this system and could therefore not contribute to cross-validation. The result files contributed by IsLab were not available when this study was performed. As most alignment systems, the three systems under investigation rely on a combination of lexical and structural methods, based on the assumption that equivalent concepts across ontologies have similar names and similar relations to other concepts. A brief description of the three systems analyzed follows.

AOAS is a domain-specific ontology matching system for anatomical entities. Its lexical component compares concept names using a model of lexical resemblance developed for biomedical terms and exploits additional synonyms from an external resource: the Unified Medical Language System® (UMLS®). The presence of shared hierarchical paths among concepts across ontologies is then used as positive evidence for the mappings identified lexically. AOAS also identifies incompatible concepts, which receive negative structural evidence [5, 6].

PRIOR is a domain-independent, generic ontology matching system, based on an information retrieval approach. The features used to establish the profile of a concept include all lexical information available (concept name, label, comments, property restriction, etc.). Profile propagation is used to integrate structural information. To the profile of a concept is added, with different weights, the profiles of its ancestors, descendants and siblings. A search engine is then used to compare profiles in a vector space model [7].

FALCON is a domain-independent, generic ontology matching system. It combines three alignment methods, evaluating concept similarity based on strings (lexical similarity of concept names), "documents" (concept names and definitions treated as bags of words and compared in a vector space model) and graph structures (structural similarity based on a bipartite graph, exploiting all relations represented in the ontology for a given concept). Other features of FALCON include the partitioning of large ontologies into smaller blocks and the strategy used for combining the three mapping approaches [8].

Noticeably, both PRIOR and FALCON allow partial matches between concept names (e.g., *Adductor magnus of thigh* matches *Adductor magnus*), while only minor term variations are allowed between matches by AOAS. Unlike AOAS or FALCON, PRIOR can exploit the anonymous concepts in GALEN. And while AOAS only identifies mappings between concepts, PRIOR and FALCON also find mappings between relationships.

Table 1 - Number of mappings from the three systems

		AOAS	FALCON	PRIOR
Measure of confidence	1.0	3,029	2,115	2,583
	[.95-1.0]	0	397	0
	0.5	81	0	0
Incompatible		22	0	0
Relationships		0	6	6
Total		3,132	2,518	2,589

Materials

The result files for the OAEI 2006 campaign for anatomy were downloaded from the participants' web sites. The reporting format required from the organizers imposes four fields: entity1, entity2, measure (of confidence) and relation. Most mappings identified by the 3 systems are between equivalent concepts (relation: =). Incompatible mappings despite lexical similarity (negative evidence) are also reported by AOAS (relation: !=). A measure of confidence (0-1, continuous) is attached to each mapping and thresholds determined heuristically are used to select valid mappings. All mappings reported by PRIOR have a measure of 1.0, while FALCON also reported mappings with measures between .95 and 1.0. The mappings identified by AOAS are accompanied by a two-valued measure of confidence (1 when supported by positive evidence, 0.5 otherwise). The number of mappings identified by the three systems is summarized in Table 1.

Methods and results

Overlap. We first computed the intersection among the lists of mappings obtained by the three systems, thus partitioning the set of all mappings into subsets with respect to their origin, i.e., according to the system or systems that identified them (e.g., mappings identified by AOAS and FALCON, but not by PRIOR). The number of mappings with respect to their origin is summarized in Figure 1. 1,429 matches were identified by all of the three alignments, accounting for about 46%, 57% and 55% of concept matches in AOAS, FALCON and PRIOR, respectively (Figure 2). The proportion of mappings specific to one system varies largely, from 14% for FALCON to 39% for PRIOR, with 27% for AOAS.

Manual validation. Then, one of us (OB) manually reviewed for accuracy all mappings not identified by AOAS. There are several reasons for explaining our bias towards this system. Unlike the other two systems, AOAS was developed specifically for aligning anatomical ontologies. In previous work, we evaluated it against a gold standard established manually and against other systems. Recall was about .9 and most mappings identified specifically by AOAS were deemed valid [6]. The mappings were classified into the following categories: certain, possible (requires additional domain knowledge) and wrong. The objective of this cursory evaluation is primarily to quantify the false positive for FALCON and PRIOR and the false negatives for AOAS. As shown in Table 2, 1,183 of the 1,383 (86%) mappings not identified by AOAS were deemed invalid. More knowledge is required to establish the validity of half of the remaining 14%.

Structural evidence in AOAS. Another element of validation is provided by the presence of positive structural evidence, i.e., the existence of shared hierarchical paths to other tentative matches (anchors) across systems. We analyze the presence of structural evidence in the various subsets for which no manual review was performed. Overall, 97% of the lexical matches identified by AOAS were supported by positive evidence. Detailed results are reported in Table 3. Except for a larger proportion of conflicts (negative evidence) – 3.1% – in the mappings identified by AOAS and PRIOR, no major differences can be observed in the various subsets.

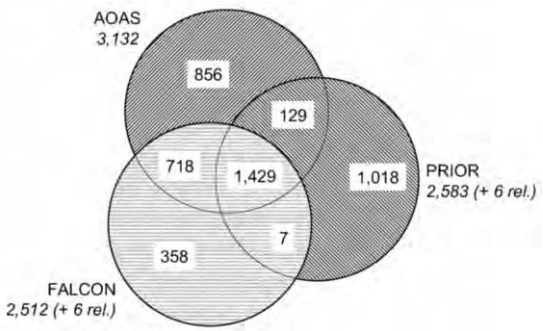

Figure 1 - Number of mappings with respect to their origin

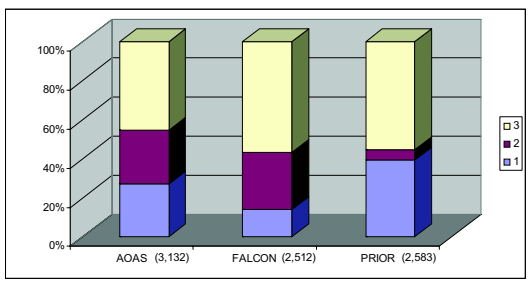

Figure 2 - Proportion of mappings identified by 1, 2 and 3 systems

Table 2 - Manual review of the mappings not identified by AOAS (excluding relations)

	Certain	Possible	Wrong	Total.
FALCON only	48	13	297	358
PRIOR only	53	80	885	1,018
FALCON + PRIOR	5	1	1	7
Total	106	94	1,183	1,383

Table 3 - Structural evidence in AOAS

	Positive	None	Negative	Total.
All 3 systems	1,382	44	3	1,429
AOAS only	819	30	7	856
AOAS + FALCON	705	5	8	718
AOAS + PRIOR	123	2	4	129
Total	3,029	81	22	3,132

Table 4 - Strengths and weaknesses of the three alignment systems

	AOAS	FALCON	PRIOR
Strengths	• Use of synonyms • Domain knowledge • Strict model of lexical resemblance • Few false positives	• Relaxed model of lexical mapping • Handles misspelling and minor term variation	• Mapping to anonymous concepts in GALEN • Information retrieval approach (more tolerant than edit distance)
Weaknesses	• Dependence on synonyms from FMA and UMLS • Very sensitive to misspelling and term variation and segmentation issues • Some false negatives	• Allows approximate matching • Many false positives • Some egregious mappings	• Allows approximate matching • Mostly false positives • No term matching • Many false negatives

Discussion

Limitations of the evaluation

The evaluation presented in this paper is partial (only the mappings not identified by AOAS were reviewed manually), cursory (some mappings were simply characterized as "possible", awaiting further review by a domain expert) and non-independent (since the person performing the review was also involved with AOAS). However, for the purpose of cross-validating three alignment systems and in conjunction with other techniques, we believe that it is appropriate in the context of this study.

Strengths and weaknesses of each system

The strengths and weaknesses of each system are summarized in Table 4 and discussed in details below.

Lexical matching constitutes an important step in ontology alignment. Systems such as PRIOR focusing on bag-of-word matching rather than term matching miss many mappings identified by the other two systems on the basis of exact matches of concept names. Examples include the match of *Arm*, the match of *Eyeball*, and the match of *Neck of mandible*.

Compared to AOAS, FALCON uses a relaxed model of lexical similarity, based on edit distance. AOAS missed some mappings due to improper segmentation of the original GALEN strings. For example, the string "SupraHyoidMuscle" was segmented at points where case changes, leading to the term *supra hyoid muscle*. However, the proper spelling for this term is *suprahyoid muscle* and the normalization algorithm used by AOAS could not match the two terms. In contrast, the relaxed approach to string matching employed by FALCON identified the two strings as a match. The analysis of the mappings identified by FALCON and not AOAS revealed about 10 segmentation issues and 15 misspellings in GALEN (e.g., "Mensicus" for "Meniscus").

Conversely, the relaxed model of lexical resemblance can lead to "egregious" mappings and therefore be extremely detrimental to the alignment. For example, FALCON identified a mapping between *Axillary artery* (in the armpit) and *Maxillary artery* (near the mandible).

Both FALCON and PRIOR allow approximate matching to happen, typically resulting in mappings where one term is more specific than the other, because one term contains a modifier while the other does not. These modifiers are often indicative of laterality (left/right) or level (in the vertebrae). For example, FALCON identified a match between *Zygomatic process of maxilla* and *Zygomatic process of left maxilla* and PRIOR a match between *Spinous process of thoracic vertebra* and *Spinous process of tenth thoracic vertebra*. While related, terms from these pairs should not be identified as equivalent. Of note, in many cases of inaccurate mapping, one term is a proper substring of the other (e.g., *Acetabulum* and *Right acetabulum*). Finally, other examples of mismatches involve not a modifier, but the head of the noun phrase or prepositional phrase, as in the mapping between *Posterior tibial nerve* and *Posterior tibial vein* (PRIOR) and between *Posterior cutaneous nerve of arm* and *Posterior cutaneous nerve of forearm* (FALCON).

AOAS is the only system to fully take advantage of synonymy for the alignment. Some synonyms are provided by the FMA, but others come from the UMLS Metathesaurus. In fact, we verified that most of the 856 mappings identified by AOAS are indeed valid and involve such synonyms. This is the case, for example, of the mapping between *Aortic orifice* and *Ostium of aorta*, and between *Shoulder joint* and *Glenohumeral joint.* In some cases, however, reliance on synonyms is an issue when the synonyms fail to be represented in the ontologies or external terminologies. For example, the mapping between *Heel of foot* and *Heel* and between *Cartilage of larynx* and *Set of cartilages of larynx* was missed by AOAS, but identified by PRIOR.

Not relying on lexical similarity, but using an information retrieval paradigm instead makes it possible for PRIOR to identify 56 matches to anonymous concepts in GALEN. Some of them are valid, including the mapping between *Artery which <serves Brain>* and *Set of arteries of brain*, and between *Bone which <IsDivisionOf (Skull <hasTopology actuallyHollowTopology>)>* and *Skull bone*. Others are not, for example, the mapping between *Kidney which <hasLeftRightSelector leftSelection>* (i.e., left kidney) and *Kidney*, or between *Potential Cavity which <locativelyContain Pus>* and *Pus*.

The more conservative and linguistically-motivated approach to lexical similarity adopted by AOAS [9] prevents a large number of false positives. As mentioned earlier, however, it is also more sensitive to misspellings and segmentation issues, as well as missing synonyms. Overall, we believe that the benefit of preventing many false positives largely outweighs the few false negatives.

We understand why generic and domain-independent systems such as FALCON and PRIOR have adopted relaxed lexical models. The resources available for biomedicine (UMLS synonyms, domain-specific model of lexical resemblance) are not available for most domains. However, pairs of long terms encountered in anatomy often differing by one qualifier (e.g., for laterality) have an artificially high similarity value when compared with edit distance or in a vector space model. Calibrating the models for a particular domain is an issue that remains to be addressed. Some mappings with a measure of confidence equal to 1 are less than perfect (e.g., between *Lamina* and *Suprachoroid lamina* in PRIOR), while near perfect matches fail to have perfect scores (e.g., between *Surface Of Calcaneum* and *Surface of calcaneus* in FALCON, with measure=0.962).

Structural validation is specific to AOAS and is designed to operate in combination with a model of lexical resemblance. In fact, structural validation is essentially used to confirm that the terms matching lexically bear some common semantics. Because our model of lexical resemblance is strict, there was no need to calibrate the structural resemblance too strictly. The minimum requirement for positive evidence is that one compatible path to another mapping be shared across ontologies. These requirements are not adapted to the validation of a more relaxed model of lexical similarity. Two terms differing solely by laterality are likely to share paths to many other mappings across systems. For this reason, it would not be sufficient to use our model of structural similarity to validate the mappings identified only by FALCON or PRIOR, which is why we performed a manual review instead.

Consequences for the OAEI Campaign for Anatomy

Evaluating the alignment of large scale, real world ontologies is an interesting, but very challenging endeavor. We showed that the absence of a reference alignment cannot be adequately compensated by the use of cross-validation. A cursory review also leaves many open questions. On the other hand, establishing a gold standard alignment would require the collaboration of domain experts and adequate funding. This study also illustrated that the conversion of the FMA and GALEN into OWL Full and, particularly, different uses of instances, classes and metaclasses by the two models tend to confuse users and impair alignment systems.

Abstract

Guideline-based clinical decision support systems (CDSSs) can be effective in increasing physician compliance with recommendations. However, the ever growing pace at which medical knowledge is produced requires that clinical practice guidelines (CPGs) be updated regularly. It is therefore mandatory that CDSSs be revised accordingly. The French Association for Urology publishes CPGs on bladder cancer management every 2 years. We studied the impact of the 2004 revision of these guidelines, with respect to the 2002 version with a CDSS, UroDoc. We proposed a typology of knowledge base modifications resulting from the update of CPGs making the difference between practice, clinical conditions and recommendations refinement as opposed to new practice and new recommendations. The number of formalized recommendations increased from 577 in 2002 to 1,081 in 2004. We evaluated the two versions of UroDoc on a randomized sample of patient records. A single new practice that modifies a decision taken in 49% of all recorded decisions leads to a fall from 67% to 46% of the compliance rate of decisions.

Keywords:

clinical decision support system, practice guideline modelling, knowledge base revision, bladder cancer

Introduction

Clinical practice guidelines (CPGs) are developed and disseminated to promote interventions of proven benefits. CPGs are produced by health professional societies or national health agencies relying on evidence-based medicine principles. They are made of structured, explicit, motivated, textual statements for managing patients according to the state of the art. However, in the "knowledge crisis" era, the amount of new medical knowledge endlessly increases [1] and the meaning of "state of the art" is a relative and evolving notion. As a consequence, CPGs are involved in a life-cycle and must be regularly updated. This process is handled by CPG providers when new research results modify current best practices. It takes at least one year to publish an updated version of CPGs.

Despite their broad dissemination, there is still considerable variation in the effectiveness of guidelines to change physicians' behavior. Many studies have shown that clinical decision support systems (CDSSs) can be effective in increasing physician compliance with recommendations [2, 3]. Defined as any software in which characteristics of individual patients are matched to a computerized knowledge base (KB) for the purpose of generating patient-specific assessments or recommendations that are presented to clinicians for consideration, CDSSs rely on formalized models of textual guidelines. Hence, as these knowledge sources are revised, it is mandatory that the delivery instrument be revised accordingly in a continuous knowledge management process. However, encoding original guideline texts into a computerized format is still an issue many authors are addressing [4, 5, 6, 7]. The management of multiple, successive, versions of a guideline is a problem CDSS developers are aware of for a long time.

In this paper, we have studied the impact of the publication of a new version of a guideline on a CDSS. We used the bladder cancer guidelines developed by the French Association for Urology ("Association Française d'Urologie" or AFU) in its revisions of years 2002 and 2004. For each textual versions, we built the corresponding KB of a CDSS, named UroDoc, and obtained 2 versions of the system: UroDoc-2002 and UroDoc-2004. After a study of both versions of textual CPGs, we first compared the two corresponding KBs. Then, we assessed how actual practices were impacted by the publication of the 2004 CPGs. We carried out a retrospective study on a randomized sample of medical records from patients hospitalized in 2004 at the Department of Urology of the Bichat-Claude Bernard Hospital, Paris, France.

Selected for best paper award.

Material and method

Textual bladder cancer guidelines

With more than 10,000 cases yearly, bladder cancer is the forth most common cancer among French men and the eighth in women. Bladder cancer represents a range of disease from relatively benign surface tumors to highly malignant life threatening carcinomas which require radical treatment. If approximately 70% of patients with newly diagnosed bladder cancer will present with superficial bladder tumors, most of them will eventually have recurrent cancer, and 10 to 20% will progress to muscle-invasive or metastatic disease. Treatment of superficial tumors is mainly based on transurethral resection (TUR). Adjuvant bladder instillation of mitomycin C (MMC) or BCG may be indicated. A strict and prolonged follow-up is mandatory to detect recurrence or progression. The standard treatment for patients with invasion remains cystectomy. However, surgical cure rates are only in the range of 10 to 30% in locally advanced bladder cancers. At present, standard therapy is still missing for numerous patient clinical profiles, hence making bladder cancer management a very active area of research.

Founded in 1896, the French Association for Urology represents and supports most of the French urologists. An expert group, the AFU Oncology Committee, publishes CPGs updated every two years to disseminate new management standards and improve healthcare quality and survival rates. Bladder cancer CPG revisions have been regularly published in 1998, 2002 and 2004. We studied bladder cancer CPGs evolution between 2002 and 2004.

Documentary-based decision support paradigm

Numerous studies have shown that the sole dissemination of textual CPGs is inefficient to modify physician behavior. On the contrary, computer-based reminders, intervening at decision time, to automatically provide patient-specific recommendations from coded patient data, seem to be the most efficient means to influence healthcare professionals in the adoption of CPGs [2, 3].

However, the success of reminder-based CDSSs is not warranted [3]. Relevance and accuracy of the advices automatically provided are often weak: Judge *et al.* [8] reported that only a little half of alerts were directly relevant to medication order when using a CDSS, Van der Sijs *et al.* [9] explained that this may lead clinicians to override 49 to 96% of the alerts. In addition, the lack of flexibility of automated approaches is often criticized: if reducing the complexity of a given patient to a set of *data* is a necessary step to feed the electronic medical record, the medical reasoning process involved in medical decision making requires a flexible and contextual interpretation of involved medical *notions*.

That is why other approaches, where guideline knowledge is structured in a way a user could retrieve patient-specific recommendations more easily than within texts, have been proposed to provide physicians with guidance [10]. The OncoDoc system, applied to breast cancer therapeutic management, has been developed according to these principles.

We developed a comparable system, UroDoc, to implement the bladder cancer CPGs of year 2002 (UroDoc-2002) and 2004 (UroDoc-2004). In each case, the KB is formally structured as a decision tree. The system need not be automatically executed from an electronic medical record. The physician can browse the KB hence controlling how each patient criterion is instantiated; she has the opportunity to assess the patient clinical states that do not need to be encoded and can be available on different supports. Thus, she identifies the path of the decision tree that corresponds to her patient and obtains in a flexible way the relevant patient-specific recommended therapy.

Modelling textual CPGs into structured decision trees

The two textual CPGs were studied in chronological order. For each CPG, the modeling work has been handled independently, *i.e.* we didn't try to build the version $d + 1$ of the CPG from its differences with version d. Following the approach to guideline implementation proposed by Shiffman *et al* [4], we first proceeded to the atomization step to extract single concepts from the recommendation's natural language text (*microscopic hematuria, grade, intravesical therapy*, etc.). Then, we carried on the deabstraction step to adjust the level of generality at which decision variables or actions were described in the CPGs to permit the operationalization in a clinical setting ("*early recurrence*" has been translated in "*recurrence at the same stage as the initial tumor or at a more advanced stage within 3 months*"). Then the disambiguation step tried to establish a single semantic interpretation for the recommendation statement (how "*biopsies may be performed on suspicious area*" should be interpreted?). The most important step was the verification of completeness to assure that both implicit decision criteria and implicit modalities of identified criteria have been explicited as decision variables and actions, and that there was a treatment (either a recommendation or a professional agreement depending on the availability of evidence) proposed for all logically possible combinations of condition states meaning that the whole set of clinical situations described by the complete expansion of the decision tree is addressed. Two different decision trees have thus been built from the two CPGs.

Comparison of the two versions of CPGs

Theoretical study

We first compared the original two textual documents from a macroscopic point of view, in terms of title, authors, general outlook, logical structure, length of comparable sections. Then we compared the two KBs built from the texts. To evaluate the evolution of CPGs between 2002 and 2004, we proposed a typology of the changes that may be found between consecutive versions of documents. CPGs can be considered as a set of recommendations $\{R_i\}_i$. Each recommendation R_i is characterized by a pair (S_i, T_i) with $S_i \rightarrow T_i$, denoting that a treatment plan T_i is recommended in the clinical situation S_i. As usual, a clinical situation is defined by a set of instantiated decision variables, $S_i =$

$\{c_{i,j}\}_j$, and a treatment plan is defined by an ordered sequence of therapeutic actions, $T_i = \{t_{i,j}\}_j$.

The set of recommendations has to be dated, thus we have to compare recommendations $\{R^d_i\}_i$ in their *d*-version to their *d+1*-version $\{R^{d+1}{}_i\}_i$. For simplicity reasons, we have dropped indices in the rest of the section. We consider that two clinical situations S^d and S^{d+1} are comparable, noted $S^d \cong S^{d+1}$, when both situations correspond to the same clinical profile in terms of therapeutic history, staging and grading of the tumor. We consider that two treatment plans T^d and T^{d+1} are comparable, noted $T^d \cong T^{d+1}$, when both treatment plans correspond to the same sequence of care in terms of therapeutic modalities (surgery, immunotherapy, chemotherapy, radiation therapy) and, in case of a surgery, when it applies to the same anatomical part. The set of all possible modifications that can occur in the update of a given CPG is illustrated by figure 1.

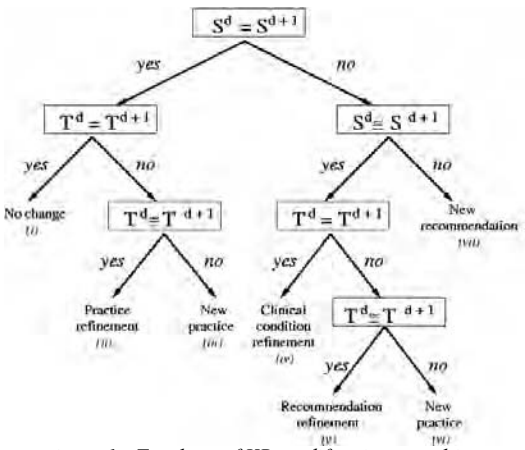

Figure 1 - Typology of KB modifications resulting from CPGs updating

Four main situations can be observed in the update process:

1. No change: an identical clinical situation lead to an identical treatment plan *(i)*.
2. Refinement of an existing recommendation. The new recommendation shares some common parts with the former one. Refinement may concern: the description of the treatment plan but not the situation *(ii)*, only the description of the clinical situation *(iv)*, or both descriptions *(v)*.
3. New practice. A totally new therapy (non comparable) appeared in an already identified clinical situation *(iii)*, or in its corresponding refined expression *(vi)*,
4. New recommendation: extending the CPG coverage, a new clinical situation is identified with its corresponding therapy leading to a new recommendation *(vii)*.

When comparing the two KBs, decision variables, single therapeutic actions, and treatment plans were analyzed literally to determine those which were common, *i.e.,* used in both KBs, those which were 2002-specific, *i.e.,* obsolete in 2004, and those which were 2004-specific, *i.e.,* new in 2004. In this first step, we used the identity relationship between objects (=). The same process was applied at a more abstract level where decision variables and single therapeutic actions were substituted by their upper concept in a kind of ontological reasoning. The relationship used for comparison was the comparability (≅). For instance, "chemo-III" and "chemo-IV" correspond to two therapeutic actions, both abstracted as "adjuvant-chemotherapy", and therefore considered comparable.

Practical analysis

We studied the impact of the publication of the new version of the bladder cancer management guideline in June 2004 upon the clinical practice of the Department of Urology of the Bichat-Claude Bernard hospital in Paris, France. We collected a random sample of patients diagnosed with bladder cancer during the year 2004. For each therapeutic decision following the diagnostic of bladder cancer, we used both systems UroDoc-2002 and UroDoc-2004 to get the recommendations of 2002-guidelines and of 2004-guideline. These two therapeutic recommendations have been compared to the treatment stored in the medical record and actually received by the patient.

Results

Comparison of textual CPGs

Both 2002 and 2004 CPGs have the same title anc coverage. They have the same number of authors (15), 80% of them participated to both CPG developments. Both guidelines are published as textual double-column documents. 2002 CPGs are shorter (13 pages) than 2004 CPGs (40 pages). General outlook is comparable (Table 1), starting with a description of the staging system (tumor, node, metastasis, TNM), followed by 3 sections describing diagnostic indications, therapeutic guidelines and follow-up protocols. However, some sections especially those describing the management of patients with positive nodes and metastatic disease are more elaborated in the 2004 version. Besides, a new sub-section specifying pathologic staging modalities has been added in the 2004 version.

Table 1 - CPG structure and volume in columns (half-pages)

	Structure	*Number of columns*	
		2002	*2004*
0.	**Introduction**	**1**	**1**
I.	**TNM staging system**	**1**	**1**
II.	**Diagnostic indications**	**1.5**	**5**
1.	*Clinical presentation*	*0.5*	*1*
2.	*Imaging tests*	*0.5*	*1.5*
3.	*Urine cytology*	*0.25*	*0.5*
4.	*Cystoscopy*	*0.25*	*1*
5.	*Pathologic staging*	*n/a*	*1*
III.	**Therapeutic guidelines**	**8**	**21.5**
1.	*Therapies*	*5*	*6*
2.	*Management principles*	*3*	*15.5*
2.1.	*Superficial tumors*	*1.5*	*2.5*
2.2.	*Invasive tumors (N0M0)*	*1*	*5*
2.3.	*Positive nodes (N+M0)*	*0.25*	*6*
2.4.	*Metastatic disease (M+)*	*0.25*	*2*

Comparison of structured KBs

Table 2 reports the formal comparison of the two KBs. It should be noticed that at the literal level, the 2004 version, although sharing common elements with the 2002 version, introduced many new ones and left apart some. Although reducing the importance of the effect, the abstraction step confirms the trend. When considering decision trees, the 2002 version identifies 366 different clinical situations whereas the 2004 version identifies 584 clinical situations. The average path length is 10 in 2002 but 11 in 2004. There are 577 recommendations in 2002 and 1,081 in 2004.

Table 2 - Comparisons of decision variables (DVs), therapeutic actions (TAs), recommendations (Recos), and of their abstracted correspondents in 2002 and 2004 KBs

	2002 specific	*Common*	*2004 specific*
DVs	8	32	23
Abstracted DVs	6	28	13
TAs	9	27	22
Abstracted TAs	4	17	5
Recos	530	47	1,034
Abstracted Recos	339	238/358	723

When comparing the two sets of recommendations, $\{R^{2002}{}_i\}_i$ and $\{R^{2004}{}_i\}_i$, we adopted two different points of view. From the 2002 point of view, each recommendation has been tested against the 2004-recommendation set to automatically determine its status: whether it remained unchanged, it was refined, it has evolved towards new practices, or it became obsolete (*i.e.,* it has no more equivalent in 2004). The same algorithm was applied for each 2004 recommendations as compared to 2002 recommendations. Table 3 reports these results and figures 2 and 3 illustrate the percentages of the different subsets.

Table 3 - Distribution of recommendation evolution status between 2002 and 2004 versions of the KB

	2002 KB	*2004 KB*
Obsolete recommendations	339	—
No change	47	47
Refinement	74	91
New practices	117	220
New recommendations	—	723
Total	577	1,081

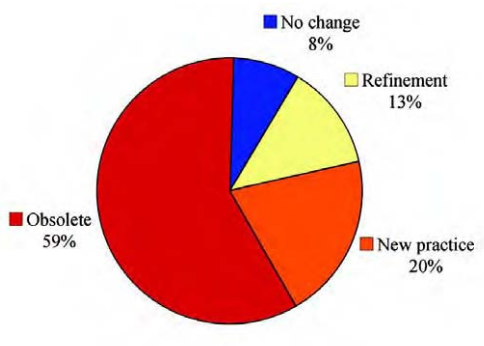

Figure 2 - Status of 2002 recommendations (n=577)

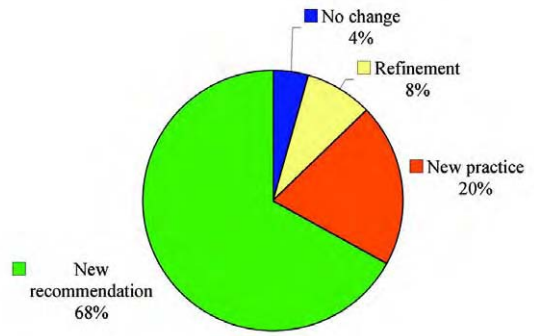

Figure 3 - Status of 2004 recommendations (n=1,081)

The overlapping of the 2004 KB on the 2002 KB is quite limited. The overlapped part (i.e., no change, refinement, new practice) is made of 238 recommendations (41%) in 2002 which projection is made of 358 recommendations (33%) in 2004. From this analysis, 339 recommendations of 2002 (59%) became obsolete in 2004 and 723 recommendations of 2004 (68%) may be considered as new.

Impact of CPG update on clinical practices

We analyzed medical records of a randomized sample of 45 patients leading to a total of 106 therapeutic decisions. Only 97 decisions, corresponding to 38 patients, were retained for the survey: 9 decisions were ruled out either because the patients were long lost (6), or decisions also involved the management of prostate cancer (3). Each therapeutic decision has been retrospectively matched to the 2002 CPGs by using UroDoc-2002 and to the 2004 CPGs by using UroDoc-2004. With respect to the 2002 CPGs, we found that 65 decisions, *i.e.,* 67% of the cases, were compliant with the CPGs. When the same therapeutic decisions were evaluated using UroDoc-2004, we found that 45 decisions, *i.e.,* 46% of the cases, complied with the 2004 CPGs. Among the non-compliant decisions, only a few cases (5 as compared to 2002 CPGs and 4 as compared to 2004 CPGs) can be explained by specific patient conditions (age) or "acceptable" physician personal choice. Table 4 synthesizes the results of the analysis.

Table 4 - Practical compliance with 2002 and 2004 CPGs

(n=97)	*# non compliant*	*# explainable*	*Compliance*
2002	32	5	67%
2004	52	4	46%

Discussion and conclusion

The 2004 evolution of bladder cancer CPGs essentially concerned the extension of CPGs coverage and thus increased the number of clinical situations for which recommendations are provided. This is particularly true for the management of patients with positive nodes and metastatic disease. This is also the case for the control of BCG side-effects which is not mentioned in 2002 while very much detailed in 2004. A particular new practice has to be

noticed: TUR which was recommended as such in 2002 has to be followed by an early post surgical endovesical instillation (EPSEI) of MMC in 2004. When analyzing the compliance of therapeutic decisions with respect to Uro-Doc-2002 and UroDoc-2004, we got the results summarized in table 5.

Table 5 - Evolution of decision compliance with 2002 and 2004 CPGs

	2002 compl.	*2002 non compl.*	*Total*
2004 compl.	41	4	45
2004 non compl.	24	28	52
Total	65	32	97

The 24 decisions that are 2002-compliant, but not 2004-compliant, are made of 21 TUR with no EPSEI, 1 decision of bladder instillation of BCG with no endoscopic evaluation, and 2 incomplete surgeries as compared to 2004 recommendations. When studying the clinical practices of the Department of Urology of the Bichat-Claude Bernard hospital, it appears that 49% of the therapeutic decisions for bladder cancer correspond to TUR decisions (figure 5). Since 2004 recommendations modified the TUR decision, this illustrates the fact that, although they were published, new 2004 CPGs were not applied in routine care. The side-effect of this delay in CPG implementation is a fall from 67 to 46% of the compliance rate with CPGs.

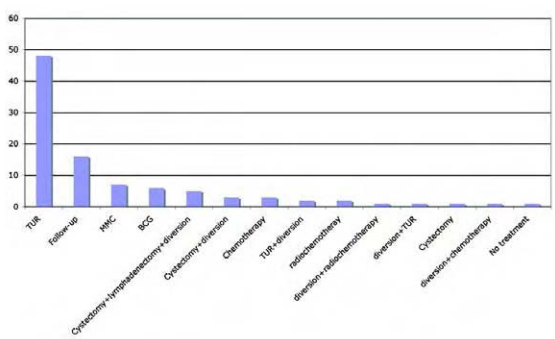

Figure 5 - Distribution of actual therapeutic decisions (n=97)

Besides, the formal comparison of KBs showed that the number of recommendations increased by a factor of 2. It is remarkable that more than half of the 2002 recommendations (339/577) have no formal equivalent in the 2004 KB since this is not consistent with CPG content. The 2004 version is supposed to cover every aspects of the 2002 version and the 339 "unmatched" recommendations should have their equivalents at the semantic level in the 723 "identified as new" 2004 recommendations. The reason is that every 2002 recommendation which contains at least one of the 8 2002-specific variables never matches any 2004 recommendation. This emphasizes the fact that in 2002 and 2004, some similar notions expressed differently have been modeled differently. As a conclusion, KB revisions following CPG updating could be improved if the new CPG version respects the terminology and point of view used in the former version. This could be achieved by explicitly using, when possible, standard terminologies to describe guideline-covered specific clinical situations in CPGs.

Abstract

This work describes the results of the implementation of a workflow management system integrated into the electronic clinical chart of a Stroke Unit. The workflow logic is based on the rules provided by the SPREAD guidelines for stroke management. In this way, the already existing clinical chart has been transformed into an evidence-based, real-time decision support system, meanwhile maintaining the same look the users were familiar with. Since the final aim of the work was to improve evidence-based behavior and detect possible organizational bottlenecks, non-compliance to the clinical practice guidelines, before and after the system introduction, have been analyzed, as well as the accuracy of the clinical chart compilation, some care process variables, and system usability. Results show that the system enhances the clinical practice without boring users. Moreover, non-compliance analysis gives rise to ideas for further improvement.

Keywords:

decision support systems, practice guideline, information systems, workflow management, stroke

Introduction

Insufficient or erroneous information at point-of-care, both for diagnosis and treatment, is a frequent and significant cause of medical error, as well as communication problems among healthcare operators and the different healthcare organizations, where patients' data are spread. Prevention of possible errors during a patient's management is a critical issue. Recent studies have highlighted the dramatic dimension of the problem, from the well-known report of the US Institute of Medicine [1], assessing between 44,000 and 98,000 deaths per year as due to medical errors in American hospitals, to an increasing number of country-based studies reporting similar figures.

Evidence-based clinical practice guidelines (GLs) have been widely promoted as a way of improving health outcomes. In the stroke management area, in particular, the study described in [2] demonstrates an association between stroke outcome and compliance with GLs. In current healthcare systems, however, scientific knowledge about best care is not applied systematically or expeditiously to clinical practice. GLs usually capture both literature-based and practice-based evidence into a textual format, which can be easily diffused but uneasily used in daily work. Thus there is a great effort to disseminate them in computer-interpretable representations, more suitable for individual clinical decision support [3]. Contemporary, there is increasing need of smooth integration of GLs into the existing hospital information systems.

The current workflow technology [4] seems to offer a convenient solution to build a cooperative system in which the activities of a care providers' team can be coordinated within a process properly designed on the basis of available best medical knowledge. This paper presents an approach to the design, implementation and evaluation of an evidence-based workflow management system (WfMS), from here on called Careflow management system (CfMS). On the basis of a general methodology, we describe a CfMS implementation in the area of Stroke management, particularly focusing on user interaction, presentation of GL suggestions and management of non-compliance to GL. We show how this technology, especially in fields where acute patients treatment is critical, helps in timely collecting the correct and most useful data and avoiding errors. The test-bed for the proposed methodological and technological solutions is the Stroke Unit (SU) in Pavia, where we implemented the system based on the SPREAD guidelines (Stroke Prevention and Educational Awareness Diffusion) [5].

The evaluation methodology

Outcomes of the CfMS have been tested following the steps below, described in detail in the subsequent sections:

1. analysis and update of the Computerized Clinical Chart (CCC) that physicians were using since many years in the SU, with the aim of ensuring that all the necessary data for testing the care process could be stored;

2. utilization of the updated CCC, without any decision support utility: during this phase, compliance to GLs was exclusively based on physicians' personal knowledge and on hospital organization;
3. development of the decision support tool, i.e. the CfMS, and its integration with the CCC;
4. utilization of the integrated system for 8 months (from its installation until November 2006). During this phase, compliance could have been affected by system reminders; and
5. analysis of collected data.

Updating the stroke unit data model

The Stroke Unit was already equipped with a CCC implemented some years ago, with the commercial tool Wincare® (by TSD-Projects). System-user interaction is based on so-called *Events*: an event is a single data entry form of the clinical chart, and it may be activated by users with competent role (controlled access). Before starting the project we analyzed all the events and their associated graphical user interface, with the aim of checking the presence of the data required for both properly executing the decision support system and evaluating GL compliance. As a result, the data model has been updated both by increasing the number of data input fields and by changing the nature of some existing data, mainly shifting from free text to encoded data. In fact, data-entry was mainly limited to free-text forms, because the initial purpose of the CCC was only to limit paper-based communication and to improve patients' data retrieval. The advantage was that information was ready to be printed *as-it-was* for summaries, discharge letters, etc.. Moreover, such CCC gave users the flexibility to represent patient's condition in the desired order and granularity. On the other hand, integration with a decision support system was not possible because of almost complete lack of structured data. In other words, free-text information stored in the CCC didn't allow a proper interpretation of the rules embedded in the GL: natural language processing is a hot research field, but results are not mature enough to guarantee full recognition of crucial data in critical patients' management [6].

Eventually, a deep examination of SPREAD GLs allowed determining the minimum data set required for implementing all the recommendations. These data have been encoded and, when possible, standard terminologies such as ICD9-CM for diseases, have been used. To maintain flexibility, in addition to encoded items, the interface still allows entering free text notes, useful to input additional details but not essential to decision support purposes.

Careflow implementation and integration

After the analysis and the consequent update of the data model, we implemented the CfMS, based on all the GL recommendations from SPREAD chapters 9 and 10, related to diagnosis and treatment of the stroke acute phase, with some site-specifications decided by the neurologists involved. Technology used to implement the whole system and to integrate it with Wincare® is based on DBMS Oracle™, Oracle Workflow™, Pl/SQL and Visual Basics (see [7] for details). Briefly, the CfMS manages the execution of the care process for a particular patient, reading his/her clinical data, verifying the GL rules and creating specific recommendations. These latter, translated in to-do lists, messages and alerts, are communicated to the right professional role via the end-user application.

Since the users were satisfied with their CCC, our choice was not to create an additional and specific interface, but to integrate all the needed functionalities within the existing CCC, making it more "dynamic" and "smart" thanks to the CfMS execution. Our philosophy was that users must perceive the new system just as an update, with some new functionalities. To obtain this goal, a middleware layer for the data sharing has been developed in order to keep the two systems (Wincare® and CfMS) independent, while granting communication. In particular, whenever there is a new data entry, the CCC transfers these data into a buffer database, usable by the decision support system and designed on the basis of the minimum data set required by the GL. Similarly, when the CfMS generates a suggestion, or a new to-do list, they are put into special tables of the same database, and Wincare® can read and show them through its interface.

Relevant functionality

A picture of the updated system interface is shown in Figure 1.

Facilitating data input

First of all, data relevant for GL rules interpretation appear as yellow input fields, in order to encourage a complete editing of the essential fields of the CCC.

Smart graphical user interface

With respect to the former system, the list of the CCC events has been transformed into a "to-do" list, i.e. events are now listed in a patient-specific, dynamic way, taking into account the patient medical condition and the time spent since his/ her admission. Different icons and colors are used to mean that an event is completed (icon with a green happy smiley), it is currently being done (orange thoughtful smiley), it has not been executed due to an exception (red sad smiley), it has been filled on the user initiative (Wincare® icon), or it still has to be done (no icon). Degree of the scientific evidence of recommendation is shown, as in the SPREAD book, by letters A-D. According to the physician needs, special attention has been put in avoiding over-information: particularly in acute situations, only events necessary to face the urgency are listed. For example, if a patient is potentially eligible for r-tPA treatment (a thrombolitic drug very effective but that requires a very careful administration), the list of events only refers to actions to be done in order to detect possible contraindications. Again, if CT scan shows an intracranial hemorrhages, that is one of the contraindications, "r-tPA Treatment" is switched off (from yellow to red) and less urgent events appear in the to-do list (see difference between lists (a) and (b) of Figure 1).

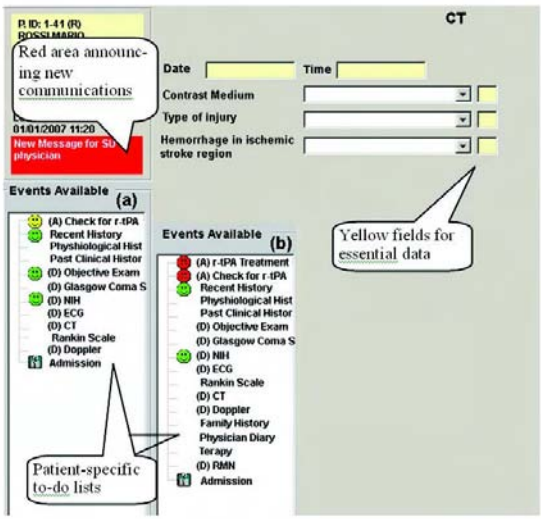

Figure 1 - A smart form of the Clinical Chart integrated with the CfMS. (a) and (b) are two different to-do lists for the same patient shown in two different points in time

Showing CfMS reminders

How to show GL reminders is a big issue in the implementation of a decision support system into a real healthcare setting. In general, pop-up windows are not well-accepted by physicians, because they are considered too intrusive. Thus, we preferred to rely upon the above described colored visualization of the to-do list: clicking the task icon, the data input form immediately appears. Moreover, a red area informs the users about new communications (red rectangle in Figure 1). This modality is minimally intrusive because users may open the communication box asynchronously, on their own will. The communication list, in chronological order, shows the priority level of each recommendation, its type (whether it is a diagnostic process, a treatment, a variable monitoring, or a message) and its positive or negative sign (if it is something to do or to rule out). Different users receive different communications according to their role (physician, nurse, physiotherapist, etc). Users may read communications for a specific patient or for all the patients currently admitted in the SU. If an answer is required, a checkbox appears near the text, allowing the receiver to say whether he/she agrees or not with the SPREAD recommendation. If a physician accepts a suggestion about a drug prescription, a record with the drug name, dosage and timing is stored and at the same time the CfMS takes care to inform the role "nurse", responsible for drug administration, sending a message with the useful details. Thus CfMS is also able to manage automatically a large amount of communication acts among personnel involved in patient care, making between-users interoperability more efficient by supporting medical and organizational knowledge sharing.

Ancillary tools

Natural language reporting

With the new system release, interpretation of GL rules is easier and safer but information is no more immediately available for nice printed free-text reports. To meet this physicians' need we developed a tool for the generation of such reports. Briefly, code descriptions are combined with associated notes (if any), according to grammatical rules, to generate the correct words and suitable introduction and conjunction sentences. The resulting reports are structured in distinct paragraphs for physiological history, recent and past clinical history, family-related history; information about past history is grouped by year and ranked in chronological order; once generated, the report may be edited by physicians before storing or printing.

Detecting and showing non-compliance

In a real-world setting, it is extremely difficult to detect non-compliance in real time. There are too many variables that could affect timely data storing and, consequently, timely automatic detection of non-compliance. This is particularly true in acute units. So, demanding that physicians justify their non-compliance has some drawbacks: first, detected non-compliance could be not real, i.e. an action has been performed but related data have not been entered in the system yet; second, users perceive the system not only a gentle reminder, but as a controller; eventually, if he's in a hurry, physician may have no time to write down justification. As a consequence, provided justification may be not reliable. For these reasons, in agreement with our clinical partners, we decided to manage non-compliance in a less invasive way. The point in time where we decided to accomplish this task is the patient discharge. This choice is based on the consideration that when physicians prepare patient's discharge, they are in team and they are not in a hurry. In addition, compiling the discharge letter requires summarizing the patient care process, and reasoning about it. Thus, presenting the non-compliance list at that moment has two advantages: overcoming the previous issues and facilitating bethinking about the case. In practice, at the patient discharge, a set of queries is activated on the patient record, and a report is produced. It shows the non-compliance list detected automatically, starting from the CCC, and gives the physicians the possibility to provide motivations that can be useful for further revision of the SPREAD GL (that is regularly updated every 2 years).

Results

The CfMS, after an intensive testing in our university laboratory, has been implemented in the SU (semi-intensive six beds unit) on April 2006. Three physician's and two nurse's workstations have been installed. Since the CfMS did not introduce dramatic changes in the end-user application, it has been accepted by healthcare personnel and entered the daily medical routine. We administered the Likert Scale SUS (Software Usability Scale [8]) to the five users of the Stroke Unit, obtaining an average value of 82.5/100, ranging from 80 to 85.

In order to evaluate the impact of the system in the daily activity, a set of queries has been developed on CfMS data, for checking both data completeness and GL compliance. Reports are produced by analyzing all medical data available for ischemic stroke patients admitted within a user-defined period. Reports contain statistics about:
