MEDINFO 2007

Studies in Health Technology and Informatics

This book series was started in 1990 to promote research conducted under the auspices of the EC programmes' Advanced Informatics in Medicine (AIM) and Biomedical and Health Research (BHR) bioengineering branch. A driving aspect of international health informatics is that telecommunication technology, rehabilitative technology, intelligent home technology and many other components are moving together and form one integrated world of information and communication media. The complete series has been accepted in Medline. Volumes from 2005 onwards are available online.

EDITORIAL

Playing an active role in the 12th World Congress on Medical Informatics has been an honour and a privilege for the Editorial Committee. We closely cooperated with our colleagues and friends of the Scientific Program Committee (SPC) and the Organizing Committee (OC).

Out of 638 submissions, 292 high quality papers were selected for publication in these proceedings by the SPC. Out of 218 poster submissions, 21 posters were nominated for a best poster award; they are included as 1 page contributions in these proceedings. While high quality contributions have been selected by the SPC, the Editorial Committee has focussed on providing proceedings with a high quality of format and presentation which made additional editing necessary. The proceedings are also appearing on CD-ROM. All accepted poster contributions are published on an additional CD-ROM.

The MEDINFO 2007 Proceedings present an excellent overview of a dynamic and quickly growing field, demonstrating methodical and practical progress from around the world. Information science and, specifically, (Bio-) Medical Informatics have become core pillars of foundational and clinical research, of medical care, and of prevention. MEDINFO 2007 in Brisbane will be the leading conference of the year, bringing a worldwide community together.

We have organized the proceedings into twelve chapters, covering topics such as eHealth, Decision Support, Improving Quality, Usability, Sustainability, Genomics, Biomedical Image and Signal Processing, and Education and Training. Within each chapter, the articles are organized according to the conference sessions; the session titles are shown in the table of contents.

The assistance of HISA has been invaluable in all editorial steps, including communication with authors, language editing, and formatting of manuscripts. We owe specific thanks to Joan Edgecumbe, Dale Proposch and Tom Morgan.

Disclaimer

While the Medinfo 2007 Editorial Committee has made every effort to ensure that all accepted contributions are published in these two volumes of the MEDINFO 2007 Proceedings, it reserves the right to:

- Edit/alter one or more parts of an original contribution, including its title, author and affiliation listings, as it sees fit in order to comply with publications requirements.

- Withhold the publication of a contribution due to one or more of the following circumstances:
  - failure to meet the final deadline for submission of all original/revised contributions;
  - failure to revise the original contribution in accordance with the instructions of the Scientific Programme Committee, including the advice of the Editorial Committee.

The Editorial Committee is not responsible for the alteration and/or omission of part or parts of an original contribution in cases where a contribution has not fully complied with the submission guidelines and has to be partially or fully re-written and/or reformatted for the final publication.

Preface from the Scientific Program Co-Chairs

The theme of Medinfo2007 is "Building Sustainable Health Systems". Particular foci are health challenges for the developing and developed world, the social and political context of health care, the knowledge that is needed for safe and effective health care, and the difficult task of building and maintaining complex health information systems. Sustainable health information systems are those that can meet today's needs without compromising the needs of future generations. It is a challenge and an opportunity to develop and implement systems that can be improved – not replaced. To achieve this and to build a global knowledge society, we need to seek increased scientific and technological co-operation, and we need to facilitate access to and use of high-quality knowledge and information.

We are pleased to report that more than 900 submissions were made to Medinfo2007. This includes full papers, panels, posters, and workshops. Submissions were made from every region of the world and from many countries, including, among others, Argentina, Australia, Belgium, Brazil, Canada, China, Finland, France, Germany, Great Britain, India, Israel, Italy, Japan, New Zealand, Portugal, Russia, Singapore, Switzerland, and the United States, making this a truly international conference.

The majority of submissions (638) were made in the full paper category. Papers were refereed by members of the biomedical informatics community and final decisions were made by the SPC members at a three day meeting in Chamonix, France in late January 2007. Of the 638 papers submitted, 292 were accepted for presentation and publication (a 46% acceptance rate). 260 were not accepted for publication, but their authors were offered the possibility of presenting their work in the Medinfo2007 poster session, and they were also given the opportunity to create a set of slides that is planned to be part of a continuous slide show throughout the meeting. 86 paper submissions were rejected (13%).

The contributions to Medinfo2007 reflect the breadth and depth of the field of biomedical and health informatics. Papers cover topics in health information systems, knowledge and data management, education, standards, consumer health and human factors, emerging technologies, sustainability, organizational and economic issues, genomics, and image and signal processing.

To recognize the truly outstanding contributions to the conference, there will be "Best Paper" and "Best Poster" awards at the meeting. A student paper competition will also be held. All decisions will be made by an international jury at the meeting itself, and the winners will be announced during the closing session of the Congress.

On behalf of the members of the Medinfo2007 program committee (listed below), we wish to thank all those who contributed to Medinfo2007 by sending in their paper, poster, panel, and workshop contributions. We give special thanks to all those who carefully reviewed the many excellent submissions. We expect that the papers included in this volume will be of great interest to anyone engaged in biomedical and health informatics research and application.

In memory of

Dr Branko Cesnik

Australia

It is with sadness that as we complete this foreword we acknowledge the passing of Branko Cesnik Melbourne on Sunday, 10, June, 2007 after a courageous battle with cancer.

Branko was one of the founders of the Health Informatics Society of Australia, the Asia Pacific Association of Medical Informatics and the Australian College of Health Informatics.

Branko was also a member of the Board of the International Medical Informatics Association (IMIA) as the Vice-President of Membership from 1999 to 2003. He was the lead editor of the Medinfo '98: 9th World Congress Medical Informatics Proceedings (Korea). In addition he served IMIA through a variety of other responsibilities, such as being a member of a Medinfo Scientific Program Committee.

Those who knew him as a colleague will remember his knowledge, level-headedness, spirit of cooperation and sharing, and above all getting things done—no matter what was required or the amount of time required. Those who knew him as a friend will remember his panache, his spirit and his zest for living life on the edge and to the fullest. That zest and spirit accompanied him throughout all of the latter days of his struggle.

His great leadership and vision were instrumental in laying the foundation for health informatics developments “Down Under” that has this year occasioned MEDINFO 2007 to come to Australia.

Linkcare – Enabling Continuity of Care for the Chronically Ill across Levels and Profession

Marius Mikalsen[a], Ståle Walderhaug[a+b], Per Håkon Meland[a], Ole Martin Winnem[a]

[a] *SINTEF ICT, Norway*
[b] *Medical Informatics and Telemedicine group, Dept for Computer Science, University of Tromsø, Tromsø, Norway*

Abstract

Chronic diseases are increasing rapidly and this phenomenon is becoming a major burden to the health delivery system around the world. A new health care paradigm with focus on chronic treatment and care will actualize the need for interoperable standards based services due to the complexity of care where different health levels and professions are involved. Given the complexity of the domain, we argue the need for a systematic and formal approach to the development of interoperable information systems if there shall be any real support of the cooperating actors. We describe our work on technical interoperability done in the Linkcare project addressing new models of care and technology to support them in the domain of the chronically ill using concrete results from an architecture built using the MAFIIA architecture framework and the UML 2.0 profile for software services, and argue that building formal architectural descriptions on the basis of shared interface descriptions and profiles are an important part of achieving continuity of care based on sustainable health systems.

Keywords:

medical informatics, information systems, systems integration, continuity of patient care

Introduction

The number of patients suffering from chronic diseases has increased rapidly over the recent decades. The disease burden is changing from acute to chronic care, 35.000.000 people died from chronic diseases in 2005, and 60% of all deaths are due to chronic diseases [1].

The new conditions require that we rethink traditional models of care. One prominent aspect of new care models used for chronic conditions is the cooperation of several different stakeholders in the care process [2]. Stakeholders include the patient himself, his relatives, and caregivers.

Additionally, patients are no longer passive consumers of health services, but are instead demanding more control over their own treatment, together with increased responsiveness and improved quality of care services provided by the involved healthcare institutions. Today, healthcare systems are expected to maintain the continuity of care, shared care, and the empowerment of patients in the management process [3].

The new models of care, including increasingly cooperating stakeholders and empowered users, would benefit from interoperable technology to support continuity of care, e.g., shared access to electronic patient records (EPRs). The situation today is that most stakeholders in the care model have their own proprietary systems, with no or limited possibilities for exchanging information with the outside world in a standardized fashion. Development of interoperable healthcare services would make for more efficient work processes and constitute considerable savings. Walker et.al. [4] argue that the value of health care information exchange and interoperability (HIEI) in the United States alone can yield a net value of $77.8 billion per year once fully implemented.

There are obstacles to interoperability though. Iakovidis lists reasons such as organizational and cultural matters, technological gap between healthcare professionals and information science experts, and legal requirements as to why integrating services in healthcare is a challenge [5].

This article presents Linkcare[1], a European Union project, addressing new models of care for the chronically ill and the technology to support them. Three standalone systems in three different countries (Norway, Cyprus and Spain) supporting different aspects of care of the chronically ill provided the outset for the Linkcare project. This is a relevant scenario as cooperation between different stakeholders using different systems is what characterizes care for the chronically ill.

There is a need for a new way of designing information services in healthcare to ensure an interoperability level that supports coordinated management of care.

In this paper we describe our approach to achieve interoperability between the above mentioned systems. We define interoperability as [9]: *"A system's ability to exchange information with other systems and to mutually use the exchanged information".* This ability is fundamental in order to allow stakeholders in the continuity of care process to provide high quality care to the chronically ill. We

1 Linkcare project (eTen, Grant Agreement Number C517435)

will show how we applied the MAFIIA architecture framework [9] together with the UML 2.0 profile for software services [13] to build an architecture enabling sustainable interoperability between systems in this domain.

This article is organized as follows. First, in the Methods section, we describe the methods used to build the architecture, namely the MAFIIA architecture framework, the UML 2.0 profile for software services and the Linkcare process. Second, the Results section presents the results from applying the methodology as a set of MAFIIA viewpoints. In the Discussion section we present the experiences gathered in our work, before making our concluding remarks.

Methods

This section details the background information relevant to the research presented in this paper. We cover the MAFIIA architecture framework, and the IBM UML 2.0 Profile for Software Services, and explain how these were applied by describing the Linkcare process.

MAFIIA

The service architecture that is presented in this document is created using MAFIIA/H (Modelbased Architecture description Framework for Information Integration Abstraction/Healthcare) [9]. MAFIIA is an architectural description framework for software intensive systems with special a focus on Information Integration Systems (IIS).

An architectural description created using MAFIIA consists of a set of views. Viewpoints are used to create a view. The view consists of one or more models that describe and present different aspects related to structure and behaviour for a target system. Five different viewpoints are defined in MAFIIA. They are; *i*) The Context Viewpoint which describes all aspects of the Target System's environment, which is of importance to be able to document all the interfaces between the Target System and its environment, and what the Target System is intended to do in its environment. *ii*) The Requirements Viewpoint, which document all specific requirements related to the Target System. *iii*) The Component Viewpoint which identifies and documents specific physical or logical components. *iv*) The Distribution Viewpoint which describe the logical distribution of software and hardware components. The distribution view shows if some components cannot be separated and if any must be separated. *v*) The Realisation Viewpoint which describes any constraints on how the target system's components should be implemented and deployed into its environment.

In addition to the viewpoints, a MAFIIA description includes description of concerns, system assets and reference architectures. Concerns are related to the documentation of the functional aspects of the target system and its environment. A concern is visible and treated in relation to any view. Concerns are related to functionality. System assets are sources of information that can be used when developing the architecture descriptions. The reference architecture is a high-level, generic architecture which is used as the basis for development of concrete system architectures, and to compare architectures of existing systems to each other.

UML 2.0 Profile for software services

The UML2.0 Profile for Software services is a profile for UML 2.0 which allows for the modeling of services and service oriented architecture solutions. A UML profile extends the expressiveness of UML with domain specific knowledge, in this case software service specification. The use of a service oriented architecture approach in Linkcare followed from the fact that the original system platforms already were build for the web and web services.

We present a subset of the profile, intended to explain the results and discussion sections. The complete profile is explained by Johnston [13], and the following are relevant excerpts. A **Service Partition** represents some logical or physical boundary of the system. Service partitions are used to represent the web, business, and date tiers of a traditional n-tier application. Any owned parts of a partition shall be a **Service Provider.** A Service Provider is a software element that provides one or more services. A service provider has a property that captures information about its location, but the meaning of this is implementation independent. A **Service Gateway** is only available for use on partitions and not directly on service providers. Gateways are used on partitions to expose services. A **Service** is the model element that provides the end-point for service interaction (in web-service terminology). A **Service Consumer** is any component (includes services) that consumes services. A **Service Channel** represents the communication path between two services. Interaction may occur over a channel, but the channel does not represent any particular interaction. In web services, each service denotes the bindings associated with it, and in the modeling profile, you denote binding either on the communication between services or between a service and a consumer.

The Linkcare process

The guiding principles of the Linkcare architectural process was the following. First, it was essential to preserve the heritage application, that is the original systems that the Linkcare services were built on, and minimal change should be introduced upon these systems. Second, based on a market survey performed in the project, the services created should meet concrete needs in the market. Third, it should be easy to compose new services compliant to the architecture.

We applied the MAFIIA workflow, starting with definition of system concerns and assets, before specifying the five architectural views. First, we used the Linkcare heritage systems as the foundation for capturing the core business processes (functionality) that must be described in the architecture and identified all relevant stakeholders in relation to the Linkcare services (described in the context viewpoint). Second, from the use cases, architectural requirements were defined (requirements model). Third, in the component viewpoint, the resulting system informa-

tion model was described, together with models that show how the Linkcare services are composed, the collaboration of services, and the interfaces of the services. Fourth, in the distribution viewpoint the logical distribution of Linkcare components were modelled, and in the realisation viewpoint we investigated the platforms on which the Linkcare systems were running to identity constraints influencing the realisation of the architecture (such as technical platforms and development processes).

To enable information sharing and version management in the process a CSCW tool named eRoom was used. The modelling was done using Rational Software Architect, and the complete architecture was written in Microsoft Word. Three project meetings, and one two day workshop were used to cooperate and decide on the architecture.

Results – viewpoints of the architecture

In the following we introduce core results from the MAFIIA viewpoints modeled using the UML 2.0 profile for software services.

Concerns

One of the main concerns was identified to be interoperability as defined by MAFIIA. Another important concern was security, but it is outside the scope of this paper to address this.

System assets

Relevant standards, a project dictionary, and software profiles and patterns were identified as important assets. We applied Chari et al's [8] framework for weighing the scope and usability of a set of selected standards, and found that CEN ENV 13940 (Health Informatics System of Concepts to support continuity of Care) was the most appropriate standard. The dictionary, an agreed upon reference list of concepts, was created based upon scenario descriptions and story boards from the three heritage systems, and, as far as possible, mapped to the terminology of the chosen standard. The profile chosen was the UML 2.0 profile for software services, and web service patterns such as the publish-subscriber, asynchronous query, command façade, and message bus pattern were used to guide the design.

Reference architecture

The MAFIIA reference architecture divides the target system (in our case, the Linkcare services) into a set of logical tiers, and defines how the system interfaces with the environment. A tier is a logical partitioning of a system where each tier has a unique responsibility. Each tier is loosely coupled to the tiers directly above and below. All components in the Linkcare architecture were linked to the reference architecture in the component viewpoint.

Context viewpoint

The context viewpoint consists of the business aspects model, the environment systems model, and the business to system mapping model.

The business aspect models documents any business related concern that increases the understanding of what problems the target system solves, or what functionality it implements (e.g. stakeholders). Incorporating the results of the Linkcare process (market analysis and studying the Linkcare systems), we identified 17 core stakeholders modeled in a UML use case model/actor hierarchy accompanied by text outlining each stakeholder.

The Environment Systems model documents other technical systems (environment systems) that are involved in the implementation of the business models, or influences the operation of the target system. We identified seven services that constituted the Linkcare services (the target system). These services are modeled as a Service Partition and made available for other services (Service Consumers) through Service Gateways. This was done in order use the gateway construct to control the access to services as the partition in Norway differs from the Spanish partition as different services are provided.

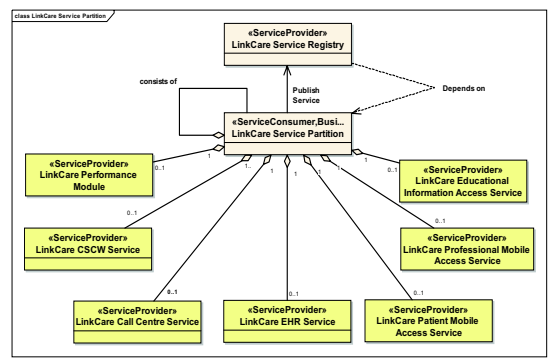

Figure 1 - The Linkcare service partition

Applying the service profile in this way implies that all Linkcare services can be accessed through well-defined interfaces (the gateways). We designed a Linkcare Service Registry that controls the location and availability of the Linkcare services (using the concept of location in the Service provider). This structure enables new Linkcare services to be added, existing services to be modified and relocated without notifying its clients and communication (Service Channels) between Linkcare service partitions can be managed through the gateways.

We used UML component diagrams to stereotype environment systems either as Service Providers or Service Consumers according to the software services profile. UML Sequence diagrams were used to detail the interaction between the Linkcare services and the environment systems.

Requirements viewpoint

Having a clear understanding of what were to be solved following the context viewpoint, we gathered requirements for the target system We organized the requirements into generic requirements for all the services, requirements for each service, and generic interoperability requirements.

Component viewpoint

The component viewpoint consists of the system information model, the system decomposition model, the system collaboration model and the component and interface specification model.

The system information model describes the most important information elements in the Linkcare system. As in the dictionary, the elements in this model were mapped to the CEN standard as far as possible. The model was built using a UML class diagram and the elements were additionally explained using text.

The system decomposition model describes how the target system is divided into different subsystems and components. The Linkcare services were modeled as being part of a Service Partition consisting of one to many Service Providers (the services). The Service Partition publishes services to the Linkcare Service Registry. Interaction with the service registry was detailed in a UML sequence diagram. A UML component diagram was used to stereotype the components to the MAFIIA reference architecture.

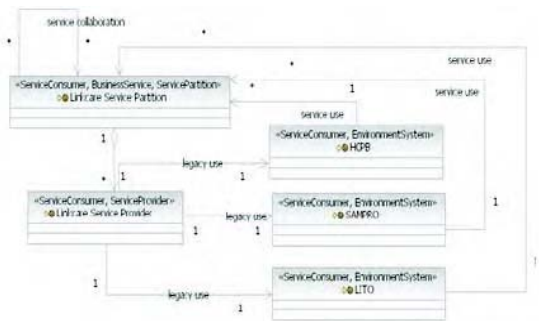

Figure 2 - Mapping to MAFIIA Reference architecture

A UML composite structure diagram were used to model the Service Gateways on a partition, and a UML collaboration diagram were used to model the Service Channels on the gateways.

In the system collaboration model we defined the main interactions between the components in the architecture using a component diagram showing use relations. This was elaborated with text explaining the collaborations, and detailed using UML communication diagrams showing the intra-service communication.

In the component and interface specification model each interface has a specification that shows which methods are available and the input/output parameters of these methods.

Distribution viewpoint

In the distribution viewpoint we modeled the logical distribution of services focusing on what functionality could be distributed together and what should be kept separate (e.g. for business or security reasons). We used a UML deployment diagram and identified four nodes (a node is something that can host software).

The original Linkcare system instances are kept on separate application servers. This is because these are separate systems, maintained by separate organizations in separate countries. The services will cooperate through the Linkcare services, which will help to keep the core business functionality separated, and avoiding building monolithic systems.

Some services, such as the Linkcare patient mobile access service and the Linkcare patient mobile access service are services that typically require rich clients and introduce special requirements on services. Examples of which are extended session logic to handle session interruptions (e.g. when transferring measurement data) and extended security mechanisms.

The Linkcare EHR service is also kept separated. This is because sensitive data typically is transferred using this service, and extra security mechanisms (such as firewalls, log on mechanisms etc) is needed.

The Linkcare service registry service will receive a higher amount of service requests (service lookup) than other services. In order for this not to influence other services, this service is also kept separate.

Realization viewpoint

In the realization viewpoint we considered the technical platforms that the original Linkcare systems were running on. The Norwegian and Cypriot system ran on .NET technology, while the Spanish system is based on Oracle solutions. In the realization view we outlined how web services (one way of implementing services) was to be done on the different platforms. We were focusing on, service description, service implementation, service publishing, discovery and binding, and service invocation and execution.

Discussion

The reason we chose to use MAFIIA in this domain is because it is a proven and documented framework for creating information integration architecture descriptions. An overview of other projects in which MAFIIA is used is provided by Walderhaug et al [9]. In Linkcare we use MAFIIA to ensure that the architectural description created for Linkcare is inline with requirements to architectural descriptions for interoperable systems, and contains the necessary viewpoints. Using the viewpoints and the guidelines that MAFIIA provides, allows us to "think right" when designing the system and ensures that all relevant information, such as important stakeholder, what standards are applied, decomposition of the system and the systems environment and how the system relates to the environment, is sufficiently documented. We believe that the lack of such documentation can considerably hamper the development of interoperable and sustainable systems for continuity of care.

In addition to enforce the presence of essential documentation, the use of architecture frameworks also ensure that the architecture is described on a sufficient level of abstraction, making it more resilient to change in the

domain it is addressing. It is important to note that abstract does not imply informal. On the contrary, MAFIIA suggests using UML as the formalism when describing models. We are inline with Fowler 10], in that there are three ways of using UML; as sketch, as blueprint and as programming languages. We have used UML as blueprints to describe interfaces, and let the implementation of components be hidden in the architecture. This is inline with other current standardisation initiatives see e.g. the Healthcare Service Specification Project [11], a joint effort between the OMG and HL7.

We have used design patterns and the UML 2.0 profile for software services when modelling the architecture. Patterns describe a well proven solution to a recurring design problem. By applying agreed upon patterns (such as the publish-subscriber pattern) we are one step closer to having interoperable systems. A UML profile can be used to further specialize the architecture design. The UML profile defines stereotypes, tagged values and constraints that can be assigned to modelling elements in the design process [13]. We have designed our architecture using the UML 2.0 profile for software services, modelling our services as service partitions with stereotypes like service gateways, communication over service channels, and the notion of service providers and consumers. We experienced several benefits of using this approach. First, since the MAFIIA framework was already assuming the use of UML, applying a UML profile in the framework was straightforward. Second, the profile incorporated software service design terms, allowing us to unambiguously represent the system artefacts in a formal language. Third, the UML Profile assists in communicating concepts in the project. A Service Provider for instance, is a well defined concept and elements stereotyping this concept are bound by the constraints as defined in the profile. We used the profile in the tool it was created for, which is Rational Software architect, so a potential drawback of the profile is that it is not automatically applicable in other tools.

Conclusion and future work

In this paper we have argued for a systematic and formal approach to the development of interoperable information systems using architecture frameworks such as MAFIIA that en-able formal software interface descriptions. We have shown how we applied a UML profile providing us support in design-ing our architecture inline with best practice. Healthcare enter-prises could impose vendors to apply the same design patterns in their system design, thus preparing the ground for interoper-able healthcare enterprises. Consequently, we are currently continuing our work on profiles by creating domains specific healthcare profiles that incorporate information from standards (such as CEN) in support of developing interoperable healthcare systems (see e.g., [12]).

Sustainable Ubiquitous Home Health Care – Architectural Considerations and First Practical Experiences

Michael Marschollek, Klaus-H. Wolf, Oliver-J. Bott, Mirko Geisler, Maik Plischke, Wolfram Ludwig, Andreas Hornberger, Reinhold Haux

Institute for Medical Informatics, Technical University Carolo-Wilhelmina of Braunschweig, Germany

Abstract

Despite the abundance of past home care projects and the maturity of the technologies used, there is no widespread dissemination as yet. The absence of accepted standards and thus interoperability and the inadequate integration into transinstitutional health information systems (tHIS) are perceived as key factors. Based on the respective literature and previous experiences in home care projects we propose an architectural model for home care as part of a transinstitutional health information system using the HL7 clinical document architecture (CDA) as well as the HL7 Arden Syntax for Medical Logic Systems. In two short case studies we describe the practical realization of the architecture as well as first experiences. Our work can be regarded as a first step towards an interoperable – and in our view sustainable – home care architecture based on a prominent document standard from the health information system domain.

Keywords:

Home care, information system architecture, standards, sensors.

Introduction

Telemedicine in general and telemedical systems for home care have been a key interest in medicine and medical informatics in the last two decades. Many research projects and funding programs have been conducted and some of the solutions developed have been successfully introduced in medical care and are commercially available. On the one hand there is a considerable advancement and maturity of the underlying technologies and methods, e.g. computer systems, ubiquitous computing, sensor systems, signal analysis, networks and health information systems, and on the other hand there is first proof that specific patient groups stand to benefit from tele home care [1]. Despite this there is no widespread use of these technologies as yet. The reasons for this lack of sustainability are manifold and it is often argued that, apart from technological barriers, evidence for cost benefit is sparse for tele home care systems [2], that profound changes in the work processes of care providers are required and that physicians lack the resources to interpret huge amounts of sensor data recorded in home settings [3]. In particular, the lack of utilization of standards such as the HL7 Clinical Document Architecture (CDA) [4] or prEN 13606 [5] and the inadequate integration into regional health information system infrastructures, if existent, are regarded as key factors [6, 7]. Only few examples of the use of standards in home care can be found in literature. Van der Linden et al. present PropeR, a re-usable, modular EHR system based on open source components such as the openEHR standard, and report on its use for multidisciplinary care of stroke patients [8, 9], but make no statement on the representation of sensor data. In [10] the processes in home care are described in detail and a framework for home care cooperation is proposed. The authors use the XML standard for messaging between different health information systems.

Concentrating on the use of standards from the health information system domain, we aim:

- to elucidate the requirements for sustainability in home care systems (aim 1),
- to propose a functional, adaptive and modular (and in our view sustainable) architectural model (aim 2), and
- to report on two current projects of the authors and their status of implementation (aim 3).

The research questions addressed are the following:

Q1: What are the basic requirements for sustainable home care architectures with respect to the usage of standards?

Q1.1: What are the categories of data processed in home care, what are the basic paths of information flow, and who are the participants?

Q1.2: What are suitable forms of medical data representation for further use in transinstitutional health information systems?

Q2: What is an architectural model suitable to meet these requirements and how can it be implemented?

Materials and methods

Based on our previous experiences in building home care systems and with regard to the respective literature we summarize the basic architectural requirements for a sustainable, standards-based home care system (first section in *Results*). We then propose an architectural model along

with the strategy for its practical realization in the following section, employing the *Three-layer Graph-based meta model (3LGM²)*-methodology for statical modeling of health information systems [11, 12]. In the final two sections in *Results* we report on two case studies using our architectural model and present their current status of implementation. In the *Discussion* we balance advantages and disadvantages of our architecture and finally conclude with an outlook on our future work.

Results

Requirements for sustainable home care architectures

In home care, mostly two different categories of data are gathered. Firstly, there are sensor data that are inherently a very heterogenous group, with sensors that measure just one parameter once a day, e.g. a sphygomanometer for blood pressure measurements, to multi-sensor devices that continuously record multiple channels and transfer a data stream to a computer system, e.g. a 12-lead ECG. Different persons with individually different diseases or functional disabilities will need customized sensor device compilations that fit their situation best. Therefore there is an urgent need for device interoperability standards that allow to build self-configurating 'plug-and-play' sensor sets with known features [13]. The ISO/IEEE 11073 medical device standard is a candidate [14], though at present hardly used outside intensive care units. Apart from medical sensors, context sensors that provide valuable information for the interpretation of the medical data also should be considered, e.g. accelerometers for the classification of activities of daily life (ADL) [15].

A second category of data are data actively provided by the persons themselves, from relatives and care givers. These may either be structured, e.g. in a standardized questionnaire for well-being, and therefore can be represented with reference to code systems such as SNOMED CT [16], or unstructured such as e.g. in free text in emails or spoken comments. The semantic integration of the latter into existing health information systems remains a largely unsolved problem. The addressees of home care not only are a source but also a target of information, because feedback is a necessary precondition for promoting self-management and patient empowerment.

When multiple sensors are used in home care, huge amounts of data will be recorded every day. There is an irrevocable need for intelligent *processing* of these data, which may be done already within the sensor device, on an additional mobile device worn by the patient, or on a computer at the patient's home, probably all three in form of cascading preprocessing procedure. Data fusion is necessary both on technical and content level, and conclusions should be drawn considering all available data from a patient, including those stored in her or his electronic health record (EHR). As there are different groups of recipients of information – the patients, their care givers and their physicians – with different informational needs and levels of 'health literacy', there should also be different, configurable forms of data aggregation and presentation to fit user needs.

In order to achieve semantic interoperability the heterogenous data gathered from multiple sources have to be represented in a consistent form, so that they can be used in transinstitutional health information systems. A prominent standard for clinical documents is the HL7 CDA, which is designed primarily for clinical documents such as discharge letters or diagnostic findings, and not for huge amounts of sensor readings.

An architectural model for standards-based home care

We propose an architectural model for a sensor-based home care system that makes use of the HL7 CDA (version 2), for data representation and includes a decision support infrastructure based on the HL7 Arden Syntax for Medical Logic Systems and its Medical Logic Modules (MLMs) [17].

Figure 1 shows the general component model of our architecture. The patient or respectively the person is the primary source of data in the home care environment, but relatives and care givers may also provide valuable data on her or him, e.g. in the form of questionnaires or observations. Thus these are also part of the architecture. All data gathered are transformed into CDA documents and then transferred to a home server with a personal electronic health record (pEHR) system. Attached to this system is a decision support system that automatically retrieves stored CDA documents, analyzes them and in turn produces synopses or reports in CDA format or as messages, e.g. email alarms to a health care provider. The processing of the data takes place in two stages: firstly, the huge amounts of sensor data are preprocessed by employing temporal abstraction methods, intelligent filters and machine-learned classifiers to aggregated data units in CDA format. Secondly, the data are analyzed along with other CDA documents on the patient from 'external EHR' systems, i.e. other components of the transinstitutional health information system (cmp. Figure 1), with predefined MLMs. The MLMs contain medical knowledge coded in Arden Syntax to extract medically relevant information that in turn can be used e.g. to trigger alarms. The model architecture also contains two loops of feedback (cmp. Figure 1, dotted arrow) to the patient: an inner loop with machine-generated reports made available via an interface, e.g. the home TV set, and an outer loop, where the feedback is posted by a health professional, e.g. a General Practitioner, on her or his institutional system and then transmitted via the transinstitutional communication infrastructure to the personal EHR at home and then sent to the interface.

Figure 2 shows the 3LGM² model of the architecture described, with all entities, functions and relationships subdivided into three distinct architectural layers: the domain layer and the logical and physical tool layer.

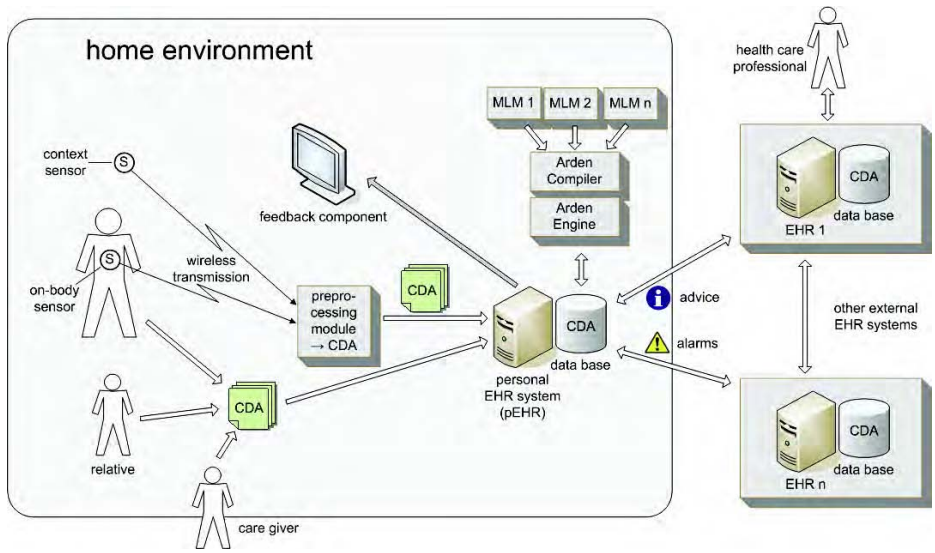

Figure 1 - Component model of the proposed architecture based on the HL7 clinical document architecture standard (CDA). pEHR = personal electronic health record; MLM = Medical Logic Module

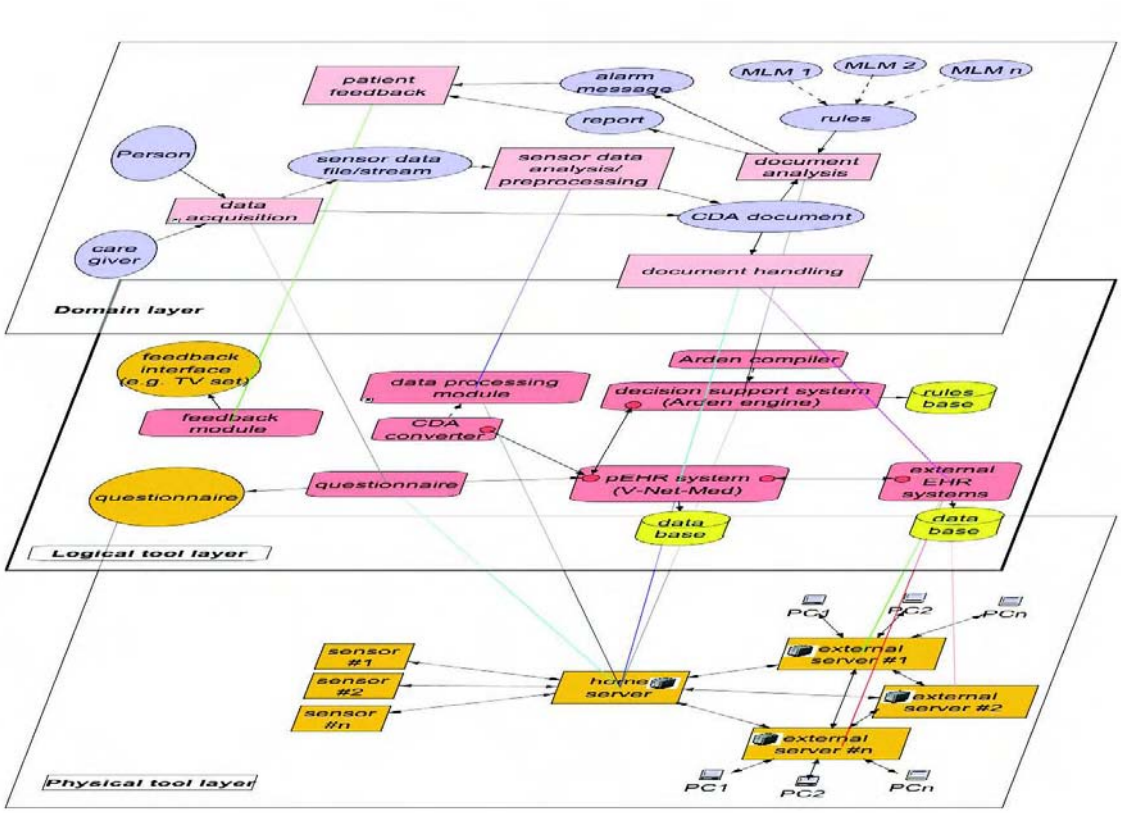

Figure 2 - Three-layer graph-based meta model (3LGM²) of the proposed home care information system. pEHR = personal electronic health record; CDA = clinical document architecture; MLM = Medical Logic Module

Case study 1: Laboratory Installation

In our health-enabling technologies lab, a complete apartment equipped with different sensor technologies, we have installed a prototype system with a personal EHR system developed in our institute [18]. We experiment with different wireless as well as cabled sensors, e.g. triaxial accelerometers, that transfer real-time data to the system which then are analyzed and aggregated into CDA level 3 documents (cmp. Figure 1). In addition to the sensor data, data on the persons' well-being are recorded with computerized questionnaires and stored subsequently, currently in CDA level 2 because we use a non-standardized questionnaire that is not listed in a coding system. We also use an Arden compiler that was constructed to retrieve CDA documents from the EHR system, to analyze them and to generate email messages, e.g. to a health care professional. This compiler was developed and tested in a home care project providing telemedical support for two patients having received a heart-and-lung transplantation [19]. A feedback component is included in the system in the form of a digital TV set with a media portal software. It features a "health" plugin currently showing a frequently updated graph summarizing a person's activity level that is recorded with a wearable wireless accelerometer unit.

Case study 2: The LASS project

The *LASS* project – a German acronym for self-sufficient and self-determined life in old age – aims at assessing the use of health-enabling technologies (e.g. sensor systems for fall detection) to improve both the quality of life and the efficiency of care for elderly people in their home environment. As part of this project, we currently establish an architectural infrastructure as decribed above in Figures 1 and 2.

In a case study [20] we recorded annotated data from five elderly persons over a period of two weeks with a multi-sensor device (*Sensewear Pro 2, Bodymedia, Pittburgh*) and – employing methods of our previous research on this topic [15] – constructed machine-learned classifier algorithms for the classification of activities of daily life and body position that are used by our data preprocessing module. The data from the multi-sensor device are subsequently transformed into a CDA level 3 document that, once stored in the personal health record, can be analyzed by the Arden engine described in the previous section. The specific aim is to identify elderly peoples' activity profiles that provide valuable information on the persons' behavior as well as context information for other medical data recorded in home care. We also installed specially prepared, easy-to-use PC systems in four of the elderly persons' homes and tested daily questionnaires on well-being, the acceptance of which was good. The answers were stored in CDA level 2 documents as stated above.

Discussion

The importance of using standards for information interchange in the health care domain has often been stated and has partly been realized in institutional health information systems. For transinstitutional health information systems – and home care can be considered as part of these – they are vital in order to achieve interoperability and thus sustainability, in this context denoting that such a system meets the requirements for future use. Yet in the past often proprietary document 'standards' or formats were used in this field and still are. In addition to this, no generally approved form of representation for sensor data exists.

Our approach aims at bridging the gap between multiple data types encountered in home care by persistently using a prominent clinical document standard – the HL7 CDA. An obvious advantage of this approach is that such documents can easily be used within existing transinstitutional health information systems. Furthermore their semantics are clear and thus they can be used along with other clinical documents by decision support systems, as demonstrated in our architecture. The installation of a personal in-home EHR system with a decision support component has – apart from reducing data transfer costs – the benefit that decisions can be made in a timely manner and that the data recorded are kept in a private area within a secure system. So the patient may decide which information to pass on. A security solution based on a ticket-based electronic consent system for granting scalable access to the information stored in the personal EHR system has been developed by some of the authors and is part of the system used [18].

Limitations

The HL7 CDA standard is not primarily designed for the representation of sensor data, and the XML files tend to grow large. Therefore intelligent preprocessing is needed, bearing an inherent but unavoidable loss of information. Parts of our prototype architecture have only been tested in our health-enabling technologies lab so far. Further evaluation is necessary.

Apart from this, there is still a lack of analyses regarding the costs and – measurable or perceived – benefits of such a home care system, both for the patients respectively users and the health care professionals. Some studies imply a reduction of costs as the duration of hospital stays is reduced [1], other studies show an increased overall cost as the technology for monitoring and feedback is expensive [21]. Our future work will include a cost-benefit evaluation of the proposed system.

Conclusion

We have proposed an architectural model for a sensor-based home care system that makes use of two prominent standards from the domain of health information systems, the HL7 CDA (version 2) for semantically accessible data representation and the HL7 Arden Syntax for Medical Logic Systems for medical knowledge representation and decision support. We believe that the use of standards is an important precondition for building an interoperable and therefore sustainable home care system [22].

Our future work will be directed towards the evaluation of all parts of our prototype system in a field study outside lab

conditions. Furthermore we will develop and implement further preprocessing modules and transformation components for several sensor devices as well as MLMs with the help of our medical partners. Besides this, we will integrate care givers into our system, both laypersons and professionals.

Abstract

Clinically relevant family history information is frequently missing or not readily available in electronic health records. Improving the availability of family history information is important for optimum care of many patients. Family history information on five conditions was collected in a survey from 163 primary care patients. Overall, 53% of patients had no family history information in the electronic health record (EHR) either on the patient's problem list or within a templated family history note. New information provided by patients resulted in an increase in the patient's risk level for 32% of patients with a positive family history of breast cancer, 40% for coronary artery disease, 50% for colon cancer, 74% for diabetes, and 95% each for osteoporosis and glaucoma. Informing physicians of new family history information outside of a clinic visit through an electronic clinical message and note in the EHR was not sufficient to achieve recommended follow-up care. Better tools need to be developed to facilitate the collection of family history information and to support clinical decision-making and action.

Keywords:

family history, electronic medical records, clinical decision-making

Introduction

Family history data often goes unrecorded or is available only as uncoded free text in the electronic health record (EHR).[1,2,3] Patient provided family history information may provide incremental value if one can learn of increased risks that may influence care management.[1,4]

Although sophisticated family history assessment is most expertly done by those trained in this area, much can be learned about a patient´s risk from whether a relative with a condition is a primary or secondary relative, how many relatives have the condition, and the approximate age at which they were diagnosed.[5,6] Clinical decision support can aid physicians in identifying patients "at risk" due to family history and in determining appropriate follow-up and monitoring.[7,8]

In this study, we assessed the availability of coded or structured family history information in EHRs and the extent to which solicited input from patients would identify those at higher risk as compared to risk assessed using information readily available in their EHR alone. We also assessed whether physicians took action to change care management based on new family history information provided by a patient outside of a clinic visit.

Methods

Study setting

Partners HealthCare System is an integrated healthcare delivery system in the Boston, Massachusetts, United States (U.S.) area that includes two major academic medical centers, several community hospitals, and an extended physician network. A comprehensive EHR is in use at the majority of ambulatory care practices. This EHR includes the ability to capture provider notes, results of lab and diagnostic tests, problem lists, medication lists, and automatically generates patient-specific reminders for health maintenance items. However, at the time of this study, input of structured or coded family history information was not supported.

Patients who choose to enroll are able to electronically communicate with their physician practice through a secure web-based patient portal called *Patient Gateway.* At the time of the study, features of *Patient Gateway* included patients being able to view their EHR medication and allergy lists, and request prescription renewals, appointments, and referrals.

Recruitment

Patients were recruited from a single Partners-affiliated ambulatory primary care practice in the suburbs of Boston. A packet was sent through postal mail with a cover letter, consent form, opt-out card, privacy notice, and a return envelope to send back the consent form.

Once consent was received, a paper-based survey that asked about medications, health maintenance status, and family history was populated with patient–specific data and sent to consenting patients. A two-step process was required to distribute the survey because of the specific medical information included that could not be generated without patient consent. The Partners Human Research Committee approved the study and the survey was administered from November 2003 – Feburary 2004.

Up to two reminders were sent to non-responders to solicit consent forms and also to complete the survey once they had consented. Survey data on medications and health maintenance are reported elsewhere.[9,10]

Surveys

Patients were asked to provide family history information in a structured format that required specifying the number of family members by degree of relationship and age category that had been diagnosed with a condition. In addition to requesting information on six specific conditions (glaucoma, osteoporosis, coronary artery disease, diabetes mellitus, breast cancer, and colon cancer), patients could complete the form for other conditions for which they had a positive family history.

Patients were then instructed to return the surveys to researchers who provided a copy of the survey back to patients. Patients were informed that information provided in their surveys would be shared with their primary care physicians and may become part of their medical record.

Surveys were tracked and analyzed using Microsoft Access. Once a survey was received, researchers created a note within the patient's electronic health record with Partners Health Information Services approval. This note reported on the information provided by the patient and clearly identified the source of the information as obtained from the patient through a research survey. Physicians were sent a clinical message within 90 days through the EHR messaging system that informed them of the new note in the patient's record.

Analysis

Patient provided family history information was compared with information readily available in the EHR. Readily available was defined as family history information recorded on a patient's problem list or within a note template containing a family and social history section.

To evaluate physician action in response to the family history note, electronic health records were reviewed for visit, medication, and procedure information consistent with recommendations made in these clinical areas by local experts, based on guidelines from the Risk Management Foundation of the Harvard Medical Institutions, Inc., the U.S. Preventive Services Task Force, American Heart Association, National Cholesterol Education Program, American Diabetes Association, and National Osteoporosis Foundation.[11-19]

P-values were calculated for comparisons between respondents and non-respondents using a chi-square test for proportions and Wilcoxon rank-sum test for continuous variables.

Results

Among 1098 patients solicited, 189 patients consented and a family history survey was completed by 163 patients. Respondents and non-respondents were similar in the proportion that were female (66% and 67%, respectively), and their average number of medical problems (4.8 and 4.4, respectively) and medications (3.5 for both) listed in the EHR. Respondents were significantly older than non-respondents on average (50.6 years and 46.8 years, p=0.001).

New information identifying higher risk profile

Fifty-three percent (53%) of the respondents had no family history information in the electronic health record either on the patient´s problem list or within a templated family history note.

For glaucoma, osteoporosis, and colon cancer over 90% of the patients determined to have a positive family history were identified based solely on new information provided by the patients in the survey. (Table 1) A family history of diabetes, breast cancer, or coronary artery disease was more frequently available within the EHR, although more than 80% of patients with a positive family history for these conditions were still identified through the survey alone.

Table 1 - Sources of positive family history information and changes in patient risk level

Condition	Source of Positive Family History		Change in Risk Level with Info from Survey Alone		
	EHR and/or Survey N(%)	Survey Alone N(%)	Reduced N(%)	Did Not Change N(%)	Increased N(%)
Glaucoma	20	19 (95%)	0 (0%)	1 (5.3%)	18 (94.7%)
Osteoporosis	22	20 (91%)	0 (0%)	1 (5.0%)	19 (95.0%)
Diabetes	51	42 (82%)	1 (2.4%)	10 (23.8%)	31 (73.8%)
Breast Cancer	47	40 (85%)	0 (0%)	27 (67.5%)	13 (32.5%)
Colon Cancer	68	66 (97%)	0 (0%)	33 (50.0%)	33 (50.0%)
Coronary Artery Disease	82	67 (82%)	0 (0%)	40 (59.7%)	27 (40.3%)

Table 2 - Recommended actions occurring following clinical message indicating new family history information

Condition & Recommendations (N=total patients with increased risk level due to family history information from survey alone)	Patients Meeting Criteria for Physician Action N	Patients for Whom Recommended Action Occurred After Clinical Message was Sent N (%)
Glaucoma (N=18)		
visit w/in specified time	18	14 (78%)
consider IOP	16	1 (6%)
Osteoporosis (N=19)		
visit w/in specified time	13	6 (46%)
DEXA scan	12	5 (42%)
Diabetes (N=31)		
visit w/in specified time	31	23 (74%)
Consider fasting glucose or HbA1c	31	26 (84%)
Breast Cancer (N=13)		
visit w/in specified time	13	5 (38%)
clinical breast exam	13	3 (23%)
mammogram	13	8 (62%)
referral to genetic counselor*	13	0 (0%)
Colon Cancer (N=33)		
visit w/in specified time	32	13 (41%)
colonoscopy	9	2 (22%)
genetics referral for HNPCC*	1	0 (0%)
Coronary Artery Disease (N=27)		
visit w/in specified time	27	13 (48%)
lipid profile	27	19 (70%)
cholesterol lowering med	11	3 (27%)
blood pressure lowering med	7	3 (43%)
aspirin advice/use	27	5 (18%)
smoking cessation counseling	0	n/a**
exercise/nutrition counseling/referral	22	8 (36%)
consider plasma homocysteine or C-reactive protein	27	2 (7%)

*genetic tests may not have been documented in accessible EHR data
**n/a = not applicable

New information provided by patients led to an increased risk level for 50% of patients with a positive family history of colon cancer, and the majority of patients with a positive family history for diabetes (74%), osteoporosis (95%), and glaucoma (95%). Increases in risk were found for 32% of patients with a positive family history of breast cancer and 40% with coronary artery disease.

Physician action in response to clinical messages

Overall, of the 21 actions physicians should have taken across all conditions in response to new family history information, 16 of the actions were carried out less than 50% of the time. (Table 2) However, for the smoking cessation counseling action, no patients met the criteria of being a current smoker so no action was required. Although patients at higher risk of glaucoma had visits with their physicians more than three quarters of the time after clinical messages were sent, only 1 out of 16 patients (6%) had a documented intraocular pressure measurement (IOP). For osteoporosis, fewer had visits (46%) than did the glaucoma patients, but 42% did receive a dual x-ray absorptiometry (DEXA) scan within the specified time after the clinical message.

In follow-up to new information regarding a patient's family history of colon cancer, only 2 out of 9 (22%) patients meeting the criteria to have a colonoscopy received one. However, 15 of the 33 patients at higher risk for colon cancer had already had a colonoscopy sufficiently recently that they did not meet criteria to have one within a year of

the clinical message. This finding may be reflective of compliance with general screening guidelines for patients regardless of risk level associated with family history. The same may be true of diabetes and breast cancer actions; 84% of the patients meeting the criteria for fasting glucose or HbA1c tests and 62% requiring mammograms had received them within the time specified by the guidelines.

Although referrals for genetic testing related to breast or colon cancer were not documented for any of those patients meeting the criteria, these may have occurred but not been documented in the generally accessible EHR data.

For coronary artery disease (CAD), 70% of patients with a positive family history had a lipid profile done after the clinical message was sent which may also reflect general screening. However, only 27% of patients meeting the criteria for cholesterol lowering medications and 43% of those for blood pressure medications received these prescriptions after the clinical message. Only 36% of those patients with a positive family history for CAD and an LDL >130 and/or body mass index (BMI) of >25 had documented exercise and nutrition counseling or referrals.

Discussion

Accurate and current family history information is becoming increasingly important with the advent of genomics and the promise of personalized medicine. Typically, patients are asked about their family history at their initial visits with their primary care physicians, but this information is generally recorded as free text in notes, and updating this information is done sporadically or not at all. When the information is captured in unstructured format, it is inaccessible to automated clinical decision support. As a result, physicians are missing opportunities for providing optimum screening and prevention for those patients at higher risk for certain conditions based on their family history.

In this study, we found that significant family history information indicating that patients were at an increased risk for certain conditions was frequently missing from the EHR, at least as structured or coded information, or within a templated note. This was particularly true of glaucoma, osteoporosis, and diabetes. Coronary artery disease, breast and colon cancer family history information were more readily available, perhaps due to greater prevention emphasis, patient knowledge of risks, and focus of physicians on soliciting this information. More structured tools to support the electronic capture of this information could help to guide comprehensive data collection for all conditions in which there are known care implications when an individual is at risk due to family history. Decision support that uses this information would also ensure the physicians take appropriate actions when patients have positive family histories.

A recent study reported that, whereas 96% of patients understand the importance of knowing one's family medical history, only 30% have collected this information.[20] Recent U.S. national efforts, such as those by the Centers for Disease Control (CDC) and U.S. Surgeon General's Family History Initiative, have been encouraging patients to complete their family histories and discuss them with their physicians.[21] As personal health records gain momentum and are designed to include family history, the numbers of patients with more comprehensive electronic repositories of this important information will increase.

To get the greatest value from this patient data, however, it will be important to create effective processes to facilitate the transfer and use of this information without undue burden on busy primary care physicians. Sending an electronic clinical message outside of a patient visit to alert physicians of new family history information was investigated in this study as a proxy for patients completing data online and then submitting it to their physicians through a patient portal, such as *Patient Gateway.* Our results show that simply sending a message outside of a visit is not sufficient for achieving appropriate screening rates for patients at increased risk due to family history.

The lack of physician follow-up may be due, in part, to the information being presented outside of a visit when a physician would not be able to discuss it with a patient and when action would be outside the normal physician workflow. In addition, no clinical decision support was provided so that physicians could evaluate the importance of the information and know what action was required. Tools that support the electronic capture of coded data by patients, deliver this information to physicians around visit time, support provider review and documentation in the electronic health record, and offer clinical decision support integrated with electronic ordering to guide appropriate follow-up are important for closing this gap in patient care.

Limitations

The response rate was low, probably in part because a very large packet was sent and a two-step enrollment process was required. The responders were somewhat older than non-responders and may have differed in other ways not measured. In addition, the study was uncontrolled. Whether any recommended actions occurred between a patient's receipt of the survey and when a clinical message was sent were not specifically assessed.

Conclusions

Clinically relevant family history information is frequently missing or not readily available in electronic health records. For all diagnoses of interest, patients often provided family history data that might influence use of screening tests, especially for glaucoma, osteoporosis, and diabetes. With the increased emphasis on family history as the field of genomics becomes more sophisticated, these results demonstrate the potential benefits of soliciting information from patients in a structured format outside of visits. However, sending clinical messages to physicians informing them of new family history information outside of a visit is not sufficient to ensure appropriate screening occurs. Better tools need to be developed to facilitate the flow of family history information from patients to their

primary care physicians and to support clinical decision-making and action.

Abstract

Surveys of patients consistently demonstrate a very strong interest in having secure electronic access to their own laboratory test results. In recent years, a number of health care providers and lab service centers have offered this capability, which now extends to millions of patients in the United States. Yet, little has been published on the methods of making lab results available. This case report identifies the objectives, methods, and results of a feasibility pilot conducted at Partners Healthcare from May to September, 2006. A candidate set of results were identified, approved for release, programmed into Patient Gateway, Partners' secure patient portal, and studied. Patient and practice feedback was positive. No noticeable rise in patient concerns was observed by practice staff or through patient surveys. One-half of patients who viewed results accessed reference information linked to a result. Organizational and practice-level issues necessary to support continued rollout are described.

Keywords:

Personal health records, diagnostic tests, communication, continuity of patient care, computerized medical records systems.

Introduction

In May, 2006, Partners HealthCare (Boston, MA, USA) began a feasibility pilot to introduce online laboratory results to patients in two primary care practices, via an established, self-developed secure internet portal, *Patient Gateway.* This paper aims to describe the rationale, design, and results of the four-month pilot to share our learning.

Partners' approach was informed by other organizations who have shared online results, notably Group Health Cooperative (Seattle, WA, USA) and CareGroup (Boston, MA, USA). The project context included: a) the desire for a short development time frame, b) the need to coordinate with provider workflow, c) the need to align with practice and organizational policies, and d) the need to address clinical information systems environment dependencies. Releasing laboratory results non-electronically will continue. Practical ways to address these challenges, while somewhat unique for each organization, are the focus of this paper. Since September, 2006, the new features are being deployed among primary and specialty care clinics as a result of the success of the pilot.

Materials and methods

Partners HealthCare, a large integrated delivery network in Eastern Massachusetts comprised of two teaching hospitals, three community hospitals, four specialty hospitals, and a large number of community physicians in primary and specialty care, offers providers an enterprise ambulatory electronic record, the LMR (Longitudinal Medical Record), a patient portal extension, *Patient Gateway* (PG) [1], the CDR (Clinical Data Repository) that stores laboratory results, and other related clinical systems components.

LMR (used by over 3,500 physicians) is interfaced with PG (used by over 30,000 patients since its launch in 2002). PG enables authorized patients to view real-time chart information abstracted from the LMR – currently medications, allergies, and future/past appointments. Laboratory test results are available to providers and staff who use LMR through a simple viewer. Results pending physician action across multiple patients are displayed through an advanced viewer, the Results Manager (RM) [2].

Pilot objectives and metrics

The primary pilot objective was to offer patients secure online access to their own lab results, striking a balance between the goals of "clinical transparency" (avoid withholding information) and "clinical sensitivity" (avoid violating patient and physician communication preferences). A second objective was to understand what technical, workflow, and organizational challenges must be addressed in order to successfully scale the new capability to all practices and patients. Pilot success would be measured by usage, spontaneous and solicited feedback from patients and providers, and brief surveys of patients about their experience.

Results feature design

The feasibility pilot introduced two new features – patient access to browse laboratory results in PG ("Patient Results"), and provider ability to take a Results Letter she

had created using RM in LMR, and instantly send it electronically to the patient, via PG ("Online Results Letter").

Expert panel. An expert panel of 7 clinicians was formed to identify the laboratory results to release and their timing rules (immediate release, or two business day embargo). The expert panel identified approximately 50 different results (chemistry, hematology, drug levels, endocrine, etc.). Since each clinical result (e.g. potassium) may correspond to multiple CDR items (e.g. serum potassium, blood gas potassium, serum potassium from another lab, etc), a total of 170 unique CDR items were included in the pilot. CDR results from all dates (matching a CDR code) were displayed.

Release Framework. Each CDR result was assigned a release category of "release now" or "release in two business days". The immediate release assignment meant that once the result was available in the CDR (to the physician) it was also available to the patient. The embargoed release meant that the result was "held" from display in PG for two business days once it was available for review by the physician. The embargo clock began when the result became available (not pending). Release timing (immediate or 2 day embargo) was not predicated on whether the result was in reference or out of reference range. Software changes in the CDR system would be required to accomplish this, and were out of scope for the pilot.

PG Patient Results design. In the patient portal, a new menu item under the "Health Record" menu was introduced: "Results". This opened a "Results Summary" page with a table of results (Figure 1). Each row in the table lists a single result "name" (e.g. CBC – Complete Blood Count) and most recent value, using the CDR display name familiar to physicians. The name is hyperlinked to a "history" page (e.g. CBC results from all dates). On the Results Summary page, the "date" is hyperlinked to a "Specimen" page (e.g. CBC, PLT – Platelets, etc. for a given date). Sorting by column is supported.

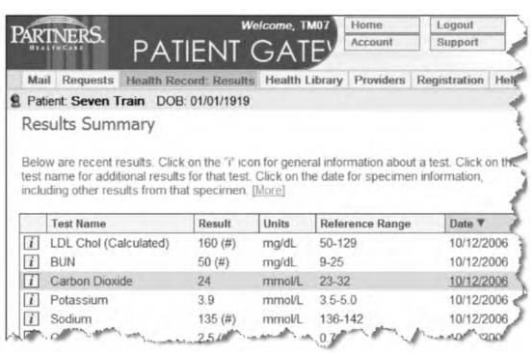

Figure 1 – Results Summary page in Patient Gateway

There is no patient notification of a new result. A "pending" result was displayed as "pending" to indicate it was not yet available (to providers). An embargoed result displayed as "held" during the embargo period, to indicate it was available for review by the provider, but not available yet in PG to the patient. Once displayed, each result included the test name, result value, "#" character if the value is out of reference range, units, reference range, and an "information button" with a hyperlink to general reference information about the result that opens in a separate window and is not maintained by PG.

General reference information in context was a design requirement. Lab Tests Online® (LTO), www.labtestsonline.org, a public resource for patients and caregivers with professionally reviewed articles, was selected for use during the pilot because of the breadth and quality of its content, and the ability of an outside site (like PG) to directly address a search query for a specific item.

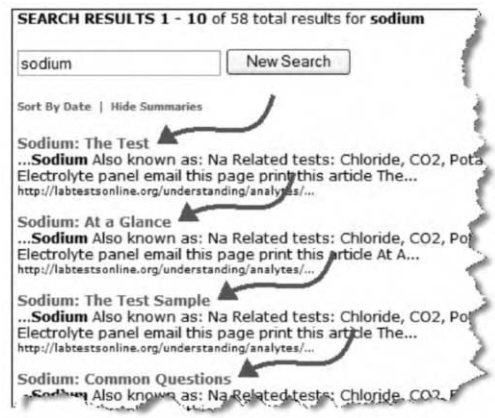

Figure 2 – Lab Tests Online® search results for Sodium

To minimize maintenance and gain sensitivity of the information retrieved given a variety of user interests, the information hyperlink avoids tight coupling to a single LTO page – but rather – executes a search query using the name of the result, bringing the user to the "Search Results" page in LTO (Figure 2). Each link works this way. If LTO were to modify their syntax for search queries, every PG link would break, making it easier to detect the problem, and simple to correct and maintain across all 170 CDR results items.

LMR Physician Results Letter design. The new LMR feature for sending a Results Letter was essentially a button called "Send to PG" placed on the RM screen to allow the provider to take action – to make a Results Letter available to the patient via PG. When this happens, the patient is notified that a message from their doctor is waiting for them in PG. Multiple patient Results Letters can be "sent" as a batch to individual patients, just as batch printing is supported. In addition, the Results Letter display in LMR was enhanced to indicate when the patient had "read" the document (the display includes "first opened" and "last opened"). Before and during this pilot, providers had the ability to type or copy/paste results from LMR into a PG message and send that message to the patient. Both methods were voluntarily used during the pilot by physicians to provide interpretation of results to the patient.

Configuration tool. A setup tool was created to activate the feature for each practice (default: all patients belonging

to that practice have the new features). In addition, a tool was created for activating the feature for a discrete list of patients to support limited deployment during the pilot. Auditing tools for pilot analysis recorded whether a patient ever looked at the new Results page in PG, or whether a patient ever received a Results Letter from a provider. Patient web surveys were sent to participating patients using Perseus SurveySolutions® software. Survey results were submitted anonymously.

Participant recruitment

Two primary care practices volunteered to offer the new features to their patients and physicians. Practice A activated the features for 2 (of 8) physicians and all of those physician's patients. Practice B activated the features for all 8 of their physicians, and all their patients. Patient and physician use of the new features was completely voluntary. Physicians attended a single brief training session to familiarize them with the results that patients could see, and with the new button in LMR to send a Results Letter online to PG.

Patients were notified of the new feature and invited to try it in two ways. A PG message was sent to each eligible patient (within the secure PG portal), which also triggers a notification message to the patient's preferred email address (e.g. gmail, yahoo, etc). Upon signing in to PG, a Home page message announced the new features. This page displayed each time a user signed in.

Pilot physicians and staff were contacted about their experience 8 weeks after the pilot began; after twelve weeks, a brief 10-item web-based survey was administered to patients who had used the new features to assess usability and impact.

Spontaneous "feedback button" information from users was also collected.

Results

Demographics and usage for PG results

The pilot users included a total of 10 physicians in 2 practices who offered the PG Results feature to 3,583 patients with a PG account (mean age 42 years, 49% female) as shown in Table 1. 2,417 (67%) of those accounts had been activated (included an external email address for patient notification). Ten percent of email notification messages were returned "undelivered". Over the next 8 weeks, 842 patients signed in to PG, and 594 (71%) viewed the Results page. Patients in practice A who viewed PG Results also viewed LTO reference information in 50% of cases. Spontaneous feedback from patients was uniformly positive. Suggestions for enhancements included: showing more results; showing radiology and cardiology reports; adding a graphing feature; and some usability improvements.

The survey results (Table 2) were strongly positive. They were collected anonymously (an IRB waiver was obtained since a survey response was considered an implied consent), so demographics are not available. Among 128 respondents, 89% felt the feature was "easy to use", 85% felt results were clearly presented, 68% felt they would recommend the site (with the new feature) to others, and 64% found the LTO reference information "very helpful". Three-quarters of respondents said they viewed the reference information. One in six respondents (17%) said they had questions for their provider as a result of seeing their results information. 31% wished for additional results, and 23% felt improvements would make the feature even more valuable.

LMR results letter "sent to PG"

In the first 6 weeks of the pilot, 5 providers sent 121 Results letters to 107 patients. A total of 65 patients (61% of 107) opened 70 letters (58% of 107). Fifty letters (41%)

Table 1 – Results: Patient Demographics, Account Activation, Results Usage, and Survey Completion Rate

Practice	Pilot MDs	PG Accounts	Pt Mean Age %F	Account Activated	Signed in	Viewed Results	Survey Invited	Survey Complete
A	2	140	49 (62% F)	113 (81%)	64	54 (84%)	180	15 (8%)
B	8	3443	42 (48% F)	2304 (67%)	778	540 (69%)	594	113 (19%)
Total	10	3583	42 (49% F)	2417 (67%)	842	594 (71%)	774	128 (17%)

Table 2 – Results of Patient Survey: PG Results feature

PG Results: Patient Survey Question	Strongly Agree	Agree	Neither	Disagree	Strongly Disagree	Uncertain	Not Answered	N
1. Results easy to use?	33%	56%	3%	4%	2%	1%	1%	128
2. Results clearly presented?	30%	55%	6%	3%	3%	2%	1%	128
3. Would recommend to others?	29%	39%	24%	2%	2%	3%	1%	128
5. Additional info: Very Helpful?	27%	37%	12%	2%	1%	2%	20%	128
Patient Survey Question		**Yes**		**No**		**Uncertain**	**Not Answered**	**N**
4. Viewed additional information?		75%		18%		6%	1%	128
6. Questions for your provider?		17%		72%		7%	4%	128
7. Want additional results?		31%		30%		34%	4%	128
9. Could it be more valuable?		23%		38%		31%	7%	128

were opened in the first week, 60 (50%) by the end of the second week, and 70 (58%) by the 26th day.

Fifteen (19%) of 80 patients who viewed the Results Letter sent by their physician responded to a brief survey. 13 (87%) felt it was easy to use; 10 (67%) felt they would recommend it to others; 10 (67%) preferred receiving the letter "Online only" and 4 (27%) liked receiving it "both online and printed"; a few suggested offering a "tabular" format with export to a spreadsheet. Ad hoc physician feedback was positive; and one physician asked if he could be notified when an online letter was *not* opened by the patient, so clinical staff could escalate if needed.

Spontaneous and solicited feedback from pilot physicians was positive. Some physicians reported that they no longer send hard copy Results Letters via postal mail, while others continue to do so. Physicians reported *no* increase in messages from their patients about clinical inconsequential results, such as an abnormal MCHC (mean corpuscular hemoglobin concentration). They reported *no* extra time expenditures as a result of the new features.

Discussion

What have we learned from this pilot? Patients and their providers have long communicated about laboratory results. Patient access to their medical chart has been legally mandated for decades. Why is patient *electronic* access via a secure portal so important?

Poor communication and disrupted follow-up of abnormal results are a problem in emergency rooms [3] and ambulatory care [4,5]. Furthermore, patients during emergency, primary or specialty care are all too often unaccompanied [6,7,8] by the clinical information from their previous care, leading to poor quality. This can also be costly, especially when errors in test follow-up and interpretation are contributors to malpractice claims [9], as they commonly are.

Physicians play a role in communication breakdowns – usually despite their best efforts and due in large part to a lack of adequate "systems" in place to support error-free practice [10]. When asked directly, many physicians freely acknowledge the need to improve their processes for results management, voicing worries about delays and results-tracking failures [11].

Can communication failures be mitigated or avoided entirely through process understanding and with the help of information transparency? Many patients think so – they want access to their own clinical information, including laboratory results [12,13]. Patient safety experts also believe changes will help, such as explicit criteria for communication of abnormal results, test-tracking systems for ordering providers, and the use of information technologies [14]. Many physicians, recognizing that their usual methods of "surveillance" for clinically important information can be fragile at times, believe that patients [15] and automated systems [16] can help.

So, if patients, providers, and safety experts support transparency, what makes it so challenging to share laboratory results electronically using a secure patient portal? Our pilot experience identified the following challenges:

Clinical sensitivity. Individual physicians resist changes that they feel will create anxiety among their patients, such as an abnormal test result without proper interpretation and delivered at an appropriate time in an appropriate way. When a patient views a result online for the first time, is it empowering? Is it an alarming indicator of a new, serious problem? Will it reinforce the confidence placed in the physician, or create friction?

Secure messaging, Results Letters, LTO, and other tools that enhance *interpretation* of results are important. Any communication approach (e.g. telephone, face-to-face, etc) can lack sensitivity, not just electronic information sharing. Also, if a less permissive provider denies their patients electronic access to results, the patients can still access them from another.

Physician workflow. Results management practices by physicians are extremely varied, even for the same physician. Physicians are notified of results by phone, pager, paper, fax, or computer. The timing of their notification varies from immediate and predictable, to delayed and unpredictable. Some physicians have staff to help them manage results, while others do not. Those who practice part-time or cover for others may not have access to results that are ready for review.

Systems to improve results management must address the larger context challenges, not just the technology. An important reason to offer patients direct electronic access to their results is that it prevents the unintended isolation of information from the patient, particularly when overworked physicians and staff are unable to detect and correct notification errors.

Individual fears. The fears of individual physicians and organizational leaders can cause inaction. Despite years of experience at Partners and elsewhere, uninitiated physicians are convinced an "avalanche" of electronic messages, worried patient telephone calls, malpractice risk, and un-reimbursed tasks will befall them with the activation of online lab results.

Education and leadership are needed to support medical professionals as secure patient portals are introduced. Vigorous efforts are needed to address the fears that are unsupported by data, since they are emotionally based and may be refractory to modification through data alone. Direct physician experience is often the most effective antidote for fear.

When concerns *are* supported by data, they should not be ignored. An example from our pilot experience is illustrative. Two business days from having their tests, patients have access to up to 50 different results, whether their physician has reviewed them or not. Pilot physicians are comfortable with this since results are reviewed and interpreted quickly in their practices. Different practice physicians (beyond the pilot) have questioned whether more delay is needed than two business days, since part-time physicians may not see test results for a week or

longer. Many physicians "batch" their review of results – waiting 3 weeks or longer to write a results letter to a patient, once all results are back (e.g. pap smears take 3 weeks). Work to address these practice variations is underway.

Engaging the patient. In many ways, we are exquisitely attuned to our patients. Yet, in the jumble of priorities, time pressures, reimbursement challenges, risk management, regulations, privacy concerns, budget priorities, and strong practitioner autonomy, the voice of the patient can be weak.

It is critically important to engage patients directly in change efforts and to value their perspective. Patients are invited on the expert panel that recommends additional chart information to share, and patient-employees are participating on another key project. The direct involvement of our patients is key.

Conclusion

Partners' feasibility pilot for sharing a limited set of laboratory results with patients in primary care was successful as measured by usage, patient satisfaction, and physician-reported experience. Now that pilot has ended, the features are being activated for additional practices beyond the pilot.

Our work identified a number of issues and challenges – some with the technology, and others due to workflow and organizational issues. Having gained experience in sharing laboratory results electronically, we plan to leverage the expert panel, lessons learned in the pilot, and patient enthusiasm to accelerate our progress toward medical information transparency.

We believe that electronic patient access to their own results and other medical chart information, if provided with appropriate privacy safeguards and clinical sensitivity, offers a powerful remedy to communication breakdowns. Confidentiality – keeping clinical information isolated from others who do not need or have authority to access it – is critically important. But clinical information isolated from the *patient* can be a critical mistake – unhelpful, inappropriate, and potentially quite dangerous.

We look forward to the challenges ahead of accelerating information transparency for patients while at the same time strengthening the physician-patient relationship, built upon caring, communication, and trust.

Acknowledgments

We are grateful to Ted Eytan MD, Group Health Cooperative, Seattle, WA, USA, who provided useful guidance throughout this pilot.

An Evolving Systems-Based Methodology For Healthcare Planning

Jon Warwick and Gary Bell

London South Bank University, London, UK.

Abstract

Healthcare planning seems beset with problems at all hierarchical levels. These are caused by the 'soft' nature of many of the issues present in healthcare planning and the high levels of complexity inherent in healthcare services. There has, in recent years, been a move to utilize systems thinking ideas in an effort to gain a better understanding of the forces at work within the healthcare environment and these have had some success. This paper argues that systems-based methodologies can be further enhanced by metrication and modeling which assist in exploring the changed emergent behavior of a system resulting from management intervention. The paper describes the Holon Framework as an evolving systems-based approach that has been used to help clients understand complex systems (in the education domain) that would have application in the analysis of healthcare problems.

Keywords:

Healthcare Systems, Systems Thinking

Introduction

In recent years there has been a growing acceptance among those working in the field of operational research that effective planning, conflict resolution, management and the control of change have become more and more difficult in domains that display 'soft' characteristics. Indeed, the emphasis in such situations often changes from one of 'achieving goals', to one of 'understanding and exploring' the problem situation and a number of methods have evolved to help decision makers better understand the web of complex issues with which they are faced [1].

Within the context of health informatics, and indeed of healthcare planning in general, there seems to be agreement that the issues faced by practitioners, decision makers and those involved in establishing policy are in a domain that could be described as [2]:

"… more information intense, more organizationally complex, more turbulent, more paradoxical, more subjective, and more emotionally charged than other industries and businesses."

The characteristics of this description are typically those of issues situated in the 'soft' domain (as described in [1]) and in response there has been some interest in using 'soft' approaches to help decision makers in the healthcare environment understand the issues they are faced with and resolve problems. To date, these approaches seem to have been largely restricted, quite understandably, to applications of systems theory and in particular soft systems methodology (SSM) either in an extended form (see for example [3, 4]) or in combination with other techniques [5]. Other more traditional operational research methods have also been used [6].

In this paper we describe the Holon Framework which is itself an interdisciplinary approach derived from the systems movement and software engineering. It has had some success in teasing out key issues within 'soft' domains and, we argue, could provide those engaged in healthcare planning with an approach for better understanding the issues they are faced with and a means for better controlling change processes in what is often a turbulent environment.

Organizational complexity and 'messes'

All planning processes have limitations. The extent to which these limitations restrict the effectiveness of the resultant plans will, to a certain extent, depend on the nature of the organization concerned and the organizational culture. In terms of healthcare planning, a number of authors have tried to produce a taxonomy of healthcare issues and one such is that of Braithwaite, Hindle, Iedema and Westbrook [3] who characterize four deep-seated problems in healthcare and describe their occurrence in terms of a quasi hierarchical domains. The first domain is that of high level policy formulation and its implementation. Policy formulation is often highly politicized and contested and even what seems to be relatively clear policy is sometimes interpreted and actioned inconsistently. The second domain is the organizational or institutional domain in which the complex nature of interacting, collaborating and co-operating healthcare organizations which make up a national healthcare service can lead to fragmentation of policy, conflicting interpretations and goals, poor communication and a perceived lack of resources. The third domain relates to the service level where clinicians and patients interact. Issues here relate to resources and workloads, unachievable patient expectations and lack of communication between clinical groups. The fourth domain is at the individual level of one-to-one interaction between health professional and patient. Here the issues relate often to the difficult choices that must be made, bal-

ances between organizational and individual work duties, low morale, work loads etc. In terms of producing effective decision making processes we can add to this list the potential problems relating to achieving 'buy-in' both from clinical and non-clinical staff and from senior management, the difficulty of embracing creativity and intuition within the process and the desire for plans which are sufficiently detailed so as to give clear direction but also remain flexible in response to environmental changes. Classic texts such as Mintzberg [7] document many of these issues.

We believe, as do others working in the field of systems theory, that resolving these issues centres around the ability to understand the nature and culture of the organization and to be able to capture some of the complex behavior and beliefs of actors within the organization. This belief is, of course, not new. Ackoff [8] contends that managers are not confronted with problems that are independent of each other, but with situations that consist of dynamic, transient and complex problems that interact with each other. He calls such situations 'messes'. Furthermore, he states [8]:

"Messes are systems of problems, the sum of the optimal solutions to each component problem taken separately is not an optimal solution to the mess. The behavior of a mess depends more on how the solutions to its parts interact than on how they act independently of each other."

The taxonomy of healthcare issues of Braithwaite, Hindle, Iedema and Westbrook briefly described above, captures some of the key problems that must be addressed if complex healthcare issues are to be addressed and which encourage the use of systems based enquiry methods. Firstly, the four domains at which the issues have been identified illustrate the range of 'voices' that must be heard if a full understanding of the problem situation is to be gained. Secondly, these 'voices' speak with very different volume in terms of their political and organizational power. Thirdly, the range of issues addressed through the four domains is huge and includes at one extreme high level policy development and at the other the one-to-one patient-clinician interaction. Fourthly, there is a key issue of complexity which is usually thought to be addressed through the application of systems thinking ideas but is often not clearly understood by stakeholders within the context of the problem. We shall return to the issue of complexity shortly.

Much work has been carried out in recent years in developing problem structuring methods that aim to provide tools for thinking about these messes [1]. Systems thinking has its advocates in healthcare applications [9] and one approach derived from systems thinking is Checkland's Soft Systems Methodology [10]. Soft Systems Methodology advocates two streams of enquiry which explore the facts and logic of the situation from the perspectives of those involved (logic-based enquiry) and also the myths and meanings which constitute what we (as individuals) mean by an organization and organizational culture (cultural enquiry). Cultural enquiry will include roles, norms, and values as well as political and other power related relationships and control processes. Note here that the phrase 'myths and meanings' encompasses a wide range of descriptors and is used to contrast with 'facts and logic' which make up the complementary stream of enquiry.

SSM refers to the importance of enabling change that is both systematically desirable and culturally feasible. Three questions arise at this point. Firstly, how will we know if the planned changes are culturally feasible? In other words, how do we uncover and explore the organizational culture that we are working within? Secondly, it may be the case that the changes are not culturally feasible within the current dominant culture so how might we perhaps influence change in the organization's culture? Thirdly, how can we ensure that the systematically desirable and culturally feasible change is enacted? In other words, how can we control the change process once changes have been identified?

The first two questions we have addressed in other work describes later in this paper. The third is key and we shall concentrate on this since the world of systems theory, information systems and, indeed, IT in general is littered with stories of system changes, organizational restructuring and IT interventions that have failed at the implementation stage [11]. UK healthcare services are no exception to this with new IT systems failing to produce the expected benefits and massive organizational change generating unexpected consequences [12]. Part of the explanation for this can be related, no doubt, to poor implementation procedures or IT system specification, but there are also issues related to complexity which need to be addressed. For example, in relation to the implementation of IT systems within healthcare, it has been noted that [5]:

"Given the complexity of the context, health informatics cannot simply focus on technical or information systems aspects alone. It has to take account of their relationship with clinical and managerial processes and practices as well as deal with multiple stakeholders and organizational cultures and accompanying politics."

We would argue that this statement does not, potentially, go far enough. It may well be the case that there are complex formal managerial and organizational relationships that need to be considered, but complex systems may well have a host of *informal* processes and relationships that are hidden from key stakeholders and organizational charts. The influence of informal processes and relationships may only become apparent once organizational changes are made.

Brookfield and Smith [13] argue that there is an inherent weakness in the management maxim that 'if you can measure it, you can manage it'. Specifically the weakness is concerned with the measurement techniques used which often assume linearity of relationships and a reliance on *a priori* data as a predictor of future performance. If we couple with this a recognition that we may well only have a partial understanding of the effects of system intervention (what Simon referred to as bounded rationality [14]) then predicting how a system may react to structural or environ-

mental change and controlling the change process itself becomes difficult.

System complexity results in only a partial understanding of the true dynamics of the system [13]. Important here are macro and micro system properties and the notion of 'downward causation'. Downward causation is the process through which a system's micro components adapt to macro level intervention and this adaptation can, potentially, be very unpredictable. Thus the effect of macro level managerial intervention could be unpredicted micro level changes the emergent properties of which may subsequently influence the properties of the wider system. Brookfield and Smith argue that there is:

" ... a degree of uncertainty associated with intervention outcomes from a managerial perspective because the performance metrics of models of intervention (their motives, logic, organizational scope, timescales, and implementation) cannot capture easily, if at all, emergent system responses."

Many public bodies in the UK (and this applies particularly to health and education) are subject to high levels of government scrutiny which involves target setting and the measurement of 'quality standards'. Clearly these issues relating to our ability to measure and predict system change are crucial in understanding how systems will respond to management intervention. It is difficult to predict system responses to change however systematically desirable and culturally feasible they might seem to be. Thus high level policy formulation in the earlier taxonomy may have unpredicted effects at the lower levels relating to clinical groups and individual personal transactions. Brookfield and Smith go on to contextualize their argument within the UK healthcare environment and use the introduction of Payment by Results [15] as part of the UK healthcare system as illustration.

The Holon Framework

The Holon Framework [16] takes from the systems movement the notions of systematic wholeness and systematic analysis and combines aspects of SSM with the Goal/Question/Metric (GQM) method [17]. The GQM method is an integral part of a goal-oriented measurement initiative [18] which aims at the continuous improvement of software processes and products and which we now adapt for use with SSM in 'soft' contexts. The GQM method is a mechanism for defining and interpreting a set of operational goals using measurement which address the specific needs of a project and organization. Thus, within its process model the Holon Framework has two modes of working in that the 'soft' part relates to improvement by addressing questions associated with 'the what', 'the where' and 'the who' while the 'hard' part relates to control by addressing 'the how', 'the why' and 'the when'. Checkland argues that researchers who apply systems concepts to investigate social situations face difficulties because these situations are never clearly defined. He prefers to use the word 'Holon' rather than 'system' as it highlights a distinctive approach to investigating such situations. We consider a Holon to be an abstract representation of a social situation that captures all problems. It is used as a framework to discover relevant issues from stakeholders' points of view; these are organized in a layered structure.

The Holon Framework combines soft elements (Framing, Enquiry, Visioning) and hard elements (Metrication and Modeling). It addresses 'the who', 'the what', and 'the where' type questions for the current state S_0, and generates a vision of a desired state S_1. Additionally, this produces a relevant metrics programme, and the collected metrics can be used as dynamic behavior patterns. It is then possible (using modeling techniques such as system dynamics) to tackle 'the how', 'the why' and 'the when' type questions. The metrication and modeling stages of the framework we see as crucial in application to complex systems.

Table 1 - Aims of Holon Framework Stages

Stages	**Stage Aims**
Framing	This stage has a number of objectives among which are that the stakeholders are identified and become familiar with the framework and that the investigators gain a broad understanding of the situation so that relevant holons (and sub-holons) can be identified and labelled.
Enquiry	This stage aims to identify the problems as perceived by the stakeholders.
Visioning	This stage attempts to collate various problems into themes to be addressed. These can be linked with a sub-holon hierarchical level.
Metrication	This stage analyses the themes and links the emergent problems with the appropriate hierarchical level. Metrics are generated to characterize specific problems.
Mathematical Modeling	This stage aims to analyse the data further using appropriate modeling techniques – for example a system dynamics model might be used to explain the situation of concern.
Action	This stage aims to facilitate change having achieved understanding of the area of concern

While it is essential to generate a vision of future activity and to use the associated metrics to measure our progress towards the vision once action has been undertaken, it is

also crucial to understand, through the modeling stage, how the system is evolving and the emerging dynamics that are being exhibited via the data collection process. Morecroft argues [19] that dysfunctional behavior can be prevented by investigating the systemic consequences of various decisions so that there is advantage to be gained by turning to traditional modeling techniques such as system dynamics. Thus as the system moves, perhaps, to a new equilibrium point as a result of the management intervention we can observe and understand this process better through the modeling and metrication stages.

The most important traits of this framework are:

- it provides an holistic view of a situation;
- the use of a soft methodology to enable the capture of the stakeholders' point of view;
- the researcher's role is that of a facilitator;
- the monitoring and controlling of the effects of bounded rationality and seeking to uncover new emergent system behavior;
- an enhanced understanding of the problem situation by the client group and the development of a desirable and feasible vision;
- the creation of a relevant metrics programme;
- production of the 'best solution' to achieve the vision given cost and other environmental constraints;
- the continuous use of system dynamics models to examine various 'what-if' scenarios and enhance understanding of the effects of macro management intervention.

The Framing and Enquiry stages are means of exploring issues, drawing out themes, boundaries and experiences that the stakeholders feel are important within the problem context. These first two stages encourage a thorough examination of the current state, S_0, resulting in its definition. Next we move to Visioning in which the client group explore a vision of the future that they feel is achievable and desirable. The vision will be expressed in terms of the holon structure used throughout the enquiry and may be expressed formally in terms of root definitions. It is important though that the discussion of S_0 and the vision, S_1, are linked through issues and problems. The stakeholder group should identify the critical issues and problems which require resolution if movement towards the vision is to be achieved. The issues and problems will generate goals, questions and metrics. The Metrication stage allows the stakeholders to learn more about the problems and issues in S_0, and the subsequent Metrics Collection stage enables them to measure their progress towards S_1. This is followed by the Action stage in which modeling is undertaken to clarify the processes which can effect movement from S_0 to S_1.

We have applied the emerging Holon Framework to situations characterized as 'messes' and have been able to demonstrate the value of the approach [20]. In addition, previous work with the Holon Framework with regard to the first two questions posed earlier has encouraged the view that it is possible to capture aspects of organizational culture and perhaps to influence changes in culture by using the framework [21]. We have also been able to demonstrate the organizational learning opportunities that are uncovered by use of the framework within the domain of higher education [22] a domain which has many of the same characteristics as the healthcare domain and, indeed, many other complex human activity systems.

Conclusions

The healthcare domain is characterized by many of the same problems that afflict other complex systems in the management and business domains. What is different, however, is the critical nature of many of the decisions that need to be made whether these are part of the care process itself, or related to improving delivery, care and management of services. This emphasizes the need to monitor and control the effects any of intervention directly resulting in system change. There are many interested parties (representing the public, health professionals, politicians and commerce) and, as stated in [9], there needs to be a:

"... judicious consideration and balancing of cultural, managerial, clinical, technical, legal, political and economic issues."

Soft Systems Methodology has been used to some effect to help decision makers understand some of the issues, but we would argue that it has some shortcomings in application to healthcare services that the Holon Framework can help to overcome. In particular we feel that:

- The Holon Framework captures and structures different perspectives of the problem situation in much the same way as SSM would do. To that extent, it has the capacity to allow participant to explore both the systemic issues and the cultural (indeed personal) issues that reflect their actions within the system;
- The framework can also allow exploration of organizational culture and provides a framework within which organizational learning can take place;
- The framework allows the development of a vision and, furthermore, the identification of metrics that will measure progress from the current position towards the vision;
- Metric data collection provides reference mode behavior which can be used as a basis for system dynamics modeling so that underlying dynamic effects within the system can be uncovered. This provides a means of measurement of progress towards the vision and also a window on the system through which unexpected properties emerging from the system may be observed and investigated. These unexpected changes bought about as result of management action will result in learning taking place as the client group seek to understand the nature of this difference between expected and observed outcomes.

The modeling and metrication stages provide stakeholders with the means to uncover system changes at the micro level as they occur and begin to produce emergent effects. Stakeholders are not bound to traditional linear models or a

priori data in trying to assess system response to any macro managerial intervention, but can use the emerging metrics to confirm beliefs or to uncover variance from expectation which might lead to significant learning opportunities regarding their own beliefs and actions, or perhaps those of others.

One strength of the Holon approach lies in discovering the complex interrelationships among the issues at play within the 'mess', and this may be explored using, for example, system dynamics. As an example from one education case study [20] admitting poorly qualified students increases the pressure on student support resources, decreases course quality, increases the burden on academics and yields an increased withdrawal rate among students. This results in the need to find additional students the following year. Dealing with poorer students reduces the academic productivity of staff, which reduces the reputation of the institution and the course. A spiraling negative loop structure begins to dominate and management intervention is required coupled with appropriate resource allocation to reduce the dominance of this loop. Such actions can be explored systematically and dynamically using appropriate modeling methods within the Holon Framework.

We argue, therefore, that the Holon Framework would have considerable advantages over other systems approaches in application to the healthcare sector both in helping to understand and to deliver system change.

Model-Centric Approaches for the Development of Health Information Systems

Mika Tuomainen[a], Juha Mykkänen[a], Heli Luostarinen[a], Assi Pöyhölä[b], Esa Paakkanen[a]

Abstract

Modeling is used increasingly in healthcare to increase shared knowledge, to improve the processes, and to document the requirements of the solutions related to health information systems (HIS). There are numerous modeling approaches which aim to support these aims, but a careful assessment of their strengths, weaknesses and deficiencies is needed. In this paper, we compare three model-centric approaches in the context of HIS development: the Model-Driven Architecture, Business Process Modeling with BPMN and BPEL and the HL7 Development Framework. The comparison reveals that all these approaches are viable candidates for the development of HIS. However, they have distinct strengths and abstraction levels, they require local and project-specific adaptation and offer varying levels of automation. In addition, illustration of the solutions to the end users must be improved.

Keywords:

health information systems, modeling, information systems development

Introduction

The understanding of healthcare activities is central for the development and integration of health information systems (HIS). The specification and improvement of healthcare processes is pursued in relation to complex activities which involve lots of communication in the changing healthcare environment. To support these needs, health care actors are increasingly applying methods and best practices of business process development and enterprise modeling for analyzing care activities and clinical routines, building patient-centric processes and improving the knowledge and understanding of health care organizations [1, 2]. *Models* are used to illustrate, identify improvements or simulate organizational processes and individual activities in healthcare. Modeling also supports the specification of requirements and creates a basis for the implementation or integration of health information systems.

Modeling is used widely in software engineering and information systems development projects. Models are produced to aid the communication between users, healthcare managers, architects, designers and developers. Models add clarity to the application domain and the design, providing formalization and abstraction to the understanding of problems and solutions. Good models support complexity, cope with changes in the requirements, are economically implementable and promote information and knowledge longevity [3]. Models contain observations, requirements and assumptions about the current or prospective state and solutions of a specific domain. Numerous approaches, methods, notations and tools have been suggested and used in modeling. However, an analysis of different modeling approaches is needed for identifying a suitable approach for given development needs of HIS. It is also necessary to identify which aspects are covered by different modeling approaches and which features of different modeling approaches support the specific needs of healthcare.

In this study, we compare three model-centric approaches in relation to the development and integration of health information systems. The aim is to identify the strengths and weaknesses of different types of approaches and to bridge the gap between the healthcare knowledge and software development. The comparison is based on the use of a conceptual framework, the literature, and our experience of applying these approaches in service-oriented HIS development and integration.

Materials and methods

In this section we introduce three model-centric development approaches and a framework for the analysis and comparison of these approaches. For this analysis, we have selected three very different model-centric approaches which have been applied varyingly in our projects and which can be applied in the development and integration of health information systems.

An analysis framework for modeling approaches

To provide a systematic approach for this study, we are using a structured framework for assessing different modeling approaches. The *main purpose* of each approach is a viable starting point for such an assessment. In addition, we especially consider the support provided by each approach in different phases of an *information systems development (ISD) value chain* [4]. This chain initiates from the *understanding of the target domain*. It then proceeds to the *specification of goals and requirements* and to the *design* and *development* of solutions. The solutions are then *used in the healthcare environment*. To assess the completeness of the approach, we consider distinct aspects of information systems [5]: *structure* (which concepts and entities are included), *function* (which tasks are performed), and *behavior* (when and using what kind of

interactions the tasks are performed). Each aspect has different features in different phases of the ISD chain. We argue that a modeling chain which supports the traceability of these aspects in different phases reduces the distance between healthcare knowledge and software development [4].

Other aspects which improve the traceability should also be considered in relation to HIS [4]. Due to the information-intensive nature of healthcare, special emphasis should be paid to *semantic elements and entities* in different phases to achieve a shared understanding of complex health information and processes. In addition, the *illustration of solutions to the end users* already in the early phase of the process is beneficial. Furthermore, the support for *accurate, consistent, atomic and unambiguous documentation of the requirements* promotes the utilization of tacit knowledge and shared understanding.

In addition, we consider how *definitive* the approach is, or how many local and project-specific extensions are needed or allowed, and if there are guidelines to produce the results on a specific *abstraction level*. Furthermore, the *visibility of end users or process participants* in the models is considered. Traceability and productivity can also be improved by providing *automatic transformations or generation* of implementations from the models. Finally, the specific usage contexts and the *dissemination* situation of the approach are considered.

Model-Driven Architecture (MDA)

The *Model-Driven Architecture (MDA)* by the Object Management Group (OMG) supports software development through modeling techniques such as Unified Modeling Language (UML) [6]. Its abstraction levels separate logical and technological models: *computation independent* (CIM), *platform independent* (PIM) and *platform specific* (PSM). Three primary goals of the MDA are portability, interoperability and reusability through architectural separation of concerns.

A *computation independent model (CIM)* shows the system in its operation environment. The structure of the system, however, remains hidden or undetermined. The domain model of CIM helps in presenting exactly what the system is expected to do. A CIM often consists of several UML models, some providing more detail than others, or focusing on particular concerns. The primary user of the CIM is the domain practitioner, and it aims to bridge the gap between domain and IT experts. CIM is used as an aid to understanding the problem, but also as a source of a shared vocabulary for use in other models.

A *platform independent model (PIM)* describes the system without showing aspects which are specific to the platform, or the technology that is used to realize the system. A PIM might consist of various enterprise, information and computational models. A PIM is suited to one or more architectural styles. Concepts such as technology-neutral virtual machines can be used for platform independence in PIMs [6].

A *platform specific model (PSM)* is produced by transforming a PIM. It combines the specifications in the PIM with details which specify how the system uses a particular type of platform to provide an implementation [6]. Transformations between PIMs and PSMs can also be repeated: each new platform provides new features to the implementation. Thus there can actually be several levels of PIM and PSM descriptions and several definitions of a platform even within one system.

In an MDA specification of a system, the requirements in the CIM should be traceable to the PIM and PSM constructs that implement them, and vice versa. An MDA tool might transform a PIM directly to deployable code, without producing a PSM that would be visible to the user. This requires models on a very detailed level or many tool-specific assumptions. In practice, the application of MDA requires specific interpretations which are not provided in the MDA specifications. For this study, we have used the approach of an MDA toolkit [7] which defines the use of UML models on CIM, PIM and PSM levels and the phases of the software development lifecycle.

Process Modeling with BPMN and BPEL

Business Process Modeling Notation (BPMN) [8] is a graphical notation for process modeling. It aims to be understandable by different users from business analysts to developers and people who manage and monitor business processes. *Business Process Execution Language for Web Services (BPEL)* [9] provides an XML-based language for the specification of business processes and interaction protocols. BPMN specification contains a mapping to BPEL. Hence, BPMN and BPEL can be used together for the modeling and web services-based implementation of processes.

There are three basic types of BPMN process models. The *private processes* are internal to one organization and often describe accurate workflows. Private processes can be transformed to executable BPEL descriptions. *Public processes* describe the interactions and messages between the private processes and other participants, displaying the communication activities and the flow control mechanisms. *Collaboration processes* in BPMN describe interactions between two or more business entities (public processes). Collaboration process can be potentially mapped to collaboration protocols of electronic business such as ebXML or RosettaNet. BPMN can be extended using BPMN artifacts that provide extra information in modeling tools. Such artifacts can be used to support the requirements of a vertical domain such as healthcare. Although the graphical diagram is the most notable part of BPMN, non-graphical attributes play an important role when BPMN models are mapped to execution languages.

BPEL descriptions aim to support the automated execution of processes, defining the process from the standpoint of one participant only [9]. External partners of the process are defined as web services and contacted through interfaces described using WSDL (Web Services Definition Language). The external view of a BPEL description is also a web service. Public BPMN processes can also be transformed to *abstract BPEL descriptions* which describe interactions and hide other than communication-related aspects of the executable process. The BPEL specification does not include a graphical notation, but the notations have been mostly tool-specific. BPMN has been suggested as a generic graphical notation for BPEL [8].

HL7 Development Framework (HDF)

The *Health Level 7 (HL7) Development Framework Methodology Specification (HDF)* [10] is a framework for analyzing, designing, and documenting the processes, tools, actors, rules, and artifacts of the HL7 version 3 standards development. The approach is based on the use of a model-driven methodology and the derivation of specifications and other work products from a common set of reference models. It supersedes the earlier Message Development Framework [11].

An essential element in the HL7 Version 3.0 and the HDF is the *HL7 Reference Information Model* (RIM). All information models in the HL7 version 3 standards are based on the RIM and follow structural vocabulary specifications. The RIM is described using UML class diagram notation [11]. In addition, other modeling practices of the HDF apply some UML models directly. The HDF UML profile also defines extensions to the meta-model of the UML.

The *development process* of the HDF has seven phases [10]: project initiation, requirements analysis and documentation, specification modeling, specification documentation, specification publication, specification approval, and standard profiling. The requirements analysis and documentation, specification modeling and standard profiling phases are within the scope of this work. Several diagram types, models and design and documentation tools are utilized in these phases. The *requirements analysis and documentation* phase produces artifacts which describe the healthcare business in a given domain using its terminology. In this phase, the business processes are described using *storyboards*, *use cases* and *activity diagrams*. In addition, spreadsheets and class models are used for *message contents* and *domain analysis models (DAMs)*. The *business rules* are described by defining *relationships, triggers and constraints* to the exchange of data, and *state diagrams*. The domain experts usually develop these specifications and a *glossary* which are then used by technology experts for developing HL7 v3 messaging specifications. In the *specification modeling* phase, the reference models are constrained into design models, based on the artifacts from the previous phase. Some of the artifacts produced in this phase can be balloted as standards. Central information design models include *domain information model (DIM), constrained information model (CIM), and serialized constrained information model*. In addition, sequence and collaboration diagrams are used to describe the needed interactions and application roles and to link them to specific messages. The reuse of design model components and the harmonization of design models with the RIM are also considered. In the *standard profiling* phase, the specified standard can be profiled: its elements are annotated, constrained, extended, or left unchanged. This leads to a set of specification profiles and conformance statements. The specifics of the information exchanged, the dynamic model and the acknowledgement responsibilities are defined. In addition, this phase considers user documentation and Implementation Technology Specifications (ITS) such as XML schemas for the developers.

Results

The analysis of the three model-centric approaches is presented in Figure 1 and Table 1. Figure 1 relates the suggested modeling artifacts of each approach to the ISD value chain. Table 1 organizes the other considerations of our framework. In addition to these considerations, some specific features of each approach were observed during the analysis.

The MDA is an overarching approach. It aims to support all aspects of application development in a way which isolates technology changes from the logical solutions. The other approaches in this comparison could be included in an MDA-based approach. The MDA has been used in very different ways, and the meta-level foundations for the MDA are not required in various tools or projects. Hence, there is no "one MDA" but its application depends on situation-specific needs.

Process modeling with BPMN excludes many aspects of the holistic systems development, such as organizational structures and resources, functional breakdowns, data and information models, strategies and business rules [8]. Users are not especially considered beyond "user tasks" in BPMN. On the other hand, BPEL engines provide valu-

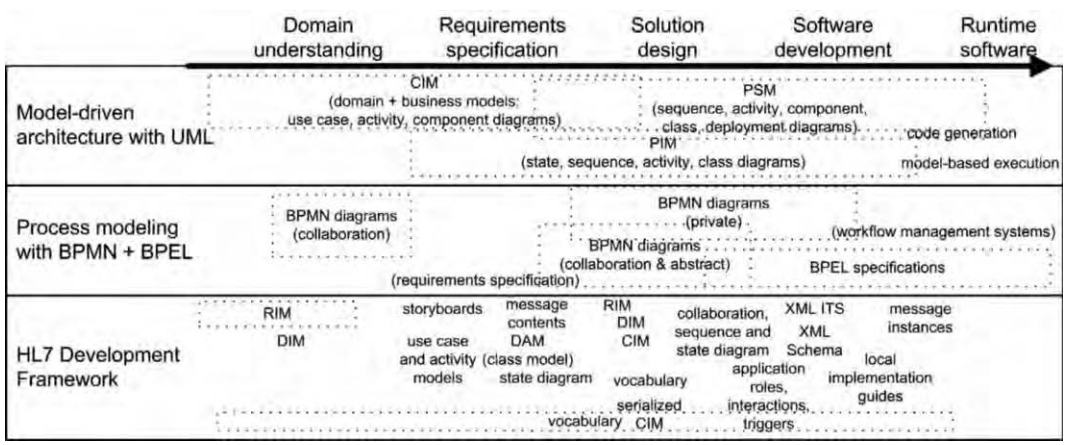

Figure 1 - The modeling artifacts of the three approaches in relation to the information systems development value chain.

Table 1 - Summary of the comparison of the three model-centric approaches.

Consideration	Model-Driven Architecture	Business Process Modeling with BPMN and BPEL	HL7 Development Framework
Main purpose	model-based software development, insulation of business from the changing technology	process modeling notation and process execution	model-based production and management of interoperability standards
Structure & information	class and other UML diagrams on CIM, PIM and PSM levels	BPMN: little description, BPEL: through XML/WSDL interfaces	RIM, domain analysis and information models, constrained models, XML schemas for messages
Functionality	use case, class and other UML diagrams	on process level only, internal functionality in private BPMN	interaction names, receiver responsibilities for messages
Interactions	sequence, activity and other UML diagrams	abstract and collaboration BPMN: generic, BPEL: specific	triggers, application roles, interactions, UML diagrams
Main users of the method	CIM: domain practitioners, PIM, PSM: IT experts	business analysts, business process owners and designers	accurate user roles specified for different phases
Semantic specification details	CIM focuses on information viewpoint, including vocabulary, more specific in PIM and PSM	little emphasis on information or semantics other than parameters of interfaces	glossaries, data types and vocabularies specified for more rigorous information support
Illustration to the end users	CIM: vocabulary, environment, functionality	BPMN: visualized processes can be examined	storyboards, use cases and activity diagrams
Requirements quality	documentation identified but not specified for the requirements	many requirements are implicit in the process descriptions	on generalized level (for all standards), but clearly traceable
Definitiveness	very loosely defined, accurate methods and tools needed	not in notations and languages but in tools and methods	accurate phases and outcomes specified, messaging presumed
Abstraction levels	CIM, PIM and PSM, lots of freedom within levels	BPMN: private, public and abstract; BPEL: execution level	models and tools defined for all specification phases and steps
Visibility of users / health professionals	evident in use case models, CIM and PIM emphasize communication with users	BPMN: user interactions, lanes, pools, activities; BPEL: no distinction between user and system steps	storyboards, use cases, activity diagrams, indirectly through application roles and triggers
Automated implementa-tion	transformations of models to executable code emphasized, various different possibilities	BPEL can be generated from private BPMN; BPEL is executed in workflow engines	implementation based on the specifications, little automation due to local variability
Dissemina-tion	promoted widely, solutions mostly tool-specific	promoted for business process management, increasing support	healthcare-specific, mostly used for standardization only
Other relevant aspects	requires more detailed methods, has been interpreted varyingly in different tools and methods	focuses on process modeling and management, relationships to other aspects remain undefined	currently under revision, new dynamic and static model approaches being refined

able information about the activities related to the processes. As the user interactions are typically required as a part of the processes, the approach can be complemented with models for user interface design.

The HDF focuses on the information aspects, and the functionality is mostly implicit in the application roles and their responsibilities. The dependencies of the related interactions and triggers are illustrated in some domains, but they are not always specified. The HDF process has clear participation roles, but the requirements dilemma of standards is evident: the requirements are generalized, and it is not always easy to find the origin of the solutions. HDF does not provide many guidelines or automated tools to support the implementation.

Discussion

The three modeling approaches clearly support the documentation and communication purposes and shared understanding in the development of HIS. However, none

of the studied approaches covers all the necessary aspects, or they do not provide a detailed support for different phases of the ISD chain. The description of processes, relationships and activities in healthcare is supported by clear notations and abstraction levels in the modeling approaches, but models do not generally suffice to provide atomic or unambiguous requirements. Furthermore, the reference from the solution models to the actual needs of the healthcare domain easily remains unclear.

In particular, improvements or local solutions are needed in the illustration of the solutions to the end users and stakeholders, the identification of aspects which are not covered by the approach and in the selection of graphical or textual notations for these aspects. The graphical models can always be introduced to the users, but this does not illustrate all the necessary aspects to them. In addition, the accurate specifications of the semantic aspects and the careful referencing to the needs and requirements are mostly left to the users of the approach.

The most notable differences in the studied approaches are related to the level of detail in the information models, functionality definitions, support for automated implementations and the definitiveness of the approach. These differences mainly stem from the different purposes of the approaches. All the approaches, however, have identified the distinction between the domain and IT expertise in the modeling efforts.

The many applications of the MDA to various specific needs make it an attractive approach as a reference framework, but also require detailed refinements which are not commensurable. The process modeling with BPMN and BPEL provides a lightweight and clear approach for end-to-end specification of processes, but leaves many aspects of the solutions unspecified. The HL7 Development Framework naturally provides the most advanced support for healthcare-specific requirements. It also emphasizes semantic aspects and provides most support for different phases of the ISD process. However, it focuses on standardization and messaging, and does not provide advanced automation or clear functional specifications.

Conclusions

The compared approaches are all viable modeling candidates for HIS. Their distinct scopes and strengths guide the selection according to different requirements. The approaches are extensible and non-exclusive. Besides the main scope, the selection depends on how definitive a guidance for the specification process and what kind of automation is desired.

All the approaches, however, require additional semantic definition and the illustration of the solutions to the end users. The approaches should be locally combined or complemented with the documentation of these aspects. In the future, accurate ontology-based approaches, user interface illustrations or domain-specific modeling extensions should be included in them. Many additional approaches such as two-level information modeling and various domain-specific modeling approaches have also been suggested to support accurate semantics and domain-specificity. They could be included in a comparison using the specified analysis framework.

Acknowledgments

This work is part of the SerAPI project, funded by the Finnish Funding Agency for Technology and Innovation TEKES grants no. 40251/06, 40353/05 and 40437/04, together with a consortium of companies and healthcare organizations.

Software Engineering Principles Applied to Large Healthcare Information Systems A Case Report

Fabiane Bizinella Nardon[a], Lincoln de A Moura Jr.[a]

[a] *ZILICS – Health Information Systems, São Paulo, Brazil*

Abstract

São Paulo is the largest city in Brazil and one of the largest cities in the world. In 2004, São Paulo City Department of Health decided to implement a Healthcare Information System to support managing healthcare services and provide an ambulatory health record. The resulting information system is one of the largest public healthcare information systems ever built, with more than 2 million lines of code. Although statistics shows that most software projects fail, and the risks for the São Paulo initiative were enormous, the information system was completed on-time and on-budget. In this paper, we discuss the software engineering principles adopted that allowed to accomplish that project's goals, hoping that sharing the experience of this project will help other healthcare information systems initiatives to succeed.

Keywords:

Healthcare information systems, software engineering, electronic health record.

Introduction

Several studies show that most software projects fail. An important survey in the past pointed out that only 16.2% of the software projects are completed on-time and on-budget [1]. If a large organization is involved, as it is the case of most public healthcare information systems, statistics shows that only 9% of their projects will finish on-time and on-budget. Due to its inherent complexity, healthcare projects face even higher risks and there are many reports of failed healthcare information systems. Recently, a report on the NHS software initiative, one of the most ambitious public healthcare information systems, described that the project has been failing on delivering what it was promised, with some of its contractors, formed by large and reputable companies, giving up and leaving the project [2]. In contrast, large amounts of money are spent on such projects every year, with a low success rate.

As suggested by Robert Grady in his book [3], as in medicine, great progress occurred in a relative short time when the rules against dissection were eased, we must experience a similar renaissance period in software development, making software autopsies to gather information that will help us to decrease the rate of software failure in healthcare. In this spirit, this paper describes how the public healthcare information system of São Paulo city was built from a software engineering point of view, aiming to show the techniques adopted that allowed to deliver one of the largest healthcare information systems ever built on time and on-budget.

The City of São Paulo healthcare information system

São Paulo is one of the largest cities in the world, with 10.3 million people in the city and some 18 million in the Metropolitan Area.

In June 2003, São Paulo Public Health came to operate as a "full managed-care" city, which means that resources from the National Health Fund are transferred directly to São Paulo City Department of Health (SPCDH) on a capitation basis. In exchange, the city agrees to meet certain production and quality goals, and has to send monthly reports that allow the Ministry of Health to assess if those criteria are being met.

By becoming a "full managed-care" city, São Paulo Dept of Health came to manage the following yearly figures:

- 10 million primary care consultations
- 8.5 million specialized consultations
- 550 thousand hospital admissions

São Paulo decided to invest in an Information System that would support Patient Flow Control and provide an Ambulatory Electronic Health Record System [4]. The core conditions that underlined the project can be summarized as:

- The information system would not only be fully compliant with all National Standards; but also help to promote them;
- Open standards and open source-code should be used at all levels, whenever feasible;
- Whenever possible the project should use the results of previous projects, existing technologies and concepts;
- São Paulo City would receive source-code and consulting support from the Health Ministry and, in return, would send back to the Ministry all deliverables from the project;

- Finally, and most importantly, the system should be fully integrated and provide a framework for continuously embodying new functions in an easy and natural way.

The requirements and concepts summarized above were described at length in a Term of Reference prepared by São Paulo City Department of Health. The Term of Reference defined 4 major sub-projects that should result in one and only one Information System:

Municipal health register, whose objective is to handle and process the identification data for health care users, workers and organizations, as well as the relationships among them. The Register is the prime data source for all other modules, as no operation can be carried out unless its actors are registered.

This subsystem also stores and processes all standard vocabularies in use within SUS. All data within the Municipal Health Register are fully compliant with SUS.

Patient flow control handles all requests for health care services (consultations, procedures, inpatients admission and emergency) and finds the best possible match, based on criteria such as budget, distance, availability and waiting time. This module also processes authorization requests for high-cost high-complexity procedures. This is standard-procedure under SUS. It also handles exceptions, i.e. whenever resources use exceed predefined limits or are unavailable, an accredited doctor handles the exception, either by extending the budget, finding available resources or holding the request for some time, if that is the case.

This module also processes patient flow control within the health care unit and copes with waiting lists, either local or in other reference layer.

Ambulatory electronic health record collects an essential dataset from the encounter and triggers related actions, such as notifying diseases or work-related diseases, when such conditions are met.

Role-based access control system is a single sign-on system that identifies the user and its user profile, thus enabling or disabling access to system's functions. Of course, all users have to be recorded in the Register, before being authorized to access the system. Initially, some 40 profiles were defined. Through system usage the Dept of Health decided to delete some and created other profiles, totaling more than 60 profiles currently.

To develop the project, SPCDH hired several companies that, under its management, focused on specific subprojects or on threads such as hosting, communications, equipment, software development, training and support.

The resulting information system came to be known as "SIGA Saúde", which means "following health" and is an acronym for "Integrated System for Health Care Management".

As of this writing, SIGA Saúde is in use in 372 primary care units for a) registering patients, workers, health units and their services; b) scheduling local appointments.

The actual numbers of SIGA deployment as of November 6 to 12, 2006 as informed by São Paulo City Health Department are described in Table 1, below.

From a software engineering point of view, the project had almost all the risks that usually take projects to failure: the requirements were not well defined, the scope was large, the timeframe to deliver the first version of the project was very short (about 9 months), the project team was huge (about 80 people) and informaticians had different skill levels in the technology involved, ranging from beginners to experts. Most of the team members had never worked together before and the team was not all in the same geographic location.

Table 1 - SIGA Saúde production, October 2006

Item	Amount
Primary Care Units Using SIGA Saúde	372
Primary Care consultations scheduled	1,657,023
Specialized Consultations scheduled	35,250
High-Cost Procedures Requests Processed	223,225
Patients Registered	8,357,863

Despite all odds, the team succeeded in delivering the system on time. As shown in the timeline of figure 1, the contract was signed in January of 2004, it took about two months to assemble the team and define the use cases that would be implemented. In March 2004 the first use cases started to be specified. The implementation of the software started in May 2004, and in September of that year the information system was deployed and in production with all the features planned completed. In about 4 months, more than 2 million lines of code were produced and about 300 use cases were implemented. Since then, new features and improvements have been added to the system.

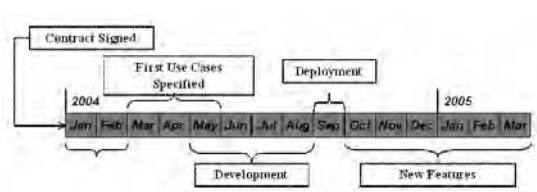

Figure 1 - The project timeline

The following sections will describe the methods and techniques used for achieving these results, in the hope to give an insight on how software engineering principles applied to large health care information systems can be a key success factor for any large project.

Methods

In a large project such as São Paulo City's Health Information System, it is important to have the methods and the architecture of the system well defined before the first requirement is captured and the first line of code is written. Our strategy for that project was based on six pillars:

- Well-defined software development process;
- Component-driven software development;
- Well-defined project guidelines and coding standards;
- Continuous integration;
- Project management;
- Knowledge sharing.

Software development process

Our development process was based on the principles of the Unified Process [5]. The software was produced in an incremental process, in such a way that new parts of the information system were delivered at each iteration. The system specification was made using the use case methodology proposed by the Unified Process. However, our use case document templates were modified to allow non-technical stakeholders to better understand what was specified and how that would look like in the real system. Thus, we added to the template a draft of the screen prototypes with a clear description of the behavior expected for each screen visual element. These use case documents were discussed with the stakeholders and after they were formally approved by all, the same document was used by the implementation team to implement the use case.

The iterative process worked very well and allowed to diminish the risks of the project, since stakeholders were able to see the results early in the project and thus they understood the development process better and communication became easier as the project evolved. The first module of the system went into production by the end of May 2004 and by then the team and the stakeholders had a clear understanding of how the development process worked.

Each iteration took about 6 weeks, with typically 4 weeks of coding, one week of testing and one week for the stakeholders testing and approval. At each iteration, while the development team was coding, the system analysts were specifying the use cases of the next iteration.

Component-driven software development

One of the principles we set out for this project was that no piece of functionality should be coded twice. To accomplish that, we adopted a component-driven software development. As each use case was ready to be implemented, a group responsible for the architecture of the project would identify which existing components could be reused, which ones should be modified and which new components should be created.

There were well defined and well documented rules about how a component should be constructed, so we would guarantee that it could be reused by other parts of the system. When a new component was developed, all the team was automatically informed of it, avoiding duplication by lack of knowledge on the components available in the component library.

In the few situations where we identified a feature implemented twice, a "refactoring" process was made on the system to eliminate the duplicated component.

The component-driven strategy increased the productivity of the team, not only because it improved reuse of code, but also because it decreased the number of errors. Once an error was identified, the corresponding component was fixed and automatically all the modules of the system that used it were also fixed.

Project guidelines and coding standards

Since different teams, with different background and skill levels were working on the project, it was important to enforce that all the teams followed defined guidelines and coding standards. The main goal here was to have a homogeneous source code, making it easier to modify and reuse the software.

These were the main guidelines defined for the project:

- A standard for directory structures, defining where each artifact, from specification to code should be stored;
- A standard for compiling and packaging the system, defining standard scripts to build all the components using the same procedure;
- A standard for code style, that was enforced automatically by tools that verified if the code produced was compliant to the standard;
- A standard for documentation, creating templates either for software specification and for code documentation;
- Guidelines for implementing new use cases, defining the technologies that would be used and how they should be used.

The project was based on open-standards and on open-source paradigms. Java Technology was chosen from the first moment for its ability to generate systems that run on any platform; to make extensive use of object-oriented analysis, and to create reusable software components. Although the system should run on a variety of equipment, a basic platform was defined with Linux as the standard operating system, JBoss as the application server and Oracle as the database management system. The only proprietary piece of software chosen was Oracle, as for the foreseen volumes no free-software database management system was considered suitable for the task. The system was developed in three-layers as depicted in Figure 2.

The application is web based, which lowered costs, since new versions are installed at only one place – the server. Also, users use simple diskless thin-clients to access the system, which also decreased maintenance costs.

The persistence and business layers of the system were implemented using Enterprise Java Beans 2.0 technology. The web layer was implemented using Struts and Tiles frameworks.

As happens with any complex technology, this architecture allows to use many different paths to implement the same functionality. If the developer is free to choose its own solution, the result is a heterogeneous code, with hard maintenance, and a potential increase in the number of errors. Also, when not well guided, beginners in the technology tend to make mistakes that well experienced developers would not.

To avoid this problem our strategy was to capture the knowledge of the most experienced developers and code this knowledge as metadata. Then, the developers would annotate the code with metadata stating the desired behavior of the use case and our framework would process these annotations and generate "expert code". The code generation strategy eliminated boilerplate code, enforced the guidelines and standards, increased productivity and made beginners to produce code as an expert would.

Differently from other coding generation tools available, however, our code generation strategy was conceived to allow extensions, making the system flexible.

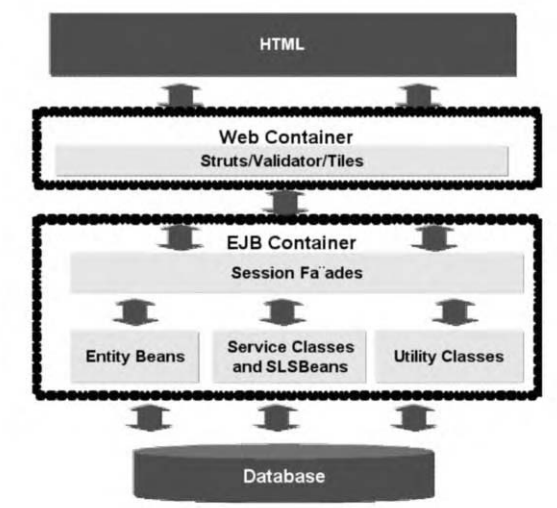

Figure 2 - System architecture

After analyzing three years of statistics from the project, it is interesting to notice that the most modified files of the system were files that implemented the user interface. Not coincidently, the user interface implementation was the only part of the architecture that didn't have a well-defined guideline or code standard. Although we had defined that the user interface should be coded using the Struts Framework and the Tiles technology, this was not enough to avoid beginners' mistakes. This clearly shows that besides defining the frameworks that should be used, it is important to create guidelines on how to use them.

Continuous integration

Continuous Integration [6] is a software development practice through which members of a team integrate their work frequently. The goal is to identify integration errors as soon as possible, reducing integration problems.

This practice is very important when multiple teams are involved and when component-driven development is used.

Our strategy was to integrate the software daily, using an automated tool. All the projects artifacts were stored in a central versioned source code repository. Each day, our continuous integration tool retrieved all the code produced and integrated it. If errors occurred, the developer responsible for it would receive an email alerting that his/her work had generated an integration error and this should be fixed.

As a result, in the last day of the iteration, we were certain that when joining the pieces together the software would not have integration problems. This contributed to decreasing the time spent solving integration problems and accelerated the development time.

Project management

Managing a large project as this one is always a challenge. Managing the human resources involved is certainly the most difficult task for project managers. The most subjective aspects of human resources management are out of the scope of this paper, but it is important to share some techniques that played an important role in the success of this project.

The project had a well-defined issue tracking process. This process stated clearly how each issue (an error, an improvement, a new task) should be addressed on the project. It started with someone registering the issue in a web based project management software. This generated an email to the project manager. The project manager would analyze the issue and either reject it or schedule the issue to resolution, assigning it to a member of the team and registering a time estimate to the issue resolution. Once solved, the owner of the issue would register what had been done and how much time was spent. Since all the process was controlled by a web-based software tool, it was possible to verify in real time, how the project was evolving, who was late on the tasks, who had time to work on other tasks, what was scheduled to be done on each iteration, and so on. Since this project management tool was integrated with the version control repository, each time a issue was solved, it was possible to track back exactly what changes had been made on the project artifacts because of that issue, what helped to identify why things changed.

This technique gave us important metrics that helped to keep the project on schedule and improved the communication among the team members.

Knowledge sharing

Knowledge sharing is very important on a large IT project. The best way to keep information about a project available for all is to enforce documentation.

In the São Paulo City Health Information System project, all project artifacts were stored in a central versioned repository. This repository was available online and could be accessed by all the members of the team.

When a new requirement was identified and the software had to change, the documentation was changed and only then the software was changed.

This approach reduced the development time, by eliminating the need for fixing poorly documented requirements. It also improved system maintainability, since even when a member of the team left the project, the knowledge was well documented and the other members could continue the work on it.

Results and conclusion

Impact data related to using SIGA Saúde is still under collection. However, current assessment reveals that outpatient services productivity has increased about 35%.

Patients' perception has changed for better, as patients have stated they can schedule appointments within the same month, against a three-month wait that was typical before SIGA Saúde. The Brazilian Press, usually very critical of public IT services published an opinion article stating their view that SIGA Saúde was a major contribution to the Bazilian Health System [7]. The project has also won a Duke's Choice Awards, granted by JavaOne 2005 Conference Meeting [8].

SIGA Saúde architecure is very innovative. By being fully web-compliant and using public Internet for providing safe role-based access to the system, SIGA Saúde can easily be deployed in other cities or regions. Also, as SIGA Saúde is fully compliant with all Brazilian standards and SUS practices, it is a tool to be used to help SUS itself be implemented throughout Brazil. Finally, São Paulo City's dimensions and complexity are so evident that taking SIGA Saúde to other cities and states requires simplification rather than new functionalities.

The techniques described on this paper allowed to deliver a large healthcare information system on time and had a significant impact on decreasing the number of errors.

The results of this project show that using software engineering principles is a key factor to avoid project failure.

There are many other aspects that could lead a project to failure, such as political forces, management changes, and others, but it is known that most IT projects failed because they can not deliver what was promised on time.

It is very important to choose the methods and the architecture of the information system before the first line of code is written. It is also important to communicate to all members of team clearly what the guidelines and methods are.

Although the techniques described on this paper were very important to the success of the project, it is also clear that they require discipline from the team and strong management, what is not easily accomplished. In this sense, choosing the right team is also an important aspect of the project.

The experience of the City of São Paulo Healthcare System should be used as an example to other public agencies that are striving to build a reliable information system. Our experience shows that applying the right software engineering principles help to achieve the goal of having an information system that will help to provide a better quality of care.

Towards Modeling and Simulation of Integrated Social and Health Care Services for Elderly

Alexander Horsch[a], Daryoush Khoshsima[b]

[a] *Technische Universitt Mnchen, Germany, University of Troms, Norway*
[b] *University of Applied Sciences Heilbronn, Germany*

Abstract

In order to estimate the impact of an innovation on a segment of the health care system under certain assumptions such as different possible regulatory or financing schemes (scenarios) prior to its diffusion, one must understand the dynamic behavior of the entire system with its essential control loops. Aim of this feasibility study was to explore the potential of System Dynamics (SD) modeling for this purpose. First, a UML-based modeling of an Innovative Care for Elderly (ICE) system for provision of integrated social and health care services to elderly living at home was done. Then monetary and quality of life aspects of the social and health care system were described by two coarse SD models. On these models the impact of the introduction of the ICE system under certain assumption (scenarios) was studied, based on data from the German Health Expenditure and German Federal Statistics Office. The simulations show plausible behavior, however, are not yet detailed enough for a final conclusion. A major problem is missing data for setting model parameters: estimates had to be made. In conclusion, SD modeling might be a useful method for studying impacts of the diffusion of an innovation in the health for elderly sector, but more research is needed.

Introduction

The demographic trends in most countries show an overproportional increase of elderly in relation to the whole population, coming along with an increase of chronically ill or multi-morbid persons, and persons that cannot live without support from social and health care. The social and health care systems have serious problems with the increasing costs of services. The diversity of care services is an additional threat for geriatric clients. The current trends will lead to a situation where it will be mandatory to utilize information and communication technology to support an independent living of elderly at their own homes as long as possible, including not only health care services, but also social services with the overall goal to intensify the personal involvement of elderly in the social life of a society as well as to deliver high-quality medical care.

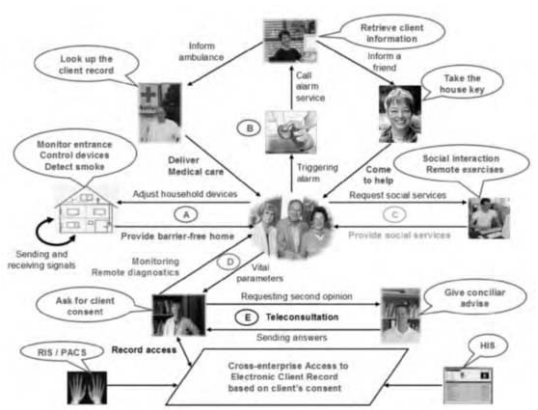

Figure 1 - The Innovative Care for Elderly (ICE) System

At the Troms Telemedicine Conference 2004 we presented the system analysis for a comprehensive telematics support of social and health service chains for elderly [7] (Figure 1) including the analysis of requirements, business processes, business use cases and system use cases of a system which in its full range covers the following components: automated house; emergency call; virtual home for elderly; telecare service. There are pilot projects and accompanying studies such as [1][2] dealing with the integration of telecare services into service delivery. And there is a variety of efforts addressing care innovations such as assistive technology or telecare in different settings. But, to our knowledge, there is no deep understanding of the entire systems dynamic behavior and the impact of innovative services on the clients quality of life under the technological and organizational intervention of introducing health care at home. This might be due to the fact that sufficiently detailed models are fairly complex and need a lot of data to be parameterized in the right way (see e.g.[1][2]). Often, the necessary information is not available and has to be estimated.

Being aware of these difficulties, we have tried to build two simulation models using the methodology of System Dynamics (SD) [10][11][9], with the goal to achieve, on a moderate level of granularity, the basis for understanding

the systems behavior and a starting point for further refinement and adjustment to relevant eHealth scenarios [8][5]. The first model is designed to investigate the economic issues of the system trying to answer the study question:

How should the costs be distributed among the different stakeholders, so that a win-win situation can be achieved? Is such a benefit-for-all situation achievable during the lifetime of the system?

The general system behavior has been explored to observe the behavior it can produce and to observe the common mode of the system behavior. The second model was created to investigate the quality aspect of the system in order to answer the study question:

How may the system affect the clients quality of life?

Main goal here was to identify the key factors influencing quality of life and to model their interrelationship in order to study the change of these entities over time, in dependence of the model parameters which describe the type of service implementation chosen in a region or country.

Material and methods

The Innovative Care for Elderly (ICE) system

As innovation to be studied in terms of diffusion into the health and social care sector for elderly, the Innovative Care for Elderly (ICE) System is used [7][8]. The system is fictitious, since this kind of overall systems does not exist, yet. It is a comprehensive telematics support of social and health service chains for elderly, which is customized to the needs of the individual client. A health manager or the ICE service provider together with the client chose the appropriate subset services, mandatory and optional ones. The Unified Modeling Language (UML) and the modeling software Together 6 (Borland) have been used for the analysis and description of requirements; business processes; business use cases and system use cases.

The main idea is to have a system that in its full range comprises the following four components (see Figure 1):

1. *The Automated House.* Such a house can offer, through simple to use interfaces adapted to the degree of disability of the occupant, e.g. various control functions for operating parts of the house (doors, jalousies, etc) and devices in the household, as well as for device communication. It includes the connection to external data networks.
2. *The Emergency Call.* This component mainly addresses sick and/or disabled persons. In case of an emergency the occupant triggers an alarm and a connection to a central help desk is established for further action. This trigger event can for example be the push on a button or a signal from a fall detection device.
3. *The Virtual Home for Elderly.* This component provides a portfolio of social and health care services. Social services comprise, for example: videophone communication with the care personnel; social interaction; consulting in critical situations; mediation of contacts to e.g. self-aid groups; support of relatives involved in the care process.
4. *The Telecare Service.* Through this service mainly the medical needs are covered. It comprises telemonitoring of the health status through e.g. vital parameters such as blood pressure, heart frequency or temperature, and all actions and services needed to handle medical or nursing tasks identified by the responsible professionals at the service center.

In addition, a teleconsulation service is included for supporting a smooth professional to professional communication.

Systems thinking

Considering a system "as a set of elements or components that work together in relationships for the overall good and objective (or vision) of the whole" [4] there are different viewpoints on SD (Figure 2). Descartes analytic thinking, based on the postulate that in separating the system in manageable pieces and understanding these pieces will lead to an understanding of the whole, when put together, is reflected by disjointed viewpoints on subsystems. This straightforward reductionist thinking usually fails to address complex systems because it is not able to capture the complexity adequately and deal with interrelationships and interactions between subsystems.

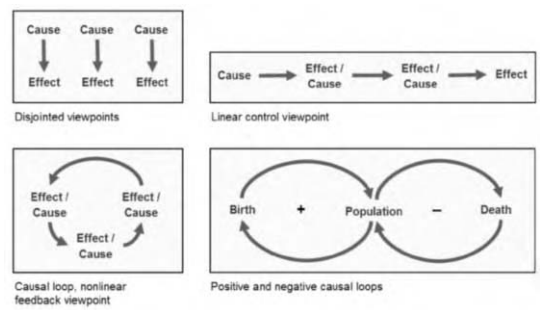

Figure 2 - Viewpoints on System Dynamics (SD)[5]

Another approach is the linear thinking, which tends to see simple sequences of cause and effect (Figure 2, linear control viewpoint). But in real systems, causes and effects are circular in their nature, not linear, forming positive or negative feedback loops (Figure 2, causal loops). Therefore, also linear thinking is inappropriate for modeling complex systems. This brings us to the point where interrelationships and control mechanisms come into the consideration, which the formal description of complex systems composed by subsystems which influence each other in a specific dynamic way.

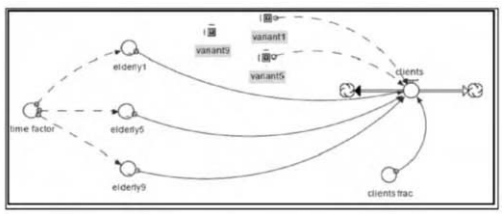

Figure 3 - Sector Frame Demographics

For our feasibility study, we used a method known as Systems Thinking [3]. This method provides:

1. *Stocks.* Represent a certain amount of units-of-measure. Four types of stocks are used: Reservoir, Conveyor, Queue, and Oven.
2. *Flows.* Represent transmission of units-of-measure from one stock to another, and can be unidirectional, bidirectional, or unit converters
3. *Converters.* Change the unit-of-measure of a flow.
4. *Connectors.* Represent information or inputs that regulate flows.

For our feasibility study we only used reservoirs, uni- and bidirectional flows, and connectors. As software tool, iThink Version 8.0 (High Performance Systems, Inc., Lebanon, NH, USA) was used. For the simulations, this software solves the finite difference equations determined by the model using iterative numerical methods (Euler, Runge-Kutta).

Results

The economic model

The unit-of-measure for the economic model is a monetary unit. Three so called *Sector Frames* these are model components which can be simulated separately have been modeled:

1. Demographics (here: Germany, see Figure 3)
2. Expenditure on system components (services)
3. Financial sources of system components (services)

For Sector Frame 1, data from the 10th coordinated population prognosis for Germany (published 2003) have been used. Figure 3 shows the Flow clients controlled by the demographic variant chosen (elderly1, elderly5, or elderly9) and the fraction of elderly using the ICE system (clients frac). To give an example of the modeling of ICE components, Figures 4 and 5 show the Social Alarm (SA) system expenditures and the financial sources modeling, respectively, with the SA cost stock being the connecting model entity. The flow into the SA cost stock is controlled by initial costs, fixed costs, extra costs, etc., the flow out of the stock is controlled by the different financing sources such social security funds (SS) and general government excluding security funds (GG) on the public funds side (PF FS), and private social insurance (PSI), private insurance enterprise (PIE), social security funds (SS), private out-of-pocket payment (PP), non-profit institutions (NPI) on the private sector side (PS FS). The complete model with the complete Sector Frames is controlled by a total number of 85 hard variables. For details and a description of the complete model in iThink see .

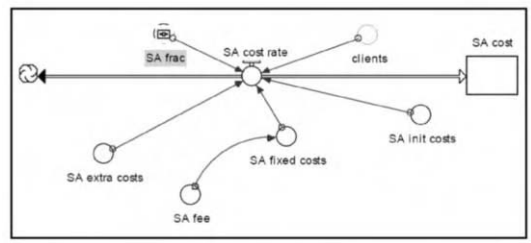

Figure 4 - Social Alarm (SA) System Expenditures

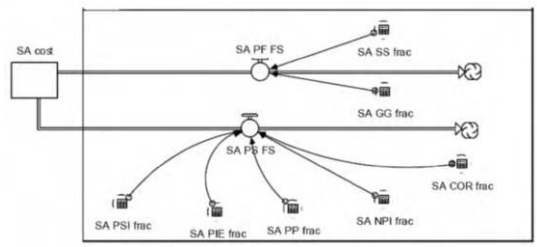

Figure 5 - Financial Sources of SA System

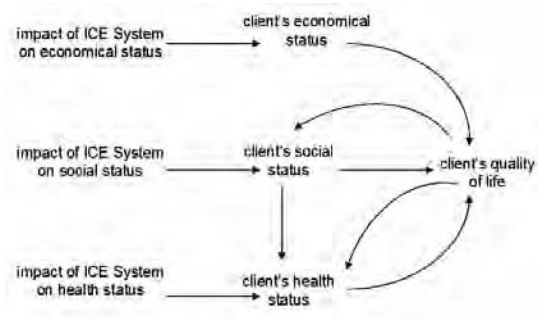

Figure 6 - Causal loops of the Quality of Life model

The Quality of Life model

The Quality of Life (QoL) model is constructed without sector frames and comprises solely soft variables. The clients QoL may be affected by many different factors, such as recognition, health, social relationships, richness of daily life, satisfaction with work. Influence on an individual changes over time. Influence on a population may be considered in a statistical way and described in terms of averages. In this feasibility study, we are interested on the large-scale influence on the QoL of a population. Our model is based on the three key factors driving the impact of the ICE System on the QoL: economical status, social status, and health status of the client. Figure 6 shows these factors which represent Stocks in the iThink and the essential causal loops QoL social status, and QoL health status. The model is controlled by a total number of 23 soft variables. For details and a description of the complete model in iThink see .

Table 1 - Parameter settings for first economic scenario

Parameter	Value	Parameter	Value
SA frac	0.1	VH NPI frac	0.25
VH frac	0.1	AH PSI frac	0.25
AH frac	0.1	AH PIE frac	0.25
TeC frac	0.1	AH PP frac	0.25
SA SS frac	0.95	AH NPI frac	0.25
SA PP frac	0.05	TeC PSI frac	0.25
VH PSI frac	0.25	TeC PIE frac	0.25
VH PIE frac	0.25	TeC PP frac	0.25
VH PP frac	0.25	TeC NPI frac	0.25
All other parameters are set to 0.			

The simulation runs

Based on statistical data from the German Health Expenditure and German Federal Statistics Office, simulations have been run under varying circumstances and assumptions over different periods of time for different scenarios in order to demonstrate how a change of parameters (population progression, financing sources, time factors, fraction of clients assigned to the different services) changes the behavior of the whole system.

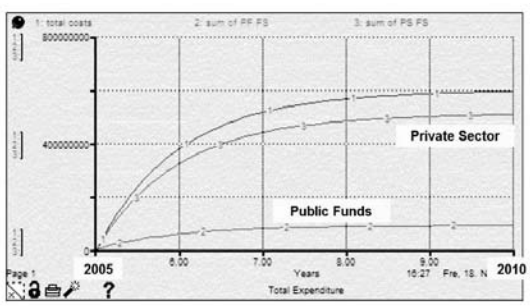

Figure 7 - Simulation Run of First Economic Scenario

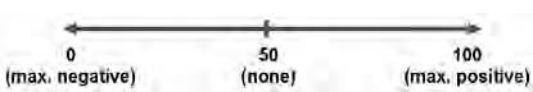

Figure 8 - Scale for Impact on Quality

For the first economic scenario, it was assumed: Germany with the middle variant of population progression, leading to middle number of elderly; 10% assigned to each service; the SA system 95% financed publicly, 5% privately; other services 100% financed privately, with a share of 25% for NPOs, private social insurance, private insurance enterprises, and private out-of-pocket payment. Table 1 shows the setting of parameters for Social Alarm (SA), Virtual Home (VH), Automated House (AH), and TeleCare (TC) service, with *frac* indicating the fraction of the population receiving a service (e.g. SA frac = 0.1 indicating 10% receive SA service) or the fraction of financing source (e.g. AH PSI frac = AH PIE frac = AH PP frac = AH NPI frac = 0.25 indicating the automated house being financed 25% by the four sources PSI, PIE, PP, and NPI), with SS indicating social security funds, PP indicating private out-of-pocket payment, NPI indicating non-profit institutions, PSI indicating private social insurance, PIE indicating private insurance enterprise as source of financing. Initial costs and running costs, as well as further parameters are included as well, see [8] for details. For the second economic scenario (not described in more detail, here), public funds reimburse the highest share of expenditure on the ICE system.

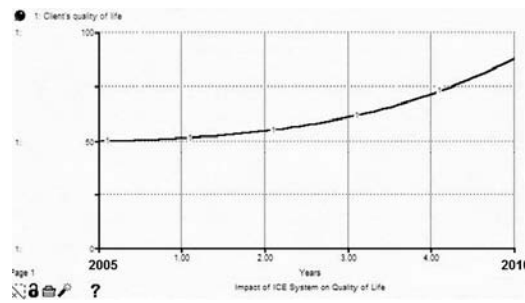

Figure 9 - Increasing QoL

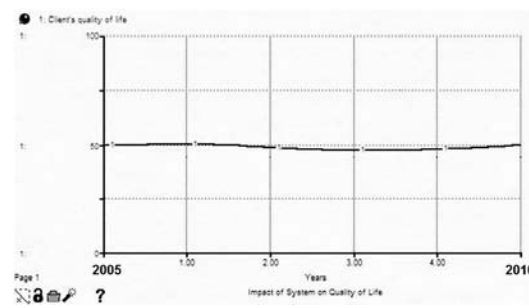

Figure 10 - Oscillating QoL

Two QoL scenarios have been considered (represented according to the scale shown in Figure 8):

1. First scenario: Dominant impact of *social aspects* on QoL, with only 10% maximal change of QoL by economic status, but 30% by social status, and 50% by the health status. Assuming the first economic scenario (private financing dominant, see above), which has a negative impact on the economic status of the clients, parameters were set to: impact of ICE system on economic status = 20 (big negative impact); on social status = 55 (small positive impact); and on health status = 55. Simulation over 5 years shows increasing positive impact of the ICE system on the QoL (Figure 9).

Assuming the second economic scenario (public funding dominant), the impact increases faster.

2. Second scenario: Dominant impact of *economical aspects* on QoL, with only 10% maximal change of QoL by social status, but 30% by economic status, and again 50% by the health status. Assuming the first economic scenario and the same impact of the ICE system on the three components of the clients status (economic, social, health), simulation over 5 years shows slight oscillation around the no-impact baseline (Figure 10). Assuming the second economic scenario (ICE system has no impact on economic status), QoL increases comparably to the first QoL scenario.

Discussion

Total costs for the ICE system to the purchaser in both economic scenarios start by zero and grow very rapidly during the first year, and increase further during the next three years. After four years there is no significant increase. This dynamic behavior of the model is reasonable since costs and expenditures on the ICE system have been taken as constant, which is not realistic: production costs for devices will probably drop, while costs for human resource may rise. It is also desirable to extend the model by a sector frame for the current care delivery system for elderly, so that it would be possible to switch between both service delivery systems.

The QoL simulations have shown exponential increase in three of four cases: if dominance of social aspects on QoL is assumed, under both financial schemes (primarily private vs. primarily public) QoL increases; if dominance of economic aspects on QoL is assumed, then QoL increases only in case of primarily public funding, but essentially stays constant in the other case.

The problem of missing data for the economic model could be tackled by involving e.g. health insurances and health care service providers of a test region in further studies with refined models. Concrete innovations introduced in a test region could serve as framework for validation studies. An empirical study based on questionnaires could help in getting realistic parameters for the QoL model.

Conclusion

The current models presented in this paper reflect the systems core components and possible dynamical characteristics. The models need substantial enhancement to make them realistic enough to give answers to our research questions. Details on costs and expenditure processes have to be included, and more variables (e.g. market saturation, clients acceptance, quality of service) have to be included. The quality of life model requires more research. It should also be refined, for example by adding direct influence of the clients economic status on the social status.

Future efforts must be put on the continuing development and validation of the models by empirical studies.

Acknowledgments

We thank the colleagues from Technische Universitt Mnchen, Ludwig-Maximilians-Universitt Mnchen, University of Troms, and Norwegian Center for Telemedicine, for the inspiring discussions. Furthermore, we thank the reviewers for their valuable comments on the first version of the paper.

Healthcare Delivery Systems: Designing Quality into Health Information Systems

Phil Joyce [a], Rosamund Green [b], Graham Winch[c]

Abstract

To ensure that quality is 'engineered in' a holistic, integrated and quality approach is required, and Total Quality Management (TQM) principles are the obvious foundations for this. This paper describes a novel approach to viewing the operations of a healthcare provider where electronic means could be used to distribute information (including electronic fund settlements), building around the Full Service Provider core. Specifically, an approach called the "triple pair flow" model is used to provide a view of healthcare delivery that is integrated, yet detailed, and that combines the strategic enterprise view with a business process view.

Keywords:

Health Information Systems, TQM, *triple pair flow* construct

Introduction

Health care providers in western society now command and require increasingly large budgets to provide health care for their patients (or clients) and their communities. Indeed, government funding to health care has been steadily growing during the last ten years. This has required health care providers to clearly define their resource usage and provide information (e.g., patient level data) on their organisational and operational processes in the provision of these services. This has seen the development of funding models that are based on the development of "best practices in health care."

Organisations responsible for healthcare delivery are presently facing competing challenges. Health managers are seeking to satisfy the ever increasing number and size of stakeholder groups with quality healthcare delivery that meets the patient's needs, whilst delivering quality healthcare data to the hospial [1]. Healthcare delivery quality, as defined in [2] "as that kind of care which is expected to maximise an inclusive measure of patient welfare, after one has taken into account the balance of expected gains and losses (variability) that attend the process of healthcare in all its parts." Clearly, the complexity of this task cannot be under estimated. It requires the development of effective management and operational processes that are capable of capturing information to support the management and control of healthcare delivery. The captured information allows healthcare providers to evaluate the effectiveness of actual patient care, the efficiency of the hospital operations, the appropriate usage of resources and the expectations of patients, physicians, other hospital staff, etc, to develop measures of quality management in healthcare provision. Information and Communication Technology (ICT) support and help management of complex processes and operations with Enterprise Systems (ES) and Enterprise Resource Planning System (ERP) providing organisational wide systems that capture the processes of the organisation (horizontal flows) [3]. Moreover, eBusiness (and eCommerce) systems support the provision of services and/or goods electronically, e-fulfilment and these systems provide management with not only an effective tool to deliver product, information and funds but provide management with a method to model the strategic possibilities and implications to support healthcare delivery.

The need for strategic vision in the executive group to be communicable to and useable by the other stakeholders in their developments is essential. This allows all stakeholders to gain a mental picture or model of what is being achieved and focuses management on: envisioning, specification, design and implementation. This can be surfaced and articulated with other stakeholders in such a way that they can see within their area, business processes and technological infrastructures that are the basis of their thinking. This will ensure that quality is 'engineered in'. A holistic, integrated and quality approach is required, and Total Quality Management (TQM) principles are the obvious foundations for this. TQM is a business philosophy that encourages an over-arching responsibility - both individual and collective - to achieve quality and customer satisfaction. Commitment must be at every stage of the delivery. Importantly, the successful implementation of TQM will require the alignment of the organisation's information systems and other management systems with the new TQM environment.

Integration of process and information technology integration in quality healthcare delivery

Many large integrated information systems, particularly in public service projects, have notoriously underperformed and disappointed [4]. Often the majority of healthcare organisations do not understand the impact and effect of operating an integrated information system that captures the core processes of the organisation. Moreover, systems of this nature dramatically and fundamentally change the

way the organisation operates and interacts with its primary organisational objective and outcome: patient care. Similarly, healthcare managers may often have different objectives in their roles to support the organisational objective [5]. In this sense: clinical practitioners will primarily focus on the processes concerning patient outcomes; senior management on trend analysis and successful long term strategies and strategic planning; middle level management and reviewers with monitoring, review, productivity and resources utilisation; and business services management with billing, budgeting and accounting. Similarly, each group will have specific key performance indicators of their area's performance in meeting the organisational objectives and outcomes.

Healthcare managers are responsible for the envisioning, specification, design and implementation of new electronic processes and must therefore take a holistic, integrated and quality approach. TQM principles are the obvious foundations for this. Total Quality Management (TQM) is essentially a business philosophy. For TQM to be successful, management decisions must be aligned and integrated into a system of continuous quality improvement to meet the expectation of the customer.

There is a large amount of literature on the topic, and there are at least two major models that are used for business excellence assessment based on TQM principles – the EFQM Excellence Model [6] and the Baldridge Award [7]. These two world benchmarks use very similar criteria and dimensions for assessment, and both include Leadership, Processes, Information, and People Involvement as critical elements. However, much of this is essentially diagnostic or aspirational – 'do we think we are a quality organisation?' or 'what should a quality organisation look like?'. The appropriateness of a direct TQM approach in healthcare is long established (for example, [1, 2, 5]) though little is instrumental in the sense that it provides tools that can directly support the development of effective, coherent, and purposeful systems within an organisational quality framework. This is particularly the case when it comes to the design of integrated fulfilment, information and fund transaction systems in complex information systems in a healthcare setting.

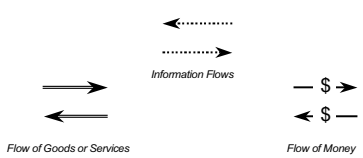

Figure 1 - The 'triple-pair' process flow model of supply chain fulfilment

Repenning and Sterman [8] correctly reported that there is a growing emphasis on business processes rather than business functions as the keystone to organisational improvement and quality enhancement. Process oriented improvement techniques such as Total Quality Management and Business Process Reengineering have proven to be powerful tools for improving the effectiveness of many organizations. However, despite the fact that it is easier than ever to learn about these performance improvement techniques and where they are being used (presumably beneficially), there appears to have been relatively little improvement in the ability of organisations to incorporate these innovations in their everyday activities. Similarly, the authors observe that the ability to identify and learn about new improvement methods no longer presents a barrier to most managers, but rather the biggest challenge is successful implementation. Repenning and Sterman [8] also assert: "You can't buy a turnkey six-sigma quality program. It must be developed from within."

A modeling approach to integrate the enterprise view with a business process view

Previous work by the authors has integrated thinking from strategic management, business process engineering, and resource-based view (RBV) of the firm and balanced scorecard (BSC) analysis to produce an integrating framework for e-business design. This framework reflects both a top-down, entrepreneurial/customer-facing view with a bottom-up, instrumental, capability-based view of what can be done [9]. The original framework, which itself essentially reflects aspirations, has then been integrated with the e-business models of Weill and Vitale [10] and the process flow modelling from system dynamics used to present a method for visualizing, communicating and then developing a shared view or consensus on the critical flow processes that can operationalise a business vision [9]. The visualisations support the critical examination of base ideas by different stakeholder groups and different domain experts; the prototype systems can then be expanded and refined of to best serve the precise needs of the organisation and its stakeholders. This, it is argued, supports powerfully the process of internal development of systems that are part of and support a quality environment within the organisation.

The 'Triple- Pair Flow' Construct for Envisioning Fulfilment Systems

All business transactions are in one way or another a supply chain fulfilment system, and healthcare delivery systems are no exception. A goods or services need is fulfilled (i.e. satisfied) by the good or service being delivered or provided with payment being received by the supplying organisation in exchange. Effectively, three flow processes comprising all such systems:

- information flows;
- money flows, payment for goods or service; and
- delivery of goods or services.

These are just the primary flows, in a healthcare system delivery of patient-care comprises a variety of service elements including medications and other consumables, and similarly money flows may be direct from patients, from insurance companies and government funding agencies. These may be seen as refinements, alternatives or extensions of the primary flows above. However, an important consideration is that each of these flows can be two-way:

Reverse information flows might include order acknowledgements, delivery notices, invoices, out-of-stock notifications, etc. It might also include information not directly related to individual order fulfilments, for example, stock position advisories and so on;

Reverse money flows might be refunds, cash-back, commissions, etc; and

Reverse goods flows might be returns, trade-ins, etc.

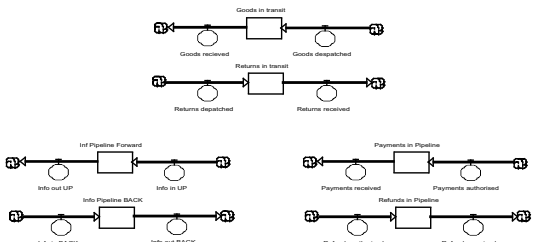

Figure 2 - The triple pair model with detail for each flow process

Joyce and Winch (2004) have described a novel construct – the "triple-pair flow" construct for envisioning such systems based on six main flows: two-way information, two-way goods and services, two-way money flows, as shown in Figure 1. If all the relevant flows relating to a particular healthcare provider could be represented within this triple pair model, then the configuration of the six flows can be mapped onto any business model that the healthcare company has in place, or wishes to adopt. Using the stock-flow diagramming convention of System Dynamics extends their construct. We will investigate how business process models can be mapped onto business models. System Dynamics is well suited to this application. There are many excellent texts that describe the principles and processes in system dynamics modelling and [11] is a leading example text. From system dynamics earliest day of development [12], has always explicitly reflected industrial and business structures as a complex inter-related set of flows of money, materials and information, and has always been concerned with the structural relationships that make up business processes as well as the softer processes. This dynamic process model perspective leads to a representation of the enterprise as a set of six sub-systems comprising stocks (or levels or inventories) and flows, as in Figure 2. This basic enhancement simply establishes that extension with detail is possible, and that the sub-structures will comprise a set of stock-flow chains. The process of expanding this to a full representation of the supply chain(s), funds transaction chain(s) and information flows can then proceed as an iterative process involving all key stakeholders. The graphical processes involved in system dynamics are proven to be of significant effectiveness in supporting team building, alignment, communicating views and thoughts with different specialist groups, and consensus building (see for example, [13-17]). It is also the basis for what [14] described as "operational thinking" within what he considered the amalgam of critical thinking skills.

An integrative design process for quality healthcare delivery and stakeholder need fulfilment

One Weill and Vitale [10] model is the Full Service Provider (FSP), which they define as "offering a full range of services in one domain … directly as well as via 'complementors' ". Critically, they include health care provision in this group. They discuss how this sector can be served by enterprises with stakeholder groups and interconnecting goods/services, information and money flows as well as characterise the FSP model by a simple schema linking these and characterise the actor and flow structure as in Figure 3. This business model reflects the situation where access to a range products or services is provided through a primary provider who might not only supply its own products or services, but also sources related products and services from partner organisations. The primary relationship in this system is between the provider and the patient, but there are additional relationships involving flows of money, product/services, and/or information between the provider and its second-level supply network partners – which Weill and Vitale consider could be suppliers or complementors (resellers and other suppliers of complementary products and services) – and between the second-level suppliers and customers.

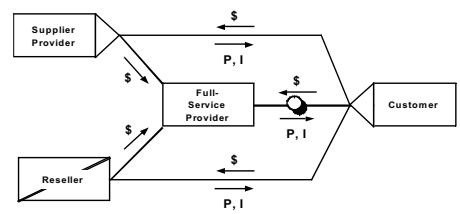

Figure 3 - Weill and Vitale's Characterisation of their Full Service Provider Model

From an overview of the fulfilment processes in a health service - patient care delivery, fund transaction and information flows, including suppliers of medications and other consumables, private and public funding bodies, and regulatory bodies, it is easy to see how these map onto the FSP model in its simple form. This then is the starting point for using the triple-pair construct in the envisioning, specification and design of systems that will engineer in the customer focus, stakeholder alignment and system coherence necessary to achieve quality healthcare delivery.

Dimensions of healthcare delivery within a full service provider perspective

Through TQM management system managers are able to integrate the vision of quality into the structure of the organisation. This must been seen at the clinical level, in the direct support of suitable patient outcomes, and from a management level, in the direct support of financial and business services and to ultimately create an accountable strategic plan for long term quality achievements. If we consider the role of a hospital as a domain in its attempt to provide quality healthcare we are able to examine the implications of the Full Service Provider Model providing a clear picture of the process of healthcare provision and the implications of TQM. The development of information system architecture with an emphasis on TQM is possible by the development of new systems or the redevelopment of older bureaucratic systems. There is a tendency when reviewing information systems in the healthcare area to create separate decision systems and management systems. Information systems within healthcare domain often fall into three categories [2]. These are:

1. Clinical or medical information systems – designed to support the activities of patient support (i.e., hospital admissions, medical records, etc)
2. Operational administrative systems – designed to provide necessary non patient care activities for the organisation (i.e., financial, personnel, payroll, etc)
3. Decision support systems – designed to provide management with information for decision making (i.e., strategic planning, analysis and evaluation, etc)

Examples of key healthcare sub-systems

If a complete healthcare organisation can be seen as a (FSP), within the Weill and Vitale classifications, then potentially new or reorganised structures can essentially be viewed. At the core will be a central service delivery subsystem, which, using the 'triple pair' flow interpretation. This reflects the technical details of the individual healthcare organisation, with the provider and the patient as the key players. In addition there would be other subsystems presenting the other inter-relationships between the FSP provider – the healthcare organisation itself – the patients and the other stakeholders.

Patient management system and government reporting

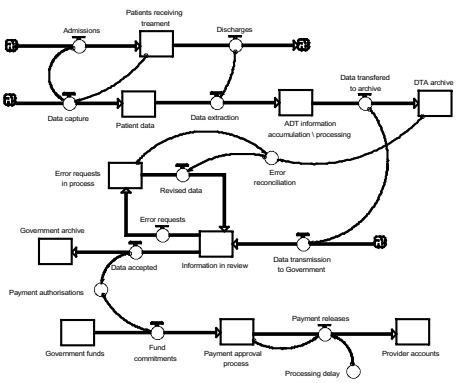

Figure 4 – Integrated process view of the ADT sub-system

The patient management system maintains the primary source of patient demographic information for the organization. It is a detailed, date related database that is an integral corner stone for health care providers as they move towards an electronic health record. Enhanced systems also maintain data encompassing patient admissions, ward transfers, discharges, appointments, operations and other clinical interactions. In one specific public health funding model the total procedures and diagnosis attributed to a patient during their inpatient stay are assigned a single code. The government health body responsible for funding and health quality uses this code in conjunction with the length of the patient's stay (LOS), time in intensive care and other critical clinical issues. The LOS is compared to the statistical mean of other patients accorded the same code from other health services and the level of funding determined. Funding is assigned to the health service retrospectively to the patients discharged from hospital. In some clinical areas such as the emergency department and surgical waiting list bonus funding can be achieved by meeting preordained patient related performance targets.

A Triple Pair Flow View of the Processes in the Patient Management System and Government Reporting

Using the construct described above, a first representation of the flow processes involved might appear as Figure 4. The sub-system is driven by the patient treatment process – this is shown at its most basic level of detail at the top as a simple admission / in-treatment / discharge process. (In a full model, this would involve a much greater level of detail as part of the core patient care delivery system.). Patient data is captured on admission, during treatment and on discharge, in the Admission Discharge Transfer (ADT) module of the clinical information system. After the data is accumulated, analysed, corrected and coded it is archived but also transmitted to the appropriate government body. This data may be checked against previous files and errors or anomalies returned to the hospital for review, after which it will be returned to the government body – this process is shown in an information recycling route. When the information is finally accepted it will be absorbed into the government body's database and, where appropriate, will trigger related payments to the hospital.

This is a first simple diagram and is based on certain assumptions about how health care activities are undertaken and what triggers particular activities. For example, in this representation, data is accumulated and analysed in the ADT system at the hospital and transmitted subsequently, possibly on a weekly or monthly basis, to the government; it is conceivable that at the present time or in the future this data could be transmitted in real time, in which case the model representation would be amended slightly. The model reflects an integrating view of how this subsystem presently operates or could operate in the future. It links the three critical process flows – patients, information, and funding, and can form the basis for debate and discussion on the effectiveness of the system and how the various stakeholders' needs and responsibilities inter-relate. While embedded within established business process engineering principles, the diagram is easily envisioned in terms of operations on the ground, enabling the focus of attention to be on the design of systems that will effectively deliver to all stakeholders. It can incorporate all-important data flow and identify trigger points which will impact on other stakeholders – for example when payments are to be triggered.

Diagnostic testing and payments sub-system

Diagnostic test order entry has ethical and security implications but in the appropriate system is a quality initiative for data entry into a diagnostic management system. It also has the advantages of reducing data entry clerk errors, save clinical time eliminating paper based sitting in a box waiting for collection and provides the clinicians ordering diagnostic tests immediate feedback on the cost of the tests being ordered and previous diagnostic interventions. Diagnostic test requests are delivered electronically to other systems both internal and external to the organization where diagnostic tests have been outsourced. Once the tests have been completed for the patient, information is returned to the diagnostic management system in the form of results. These results if in particular are of a pathology

nature can be in a cumulative format to provide instant access to trend analysis. Cost of the tests performed and billing requisition is also returned in a combination of electronic and hard copy means to the health care provider, government body, insurer or patient him or herself.

An integrated view of the processes involved in diagnostic testing

The second sub-system discussed above concerns diagnostic testing, and again a simple representation of the integrated set of process flows is shown in Figure 5.

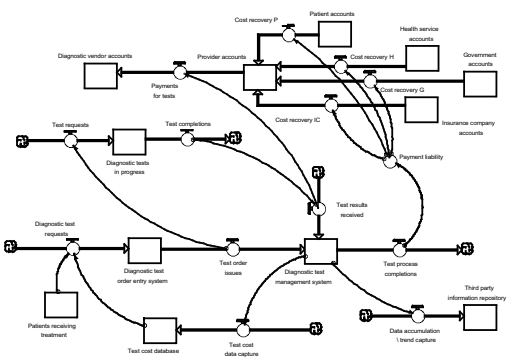

Figure 5 - Service, information and money flows involved in diagnostic testing

The central spine of the diagram reflects the process of requests for diagnostic tests being raised and then completed. Depending on hospital procedures, tests orders might be raised at the point of treatment or through a central function. When test orders are issued they trigger the request for the test at the test service providers – an internal department or external vendor – and are then logged into the diagnostic test management system. In terms of understanding the inter-related processes from the hospital's perspective, the depiction here is possibly adequate, though the vendor itself will have its own interacting system of test backlogging, information management and so on.

When the test results are received back by the management system, payments to the vendor can also be triggered. The management system will also analyse all tests completed and bill out as appropriate to the responsible institution, the patient him or herself or their insurer. As part of the system, represented as a small structure at the bottom left, a database can be maintained to provide feedback to clinicians and possibly to inform them for their future clinical decisions. Data may be accumulated, analysed for trends and so on as well as provide external agencies involved in disease containment and healthcare policy. As in the previous example, this is only a very simple representation capturing processes only at the coarsest of levels in terms of aggregation, detail, and alternate or parallel processes. Such an initial model as this will likely be the starting point for an integrated design processes for emerging systems.

Conclusions

The approach described here reflects that the highest quality levels in electronically based fulfillment systems in healthcare can indeed be best achieved where an integrative approach to system design is applied throughout the system visioning, processes specification, and detailed design process. There have been many documented failures of large ICT and electronic fulfillment systems especially in the public and health sectors where the perception was that the design processes were unable to cope with the system complexity, the diverse and sometimes competing objectives held by different stakeholders, and multiple political agendas surrounding the service.

Abstract

Faulty exchange and impaired access to clinical information is a major contributing factor to the incidence of medical error and occurrence of adverse events. Traditional methods utilized for systems analysis and information technology design fail to capture the nature of information use in highly dynamic healthcare environments. This paper describes a study designed to identify information task components in a cardiovascular intensive care unit and the development of an observational data collection tool to characterize the use of information in this environment. Direct observation can be a time-consuming process and without easy to use, reliable and valid methods of documentation, may not be reproducible across observers or settings. The following attributes were found to be necessary components for the characterization of information tasks in this setting: purpose, action, role, target, mode, and duration. The identified information task components were incorporated into the design of an electronic data collection tool to allow coding of information tasks. The reliability and validity of this tool in practice is discussed and an illustration of observational data output is provided.

Keywords:

information, systems analysis, systems design, observation.

Introduction

The communication of clinical information is the basis for coordination of patient care (1). Healthcare professionals work in teams that require circulating information to maintain team reliability. Team members use each other and Information Communication Technology (ICT) as repositories and depositories of their collective group knowledge, maintaining their own situational awareness for team coordination. Not surprisingly, faulty clinical communication and information access is a major source of error that can result in adverse events and poor patient outcomes (2). In a study designed to analyze the causes of medical errors, Leape et. al.(3) found that all seven of the most frequent medical errors identified were due to impaired access to information. These errors were primarily the result of system design faults and accounted for 78% of the total errors uncovered. Progress toward decreasing the error associated with medical care will depend heavily on better systems analysis and design.

Traditional systems analysis techniques to determine information and communication technology requirements for healthcare were originally developed for the design of business information systems. Generally, business procedures are analyzed through the use of interviews, questionnaires, focus groups, and the examination of organizational documents such as job descriptions, organizational protocols, and organizational policies (4).

There are several problems with using this approach to designing information and communication systems for healthcare. One problem is the extremely dynamic and mobile nature of healthcare work. The variability of healthcare work allows for only component segments of work to be standardized, and even these are subject to change from one instance to the next (5). Users jump from one activity to another, perform activities differently under stress, and with different levels of experience (6). In addition, healthcare practitioners are highly mobile and favor synchronous communication (7). However, healthcare team members are geographically distributed and not always in close enough proximity for face-to-face verbal communication. This is in contrast to the environment that most information systems were originally designed for; stationary workers at a desk using a desktop computer (8).

Another problem is that the use of surveying, interviewing, and focus groups alone implies that the users can articulate their work processes in an unambiguous manner. Unfortunately, discrepancies arise between reported and actual work practices, making direct observation the most reliable method for data collection (9). Direct observation can be a time-consuming process and without easy to use, reliable and valid methods of documentation, may not be reproducible across observers or settings. Clearly there is a need for tools that can make the observation processes more reliable and standardized. The purpose of this paper is to describe the development and evaluation of a mobile electronic data collection tool designed to capture information tasks of healthcare workers. It was originally developed by direct observation in a cardiovascular intensive care unit (CICU), but has since been adapted for other settings.

Methods

Development of mobile data collection tool

The electronic observational data collection tool designed for use in this study builds on previous work to develop an observational data collection tool designed and pilot-tested by Moss, Xiao, and Zubaidah (10) to determine information needs through the observation of charge nurses in a six-room trauma center operating room (OR) suite. The tool was pen and paper based and allowed coding of communication between healthcare workers. In the present study the tool was not only automated, but was refined to allow the documentation of all clinical information use, not just verbal communication.

Tool development and refinement

The original categories were expanded and new categories were added in order to characterize the totality of care in the CICU. Initially, observations were recorded on pencil and paper documenting the communication activities and information use of individual healthcare team members in their usual activities. These observations served to confirm the preliminary logical data collection codes and to identify additional codes. Observations were made during different periods of the day in 3-4 hour increments of time in order to capture various activities of each team member. During this initial stage, statements made by participants were written down as comments along with the corresponding activity.

In addition to the observations, team members were interviewed to obtain a description of unit activities (i.e., how patient transfer and family visitation is accomplished) and role responsibilities. The unit was toured to ensure the all modes of information exchange utilized were included as a tool category choice. Observations in the clinical setting were repeated until stable categories were established for each participant's information use. Approximately 50 hours were spent in this initial paper and pen phase. The observations in this phase were important in identifying who regularly participates in the care of the critically ill patient, modes of information and communication utilized, and the nature of information tasks in this environment.

The accumulated data were analyzed through the use of inductive content analysis. Content analysis involves the use of two interrelated processes: identifying specific characteristics of concepts to be measured, and employing explicit rules for identification, coding, and recording of concept characteristics (11). Categories can be identified inductively through an analysis of the content, or deductively wherein theory-based categorical schemes are defined prior to data analysis (11). First, two experienced critical care nurses reviewed and sorted the data into information categories and associated category selections individually. Then, each individual categorization was compared and a final set of categories with associated definitions was developed. Through an iterative process, selections under each category were further developed and validated in the clinical setting, until the categorical set was stable.

Tool automation

The paper and pen tool was transferred into an electronic format utilizing Microsoft Access to build a forms-based tool on a tablet computer. The observer was able to follow healthcare team members during the course of their work entering data directly into the study database through the use of a stylus pen. The data collection tool allowed rapid coding of information tasks in a uniform and consistent manner. Collecting data in this manner insured that the data were in a format amenable to analysis of information tasks.

Reliability and validity

Healthcare team members participated in every phase of the tool development. Categorizations of information tasks as well as the selections under these categories were reviewed by CICU healthcare team members for accuracy and comprehensiveness. The completed electronic data collection tool was also reviewed by CICU team members for face validity.

To insure reliable coding of information tasks in the setting, extensive training of data collectors was completed. Data collectors practiced data collection in the CICU and met with the principal investigator (JM) after each session to discuss the proper coding of each information task situation. In addition, the forms-based design of the data collection tool guaranteed that data would be collected completely and in a standardized manner.

In a study of operating room communication, an earlier version of this tool demonstrated that the tool's categorical set was able to show differences between characteristics of communication in two different settings and similarities in characteristics of communication in similar settings (12). The sensitivity of the tool's categorical set was demonstrated by comparing the original data with data obtained from a general OR suite in a comparison hospital (12). These data demonstrated that the identified categories were able to discriminate between information needs in different types of operating room suites. (i.e., demonstrated construct validity). The same technique was used in this study to determine if data would vary in an expected and explainable manner demonstrating construct validity. Observations were conducted on a medical nursing unit and compared to observations conducted in the CICU. The patient population, physical work environment, and information communication technology were all very different from the CICU.

Results

Information task attributes

The following attributes were found to be necessary components for the characterization of information tasks in this setting: purpose, action, role, target, mode, and duration. These attributes are described in detail below.

Purpose

Information task purpose is the reason for initiating the information task and was determined to fall into one of

five categories: team status, patient status, task status, instruction, and equipment management

- Team status- information task that is essential for the coordination of team members (i.e. reporting patient transfers, admissions, staff assignments; overhead page of staff member; writing patient's on-call time from OR on whiteboard, on-call assignment; patient assignment to nurse/team)
- Patient status- information task related to a particular patient's physiologic status (i.e. reporting vital signs, blood gas results; viewing monitor displays; viewing x-rays; reading test results; documenting patient assessment)
- Task status- information task that results in the performance of work or an action (i.e. verbal request for a medication, treatment, lab, or x-ray order; scheduling/ordering a medication, test, surgery, or consult in the computer; checking on/delegating a task)
- Instruction- information task related to the exchange of knowledge (i.e. directing an orientee; drug/diagnosis reference; studying/teaching/testing)
- Equipment management- information task related to the preparation, function, placement, or location of equipment (i.e. location of equipment in the unit, reporting of malfunctions; directing use of equipment; cleaning/sterilizing equipment)

Action

The information task component 'action' is a verb used to modify the information task purpose. Four attributes were found to be necessary for the description of information task action in this environment: directing, receiving, reporting, and seeking.

- Directing- information tasks related to delegating or coordinating the work of others
- Receiving- information tasks related to the reception of information
- Reporting- information tasks related to the presentation or output of data
- Seeking- information tasks related to the active search for information

Role

Role describes the functional role of the central participant being observed. These functional roles included: nurses, pharmacists, patient care technicians, unit clerks, and laboratory technicians.

Target

The target of the information task is the source or conduit of communication or information exchange. For example, information might be sought from a physician, nurse, or system database. Twenty two information task targets were identified in this study. These targets included both individuals such as physicians, nurses, and laboratory technicians as well as electronic sources such as information system databases and patient monitoring devices.

Mode

The mode of the information task is the method used by participants for the transmission or procurement of information. Seventeen separate modes of communication were identified in this context including interpersonal (e.g. .face-to-face, wireless phone), information communication systems (e.g. computerized information system), public display artifacts (e.g. whiteboard), printed material (e.g. printed reference), and personal notes.

Duration

The duration of each information task was recorded on the tool by starting the tool timer at the beginning of the task and stopping the timer at the completion or abandonment of the information task.

Reliability and validity

Tests of inter-rater reliability of the observational coding in the CICU were conducted between the study data collector and one of the investigators (JM). Both study team members observed the same nurses at the same time, entering data into separate tablet computers. This process was completed on approximately 7% of the information task observations. Analysis of these data indicated 91% percent agreement between the observers in the CICU (13).

Data analysis revealed that the tool was able to show variation and similarities in information tasks between the two types of units in an expected manner. For example, CICU nurses' information tasks were more likely to be related to managing patient data (50%) than Medical unit nurses (38%) and Medial unit nurses were more likely to be involved in information tasks related to directing the work of others (14.6%) than CICU nurses (8%). Table 1 compares nursing information tasks by purpose. Table 2 provides a comparison of nursing information tasks by action.

Table 1 - Comparison of nursing information tasks by purpose

Purpose mgt	patient	team	task	instruction	equip
CICU	50%	21.7%	11%	10.9%	6.3%
Med Unit	38.3%	23.7%	24%	10.5%	4.9%

Table 2 - Comparison of nursing information tasks by action

Action	Directing	Receiving	Reporting	Seeking
CICU	8%	21.3%	36.2%	10.9%
Med Unit	14.6%	21.9%	37.9%	25.4%

Characterization of nursing information tasks

Although data were collected on the information tasks of several types of healthcare team members, nursing information tasks are characterized in this paper to provide an example of potential data collection tool output. Twelve CICU nurses were observed for approximately 120 hours. From these observations data were recorded regarding a total of 1,631 information tasks. Duration of information tasks ranged from 1 second to 14.11 minutes with a mean duration of 33.41 seconds. Due to space limitations only a sample of these data are presented.

Patient status

Reporting information was the most frequently performed information task (43%) related to patient status, followed by seeking information (39%), receiving information (17%), and directing (<1%). More than 47% of the time nurses reported patient status information via a computerized information system. Also, nurses were more likely to seek patient status information from the computerized information system and patient monitors than any other source (81%). Unsolicited information regarding patient status was most frequently received via patient equipment alarms and alerts (20%). Nurses' most frequent reporting of patient status information verbally was to patient family and significant others (13%) and other unit nurses (10%). Surprisingly little patient status information was reported directly to residents (3%), or attending physicians (1%) in any manner.

Team status

A significant percentage of observed information tasks (21.7%) were related to directing, receiving, reporting, or seeking information for healthcare team coordination. The vast majority of these information tasks occurred face-to-face (76%) between healthcare team members. Other modes for the communication of team status information were public display artifacts such as whiteboards (5%) and telephones (4%). Almost no team status information was communicated via the computerized information system (<1%).

Discussion

Categorical structure

The categorical structure of the observational data collection tool developed by Moss, Xiao, and Zubaidah to characterize communication in Ors (10) bears some similarities to both the conceptual schema for communication space portrayed by Stetson et al. (1) and a categorization used by Coiera et al. (14) to study healthcare team communication in an emergency room. In the study of OR charge nurse communication (10) the researchers were able to determine information exchange through verbal communication and potential sources of communication error. Missing, however, was an important source of information exchange in the clinical setting: that between workers and other sources of information such as information systems, monitors, and public display artifacts. To better understand the use of clinical information in practice, we have expanded our conceptualization of communication to include any exchange of information whether between healthcare team members or team members and inanimate information sources.

To increase the granularity and usefulness of data collected we have added the category 'action' to modify and further describe the purpose of information tasks. Addition of the action modifier has allowed us to analyze the data and describe the healthcare information tasks at a level that can better inform the design and evaluation of ICT in practice illustrated by the characterization of information tasks for patient status and task status in the CICU data example.

Information task comparison

A comparison of data collected in the CICU and general medical unit illustrates the data collection tool's ability to discriminate between information tasks in different settings. For example, nurses on the medical unit were less frequently involved in information tasks related to patient status and more likely to be involved in information tasks related to task status. These variations are to be expected in this environment. Nurses in the CICU are constantly collecting and documenting patient information from patient monitors, equipment, laboratory, and physical assessments. The amount of patient data a less acutely ill medical patient generates is considerably less than a patient in an intensive care unit.

Nurses in a general medical unit are more likely to be involved in information tasks related to task status because they provide patient care in cooperation with unlicensed medical personal, delegating and coordinating the completion of patient care tasks. Another example of the increased need for general medical unit nurses to delegate and organize patient care is that only 4% of CICU nurses' actions related to task status involve directing tasks while almost 23% of these same information tasks require direction by the nurses on the general medical unit. Along the same vein, are the differences found in the frequency of information tasks associated with team status. While overall nurses in both units were involved in information tasks needed to coordinate the healthcare team at approximately the same rate, nurses working the general medical unit were much more likely to be directing team work than CICU nurses.

Implications for design

Information and communication system design in healthcare requires an understanding of how healthcare information exchange and communication occurs to enable the delivery of the correct information in the correct format. Little consensus exists in the literature as to the information needs of healthcare providers. This is not surprising, given that information needs are context specific (15) and will change with the clinical environment studied (12, 16).

Ammenwerth et al. identify the need to analyze healthcare institutions from five views: roles and responsibilities, information processing and information processing tools, communication between healthcare professionals, busi-

ness processes, and team structure and cooperation within teams (17). The tool developed in this study can serve as an aid to achieving these views of the healthcare environment. The categories of purpose, action, role, target, mode, and duration allow us to capture the use of information tools and communication between healthcare professionals during the course of their work to identify areas for system reengineering. The capacity to examine information system requirements through the use of an observational data collection tool that can be easily adapted for different settings will strengthen our ability to design systems that meet the information needs of healthcare workers.

Conclusion

In this paper we described the design and testing of an electronic data collection tool used to code observational data in a cardiovascular intensive care unit. The use of the electronic data collection tool allows a researcher to quantify and categorize the use of information during the course of clinical work, adding another dimension to traditional systems analysis. The forms-based tool design allows the observer to enter data directly into the study database using a lightweight tablet computer. Set responses and structured screen design insure that data are completely and uniformly recorded.

The tool can be used not only to inform information system design, but also to evaluate changes in interactions after the implementation of new information systems. The tool has been adapted for characterization of information needs in cardiovascular intensive care, a general medical unit, and pediatric care teams. Currently, the tool is being adapted to characterize the process of intravenous medication administration in intensive care units.

Acknowledgments

We would like to acknowledge the cooperation of all the CICU healthcare team members for their support and willingness to be a part of this study. We would also like to acknowledge the consultation of Dr. Yan Xiao on the development of this data collection tool. This study was supported by a grant from National Library of Medicine (NIH-LM008240-0).

Towards Sustainable e-Health Networks: Does Modeling Support Efficient Management and Operation?

Martin Staemmler[a]

[a] *University of Applied Science, Stralsund, Germany*

Abstract

e-Health Networks require cost-effective approaches for routine operation to achieve long-lasting sustainability. By using a model to represent (i) the network's enterprise functions, (ii) the applications used and (iii) the physical implementations, the tasks of management, adapting to changes and providing continued maintenance can be effectively supported. The paper discusses approaches for modeling, assesses their usefulness for the above tasks and decides on the use of the 3LGM meta model. Based on this concept, three ways for modeling the specific properties of an e-Health network are presented, leading to the decision to represent the hospitals involved in only one layer. As a result the model derived is presented, assessed and proved to support strategic management, day-to-day maintenance and documentation.

Keywords:

e-health network, health telematics, health information system, meta-model.

Introduction

Establishing e-Health networks tends to follow a typical paradigm: (i) planning and development, (ii) implementation and (iii) routine operation [1] with periods (i) and (ii) typically receiving partial support from regional or national grants, funding agencies or commercial organizations (e.g., health insurance company, hospital trust, etc.). As a result these two periods lead to a successful implementation, whereas period (iii) – the routine operation – reveals the sustainability of the approach taken. Maintaining routine operation proves to be the cornerstone of e-Health networks and, sadly to say, has lead to numerous failures. Routine operation of an e-Health network needs to cope with:

1. regulatory policies for health care provision
2. partners joining and leaving, changes in the way of cooperation between partners, e.g., requests for specific services for a subgroup of partners, new services
3. limited financial resources compared to the initial periods and
4. constant changes both in the technology used for the e-Health network and at each partner's site.

Item 1 to 4 have motivated an attempt to representing the e-Health network by a model in order to assist in the management decisions, to implement an effective change-management and to support the day-to-day operation including error conditions.

Modeling has been used in various ways: (i) to automatically derive a network infrastructure using ICMP and SNMP, (e.g., Scotty [2]) as public domain tool or commercial tools [3], (ii) to describe information system architectures[4, 5], (iii) to provide health specific reference information system models e.g., HISA[6], HL7-RIM[7], CORBAmed[8] and (iv) to document and analyze business processes e.g., with ARIS[9] or Bonapart[10]. However, most of the model approaches address only a part of the requirements to allow strategic management and day-to-day operation of an e-Health network. With the 3LGM the Institute for Medical Informatics, Statistics and Epidemiology, Leipzig, Germany [11,12] have developed an extensive meta model together with a tool for modeling hospital information systems. It uses three layers to represent enterprise functions on a domain layer, their mapping to application components on a logical tool layer, and data processing components and communication on a physical layer.

The objective of this paper is to use the 3LGM methodology for modeling an e-Health network and to assess its usefulness for the strategic management as well as for the day-to-day support and maintenance.

Materials and methods

The e-Health network

The "Health Telematics Network for the Support of Tumor Diagnosis and Treatment in the Euroregio Pomerania" extends to more than sixteen hospitals in the north-eastern part of Germany and in the western part of Poland [13, 14]. In general, the hospitals involved utilize a subset of the whole set of enterprise functions available:

- teleradiological services (emergency consultation, second opinion),
- telepathological services (perioperative instantaneous section, second opinion),
- telecardiological services (ECG analysis and reporting, second opinion prior to cardiac intervention),

- teleconferencing (with two and more partners).

These interdisciplinary enterprise functions are mapped to dedicated applications, thereby introducing mutual dependencies and requirements for the network topology (point-to-point versus hub-and-spoke). Additionally, the communication is based on a variety of access technologies, like dial-up lines using up to eight ISDN channels, leased lines, Internet based communication and radio links.

The revised three-layer graph-based meta model (3LGM)

The 3LGM has been primarily developed to model enterprise functions and associated applications and systems for information managers in hospitals [11, 12]. It holds three layers and defines relations to link adjacent layers.

- The domain layer models enterprise functions and entity types. Enterprise functions may use or create information about an entity of a given entity type, e.g., ADT functions use/create information of the entity patient.
- The logical tool layer holds application components, which represent dedicated tasks within an application. Communication is achieved by component to component interfaces or between a component and the user by means of an UI. As an example one could consider the ADT component sending messages to the laboratory system or the laboratory using a web-based GUI to present lab results.
- The physical tool layer contains components to support the two upper layers. This may be hardware systems (e.g., computer, network components, etc.) or even persons e.g. for handling a paper document based archive.
- Links between functions of the domain layer with application components of the logical tool layer reflect the relations “can support”, “based on” or “triggered by”, e.g., the ADT function is supported by an ADT component customized for this usage with a configuration. Similarly a link from the logical tool layer to a processing component in the physical layer represents the mapping of an application component via a configuration to a processing component.

The 3LGM tool does not only allow for the visualization of the above-mentioned items but provides analysis means to follow the execution of an enterprise function, as it is worked on by one or more - potentially communicating - application components and implemented using hardware and network resources. In addition, these analysis facilities motivated the use of 3LGM for an e-health network in order support questions like “What is required for providing a second opinion service for a CT-scan between hospital A and B?”.

Deriving the e-Health network model

Comparing the 3LGM target domain “hospital” with an e-Health network it refers not only to one hospital but to several hospitals. Three different approaches to represent this fact in the model have been investigated.

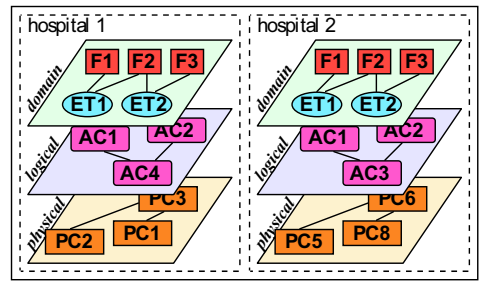

Figure 1 - Approach 1 with separate models for each hospital

The first approach relies on using separate models for each hospital as indicated in Figure 1. As a result the models shown represent two hospitals with identical enterprise functions (F1, F2, F3) and entity types (ET1, ET2) in the domain layer, some minimal differences between the application components (AC1 … AC4) in the logical layer and a mapping on separate physical components in the physical layer (PC1 … PC8). The drawbacks of this approach are (i) a repetitive modeling for at least the domain layer and (ii) more importantly the inability to perform an analysis across separate models e.g., for answering the question above.

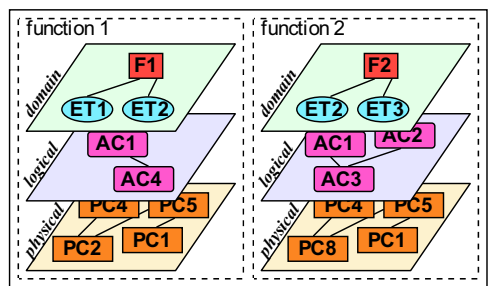

Figure 2 - Approach 2 with separate models for each enterprise function

The second approach groups into separate models according to the enterprise function F1 and F2 and is shown in Figure 2. Consequently these functions may use or create information for entities types, which are quite similar. Looking at the logical and the physical layer one finds different applications and physical components reflecting the resources of each hospital provided for a particular function. This approach causes duplicated items (e.g., AC1, PC4, PC5 and PC1) and thereby conceals a clear view.

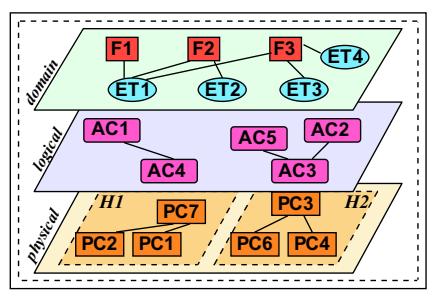

Figure 3 - Approach 3 with a model including all hospitals

The third approach focuses on avoiding the disadvantages from the ones above, however with the implication, that the definition of a physical component had to be extended to include a hospital as a grouping element (identified by the rectangles H1 and H2 in Figure 3. From this approach it becomes obvious, which enterprise functions are supported within the e-Health network (as depicted in the domain layer) and their relationship to application components.

Having modeled the inter-layer relations and dependencies an answer to a particular question could result in Figure 4, which maps the function F2 to the application component AC4 and the physical component PC6 as well as the function F3 to the application component AC5 and the physical component PC1. It is worth noting, that this approach would result in two paths if an identical enterprise function is performed between two hospitals in a cooperative session.

Since this approach provides a clear view on the e-Health network functionality it has been chosen for modeling.

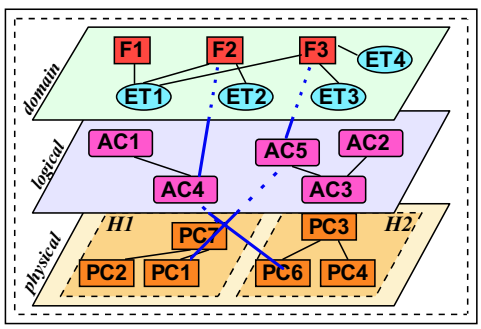

Figure 4 - Approach 3 together with inter-layer relations

Results

Figure 5 shows the model derived as a layered view. On the top layer the enterprise functions (teleradiology, telepathology, teleconference and communication/data security) have been detailed e.g. in order entry, image generation, reporting, second opinion, pseudonymization (patient identity replaced by a pseudonym) and secure transmission. Entity types identified are, for example, order, JPEG images, DICOM images, patient and tissue sample. The two types of images reflect two different usages: (i) JPEG for viewing only and (ii) DICOM for viewing and reporting at full image quality.

Application components are, for example, grouped by "Web-Viewer" and "DICOM Viewer" and hold sub-components like "Query", "DICOM Download", "Viewer". Finally the physical layer depicts a view on five hospitals with a detailed representation of their individual network infrastructure. The arrows between these hospitals and communication providers exhibit different routes between partners and clearly show potential and build-in fallback communications paths in case of a fault. Additionally, Figure 5 highlights a subset of the inter-layer relations modeled according to the selected function "emergency consultation".

Discussion

e-Health networks as well as health information systems exhibit quite some diversity reflecting heterogeneous institutional policies and communication links. Using the 3LGM tool this variety could be represented in the resulting model**.** Compared to typical network management tools [2,3], which fail to refer to applications, the 3LGM model widens the scope from enterprise functions and their relation up to network components. UML [15] diagrams allow to represent enterprise functions by means of use cases, to map processes to activity or sequence diagrams and to depict physical resources by deployment diagrams. However, UML diagrams tend to focus on specific views and provide a less integrated view on an information system with its internal dependencies and layers. Comparing 3LGM to business process oriented tools like ARIS[9] or Bonapart[10] which support simulation in time, the 3LGM model represents only static properties of the items of each layer. However, since the dependencies between the model items are known the 3LGM tool might be enhanced to support simulation for enterprise functions as well.

One of the main purposes was to perform an assessment towards the applicability of the 3LGM to an e-Health network Investigating three different approaches resulted in an approach with a coverage of all institutions in one model, but interpreting each hospital as a physical grouping component on the lowest layer. This is somewhat contradictory to the definition given with the 3LGM but simplifies the assignment of real physical components to each hospital. An alternative approach would have been to avoid the grouping and to assign real physical components by using a naming convention to a grouping for each hospital, which however would make the graphical representation less meaningful.

With the model being in place it assists in the management by various aspects: (i) effective documentation due to references included as attributes for each model item (ii) analysis functions to search for dependencies between model items, and (iii) support for error analysis and maintenance, in particular to derive fallback solutions, e.g., alternative communication paths. For enhancing the applicability towards (i) and (ii) the 3LGM would benefit from a version control mechanism.

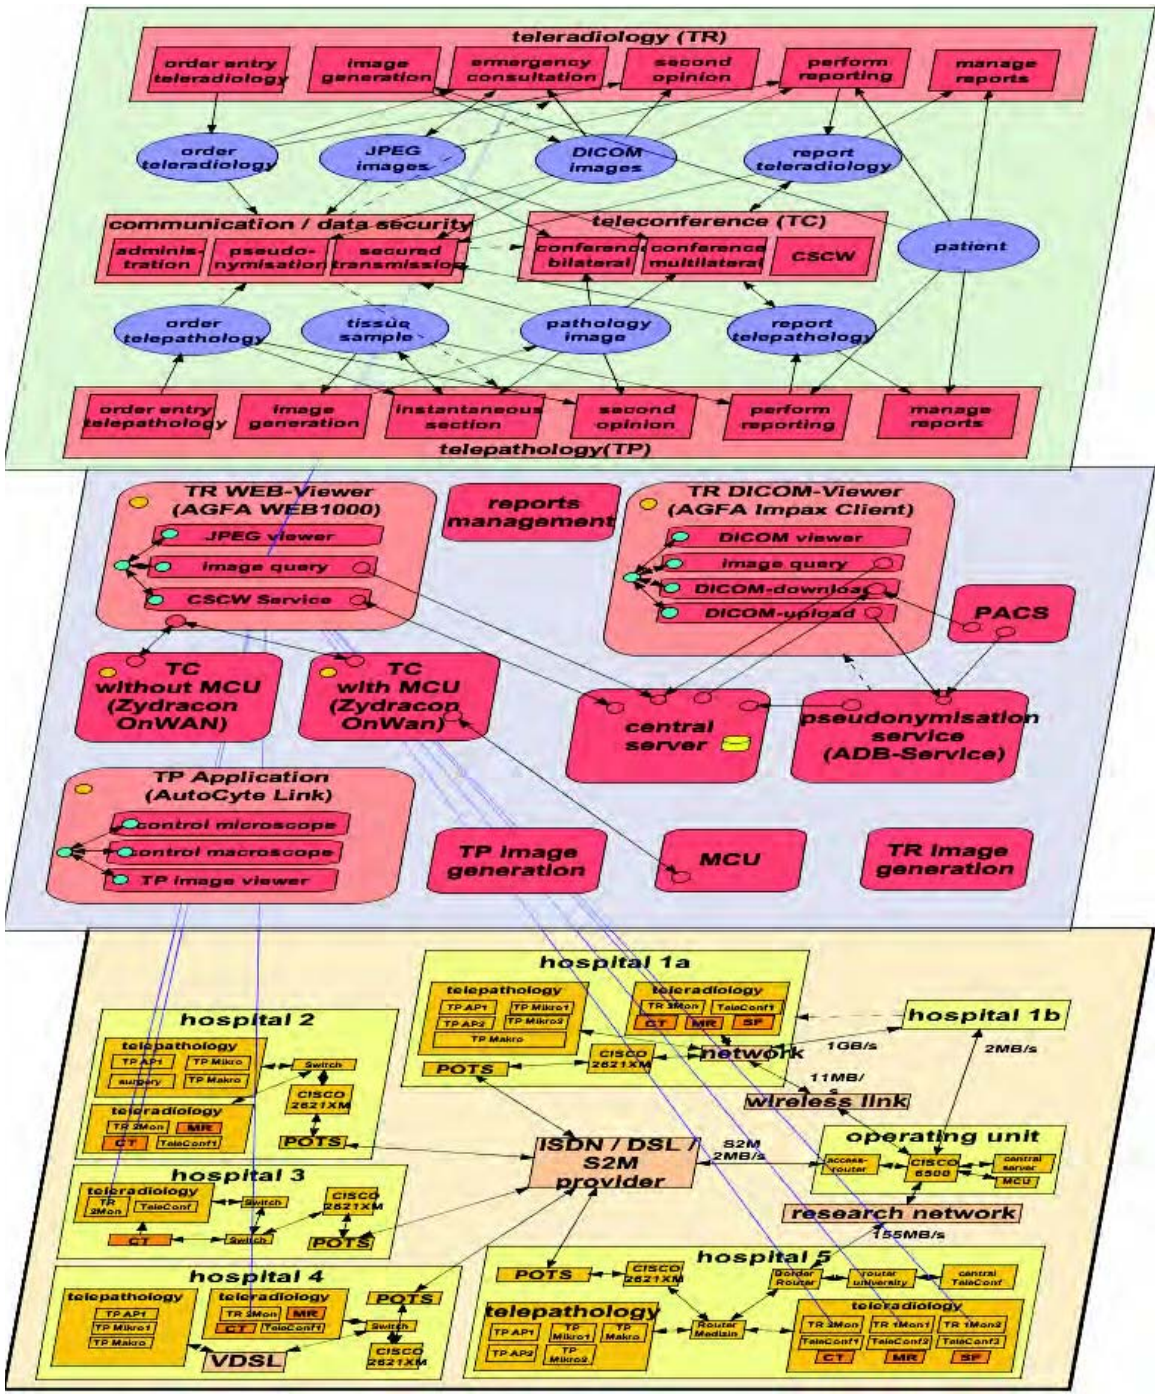

Figure 5 - The three layers as a result of the modeling

The initial effort to derive the model required a substantial amount of work, however in return, the model served both management and day-to-day maintenance. Current extensions of the network – like a dedicated sub-network between two hospitals – have been planned on the basis of this model resulting in an immediate documentation of the new enterprise function and its mapping to further and existing applications as well as to the physical layer.

Some minor handling problems, e.g., a limited workspace, missing grid lines, limited drawing functions and/or an adjustable level of detail did not have much impact on the effective work with the 3LGM.

Conclusion

The 3LGM successfully proved its applicability to model an e-health network. The model obtained serves for at least three aspects: strategic management of such an e-Health network, day-to-day maintenance and in depth documentation of the typical complex network setup. As such it contributes to the sustainability in the "routine operation" period and adds to a cost-effective support and operation.

Acknowledgments

The modeling would not have been possible without access to the project "Health Telematics Network supporting Tumor Diagnosis and Therapy in the Euroregio Pomerania" which has been granted by the European Commission for regional development (INTERREG A) together with the support of the federal state Mecklenburg-Vorpommern. Furthermore, the author wants to thank Lars Kubowicz for the fruitful discussions and the support in implementing the model.

The *open*EHR Java Reference Implementation Project

Rong Chen[a], Gunnar Klein[b]

[a] *Department of Biomedical Engineering, Linköping University, Sweden*
[b] *Department of Medicine, Karolinska Institutet, Sweden*

Abstract

The openEHR foundation has developed an innovative design for interoperable and future-proof Electronic Health Record (EHR) systems based on a dual model approach with a stable reference information model complemented by archetypes for specific clinical purposes.

A team from Sweden has implemented all the stable specifications in the Java programming language and donated the source code to the openEHR foundation. It was adopted as the openEHR Java Reference Implementation in March 2005 and released under open source licenses. This encourages early EHR implementation projects around the world and a number of groups have already started to use this code.

The early Java implementation experience has also led to the publication of the openEHR Java Implementation Technology Specification. A number of design changes to the specifications and important minor corrections have been directly initiated by the implementation project over the last two years. The Java Implementation has been important for the validation and improvement of the openEHR design specifications and provides building blocks for future EHR systems.

Keywords:

Electronic Health Records, Health Information Systems, *open*EHR, Java, open source.

Introduction

The *open*EHR foundation, a not-for-profit organization has since 2004 published a series of design specifications [1] for semantically interoperable and future-proof Electronic Health Records (EHR) systems based on more than 15 years of research and development projects in the EU and Australia. The most distinctive feature of the *open*EHR design is that it separates the clinical concerns and the technical design of EHR systems by an innovative design approach called two-level modelling [2]. The first level model takes care of the technical concerns and deals with the information structure and data types with a small set of information model classes, upon which the core of EHR systems can be built. The second level of model handles the concerns of the clinical domains, which are about how to represent and communicate the semantics of the clinical content. Because of this separation of concerns, stable EHR systems can be built without knowledge about specific clinical content necessary in different fields. The specification of clinical content can be authored and amended later, shared between health organizations since it can be loaded into EHR systems at runtime. The result is highly adaptive EHR systems and vastly improved semantic interoperability [3]. Such systems are sustainable since they can evolve as the clinical requirements changes.

A group of developers from Sweden specialized in EHR systems became inspired by the design ideas behind *open*EHR and started initial exploration in 2004. This led to the initial Java implementation of the core *open*EHR specifications. The group was invited to release the software under open source license so the work could be reused and possible enhanced by other developers. The group favoured the idea and announced the availability of the Java code initially released under GPL license. Later the same year, the software was donated to the *open*EHR Foundation and the license changed to the less restrictive MPL/GPL/LPGL triple-license to be compatible with the *open*EHR Foundation's licensing model. The action was welcomed by the *open*EHR community and the software was formally adopted as the Reference Implementation in the Java programming language in 2005.

Materials and methods

The Java implementation is implemented with the Java programming language with the Java 5.0 platform to take advantage of the "generics" and other new language features. Several well-established open source libraries have been used, e.g. log4j and commons-lang from the Apache Software Foundation. The implementation does not make any assumption of where and how the components would be used, e.g. client or server side application. A principle of the Java implementation is to be as faithful as possible with the specification while keeping the Java look-and-feel. Being faithful with the original design specifications means that the complete semantics of the design should always be correctly implemented in the Java language to ensure interoperability with *open*EHR systems implemented in another programming language. It involves mapping between *open*EHR assumed data types and native Java types.

One of the difficulties was how to properly handle invariants checking in the class specifications. It is well-known

that Design by Contract is not natively supported by the Java platform although there are 3rd party libraries aiming to support it in Java. The same effect is achieved through the use of immutable Data Value object pattern with incoming parameters checking by the object constructors. Keeping the Java look-and-feel makes the software familiar to Java developers and involves use of the standard naming convention and common Java idioms. The details of the work have been documented and explained in the *open*EHR Java Implementation Technology Specification (ITS) [4] and the design document of the Java Implementation.

The software from the Java Reference Implementation project is released under open source licenses, namely Mozilla Public License (MPL), Gnu Public License (GPL) and Less Gnu Public License (LGPL). The users can chose any one of these three that suits them best. It is worth to mention that among these three, MPL is the least restrictive and GPL is the most prohibitive for commercial use. This means that the even commercial suppliers can use this software as part of their offerings without any commitment to *open*EHR. The software is freely accessible through Internet and all changes are public and accessible through the source repository. Software bug fixes and patches contributed by developers are verified and committed to the source repository.

A set of rules have been applied in the early stage of the project to guarantee the quality of the software. Unit testing is used extensively to make sure the implementation meets the intention of the design. It provides the extra value as further documentation beside the specification since it exercises the code in real use scenarios. Unit testing is usually integrated into the build script so that the test cases can be executed by anyone at any time. Since it can be automated as part of the build cycle and run often, unexpected errors can be caught when they occur. The development guidelines require that each bug fix in the production code should be accompanied with a minimum test case that demonstrates the bug before the fix and gets passed when the bug is fixed. This so called regression test provides a safety net to the code base to make sure the old bugs will not re-appear in the subsequent versions.

The software build is managed by Maven from the Apache Software Foundation. It provides comprehensive support of software projects and handles software library dependency particularly gracefully. Unit testing of the software is seamlessly integrated with build. A Continuous Integration tool called Continuum also from Apache is used to execute the Maven build script directly for monitoring the source code changes in the source repository and make automated software builds.

The Java implementation projection software is currently change controlled by a Subversion repository hosted on the *open*EHR site. Like CVS, Subversion is an open source product for managing software changes and favoured by many open source software projects around the world. The URL to reach the root directory of the Java project in Subversion is http://svn.openehr.og/ref_impl_java.

Results

Table 1 - Software artifacts provided by the Java Reference Implementation Project

Component Name	Implemented Specifications	Brief Description
openehr-rm	*open*EHR Reference Information Model – Common, Support, Data Types, Data Structures, Demographics, EHR	Base component that provides the Java implementation of all *open*EHR Reference Information Models
openehr-aom	*open*EHR Archetype Object Model	Object validation and construction
openehr-ap	*open*EHR Archetype Profile	Implementation of the domain data types
adl-parser	*open*EHR Archetype Definition Language	Translates ADL to AOM
adl-serializer	*open*EHR Archetype Definition Language	Serializes AOM to ADL
rm-builder	*open*EHR semantics	Reference Model objects builder

The software from the Java implementation is divided into several software components each with its own clearly defined responsibility. The openehr-rm, which stands for *open*EHR Reference Model (RM), is the base component that implements all Reference Information Model specifications, namely Data Types, Data Structures, Common, Support, EHR Extract, and Demographics. It maps *open*EHR assumed data types into Java native data types and implements other higher level data types. It also implements path based queries for finding leaf nodes in a large object tree with single crafted paths. All constructors of the RM classes have annotations for the parameters so that the invocation of object construction can be done automatically. This feature is used by the rm-builder for RM objects construction with Archetypes. This component is the fundamental building block for all subsequent components. According to the *open*EHR two-level modelling approach, the core of EHR systems can be built entirely based on the RM components, e.g. EHR data query and storage mechanism can be built on top of the RM component.

We also implemented the openehr-aom and openehr-ap, which stands for *open*EHR Archetype Object Model (AOM) and *open*EHR Archetype Profile, respectively. These components provides in-memory representation of Archetypes, which are usually authored and transmitted in Archetype Definition Language (ADL) format but parsed into AOM in-memory format to be used in runtime. They also provide support for object validation and creation on single archetype constraint level.

The rm-builder component is based on the openehr-rm, openehr-aom and openehr-ap components and provides Archetype based object validation and creation support. The rm-builder guarantees that the semantics in the archetypes are faithfully reflected in the process of RM objects validation and construction. The implementation of RM, AOM and the support for Archetypes based validation and construction is often referred to collectively as the *open*EHR Kernel.

The adl-parser component implements Archetype Definition Language and transforms Archetypes in ADL textual format into in-memory AOM form. It is built on a JavaCC, which generates the parser based on a grammar file. The grammar file is directly translated from the ADL specification with necessary changes. The adl-parser is the entry point for Archetypes into any EHR system so it is of vital importance for the correctness of the behaviour of an Archetype based system. It can also be used, e.g. in an Archetype editor, an authoring environment for Archetypes to check the correctness of the Archetypes in ADL format.

The adl-serializer provides conversion of Archetypes from in-memory AOM form to textual representation in ADL format, the reverse of what the adl-parser does. It is often used before an authored archetype can be stored and transmitted between systems.

Java implementation technology specification

The Java implementation experience has been summarized and written up as the Java Implementation Specification (ITS) of *open*EHR design, [4] which is now included as part of the official release of the *open*EHR specifications. The document is still in beta version and being updated to reflect the feedback from the implementation activities. The purpose of this ITS is to provide guidance on perspective implementation of the *open*EHR design on the Java platform and make sure the semantics of the design is kept faithful in the Java programming environment. More importantly, it should also ensure that *open*EHR systems from different computing platforms are interoperable.

During the last two years, a number of design improvements have been directly initiated from the Java implementation project and indirectly from other development projects that are based on the Java reference implementation components. A number of additional minor issues, e.g. inconsistency in the documentation have also been raised, particularly during the first stage of the implementation when the specifications were just released before version 1.0.

Table 2 - Selection of specification changes accepted by openEHR due to the Java implementation

Related Specification	Description
Data Structures	EVENT should inherit from LOCATABLE.
Data Types	Date/Time classes improvements
Archetype Object Model	Missing adl_version in ARCHETYPE
Archetype Object Model	Table for missed class ASSERTION_VARIABLE added. Assumed_value assertions corrected; standard_representation function corrected
*open*EHR Archetype Profile	Fix invariants in C_QUANTITYclasses. Correct C_QUANTITY.property to CODE_PHRASE. Correct invariants for C_CODED_TEXT; correct inheritance for C_DV_ORDERED. Corrected C_QUANTITY_ITEM class. Corrected errors in DV_STATE model by adding 2 new classes
Most of the models	Use constants instead of literals to refer to terminology in RM, mainly used in the invariants part of the class descriptions
Common, EHR	Make DIRECTORY reusable, add new directory package
Demographic	Remove details /= Void invariant from PARTY
Archetype Definition Language	Numerous clarifications of the ADL syntax and semantics

Some design issues were not obvious initially but became apparent when more implementation experiences were gained. For instance, the modelling of EHR package initially included support for a directory based way of organizing records. When the requirement was identified to support a good way of organizing demographic objects, it seemed natural to extract the generic directory support into a more generic package so it can be re-used for organizing objection other than EHR compositions.

Sometimes, implementation in the programming language other than the one used or envisioned by the original designer can lead to improvement of the design itself. One example of this is within invariants checking, present in many places of the specifications, built-in terminology names are referenced in plain text format. This is recognized as an anti-pattern among Java developers since such way of handling textual constants would lead to more brit-

tle software since any deviation, e.g. a typo of the terminology name will not be caught by the compiler during software compilation phase but only show up during system runtime. A better way of doing that is to introduce a type safe enumeration pattern. This design improvement has been well taken and incorporated into Release 1.0.1.

Building blocks for EHR applications

The original Swedish team has built a pilot Child Leukaemia Treatment management application using the Java components for Karolinska University hospital in Stockholm. It is a web-based system designed to facilitate chemotherapy management for child Lymphoblastic Leukaemia patients in maintenance stage. Unlike conventional EHR applications, the clinical content is defined by archetypes and the screens are generated dynamically.

The Medical Informatics group from Linköping University has built a number of applications based on the Reference Java Implementation and made substantial contributions to the Java project. The Java Archetype Editor [5] has particularly received good comments and is now released under open source license. A web-based patient portal application has been built as part of a master student's thesis work. An ongoing EHR visualization project [6] uses the Java implementation as a way of representing EHR data.

A Biomedical Engineering Group from Uruguay funded by the Ministry of Education is building an Intensive Care Unit application, which is based on the existing Java components. The system covers admission to ICU, clinical variables monitoring, laboratory requests and tracking, instructions on medication, nutrition, fluids and tracking of instructions status, clinical logbook for each patient. The system will be installed for a one year field test in three ICUs in Uruguay during 2007.

In the Netherlands, a team of developers is building a commercial solution to support elderly care based on the openEHR Java implementation. The system supports a wide range of users from General Practitioners (GP), nurses, to elderly / disabled people and other involved heath professionals. The solution is particularly favoured by the customers since it is based on public specifications and open source software.

A research team from the Health Informatics Group, Central Queensland University, Australia is building a new version of the Archetype Finder that uses the Java ADL parser.

Since the software was released as open source in 2004, it has been constantly updated and maintained by the Java Reference Implementation team. Developers around the world have been giving feedback, bug reports and software patches resulting in overall increasing quality of the code base over time. The initial release was based on the specification release 0.95. During the last six months, the team has spent considerable effort to update the implementation towards the latest specification 1.0.1. At the same time, the code base has been re-organized to facilitate re-use and improve testability even further.

Discussion

Nowadays health information standards are becoming increasingly complicated. This makes it very difficult to rely on a textual document only for the description of the semantics of the design. If the intention of the standard is misinterpreted, the risk of creating non-interoperable software is very high. Unfortunately the formal standardization bodies CEN and ISO have not yet allowed publication of standards artifacts in forms other than human readable documents. Data structures intended for use by software development tools can sometimes be distributed as informative associated material but not as the core of the standard. Open source reference implementations can be very useful to ensure a common and complete understanding of a written specification facilitated by the fact that such software like ours is usually developed in close collaboration between the specification designers and the implementers. The software can be more detailed and precise than the textual specification and be easily understood and put to production by target developers.

The fact that a particular implementation is done on a specific platform means not only that it proves the specification is possible to implement but also that the implementation details have been worked out for that specific platform. There are a large number of similar examples in the IT industry. The Java specifications are released together with an open source reference implementation sometimes from Sun itself but also from open source organizations like Apache.

Innovative ideas need to be experimented with and verified before they become part of a formal specification. The IT industry has seen too many “committee-made” design specifications, which can be very hard to implement and truly annoying to work with if they unfortunately become formal standards and last for years. So it is really important to get some real implementation experience and let the feedback from that guide the refinement of the design specifications. Because open source implementations are readily accessible by large user base and perspective implementers, they are particularly suitable for validating new design ideas. The *open*EHR community, which consists of both clinical professionals from many specialities, technical developers and also medical informatics researchers, is a particularly good example of this. With experience from international standardization activities and open source software projects, the authors argue that an open source reference implementation is an ideal way of ensuring the quality of international standards for communication.

The open source licenses used by the Java Implementation Project are very relaxed, which means that they allow commercial applications to be built on top of these components. These licenses effectively remove entry barriers for small companies and academic researchers that may not have the resources to implement the design from scratch. If more companies choose to use this solution, it will undoubtedly increase the interoperability between EHR systems. Because of the availability of the open source

implementation, more medical informatics research activities could be performed in connection with EHR data e.g. Decision Support and Epidemiological statistics. The ground breaking design proposed by *open*EHR opens a lot of opportunities, which were not possible previously due to poor semantic interoperability between systems and brittle system design. One well-known problem in Decision Support Systems (DSS) is that the data query mechanism is dependent on the information model of the local EHR system and has to be adapted each time the DSS is integrated with a new EHR system. This issue is effectively resolved if *open*EHR two-level models are used since DSS can query an EHR system with a standardized reference information model with the aid of clinical content definitions explicitly expressed in Archetypes. These research areas are of high interest at the moment, and collaboration on these using the open source implementations are ongoing.

The open source implementation creates synergies between EHR system developers for collaboration on common EHR software components. More access to end user base and beta testers, and focused development efforts on common parts of EHR systems will most likely result in more reliable and re-usable software components that are building blocks of future EHR systems. With enough core building blocks, a common health information platform can be established, which provides essential features for any full-blown EHR system, e.g. standards compliant interfaces and semantic interoperability.

Even the application level presentation layer can benefit from generic screen form generation components [7]. EHR applications could then be built rapidly on top of the common platform with clinically defined archetypes and certain application level customizations in ways previously unimagined. Also the EHR application development can focus on solving application related problems rather than generic EHR problems. We believe this would result in a paradigm shift in how to develop EHR applications in the near future, which would dramatically increase the productivity of EHR development and therefore lead to more sustainable solutions [8] than the current way of building EHR systems.

Conclusion

The *open*EHR Java Reference Implementation project has been very useful for validation and improvement of the *open*EHR design specifications. The Open Source Software development model used by the project fits very well with the purpose of publicly available specifications. This is a sustainable way of providing major healthcare standards for interoperability that we argue should be used more.

The project creates synergies between EHR developers and encourages software re-use aiming to provide building blocks for EHR applications. Not only would this reduce costs of the software and lead to more reliable health information systems, but also improved interoperability between systems. We believe this can contribute to the overall sustainability of health information systems.

Acknowledgements

We want to firstly thank the *open*EHR Foundation for their pioneering work and Thomas Beale in particular for his invaluable guidance on the implementation work and review of the manuscript. We also want to express our appreciation of the UCL team for good collaboration and Yin Su Lim in particular for her meticulous efforts, the Linköping Medical Informatics group. and last but not least, all the early *open*EHR implementers who have tested the Java components and came back with feedback and patches. We are also grateful for the financial support for some of this work from the Semantic Mining EU- project and from Cambio Healthcare Systems.

Abstract

The aim of this project is to contribute to limiting the risk of CHIS (computerised hospital information system) failure by identifying factors which are associated with the successful implementation of CHISs in district and regional hospitals in South Africa (SA). Case studies were conducted in four regional hospitals in the Western Cape province of SA to obtain data about user perceptions of the success or lack of success of the CHISs in use. A conceptual model of CHIS use has been developed based on the results of the case studies, in order to assist in the interpretation of the differing experiences across the hospitals. Key factors in the conceptual model are perception of usefulness of the CHIS and management commitment to ensuring CHIS success, which in turn are related to effective use of CHIS and/or CHIS outputs, and allocation of resources for CHIS further development. Further development of the model will be influenced by the next phase of this project: a survey of district and regional hospitals in two SA provinces.

Keywords

Hospital information system, evaluation, model

Introduction

Increasing numbers of computerised hospital information systems (CHISs) are being implemented in public hospitals in South Africa (SA), as part of a concerted effort to improve the data available to decisionmakers at all levels of the SA public healthcare system [6]. A proportion of these hospitals is situated in environments with limited access to the resources required to run CHISs, including skilled support personnel for hardware and software, and internal resources in the form of trained personnel in various roles to enable hospitals to obtain maximum benefit from the CHIS. Vulnerability to disruption of services can result from lack of direct access to people with the required skills to support the CHIS software and hardware, since support staff may be based in a central location and have to travel significant distances to reach hospitals which may require their services. Where the required physical infrastructure is available, services can be subject to disruption, sometimes due to lack of resources (including human resources) for maintenance and repair. The successful implementation of CHISs under these conditions is a particular challenge. District and regional hospitals in environments of limited or vulnerable resources, as described, are the focus of this project.

To date, there have been few published evaluations of the CHISs which have been implemented in SA. However, the results of some of the evaluations which have been conducted [15, 17], as well as anecdotal evidence, indicate that problems have been and are being experienced with some of the CHISs which have been implemented. In the Limpopo Province (previously the Northern Province) two of the major reported problems were system performance, and system support, especially in locations remote from the main centres. In some provinces, system implementation and rollout have taken much longer than anticipated, due to problems with customisation, system performance and change management among others. Since the monetary costs of CHISs are generally high in relation to the available budget, and CHIS implementations can require significant organisational change, the implementation of systems which do not meet expectations has major implications for hospitals [21].

Decisions about the acquisition of CHISs for public hospitals in SA are made at provincial level, following a formal tender process, and the same CHIS is typically implemented at multiple hospitals in a province. All new CHISs acquired for use in the SA public healthcare sector have to conform to a common set of requirements which have been agreed to at national level. While in practice at present there is more than one CHIS in use in some provinces, several provinces (including Limpopo and the Western Cape, for example) have already decided to move towards the implementation of a single CHIS in the province, with variations in the scope of the implementation depending on the needs of different hospitals [6,7].

The development of criteria for the selection of a CHIS is particularly challenging when the same system is being selected for use in specialist referral hospitals and in district and regional hospitals, since the district and regional hospitals typically have access to fewer resources for CHIS implementation and maintenance than do the specialist referral hospitals. Current criteria used to inform the selection of CHISs for implementation in public sector hospitals in SA do not explicitly address factors which

could affect (positively or negatively) the chance of a future successful implementation [10].

Related projects

There are few practical and/or theoretical guidelines available to support decisionmaking about CHISs. One notable exception to this lack of guidelines is the set developed by Heeks and colleagues, who, in a paper on why health information systems succeed or fail, provide an important analysis of factors which have the potential to affect CHIS success [9]. They use the concept of conception-reality gaps to describe the extent to which the aims of an information system can be matched with the reality of the environment in which it will be implemented.

The literature on IS success and HIS (health information system) evaluation has provided the major theoretical basis for this project. The IS success literature reflects an approach to theory development which is based largely on analysis of relevant empirical studies, with the work of DeLone and McLean [4,5] forming the basis for much further theory development.

In the HIS domain, much of the work has been based on qualitative case studies, in some cases supported and/or supplemented by lessons from the IS success literature. Some of the work on success of HIS is reflected in the literature on evaluation of HIS. The emphasis in much of the evaluation literature is on the organisational aspects of HIS implementation, including the essential role of people as system users and system managers, and is therefore very relevant for this study [1,8,16,18,21,24].

The model of HIS implementation developed by Korpela and colleagues for the INDEHELA-methods project [12] and the ITPOSMO model of Heeks and colleagues [9] are among the models reviewed to date which specifically take account of context, although neither of them explicitly addresses the issue of limited and vulnerable resources for IS and HIS implementation and use. The INDEHELA-context project is aimed at comparing experiences between developing and developed environments [12]. Braa and Hedberg [3] and Shaw [20] report on the HISP project, which specifically addresses approaches to IS development which aim to ensure sustainability of systems in developing environments, with limited infrastructure and other resources.

Problem identification

There is a need to provide support for decisionmakers to reduce the risk of lack of success in the acquisition and implementation of CHISs for district and regional hospitals in South Africa. A model of CHIS use which is applicable to environments of limited or vulnerable resources could provide decisionmakers with a framework for assessing the potential for success of CHISs in these hospitals.

There is a general lack of 'gold standards' against which to measure the performance of HISs in hospitals [23]. This is related to the more general problem of describing, explaining and measuring information system (IS) success [2,5,19]. In their revised IS success model, DeLone and McLean [5] identify the extent to which the IS is used (or there is an intention to use it) as being one of the factors related to IS success. LeRouge and colleagues [14] have extended the DeLone and McLean concept of system use by analysing use quality as a factor in IS success. Of particular interest for this project is the extent to which the CHIS outputs are used by hospital- and provincial-level managers to support their planning for and management of hospitals. The conceptual model developed in this project describes factors associated with CHIS use, since one essential component of CHIS success is that the system, or its outputs, should be used by the intended users.

Methods

The aim of this project is to contribute to limiting the risk of CHIS failure by identifying factors which are associated with the successful implementation of CHISs in SA public sector district and regional hospitals.

Case studies

Case studies were conducted at four public sector regional (level 2) hospitals in the Western Cape province.

The objectives of the case studies were

- to describe and analyse the effects on the hospital of CHIS implementation
- to identify those factors which are associated with perceptions of the success or lack of success of the implementation, and
- to identify those factors which could be associated with the success or lack of success of the implementation.

A combination of observation of the CHIS in use and semi-structure interviews with representatives of hospital management (clinical, nursing and/or administrative), any specialist information management personnel, case managers responsible for co-ordinating services for any private patients in the hospitals, and CHIS end users was used to obtain data for the study. A standard set of questions was used as a guide for all interviews. Between four and eight interviews were conducted at each study hospital. The case study protocol and the interview guide were made available to the management of the study hospitals in advance.

Study hospitals were selected on the basis of accessibility, and in order to obtain a set of results which is broadly representative of conditions in district and regional hospitals in SA in which a CHIS has been implemented. The study hospitals had approximately 400 beds each, with similar management structures. Two of the hospitals are situated in a major urban centre, the third is approximately 100 km from the urban centre, and the fourth is approximately 400 km away.

Since the aim of successive cases in a qualitative study like this one is to extend and provide richness to the information gleaned from earlier studies, the fourth case study hospital was selected in order to assess the effect on the operation of the CHIS in a hospital which is so far from the support centre for both system software and hardware that

the distance could affect the success of the CHIS implementation.

The scope of the fourth case study was further extended to examine the use of the CHIS to support the work of clinical managers in the hospital, i.e. clinicians responsible for the management of clinical services such as family medicine and emergency medicine. This issue was not addressed in the other case studies.

All study hospitals were using the same CHIS with the same scope, and the CHIS had been in use at each hospital without major changes for at least six months. The CHIS included ADT (admission/discharge/transfer) and billing functions. Van der Loo and colleagues [22], in developing a framework for the evaluation of healthcare information systems (HISs), formulated a useful classification of the health care process. In terms of this classification, a distinction is drawn between care processes – divided into the medical care process and the supporting process – and auxiliary processes, which do not contribute directly to the care process. In terms of this classification, the CHISs typically in use in SA district and regional hospitals support aspects of the supporting process (ADT component) and an auxiliary process (billing).

Results and discussion

Comparisons between the hospitals in order to identify similarities and differences between the environments and the experiences of implementing the CHIS provided a rich picture of the use of the CHIS in the hospitals, and the perceptions of users about the CHIS.

The experience at all hospitals was that the CHIS is generally stable and reliable. Since CHIS hardware and software support is only available during office hours (although all the study hospitals provide 24-hour emergency services), delays had been experienced when problems had arisen. Delays had also been experienced due to limited availability of software support personnel, even during office hours. At the remote study hospital (400 km from the service centre) the management expressed serious concerns at their vulnerability due to the distance from the service centre, although in practice major problems had fortunately seldom arisen.

At all hospitals, there was concern about the quality and completeness of the data being input to the CHIS.

All the hospital managers interviewed were clearly aware of the importance of information as a resource for decisionmaking, and practical efforts were being made to use data from the CHIS in combination with data from other information systems to support management decisionmaking. However, managers were also concerned that they had only a limited understanding of the potential capabilities of the CHIS, and few if any opportunities to gain a better understanding of the CHIS. Due to the limited collection of clinical data via the CHIS, the available clinical data was not used at all by clinical and nursing personnel.

Despite these concerns, there were plans at all the study hospitals to extend the usefulness of the CHIS by installing terminals in wards at three hospitals, and by acquiring an additional module of the system at one of the hospitals.

The most striking differences between the hospitals were in management approaches to the allocation of resources for ensuring data quality and completeness in the CHIS, and the extent of reliance on data from the CHIS for reporting within and beyond each hospital.

Conceptual model of CHIS use

A conceptual model of CHIS use has been developed, based on the results of the case studies and theoretical models reviewed to date, including those of DeLone and McLean [5], Ballantine et al [2] and Heeks, Mundy and Salazar [9]. The aim of this conceptual model is to clarify those issues identified during the case studies which have the potential for explaining differences between the experiences of CHIS implementation in the four hospitals.

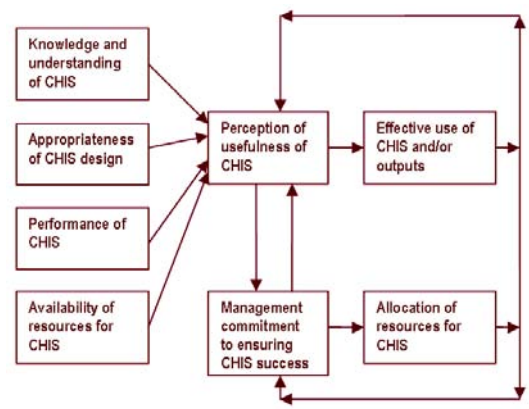

Figure 1 - Conceptual model of CHIS use

The model is based on the premise that user perception of the usefulness of a CHIS is a key determinant of whether or not the system will be used effectively (see figure 1). Factors which affect user perceptions of the usefulness of the CHIS have been identified as **knowledge and understanding of the CHIS, **appropriateness of CHIS design **CHIS performance and **availability of resources for CHIS.

At a feedback session with the interviewees at one of the case study hospitals, and during related interviews with key informants outside the study hospitals, all comments related to CHIS use at hospital level could be assigned to one of the factors identified in this conceptual model.

Perception of usefulness

The attitude of users is a key element in determining whether the potential of a computerised health information system (CHIS) implementation is realised. If users believe that a CHIS is useful for them, they will make an effort to ensure that the system works, and will use the outputs from the system. Conversely, if there is a perception that a CHIS is not useful, there will be little or no commitment by users to ensuring that the system is used correctly, and outputs from the system will not necessarily be used, especially when similar information can be obtained from other sources.

For example, the case managers at two of the hospitals, responsible for ensuring that fees were collected for private patients, were particularly enthusiastic about the potential of the system to provide the data required to enable them to ensure that accurate accounts were raised. They were frustrated by the limited understanding of some of their colleagues about the need for accurate and complete data input, and by limitations in their own understanding of the functionality of the CHIS, and were looking for ways of improving CHIS use, in order to improve the benefits gained from the system.

Effective use of CHIS and/or outputs

One measure of the effectiveness of a CHIS is whether it is used effectively. DeLone and McLean [5] use the concepts of 'use' and 'intention to use', leading to the achievement of 'net benefits' from the system to describe IS success. Heeks, Mundy and Salazar ([9] have identified information needs of the users as one of the dimensions along which a mismatch between the design of a health care information system and the reality of the environment in which it is implemented could occur. If the information needs of users are not met by the system, it is unlikely to be effectively used, and therefore could not be regarded as a success.

Management commitment to ensuring CHIS success

The context in which the CHIS has been implemented is reflected by including 'management commitment to ensuring CHIS success' as a component of the model. Allocation of resources for implementation, training and maintenance of the system is modelled as the main indicator of management commitment prior to and during system implementation. The allocation of further resources for system development would be a reflection of ongoing management commitment to the use and development of the system.

There were striking differences between the study hospitals in the allocation of personnel resources to ensuring the effective use of the CHIS: The medical superintendents of two of the hospitals had assigned specific responsibility for the preparation of management reports, based on data from the CHIS and from other systems, to full-time clerks responsible directly to them. At the third hospital, the responsibility for preparation of management reports was divided among members of the management team, and the staff member responsible for reception and fees office staff. At this hospital, the hospital manager, the most senior administrative staff member, was responsible for the final collation of hospital reports required by the provincial department of health. At the fourth hospital, an information manager had been appointed at senior management level to take overall responsibility for all reporting for the hospital. Comparing the study hospitals, the degree of user satisfaction with the CHIS seemed to correlate directly with the allocation of personnel time to ensure accuracy and completeness of the data on the CHIS. At the hospital at which there was no full-time person responsible for data management, there was the greatest degree of dissatisfaction with the CHIS, and the impression gained was that there was little management commitment to CHIS success.

Relationship between the user and management components of the model

'Management commitment' influences 'perception of usefulness' in this model. Since 'perception of usefulness' reflects user attitude to the CHIS, this link provides a connection between management and user attitudes to the CHIS.

'User perception of usefulness' could persuade management to commit resources to ensure the effective operation of the CHIS. This could also reflect the attitude of members of hospital management who use the CHIS (either directly or indirectly, via CHIS reports). This direction of influence is reflected in the model by having a two-way arrow between these two components of the model.

Conclusion

On a practical level, the aim of this project is to inform decisionmaking about the selection of CHIS for use in district and regional hospitals in SA, by identifying factors associated with the effective use of CHISs in these environments.

On a theoretical level, this project aims to contribute to the theoretical basis for evaluating CHISs and, hence, the evaluation of ISs in general. An attempt has been made to synthesise findings from multiple environments which are applicable to the complex environment of computerised information systems in hospitals, as has been recommended by Kukafka et al [13] and van der Meijden et al [23], among others. The recommendations consistently made by Kaplan [11], Lorenzi and Riley [16] and Southon et al [21], for example, that organisational and people issues must be taken into account in analyses of the use of information systems in health care, and in other environments, have been followed.

Further plans for this project include the refinement and extension of the conceptual model, based on the results of a planned survey of CHIS implementations in district and regional hospitals in SA. The aim of the survey is to test the conceptual model, and to determine the relative significance of the factors identified in the model.

Acknowledgments

This project is funded by the Medical Research Council. The support of colleagues at the study hospitals and in the Provincial Government Western Cape: Department of Health is gratefully acknowledged.

Are Problem-Oriented Medial Records (POMR) Suitable for Use in GPs' Daily Practice?

Etienne De Clercq[a], Viviane Van Casteren[b], Pascale Jonckheer[c], Peter Burggraeve[d], Marie France Lafontaine[b], Karen Degroote[b], Francis Roger France[a]

Abstract

Problem-oriented functions have been implemented in almost all Belgian GPs' software systems since 2003. We therefore investigated whether some of them – especially the explicit linking procedure between treatments or referrals and the relevant problems – can be used by GPs in their current daily practice.

In 2005, within the Belgian ResoPrim project, we organized data collection, mainly around the theme of "hypertension and cardiovascular risk factors", by 26 volunteer GPs' practices using three different software systems. Data were collected prospectively over six weeks in early 2005, and retrospectively for 2004. In this paper we report only on the part of the study that aimed to assess the linking procedure. For all patients and hypertensive patients alike, the key indicators used were the percentage of (problem-)linked drugs among the drugs extracted, the percentage of anti-hypertensive (problem-)linked drugs among anti-hypertensive drugs extracted, and the percentage of (problem-)linked referrals among the number of referrals extracted.

For all patients, the data collected relate to 10 914 contacts (7 831 patients) in 2005, and to 74 878 contacts (16 813 patients) in 2004. Large variations were observed per software system and GP, and also over time. The percentage of linked drugs rose from 2% (2004, two GPs) to 36% (2005, fourteen GPs). For linked referrals the percentage was 65% in 2004 vs. 75% in 2005.

Our study shows that some functions related to the problem-oriented patient record were spontaneously used by GPs in daily practice. This use increased during collaboration with the primary care research network. This increase was not restricted to the theme of data collection (i.e. not restricted to hypertensive patients, to anti-hypertensive drugs or to links with cardiovascular problems).

Computerized Patient Records, Primary Health Care, Problem-Oriented Medical Records

Introduction

The GPs' Electronic Patient Record (EPR) can be a rich source of information for various research purposes, such as epidemiological studies, health-care quality assessment or socio-economic studies. Although it has been questioned whether data from EPR can be used for such purposes [1-3], various advantages have also been described: the ability to record over the long term, the potential availability of numerous kinds of data, and the options for collecting data from many GPs' practices and on many patients [4-7].

The problem-oriented architecture of the patient record can provide additional advantages, not only for the care process but also for researchers, as data linkage (i.e. when treatments and actions are linked to the relevant problems), can help with data interpretation, self audit and communication between practitioners [8-13].

Since 2003, this problem-oriented architecture has been included nation-wide in Belgium's quality evaluation process. Its subsequent implementation in almost all GPs' software systems involved a major update [14].

Against this background, we undertook research within the framework of the ResoPrim project, a Belgian GPs' research network [15], to investigate whether particular functions related to the problem-oriented architecture could be used by GPs in their daily activities. Three research questions were defined:

- Are some problem-oriented functions spontaneously used by the GPs without specific IT skill or training?
- What is the impact of participation in the ResoPrim research project on the use of the problem-oriented functions?
- If present, is this impact restricted to the specific theme of the ResoPrim project, i.e. hypertensive patients and cardiovascular risk factors and management?

Methods

This paper is based on the consolidated results of the first phase of the ResoPrim project whose main theme was hypertension and cardiovascular risk factors.

Data were collected from 26 volunteer GPs' practices, which between them used three different software systems (13 using software 1, five using software 2, and eight using software 3). Data were collected anonymously through an automatic extraction procedure and through a manual procedure whereby GPs filled in an electronic questionnaire at the end of each contact. Data were collected retrospectively for 2004 and prospectively over six weeks in early 2005. Fuller details are provided elsewhere [15].

In order to study the usability of some problem-oriented functions, we explicitly extracted the single or multiple links between the referrals or drugs prescribed and the problems to which they applied. All referrals and problems (ICPC codes) were considered. However, only a small number of specific drugs (ATC codes) were extracted from the EPR, i.e. aspirin, statins and drugs related to a number of specific problems (hypertension, diabetes, epilepsy, migraine, glaucoma, herpes, gout, hypo/hyperthyroidism). Only coded drugs and coded problems entered in the patient record by the GPs were automatically extracted.

We used retrospective data (2004) to assess the spontaneous use of the problem-oriented functions, and 2004 and 2005 data to study the impact of the ResoPrim project. For hypertensive patients, we used 2005 data to compare certain automatically extracted data with the answers to questions addressed to the GPs by the electronic questionnaire (prospective study). These questions concerned either the specific drugs prescribed for hypertension (central working agents, alpha-blockers, diuretics, beta-blockers, calcium-antagonists, ACE-inhibitors and sartanes), or whether a referral had been made for hypertension in the current contact (2005) or in 2004.

The key indicators used were the percentage of linked drugs among the drugs extracted, the percentage of anti-hypertensive linked drugs among the anti-hypertensive drugs extracted, and the percentage of linked referrals among the number of referrals extracted. We applied these indicators to two populations: all patients and hypertensive patients identified by a direct question to the GPs (electronic questionnaire). Only drugs and referrals entered into the EPR during the periods 2004 and 2005 were taken into account. We used numbers of patients for the comparisons between extracted data and answers to the questions addressed to the GPs.

Quality control (four weeks) and quality assessment procedures (using a dummy patients technique) were conducted for the extraction modules developed by each software package.

Results

Prospectively (2005) we used data derived from all three software systems and from 26 practices, 7 831 patients and 10 914 contacts. For 2004 we obtained data from only two software systems for 18 practices, 16 813 patients and 74 878 contacts. For the comparisons between 2004 and 2005, only these two software systems were taken into account, with 5 090 patients and 7 265 contacts.

Prospective data collection (six-week period, 2005)

For 2005, table 1 presents the percentage of drugs, anti hypertensive drugs and referrals linked with a problem. Figures are shown for all patients (7 831 patients) and for hypertensive patients (1 554 patients) identified by a question addressed to the GPs (electronic questionnaire) for each patient attending the GPs' surgery during the six-week data collection period. Of the 17 GPs who had encoded referrals, 13 encoded linked referrals (percentage ranging from 40% to 100%); of the 21 GPs who had encoded drugs, 16 encoded linked drugs (percentage ranging from 4% to 98%).

Table 1: Percentage of linked referrals, drugs and anti-hypertensive drugs (HTdrugs) for all patients and hypertensive patients (2005)

Population	2005 All patients (7 831)			2005 Hypertensive patients (1 554)		
Software	referrals	linked referrals.	%	referrals	linked referrals	%
Soft. 1	114	92	81%	37	33	89%
Soft. 2	48	30	63%	22	14	64%
Soft. 3	182	43	24%	29	6	21%
Total	344	165	48%	88	53	60%
	drugs	linked drugs	%	drugs	linked drugs	%
Soft. 1	1 523	383	25%	1 009	271	27%
Soft. 2	564	367	65%	336	216	64%
Soft. 3	860	41	5%	533	17	3%
Total	2 947	791	27%	1 878	504	27%
	HTdrugs	linked HTdrugs	%	HTdrugs	linked HTdrugs	%
Soft. 1	870	219	25%	668	189	28%
Soft. 2	359	248	69%	230	147	64%
Soft. 3	485	27	6%	345	12	3%
Total	1 714	494	29%	1 243	348	28%

The many-to-many relationships (linkage of a drug or a referral to several problems) was seldom used and only within the first two software systems. In 2005, two GPs were using them for referrals, accounting for 1.66% of all the linked referrals (two software systems). Four GPs used them for drugs (0.67% of all the linked drugs in the first two software systems).

Among the 1 554 hypertensive patients attending GPs' surgeries in the six-week period in 2005 and identified by a direct question to the GPs, 1 491 were treated for hypertension (treatment identified by a direct question or by extracted drug codes). For these patients, asking the GPs if they were taking drugs had a sensitivity of 98%. Among these 1 491 patients, 891 (60%) had a coded anti-hypertensive drug and 196 (13%) had a coded anti-hypertensive drug linked with a hypertension code (K85, K86, K87). The percentages of the various types of coded drugs are preserved, as shown in figure 1.

Among the 494 anti-hypertensive linked drugs, 451 were linked to valid ICPC codes, 173 linked to non-hypertensive ICPC codes, and 71 linked to non-cardiovascular codes (not 'K' ICPC code).

For the 1 554 hypertensive patients mentioned above, we identified the referrals made during the data collection period either by asking a direct question to the GPs (electronic questionnaire) or by an extracted code. Among these patients, 180 had a referral for their hypertension in 2005 (six weeks period). Asking the question to the GPs had a sensitivity of 99%. Only 1.67% of the patients who had been referred in 2005 had a coded referral linked with hypertension in their EPR.

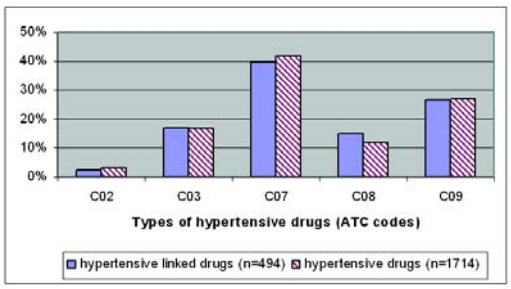

Figure 1- Percentage of the various types of anti-hypertensive drugs (N=1 714) and anti-hypertensive linked drugs(N=494) for all patients (2005): C02 (central working agents & alpha-blockers), C03 (diuretics & associations), C07 (beta-blockers & associations), C08 (calcium antagonists), C09 (ACE-inhibitors, sartanes & associations)

Comparison between retrospective and prospective data collections

For software 1 and 2 (18 GPs), table 2 presents the percentage of drugs and referrals linked with a problem in 2004 (retrospective) and 2005 (prospective). For 2004, 11 out of 13 GPs who had encoded referrals had encoded linked referrals (percentage ranging from 44% to 100%). Only two out of 15 GPs who had encoded drugs in 2004 (against 14 out of 15 in 2005) had encoded linked drugs (0.09% and 82%).

Table 2 - Percentage of linked referrals and linked drugs (2004 - 2005)

Population	2005 All patients (5 090)			2004 All patients (16 813)		
Software	referrals	linked referrals	%	referrals	linked referrals	%
Soft. 1	114	92	81%	839	501	60%
Soft. 2	48	30	63%	297	236	79%
Soft. 1+2	162	122	75%	1 136	737	65%
	drugs	linked drugs	%	drugs	linked drugs	%
Soft. 1	1 523	383	25%	8 693	1	0%
Soft. 2	564	367	65%	255	208	82%
Soft. 1+2	2 087	750	36%	8 948	209	2%

The reasons for which a patient was referred in 2004 (529 valid ICPC codes for software 1 and 2) included 76 referrals (71 patients) for a cardiovascular problem (14%). In 2005, the reasons for which a patient was referred (104 valid ICPC codes for software 1 and 2) included 15 referrals (14 patients) for a cardiovascular problem (14%). This is illustrated in figure 2 for the year 2004.

For software 1 and 2, among the 1 084 hypertensive patients attending GPs' surgeries in the six-week period of 2005 and identified by a direct question to the GPs, 335 patients had been referred for their hypertension in 2004 (referrals identified by asking a direct question to the GPs or by an extracted code). Asking the question to the GPs had a sensitivity of 99%. Only 2.69% of the patients who had had a referral in 2004 had a coded referral linked with hypertension in their EPR.

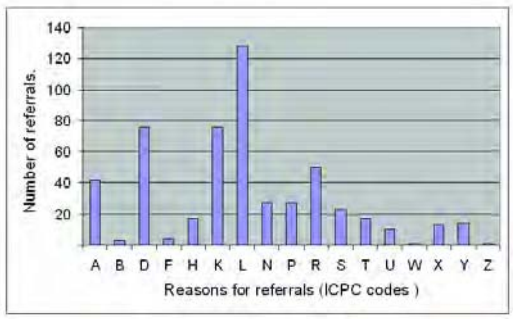

Figure 2 - Reasons for which a patient was referred (all patients, 2004, N=529, ICPC codes): A (general and unspecified), D (digestive), K (cardiovascular), L (musculoskeletal), R (respiratory)

Discussion

We found large variations between GPs, software systems and types of linked data (referrals vs. drugs). We also observed large variations over time (2004, not shown). Therefore, given our confidence level in the quality of the data (based on the quality assessment procedure), no statistical method can easily be used for a thorough examination of our findings. Yet, our (not representative) sample provides us with interesting findings regarding the use of functions related to the problem-oriented architecture of the EPR.

The linkage between referrals and problems was spontaneously used by 11 GPs before the ResoPrim project (cf. table 2, 2004 data). Yet, at that time, only one GP (table 2, software 2) extensively used the linkage between drugs and problems.

Participation in the ResoPrim project had a positive effect on the linkage between drugs and problems (36% linked drugs in 2005 vs. 2% in 2004; see table 2). Twelve GPs started using this linkage function during their participation.

For software 2 (table 2), there was a decrease in the percentages of linked drugs and linked referrals between 2004 and 2005. This was due to two GPs. The first of these never coded any drugs in 2004; while he started to code in 2005, he did so without using the linkage function. The second GP coded a few referrals in 2004 and quite a lot more in 2005, but never used the linkage function. If we withdraw these GPs from the comparison, the percentage for the linked drugs for software 2 is 96% in 2005 vs. 81% in 2004. For the referrals the figures were 88% for 2005 vs. 81% in 2004.

When investigating the potential impact of the theme of the data collection ("hypertensive patients and cardiovascular risk factors and management"), several issues were considered:

- Did the GPs link mainly drugs and referrals for patients with hypertension (as a result of their participation in the ResoPrim project)?
- Did the GPs link mainly anti-hypertensive drugs (as a result of their participation in the ResoPrim project)?
- Was a greater percentage of referrals linked with a cardiovascular problem in 2005 than in 2004?

In 2005 (see table 1), the percentage of linked referrals for hypertensive patients (60%) was higher than for all patients (48%). Yet a similar divergence can also be observed in 2004 between linked referrals for hypertensive patients identified by a hypertensive code (79%, result not shown in this paper) and all patients (65%; see table 2). It is also noteworthy that the growth in the proportion of linked referrals between 2004 and 2005 (15%) is similar for all patients (see table 2) and for hypertensive patients identified by a hypertensive code (not shown in this paper). At this stage, we cannot assume that there is a thematic effect (i.e. an impact of the theme of the data collection) on the GPs' behavior regarding linkage function between referrals and problems.

For linked drugs and linked-HTdrugs (anti-hypertensive linked drugs), table 1 shows no differences between hypertensive patients and all patients. Anti-hypertensive drugs were linked slightly more often than all the drugs (29% vs. 27 % in table 1). As shown in the results section, there was not a higher percentage of referrals linked with a cardiovascular problem in 2005 (14%) than in 2004 (14%). We can therefore assume that the effect of participation in the ResoPrim project on the GPs' use of the linkage functions is not limited to hypertensive patients, anti-hypertensive drugs or linkage to hypertensive codes.

A thematic effect of research participation on GPs' coding behavior had already been demonstrated in a previous Belgian study [16]. Our results suggest an additional extra-thematic effect related to participation in a research network such as ResoPrim. This effect might be related to GPs' interest in individual feedback, in comparisons with peers, in participating in software users' groups or in contributing to a research project. Preliminary additional findings within the ResoPrim project suggest a possible persistence of these effects.

At this stage it is still questionable whether there can be any secondary research usage of the links between drugs or referrals and problems (e.g. for quality of care or socio-economic studies). If most of the encoded referrals are linked (see tables 1 and 2), many referrals are not encoded (<12% of referral were encoded for hypertensive patients in 2005; figures not shown in this paper). If many drugs are encoded (60% of the hypertensive patients with an anti-hypertensive drug were identified), many encoded drugs were not linked to a problem (see table 1 and 2).

Some of these findings, however, are interesting because they suggest that the links have a promising secondary use. For example, the links make it possible to identify the reasons for which a drug has been prescribed. Thirty eight percent of the anti-hypertensive drugs related to a valid ICPC code (451 in 2005) were linked to a non-hypertensive problem. Sixteen percent were linked to a non-cardiovascular problem. Figure 3 shows the non-cardiovascular reasons for which an anti-hypertensive drugs was prescribed. Even for hypertensive patients, 25% of such drugs were directly and exclusively related to a non hypertensive problem (result not shown). This unexpected finding might be solved partly by a broader use of the many-to-many relationship (currently less than 1% of all the links). An anti-hypertensive drug can simultaneously be prescribed for hypertension and for another problem.

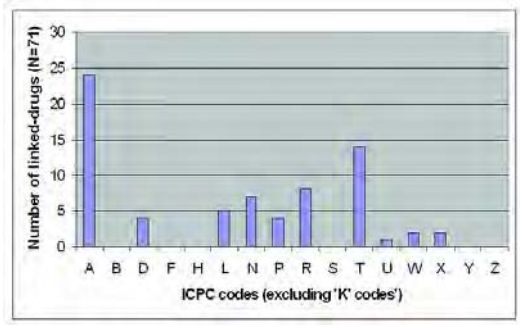

Figure 3 - Number of anti-hypertensive drugs related to ICPC coded problems, excluding cardiovascular problems (all patients, 2005; N=71): A (general and unspecified), N (neurological), R (respiratory), T (endocrine/metabolic and nutritional)

With regard to referrals, very little coded information is currently available in the patient records. Even hospital requests can not be disentangled from referrals to specialists. In this context, the link between a referral and a problem can be a rich source of information. This is illustrated in figure 2. In future, such links might also provide the profile of referrals for various groups of patients (such as hypertensive patients or patients with low income), thereby creating interesting perspectives for socio-economic research.

In order to be more useful for large-scale quality of care or socio-economic studies, the linked drugs or linked referrals should be representative samples of all the drugs prescribed or all the referrals made. At this stage, we have already shown (see figure 1) that anti-hypertensive linked drugs have the same prescription profile as all the hypertensive coded drugs, which is encouraging for further research based on this method.

Conclusion

Our study shows that, once implemented in previously non-problem-oriented software systems, some functions related to the problem-oriented architecture of the patient records can be used spontaneously by GPs in current daily practice without any specific IT skill or training.

These findings generate the hypothesis that participating in a primary care research network such as ResoPrim can stimulate the use of such functions. Within a thematic

research project such as that involving hypertension and cardiovascular risk factors, this behavioral change does not seem to be restricted to the theme (i.e. hypertensive patients, anti-hypertensive drugs, and links with cardiovascular problems). The persistence of this effect should be further explored.

Further research is still needed before the problem-linked data currently available can be used for secondary research purposes such as quality of care or socio-economic studies. Therefore it must still be determined whether these data can be treated as representative samples of the drugs prescribed or referrals made. In coming years, the problem may be solved partly by a higher number of electronic prescriptions or electronic referrals in the patient record.

Acknowledgment

We thank all the GPs and the industrial partners involved in the data collection. The ResoPrim project is supported by grants from the Belgian Federal Public Planning Service Science Policy (Nr I2/AE/207 and Nr I2/2F/207).

Can an EPR Support the Concept of Family-Centred, Individualized Developmental Care of Premature Infants and Newborns?

Abstract

At the University Children's Hospital Heidelberg the concept of 'Developmental, Family-Centred, Individual Care of Premature Infants and Newborns' was introduced to support optimal growth of premature infants. This interdisciplinary concept requires cooperation of different specialists. A well operating communication is a precondition for such cooperation.

As a patient's record is not only used for storing information but also for exchanging information, the question was if a complete electronic patient record (EPR), in contrast to the existing patient's record, could sensibly support this new concept of care. To answer this question the whole communication of the staff in the infants ward was analysed using different observation methods. These observations delivered several issues which showed that an EPR could improve communication and workflow. Therefore an EPR for the neonatology at the University Children's Hospital Heidelberg can now be designed on the basis of our communication concept.

Keywords:

Computerized medical record system, NIDCAP, communication, premature infant, newborn infant.

Introduction

The concept of Developmental, Family-Centred, Individual Care of Premature Infants and Newborns (German term: **E**ntwicklungsfördernde, **f**amilienzentrierte, **i**ndividuelle **B**etreuung Früh- und Neugeborener – EfiB) was designed at the University Children's Hospital Heidelberg, Germany. The concept is based on a 'developmental care' [1] for premature infants and on the 'Newborn Individualized Developmental Care and Assessment Programme' (NIDCAP) according to Heidelise Als [2-3]. Treatment, care and environment are adapted to the needs of preterm infants. EfiB is a modular concept: Every module continues the approaches of the two core components. For instance the modules 'light reduction' and 'noise reduction' contain arrangements to provide a suitable environment for the premature infants. Another module contains a guideline which targets at a reduction of stress during painful examinations of the small patients. EfiB aims to optimize the growth of the preterm infants. With its different modules EfiB is a comprehensive concept which involves a lot of different professions (physicians, nurses, psychologists, physiotherapists…). The introduction of EfiB required fundamental changes affecting both organisation und communication: For example before EfiB, physicians and nurses worked at the premature infants at pre-defined points of time or when it was suitable for the staff. Now they perform - for instance a treatment that is not vitally important - only when the child is awake. The introduction of EfiB started in October 2005. The modules were established step by step.

A well operating communication – that means an exchange of information – is essential for health care [4-5]. A well operating communication is an important precondition that an interdisciplinary concept like EfiB can work properly. When introducing EfiB the communication processes were regarded as not optimal. Thus, accompanying to the introduction of the modules of EfiB in the premature infant ward at the University Children's Hospital Heidelberg a communication concept was created which aimed to establish an appropriate information logistics for EfiB. The objective of our paper is to answer the question whether an enclosing EPR could sensibly support EfiB. This question was answered by the results of the analysis of the present state.

Material and methods

The communication concept was established in three steps:

1. Analysis of the present state
2. To-be concept
3. Implementation strategies.

Pilot observation

In the pilot phase of our investigation all kind of professionals involved in newborn care were accompanied in daily routine for several days. These observations showed that communication can be divided into two classes:

- 'communication during individual workflows' and
- 'communication during team-conferences, ward rounds and handing-overs'.

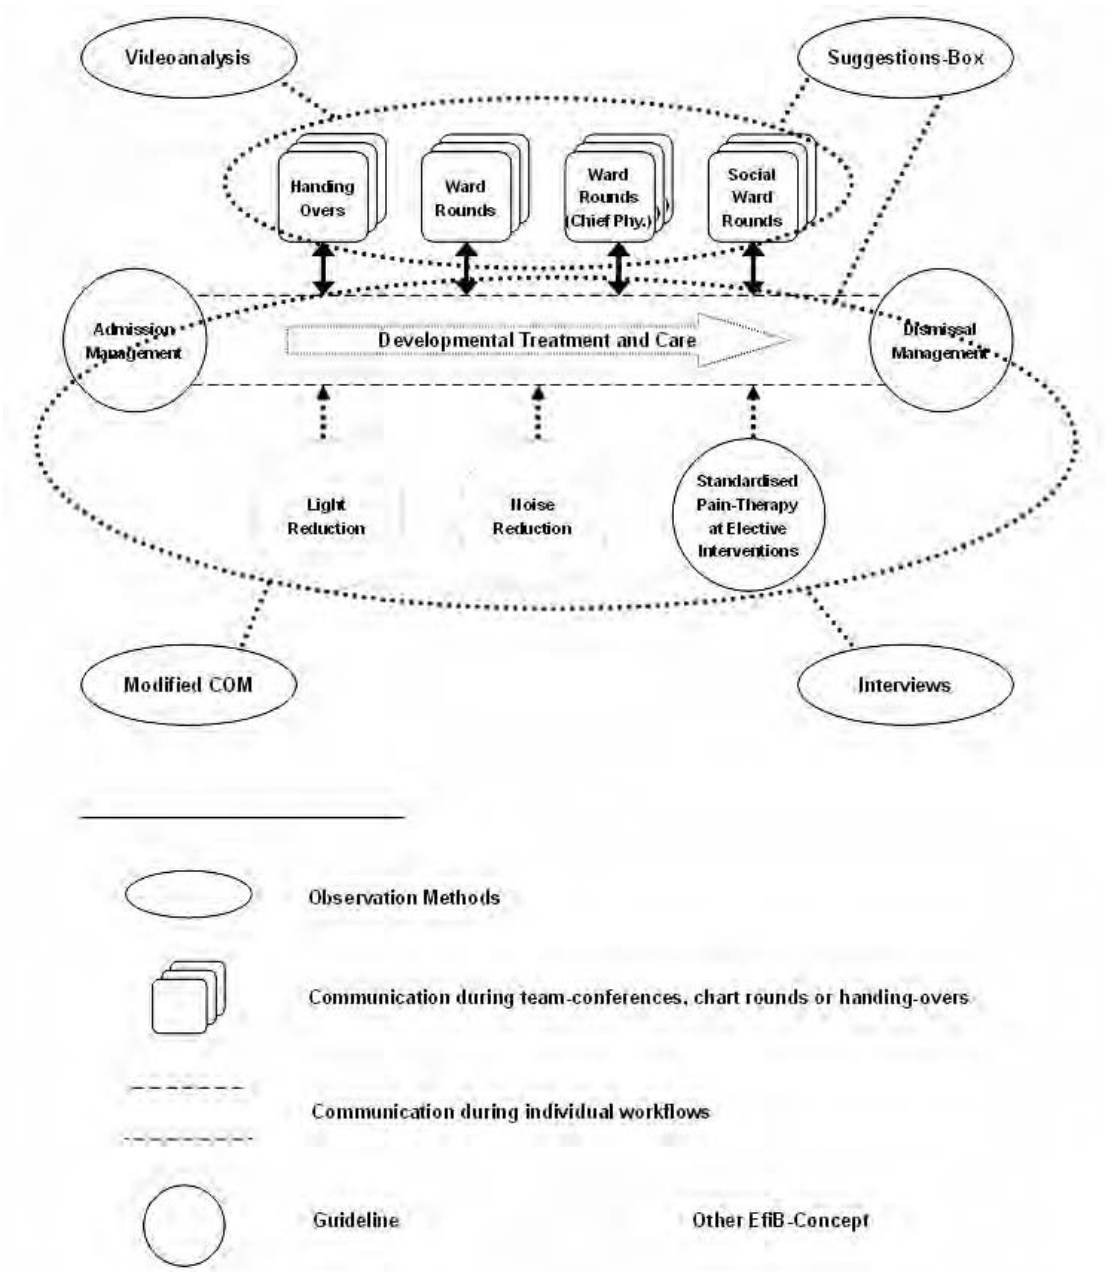

Figure 1 – Range of application of the used observation methods for analyzing the present state of communication

In contrast to communication during individual workflows during team-conferences communication takes place all the time and typically between one sender and many receivers. For these different classes of communication different observation methods were necessary. In addition particular methods were selected to reveal hidden information. Figure 1 shows the range of application of each method. All methods are introduced in the following.

Modified COM

To analyze the communication during individual workflows a modified version of the 'communication observation method' (COM) as described in [6] was used. The COM serves to measure communication load and patterns in the clinical environment. Therefore, the communication the observed person is involved in is recorded and transcribed. In the transcription communication events are identified, coded and stored in a database.

Queries on this database supply information to communication load and patterns in the observed area. Because of limited resources in our investigation we performed an abbreviated version of the COM: We refrained from recording and a transcription. The observer had to identify, code, and store communication events of the observed person during the observation (on-the-fly). That way we observed ward physicians, head nurses, staff nurses, supplying assistants and secretariat staff – three representatives of each group, each for a complete shift. In the end we had collected over 1,000 communication events in our database.

Video analysis

Analyzing communication during team-conferences with the modified COM was not feasible, as there was a too high density of communication events coding on-the-fly was not possible. So, related to the original COM, team-conferences were buffered on video. For analysis, we used besides the COM additional ideas from an 'assessment instrument for evaluating the quality of communication processes in health care' [7] and from an 'instrument to evaluate the communication process during multidisciplinary team conferences in rheumatology' [8]. That way we observed three handing-overs of the nurses, two chart rounds (which took place in a conference room and not at bedside to avoid disturbing the preterm infants), two chart rounds with the head physician of the department (also in the conference room) and three social ward rounds (participants are, beside others, a ward physician, the head nurse, the aftercare nurse and the psycho-social team consisting of a psychologist, a member of the social service and a family therapist).

Interviews

The modified COM could not be applied to all groups of professionals because some were only awhile per day in the ward (such as the aftercare nurse) or because of a too high interference of the observation (this problem for instance arose with the psychologist). To get information about the communication of these professionals, they were interviewed. We interviewed the chief physician, a ward physician, the member of the social service, a breast feeding advice assistant, three parents and the aftercare nurse.

All methods, the modified COM, the video analysis and the interviews, were accompanied by permanent, supplementary observations.

Suggestions-box

In addition to the other methods, we installed a suggestions-box to get also hidden information – information which is not apparent in observations. The suggestions-box was an offer to all staff: They could write problems, suggestions and ideas referenced to EfiB or their work on a paper and put it into the box anonymously.

Sample selection

The observed persons were randomly selected. We tried to observe as many different persons as possible of each professional group. Nevertheless, a few groups were only represented by one person in the ward, for instance the psychologist.

Results

Generally spoken, the combination of our applied methods showed a very heterogeneous communication structure. Nevertheless, the communication achieved almost ever the intended objectives: Information was mainly correct and mostly available in the right style at the right place for the right person. For instance the analysis of the videos showed, in contrast to the general observations of Verhoef et al. [8], that the participants of the analysed multidisciplinary team-conferences used a common language and haunted the same objectives. This helps to conduct a good interdisciplinary care. Furthermore, the video analysis showed that over all types of sessions (different team-conferences, ward rounds and handing-overs) an average of 3.22% of the duration was unused and that an average of 2.07% of the remaining duration was used for non-team-oriented communication (that means communication which concerns only a few persons of the group). That means, also in contrast to the general observations of Verhoef et al. [8], that there is not a huge exchange of discipline-specific information which is not relevant for the other participants.

Problems with complete new modules

We experienced, especially in our interviews and accompanying observations, that the reorganisation of existing structures and workflows including communication flows (for example the reorganisation from the conventional to the developmental care) was easier for the staff than the integration of complete new modules such as the psycho-social modules for instance. Since the psychologist, the member of the social service and the family therapist have overlapping duties and responsibilities on the one hand and different professional backgrounds and duties on the other hand, the staff nurses had to learn who is responsible for which problem and to whom they had to communicate which information.

Heterogeneous patient record

Not only the communication processes and structures were heterogeneous but also the patient record: When the introduction of EfiB in Heidelberg begun, mainly three different patient's records were used, two electronic and one paper based system. IS-H*med, the one electronic system, is a part of the hospital information system which is used in the whole University Hospital Heidelberg (beside patient's data, findings and reimbursement data is transmitted with this system). NeoDat, the other electronic system, is used only in neonatology to store a lot of specific data about newborns and to fulfil the legal requirement to deliver them to the German perinatal register. Furthermore, there is a paper based patient's record placed at the bedside. Physicians write their orders in this record and the nurses note their observations in it. If the paper based record at the bedside gets to large, older documents are swapped to a folder in the nurse's room (a separate folder exists for every patient in the ward). Lot's

of findings are transferred electronically to IS-H*med. For legal reasons the findings are printed, signed by a physician and archived in the patient's folder. When a patient leaves the hospital, all paper-based documents are archived in an additional archive-folder, except a few documents which are used when the patient comes back to the hospital for outpatient care. These documents are archived in a special outpatients-folder.

Insufficient Interfaces

In conversations with physicians we found that only demographic data can be transferred from IS-H*med to NeoDat. Electronic findings have to be copied from IS-H*med to NeoDat via copy-and-paste; some findings even have to be recorded in NeoDat separately.

Different media

Printing an electronic finding to archive it paper-based means using a different media. Vice versa, there is also a change of media when a physician enters data from the paper based patient record (for instance the weight of a child) into the NeoDat-application.

Discussion

Identified problems

The heterogeneous structure of the communication is not a weakness in general but may be caused by the cooperation of different professions. The heterogeneous patient record is a weakness which is consolidated by insufficient interfaces and different media. Copy-and-pasting findings or typing information into an electronic system costs working time and may cause mistakes. Apart from that, the paper-based record at the bedside has the typical disadvantages of a paper-based documentation (exclusive access, missing remote-access, endangerment of loss, problems caused by cloudy handwriting or dirt on the paper, effort at archiving and demand for adequate protected rooms). Moreover it was possible that parents read the patient records of their and other's children which is forbidden by law. In addition, the psycho-social team which is responsible for problems of the parents could not write their observations in the paper based record as the parents might read disagreeable information about themselves.

In the following we want to look at the strengths and advantages, as well as the weaknesses and limitations, of our applied methods.

Modified COM

Coding and storing the observed communication events on-the-fly according to our modified COM had the weakness that the acquired durations of the single events are not very precise. Therefore a quantitative analysis of the data was not reasonable. However the method was very useful to perform a structured observation and to recognize communication flows and structures. Furthermore, in comparison to the original COM, there might have been a higher attendance among the staff to participate in our study and a lower influence on their acting as we didn't perform an audio recording. Additionally, we saved resources with our modification.

Video analysis

The video analysis was highly required to facilitate the analysis of team-conferences, ward rounds and handing overs because of the high communication load. In addition to the buffering, the used video camera had the advantage that a time-index was recorded parallel. So we had the possibility to perform a quantitative analysis of these sessions. Although all participating staff were informed about the observation and gave their approval, the camera lying on the shelf didn't seem to influence their acting. It must be said that our sample size was rather low (two up to three observations per session type). Therefore, the quantitative analysis could only display a trend. Nevertheless, these analyses were also much helpful to discover communication flows and structures.

Interviews

Interviews were necessary to integrate persons and professional groups who could not be observed using the modified COM. As the interviewed persons might have been not aware of existing (communication) problems, accompanying supplementary observations were very important.

Suggestions-box

The staff used the Suggestions-Box to ask questions, to address problems and to make suggestions (e.g., to introduce a monthly group session for the parents with a senior physician and a head nurse). However, the utilisation was batch-wise. The staff had to be reminded about the offering from time to time.

Perspective

Introducing a comprehensive electronic patient record could abolish most of the weaknesses of the existing system. Additionally, an enclosing EPR could give more advantages:

- Other systems (e.g., monitoring systems or incubators) could be integrated by appropriate interfaces, so that corresponding data like heart rate or weight could be recorded automatically and permanently in the patient record.
- Data could be easily presented in a user oriented style or visualized for everybody at team-conferences.
- An electronic system could not only support communication but also workflows – for example, by calculating food quantities and compositions in addition to the weight and age of the preterm infants.
- Last but not least a complete electronic system could support clinical trials.

The Children's Hospital Heidelberg is going to move into a new building in 2008. That could be a chance to introduce such a comprehensive electronic patient record, when established workflows are going to change anyway.

Introduction of an EPR

Emanating from our communication analysis several things already changed. Small changes can be realized very quickly. For example, every staff member now wears a uniform name tag to ease communication. Bigger changes, like the introduction of a new comprehensive EPR-system, have to be designed carefully regarding the results of the presented communication analysis. An EPR can only work properly, solve the problems mentioned above and facilitate the described advantages, if the potential end-users are integrated in the design process. Additionally, it is crucial to develop a comprehensive system with communication interfaces to avoid double data entry. Our communication analysis helps to identify the communication needs of multidisciplinary health care professionals and the data to be transmitted between application systems by communication interfaces.

Conclusion

The analysis of the present state showed a lot of disadvantages of the current heterogeneous patient record. At the same time introducing a comprehensive electronic patient record seems to be, in general, very recommendable because of several reasons: On the one hand the ERP could lead to an efficient and (from the patient's point of view) good quality of care. On the other hand an comprehensive ERP optimally supports EfiB, that should finally lead to a high quality of patient care, too. Therefore the development of such an EPR should be initiated.

Acknowledgments

We would like to gratefully acknowledge all the staff of the Children's Hospital Heidelberg who supported the investigation in different ways, especially the staff and parents who took part in observations and interviews and the complete team of the premature infant ward H9. Special thanks also to Christina Weber and Victoria Ziesenitz.

Abstract and Objective

Multiple detection modalities have increasingly gained attention in population-based screening. However, the disease natural history and its efficacy have been barely addressed. We reviewed a series of articles addressing multiple detection modalities including mammography, ultrasound and magnetic resonance image between 1995 and 2005. A stochastic model was developed to estimate transition parameters pertaining to the disease natural history defined by multiple detection modalities. The effectiveness of the combination of ultrasound or magnetic resonance image (MRI) with mammography was projected using a series of computer simulation models.

The results indicated that multiple detection modalities may lead to reduced mortality. However, the benefit and the selection of detection modalities are affected by biological factors including age, breast tissue type and histological type. In addition, other social factors may also affect the utilization of multiple detection modalities.

Keywords:

stochastic model, screening, breast cancer, modality

Introduction

In Asian countries, mammography has been recommended for the early detection of breast cancers because the incidence of breast cancer has been increasing rapidly. As the occurrence of breast cancer in most Asian countries peaks at around 40-49 years, population-based breast cancer screening using mammography became controversial. This was due to the fact that mammography screening in women aged 40-49 years is less beneficial than expected in older women, and some of the associated harm is more frequent in this age group.

Recently, a series of new technologies have been used as adjunct diagnostic methods to mammography or have been proposed as possible screening tests for younger women. These include ultrasound, digital mammography and magnetic resonance image (MRI). However, as concluded in two review papers, new screening modalities are unlikely to replace mammography for screening the general population given current evidence. Therefore, they suggest that large randomized controlled trials should be conducted by comparing two or more screening tests. However, the empirical results from a larger randomized trial require long-term follow-up and enormous costs. It is timely to have a better understanding of the appropriateness and role of these new technologies in screening for the general population. The current study aimed to develop a stochastic model to describe the disease natural history for breast cancer by using different time points and screening tools based on the sensitivity of multiple modalities. Based on the estimated results, the effectiveness of the combination of ultrasound or MRI with mammography is projected using a series of computer simulation models.

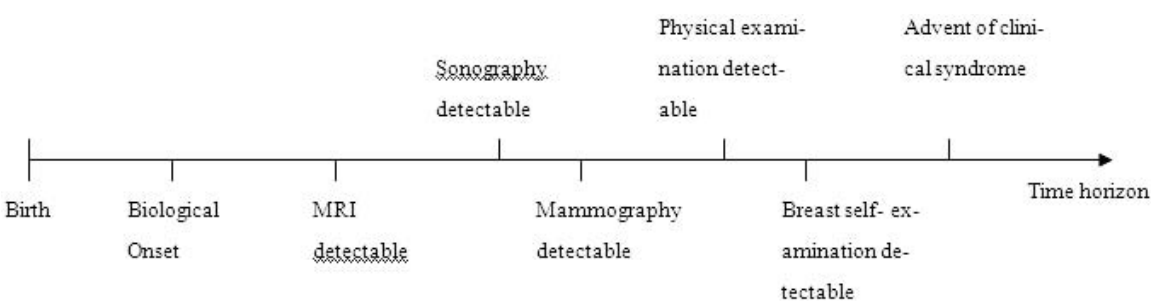

Figure 1 - Natural history of breast cancer defined by detection modalities

Methods

We reviewed a series of articles addressing multiple detection modalities for breast cancer including mammography, ultrasound and magnetic resonance image between 1995 and 2005 to obtain the performance of screening tools in terms of sensitivity and specificity. Different screening tools can detect breast cancer at different time points according to their ability to detect small or early stage breast cancer. The stochastic model to describe the progression from biological onset to the earliest detectable time point of the best screening tool, and the progress between detectable time points and between different screening tools is described below.

Estimation of transition parameters relating to disease progression with multiple detection modalities

A special case with known order of the performance of screening tools

The three available screening tools and the order of the time points with earliest detectable capability are MRI, ultrasound (US), and mammography (MA) as suggested in Figure 1. Let us treat MRI as gold standard; that is, the sensitivity of MRI is assumed to be unity. In the natural history of a special type of breast cancer, US has a better detection ability than mammography.

Patients with disease progressing beyond the earliest screening detectable point are treated as having the true disease. Since US is more capable than mammography of detecting breast cancer, the probability of detection by US or MA minus that of detection by MA only is equal to the difference of the sensitivities of the two modalities. This can be expressed as

$$P(\text{MA or US}) - P(\text{MA}) = Sen_{US} - Sen_{MA} \quad (1)$$

where P(M) denotes the probability of breast cancer being able to be detected with modality M.

The left-hand part can be written as follows:

$$\begin{aligned} &P(\text{MA}) + P(US) - P(\text{MA} \cap \text{US}) - P(\text{MA}) \\ &= P(US) - P(\text{MA} \cap \text{US}) \\ &= P(US) - P(\text{MA} \mid \text{US})P(US) \\ &= P(US)\{1 - P(\text{MA} \mid \text{US})\} \end{aligned} \quad (2)$$

Assuming constant hazard rate, the above equation is rewritten as follows:

$$\left(1 - e^{-\lambda_1 t}\right) \times e^{-\lambda_2 t} \quad (3)$$

Similarly, the relationship between MRI and MA can be expressed as follows:

$$\begin{aligned} &P(\text{MRI or MA}) \\ &= P(\text{MRI})\{1 - P(\text{MA} \mid \text{MRI})\} \\ &= 1 \times \left(P_{11}(t) + P_{12}(t)\right) = 1 - Sen_{MA} \end{aligned} \quad (4)$$

From expressions (3) and (4) together with knowledge of sensitivities of different screening tools, one can estimate λ_1 and λ_2.

Illustration

According to the Berg et al. (2004) study, the sensitivities of US and MA, and of MA only are 93.2% and 77.4%. Taking a 3-year screening interval, λ_1 and λ_2 estimated as 2.03 and 0.61. Given a constant hazard assumption, the sojourn time of staying in MRI detectable only and MRI+US detectable only are 4.6 months and 1.6 years.

Results

Types of new technologies

In addition to mammography, new technologies include ultrasound (US), magnetic resonance image (MRI), and full-field digital mammography (FFDM) with or without computer-aided detection (CAD). According to the review from Irwig et al. (2004), US together with mammography and clinical breast examination was applied to women with dense breast or normal, 'high-risk' female relatives of breast cancer patients, or high-risk women with BRCA mutation, or severe family history. MRI was further applied to even high-risk BRCA or several family members. To enhance the detection rate, FFDM with computer-aided detection was applied to average-risk women.

Natural history of breast cancer featured by multiple detection modalities

Figure 1 shows the natural history of breast cancer defined by detection modalities including US, MA, MRI, and clinical breast examination (CBE). After the onset of the biological process, the tumour can be detected by one of the modalities in the pre-clinical screen-detectable phase. Although figure 1 shows the earliest time point is detected by MRI followed by US, MA and CBE, the sequence may not be such a case. For example, certain breast tumours with micro-calcification or breasts with fatty tissue may be easily detected by MA before US. Using the information on the sensitivity of different modalities, we can calculate the probability of staying in the preclinical detectable phase (PCDP) using different modalities. The probabilities of staying in PCDP of MA+US compared with MA, given a US study by Berg et al. (2004), were shown in figure 2. The figures of dense tumour, fatty tumour and tumours with lobular type were also depicted. In addition, the time order of detecting breast cancer by these modes can be also affected by technical quality i.e. operator characteristics. To tackle this problem, we may model all possible combinations of the four modalities and quantify each type with the proportion Pi.

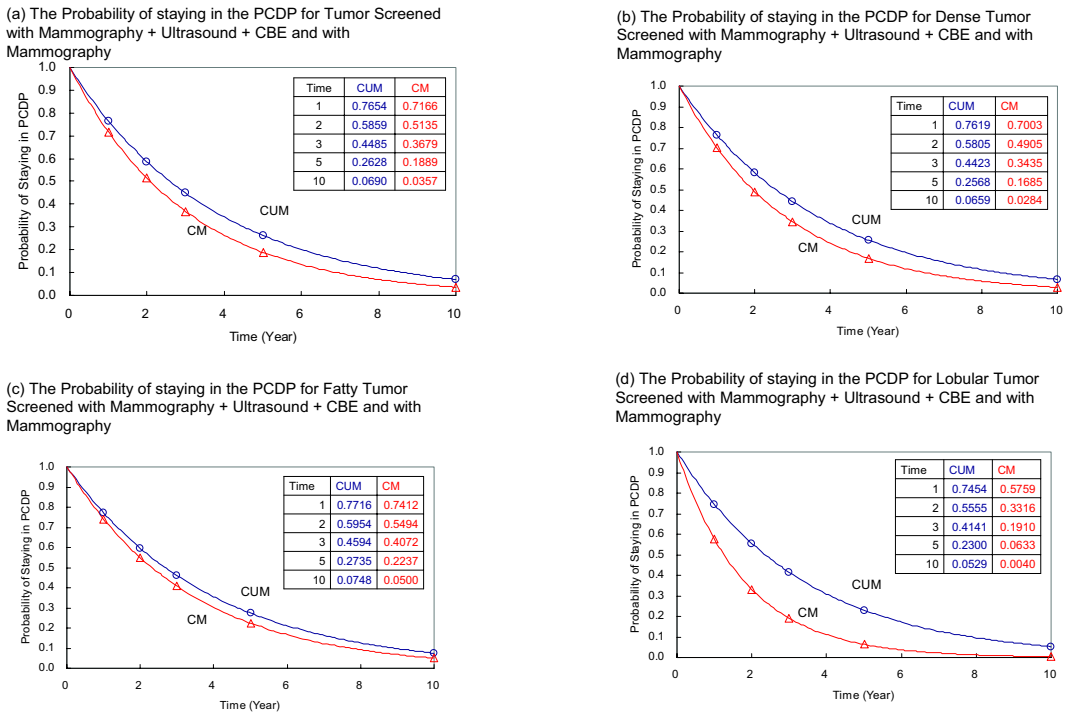

Figure 2 - The probability of staying in the PCDP for tumour screened with mammography + ultrasound + CBE and with mammography

Table 1 - The estimated results of the sojourn times between different sets of screening tools based on the stepwise method

County	Period	Partici-pants	Modality 1/Modality 2	lamda1	lamda2	Sojourn Time1	Sojourn Time2	RR of clinical cases	RR of breast cancer death

			MI+M+C/M+C	19.0107	0.5047	0.0526	1.9814	0.3742	0.7401
			MI+M+C/M+C(Density)	13.4336	0.4477	0.0744	2.2334	0.3593	0.7288
			MI+M+C/M+C(Fatty)	63.8632	0.6296	0.0157	1.5883	0.3996	0.7580

* Lamda1 is the transition rate from the earliest screening detectable point (t_1) to the earliest detectable point with the extra screening tool in modality 1 (t_2), and Lamda2 the transition rate from t_2 to the earliest detectable point with modality 2 (t_3).

** Sojourn time 1 is the average time between t_1 and t_2, and sojourn time 2 between t_2 and t_3.

For simplification, we assume that the earliest and the latest time points detected were MRI and CBE respectively. We only make allowances for the time order changing between US and MA i.e., US followed by MA, or MA followed by US. The proportion P is used for quantifying MRI, US, MA and CBE, and 1-P for MRI, MA, US and CBE. The estimation technique has been proposed using data from literature review.

Table 1 shows the estimated results on transition rates based on the studies addressing asymptomatic breast cancers. Taking the Taiwanese study (no. 2) as an example, when comparing cancers detected by MA or CBE to CBE, the time from the earliest detectable time point to MA-detectable was estimated as 1.95 years. The time between MA-detectable and CBE-detectable was estimated as 1.6 years. When considering the modality of UA, MA and CBE combined compared to MA plus CBE combined, the first time interval was estimated at nearly no time given 100% sensitivity. However, the time lag between these two detectable points was estimated as 3 years given a comparably low sensitivity of MA plus CBE, of 62.5% of MA plus CBE. Based on a biennial screening interval in 8 years, the relative risk of being clinically detected can be obtained from a simulation technique. The 5-year survival for those breast cancer cases was projected. Results of studies from UK, Netherlands, and USA were also applied in the same way.

Effectiveness of new technologies for population-based breast cancer screening

The relative risks of being clinically detected and of breast cancer death were listed. The results show that 56% of clinically-detected cases were reduced by using the MA plus CBE regime compared to using CBE only. The reduction from using UA+MA+CBE was estimated as 67% compared to having MA plus CBE together. Using the cumulative survival by detection mode from the Swedish Two-County trial, the numbers of death from breast cancer were projected. The results suggested a 27% mortality reduction from breast cancer can be achieved with MA+CBE compared to CBE only. When the comparison was made with UA+MA+CBE to MA+CBE, the reduction was estimated as 30%.

Conclusion

Multiple detection modalities may lead to reduced mortality. However, the benefit and the selection of detection modalities are affected by biological factors including age, breast tissue type and histological type. In addition, other social factors may also affect the utilization of multiple detection modalities.

Abstract

The Norwegian Centre for Telemedicine (NST) has, over the past two decades, contributed to the development and implementation of telemedicine and ehealth services in Norway. From 2002, NST has been a WHO Collaboration Center for telemedicine. In August 1996, Norway became the first country to implement an official telemedicine fee schedule making telemedicine services reimbursable by the national health insurer. Telemedicine is widely used in Northern Norway. Since the late 1980's, the University Hospital of North-Norway has experience in the following areas: teleradiology, telepathology, teledermatology, tele-otorhinolaryngology (remote endoscopy), remote gastroscopy, tele-echocardiography, remote transmission of ECGs, telepsychiatry, teleophthalmology, teledialysis, teleemergency medicine, teleoncology, telecare, telegeriatric, teledentistry, maritime telemedicine, referrals and discharge letters, electronic delivery of laboratory results and distant teaching for healthcare personnel and patients. Based on the result achieved, the health authority in North-Norway plans to implement several large-scale telemedicine services: Teleradiology (incl. solutions for neurosurgery, orthopedic, different kinds of surgery, nuclear medicine, acute traumatic and oncology), digital communication and integration of patient data, and distant education. In addition, the following services will also be considered for large-scale implementation: teledialysis, prehospital thrombolysis, telepsychiatry, teledermatology. Last in line for implementation are: pediatric, district medical center (DMS), teleophthalmology and ear-nose-throat (ENT).

Keywords:

Telemedicine, remote consultation, teleradiology, telenephrology, telepsychiatry

Introduction

With its interdisciplinary approach to problem solving, the Norwegian Centre for Telemedicine (NST) has, over the past two decades, contributed to the implementation of telemedicine and eHealth services in Norway. Through its role as a WHO Collaboration Center for telemedicin (from 2002), NST has also influenced the implementation of telemedicine services all over the world.

The Norwegian Ministry of Health has acknowledged telemedicine as a legitimate way to deliver health services in Norway and has politically and financially supported its development. In 1993, NST was appointed national competence centre with the stated purpose of coordinating telemedicine research and national development activities.. In August 1996, Norway became the first country to implement an official telemedicine fee schedule making telemedicine services reimbursable by the national health insurer. By 2006, a wide range of information and communication technologies (ICT) have been implemented in the healthcare sector in Norway.

NST has played a leading role in investigating new telemedicine applications, along with developing and strengthening routine large-scale telemedicine services. Because of the achievements in telemedicine in Tromsø, an international masters and phd-program in telemedicine and eHealth was established at the University of Tromsø (UiT) in 2005. In 2006, the Research Council of Norway appointed Tromsø Telemedicine Laboratory, which is hosted by NST, as a center for research-based innovation in telemedicine and eHealth.

We will in this paper report on some of the results we have achieved in telemedicine in Tromsø during the last 20 years. The services will be presented in order of importance for large-scale telemedicine services.

Materials and methods

The services reported in this paper are established telemedicine services that in 2006 all were recommended for large-scale telemedicine services in North-Norway [1]. Evaluations of the presented services have mainly been published as reports at the Norwegian Centre for Telemedicine (www.telemed.no). Most reports have been written in Norwegian. A brief overview in English can be found in [2].

The Tromsø telemedicine experience

North-Norway is characterized by a scattered population and a scarcity of health service specialists, most of whom

are centered in Tromsø. This was also the starting point for telemedicine in Tromsø – to offer specialist services in the rural districts. The initial initiative for research on pilots in telemedicine was initiated by the R&D department at the Norwegian telecommunication company Telenor. The research activities were soon moved to Tromsø as the University Hospital of North Norway (UNN) has a reputation for being open to new ways of addressing the challenges of the rural region of Norway.

Telemedicine is widely used in Northern Norway. Since the late 1980's, UNN has experience in the following areas: teleradiology, telepathology, teledermatology, teleotorhinolaryngology (remote endoscopy), remote gastroscopy, tele-echocardiography, remote transmission of ECGs, telepsychiatry, teleophthalmology, telenephrology/-dialysis, teleemergency medicine, teleoncology, telecare, telegeriatric, teledentistry, maritime telemedicine, referrals and discharge letters, electronic delivery of laboratory results and distant teaching for healthcare personnel and patients.

Several hospital departments employ videoconferencing on a regular basis to conduct remote medical consultations and for training and meetings with colleagues. In recent years, the focus has changed towards off-line tele-consultations. Dermatology, ear-nose-throat (ENT) and screening for diabetic retinopathy have become routine services in the region.

In June 2005, Helse Nord (which manages the North-Norway Health Region) established an expert group (HNEG) that performed a systematic review of the tested telemedicine services that were suitable for large-scale implementation. Their evaluation [1] was based on clinical needs, cost/benefit compared with transportation of patients or health personnel, requirement to the service's functionality and user-friendliness, and requirements for relevant training.

The HNEG made its recommendations based on a study of 282 projects from NST's project portfolio and response from clinicians and researchers at UNN and UiT. After the review with use of a sorting key, 54 projects were identified for further evaluation. These were distributed among 21 different subject areas/themes. These were: acute medicine, cardiology, endocrinology, geriatric, dermatology, communication, nephrology, neurosurgery, nuclear medicine, obstetrics/gynecology, oncology, orthopedic, pathology, pediatric, caring, primary care and district medicine, psychiatry, radiology, distant education, ear-nose-throat and ophthalmology. The projects were evaluated through 7 points (type of project, relevant for evaluation, target group, need for the service, cost/benefit, requirements/premise and total rank). After an examination of the different telemedicine projects, the group decided to organize the four thematic areas into four groups in accordance with priority:

Group 1 – Must be implemented: Teleradiology (incl. solutions for neurosurgery, orthopedic, different kinds of surgery, nuclear medicine, acute traumatic and oncology), digital communication and integration of patient data and distant education.

Group 2 – Should be implemented: teledialysis, prehospital thrombosis, telepsychiatry, teledermatology.

Group 3 – may be implemented: pediatric, district medical center (DMS), teleophthalmology and ENT.

(*Group 4* – not recommended.)

The success factors for a successful implementation were: usability, user participation, adequate training, potential for research, stated requirements for Mean Time Between Failures (MTBF), and good communication between ICT personnel and clinicians.

The HNEG did not find any reasons to give priority to projects within emergency medicine (excl. prehospital thrombolysis), cardiology, endocrinology, geriatric, gynecology / obstetric, pathology, and homecare, except for the general improvement gained through the use of digital communication and distant education.

The highest ranked services (group 1 and 2) are presented in the following.

Teleradiology

Radiology has been a routine service for many years. This has been a pioneering activity, where the radiologist very early started to use and transfer digital images. The development was driven by enthusiasts at the radiology department, among them Dr. Jan Størmer, who very early saw the potential of this service. In fact, the first database solution was developed by Dr. Størmer himself. The Radiology Department at UNN (former RiTø) is linked to all hospitals in the Northern Norway Health Care Region for teleradiological consultations. UNN is used for as a reference for second opinions. In the beginning, the traditional x-ray images were digitized and transferred to UNN in digtal form. The radiologists at UNN examined the images on the screen, and reported their diagnoses.

One of the earliest remote site users was Troms Military Hospital (TMS). The hospital has no radiologist and for the most part does not take in patients in need of emergency assistance. In September 1992, teleradiology was established between TMS and UNN. X-ray pictures scanned at TMS and transferred to the radiology department, UNN. Before the teleradiology service was established, radiologists at UNN visited TMS one day a week. After the teleradiology service had been installed, TMS received immediate examination of their images. In 1995, the service was all-digital. TMS uses the teleradiology service offered by UNN more than any other hospital in the region.

Problem: To provide radiology services in Nordland, Troms and Finnmark County.

Solution: In the beginning, scanned x-ray images were transferred to UNN via ISDN lines. Later, all-digital solutions were introduced.

Equipment: An in-house developed database for administration of digitized x-ray pictures (RIS), a digtalization unit (scanner) at remote hospitals, and access to ISDN services. (Later connection to the Norwegian Health Network.)

Lessons learned:

- Radiologist at UNN became available 24 hours a day for all connected hospitals.
- Less need for travel for both patients and radiologists.
- Vendors of PACS / RIS did not follow the DICOM standard. The radiology department had to put a lot of effort into securing interoperability.
- Study: 90% of 2280 interviewed patients were very satisfied with the fact that the service offers radiology locally and that the waiting time is minimal [3].
- Effect of teleradiology: reduced need for meetings. Reduced response time from Radiology Department.
- More than 20.000 examinations were performed in 2005.

Helse Nord Expert Group recommendations [1]:

- Teleradiology is one of the success stories in telemedicine. It is used both for emergency and elective purposes, and has become increasingly important in regional clinical cooperation.
- Teleradiology has been the foundation for telemedicine services in other areas, such as neuron surgery, traumatology, orthopedic, general surgery, vascular surgery, heart surgery and oncology.
- Teleradiology is suited for large-scale operation, and the established model is a good model for other clinical areas.

Digital communication and distant education

Figures from Finnmark County (74.000 inhabitants) show a saving of about 125.000 Euro each month from using video conferences (VC) for meetings. The use of VCs started in 1989, and was routinely used from 1994. It has been important for the development of health care in the northern area. Specialists, doctors, and patients have been able to meet without traveling. In fact, most of the VC activity is in the north. Helse Finnmark alone uses 1/3 of the traffic in the Norwegian Health Network. All hospitals in North-Norway use VC. The biggest users are the outpatient clinics. The success factor is that VC has become integrated into the work of doctors, psychologists, nurses, etc.

The use of VC in education has been very important for the development health services in North-Norway. It is expected that PC-based VC solutions will improve the use even more.

In 2000, NST collaborated with the IT department and medical departments at UNN, 5 GP offices, Norwegian Health Network and Well diagnostics. Together they established a service for electronic entry of discharge letters between the hospital and GP offices. In 2004, this service was included to cover all hospitals and GP offices in Helse Nord (that were connected to the Norwegian Health Network). In addition, the GPs could send referrals and x-ray requisition to all hospitals in the area.

Helse Nord Expert Group recommendations [1]:

- Digital communication (DC) represents a high volume service that covers the whole health service. With multimedia enclosures in electronic health records (EHR), DC will be included in many demanded services (e.g., heart sound, dermatological images, etc.)
- Further education is one of the main tasks for Helse Nord. This service has a high volume, and is important in guaranteeing a high degree of expertise throughout the chain of treatment.

Teledermatology

Teleconsultation within dermatology started in 1988 between UNN and Kirkenes Hospital. In 1996, UNN established teleconsultations with Hammerfest Hospital. Both remote hospitals set up teleconsultations once a week, normally with 10-12 patients. These consultations last for 2,5 to 3 hours altogether. In addition, specialists travel from UNN to the Vadsø health care service 6 times a year. Both Kirkenes and Hammerfest hospitals have equipment for treating dermatological diseases and are able to offer their patients treatment locally.

Two teledermatology services are offered:

- Videoconference (VC) consultations: Patient and GP (or other health workers) meet with the specialist through VC. Most patients get immediate response and treatment is started (if needed). This service is in regular use between UNN and Finnmark.
- Still pictures: pictures and referral (from GP to specialist) are enclosed in emails.

In 2003, 84 of 200 GP offices in North-Norway had such equipment.

Problem: To provide dermatology services in Troms and Finnmark County.

Solution: From the beginning: Videoconference equipment at both places. Later also use of email with enclosures (images, referral letter).

Equipment: A video camera is attached to a codec and the signals are transmitted via ISDN. The codecs are H320 standard and the service uses 384 kbit/s. For email: Specialized software, digital camera, dermatoscope.

Lessons learned:

- Initial skepticism made recruitment of specialists difficult. However, simple pilots proved beneficial in spite of the limited technology.
- General practitioners who use this service are generally satisfied, and they have gained new knowledge in the field. This new knowledge has enabled them to do a better screening of patients that need to be referred to the hospital.
- In this way, both patients and accompanying persons need to travel less frequently

- With the introduction of email service instead of VC, more patients were refereed to the specialist clinic. This effect was a result of less available information.
- As many telemedicine services, the GPs become updated within dermatology and gradually took care of more cases themselves.
- Patients do not have to travel to UNN. They need only to meet with their GP.
- Equipment can be used in other settings, e.g., wound treatment (homecare), psoriasis and other chronic diseases.

Another lesson, which goes for most of the telemedicine services that have been established, is that cost saving depends on volume. The cost-effectiveness of telemedical services and electronic messages is often dependent on investment costs, the number of consultations or electronic messages per year, as well as the costs of traveling to a specialist hospital [2].

Helse Nord Expert Group recommendations [1]:

- The VC-based teledermatology solution has considerably improved dermatology competence in primary care. However, the solution is resource-demanding and the GP becomes often a ”secretary” to the specialist. Thus, the use of other groups of supporting personnel should be considered.
- The use of this service is decreasing. Possible explanations are increased level of competence in primary care and decreased enthusiasm. In addition, a dermatologist has been employed in Karasjok. He is also ambulating to Vadsø.
- VC-based teledermatology is recommended for large scale operations.

Telenephrology/teledialysis

The aim of the teledialysis service was to improve the quality of patient care by supporting patients and nurses at the remote centres (i.e., the satellite staff) with the same quality of follow-up care and support offered at UNN. With the help of telemedicine, a common workplace was created by integrating satellite staff into UNN's everyday routines. Daily communication with the satellites is established using IP-based videoconferencing.

Hemodialysis (blood- or machinedialysis) is performed 3 times per week in a health institution. The treatment takes 5 hours each time. In Norway, hemodialysis is performed at 11 hospitals with nefrologic competence. Each of these hospitals has at least one satellite. (Total 28 satelites.) Specially trained nurses manage Satelite dialysis.

Videoconferencing is used in the following areas:

1. Nursing (Day-to-day contact between nurses). In these meetings, urgent problems are discussed every day in a 15-minute session to each satellite.
2. Rounds. (Doctor and nurse). Review of all the patients and patient rounds. Ultrasound equipment is used as required. Every 14 days, alternating between Alta and Hammerfest in Northern Norway.
3. Training (In-house training once every 14 days). The satellites participate in in-house training at the University Hospital of North Norway through videoconferencing.
4. Acute problems are dealt with as needed.

Problem: To improve the quality of patient care by providing patients and nurses at the remote centers with the same quality of follow-up care and support as that received by patients and health staff at UNN.

Solution: With the help of telemedicine, a common workplace was created by integrating satellite staff into UNN's everyday routines. Daily communication with the satellites is established using IP-based VC.

Equipment: VC equipment, ultrasound equipment, digital stethoscope, dialysis software consists of: 1) A database archive which stores data from the dialysis as well as computer data, and 2) A program which keeps track of the current status of the dialysis machines to which patients are connected.

Lessons learned:

- UNN experienced improved reliability of advice given. The staff is integrated into a virtual team.
- Alta and Hammerfest experienced faster response, higher information quality, and improved safety.
- Patients experienced improved continuity in check-ups and treatment through direct contact with UNN staff (instead of through the nurse).
- Costs are saved because patients no longer need to travel to UNN for regular check-ups. Specialists travel less frequently to Alta and Hammerfest.

Helse Nord Expert Group recommendations [1]:

- Teledialysis is well established in Troms and Finnmark County, but not developed in Nordland County.
- Teledialysis should be expanded to new sites even though the volume is low.
- The first satellites were established in Hammerfest and Alta. Later a satellite was established in Kirkenes at a significantly reduced cost compared to the two first satellites. The cost of establishing telemedicine for satellite dialysis units is considered to be a small cost compared to the benefit, given the high reimbursement fees per dialysis treatment.
- The project has been very well received among the patients who to a larger extent are able to receive treatment and follow-up close to their homes.

Prehospital thrombolysis

Each year, 12-15.000 Norwegians get a stroke (cerebral infarction). Thrombolysis treatment of the cerebral infarction can, if the treatment is started within 3 hours from the symptom occurred, limit the brain damage and reduce the mortality and function failures. A treatment can be started after image diagnosis by CT or MR and clinical evaluation by a specialist [1].

Prehospital thrombolysis was started in Troms County in 2000. Community doctors and ambulance workers were trained to perform thrombolysis for acute cardiac infarction (thrombosis) based on a precise algorithm and practical procedure. ECG was sent via a mobile phone or network to a PC at UNN [1].

Studies have shown that the effect increases with increasing distance from UNN. In 2004, all ambulances and casualty clinics in North-Norway were equipped with defibrillator and ECG-equipment.

Lessons learned:

- Telemedicine can increase the availability of thrombolysis treatment through faster diagnosis. In addition, treatment can be given decentralized [4].
- For difficult cases, stroke units at the large hospitals can be contacted for advice throughVC.

Helse Nord Expert Group recommendations [1]:

- This service has a large volume and good prospects. It is recommended for large-scale services.

Telepsychiatry

Telepsychiatry has traditionally been based on videoconferencing or other means of two-way audio-visual communication. It has been used in mental health care for close to 30 years. Use in Norway has expanded steadily, particularly in North Norway [5]. Telepsychiatry includes professional supervision, education, clinical cooperation as well as actual clinical practice.

Reduced costs and improved technical solutions have increased both interest in and use of telepsychiatry. Loudspeaking telephony, videophone, phone conferencing, videoconferencing, and electronic intra- and Internet communication can overcome geographic distance between patient and therapist as well as promote cross-disciplinary collaboration, networking, and skills development. More recent developments in web-based services offer promise for expanding the reach and impact of ICT in mental health.

Lessons learned:

- VC is widely used in psychiatry, both for therapeutic and administrative purposes.
- Use of VC has considerably reduced travel costs.

Helse Nord Expert Group recommendations [1]:

- VC in psychiatry is well suited for large-scale implementation.

Results and discussion

In almost twenty years, UNN and The Norwegian Centre for Telemedicine have been in the forefront of developing telemedicine services, both regionally, nationally and internationally. Today, telemedicine is widely used in Northern Norway and is well integrated into routine health service provision. Documented areas of benefit are [2]:

- *Economic*: Travel costs, number of hospital admissions, time spent by health practitioner, and paper and postage.
- *Qualitative*: Time for other tasks, improved data quality, patients do not have to travel, health benefit where "time counts", screening of patients, competence in medical disciplines, professional confidence, access to specialists, efficient use of specialist expertise, and patient empowerment.

As of 2006, the services presented in this paper are referred to as traditional telemedicine services. The current focus of both the European Commission and others is on how to exploit ICT in efforts to support patients and the general public with tools that enable them to take better care of their own health. This increased focus on health promotion and disease prevention, along with improved collaboration between patients and health care systems, is motivated by many factors; the elderly-boom, population growth in general and growth in chronic diseases in particular, as well as an increase in lifestyle related diseases. New technologies, such as mobile terminals and wearable sensors show promise as a means for meeting these challenges. NSTs work with personalized healthcare since 2000 reflects our intention to be at the forefront of this new frontier.

Abstract

The risk of epidemics and emerging or re-emerging diseases such as avian flu, tuberculosis, malaria and other vector-borne diseases, is rising. These risks can be contained with prevention, early warning, and prompt management. Despite progress in information technology, communication is still a bottleneck for health early warning and response systems in post-disaster situations. This paper presents Satellites for Epidemiology (SAFE), a component-based interoperable architecture for health early warning that employs satellite, radio, and wireless networks, geographic information systems, integration technology, and data mining to promptly identify and respond to a disease outbreak. In a post-disaster situation, a mobile health emergency coordination center is established and integrated to public health services for health monitoring. The added-value of SAFE for post-disaster health management will be demonstrated as part of an earthquake readiness exercise regarding a typhoid fever epidemic, in the island of Crete. Advanced communication and data mining techniques in SAFE offer new tools to the "Epidemic Intelligence" and contribute to advanced preparedness and prompt response by lifting communication barriers, promoting collaboration, and reducing the isolation of affected areas.

Keywords:

health early warning, telemedicine, satellite communication, epidemic intelligence, public health surveillance

Introduction

Identification and monitoring of potential risks to human health has become an important part of the so-called "Epidemic Intelligence"; a new movement in surveillance as the population becomes less tolerant to epidemic prone diseases, making their fast detection and response an increasing priority [1]. Health early warning systems in remote and inaccessible areas or those prone to natural or man-made disasters, enabled by satellite communications, can significantly limit the risk of onset and the effects of epidemics and contribute to settling public health issues. Economically speaking, satellite communications save money by enabling rapid and coordinated response and optimal adjustment of resources when deploying an emergency plan [2].

The SAFE project aims to develop and demonstrate the added value of satellite communication services including low and high bandwidth access to the Internet, co-operative working, and geolocalisation for all phases of biological crisis including prevention, early warning, and crisis management. In this way, SAFE will contribute to a roadmap on how satellite services, by enabling or restoring access to information, will be integrated in European healthcare systems and civil protection procedures to further facilitate interaction and communication.

A practical exercise of early warning at the onset of a typhoid fever epidemic will be demonstrated on the island of Crete, Greece. The scenario, based on epidemiological monitoring after an earthquake, will validate the SAFE approach within the user community and if successful, SAFE could become part of regular earthquake readiness exercises. Furthermore, other applications of the SAFE approach are envisaged as related to early warning and management of re-emerging diseases such tuberculosis, but also to biological and radiological threats. Demonstrations of SAFE mainly in the frame of readiness exercises can be implemented all over Europe upon user-request, promoting the added value of SAFE and allowing potential end-users and stakeholders to assess the use of the SAFE system according to relevant criteria such us availability, interoperability, and security.

The rest of the paper is organized as follows: Materials and Methods (next) is dedicated to the SAFE technical architecture. It is followed by the results section, which focuses on the envisaged demonstration for typhoid fever and the evaluation methodology. In the discussion section, SAFE is placed in the context of readiness exercises and current early warning and response systems. Conclusions summarize the paper.

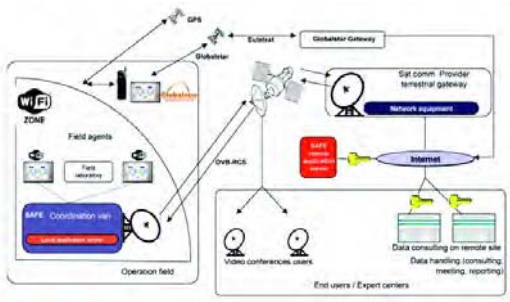

Figure 1 - The SAFE Architecture

Materials and methods

SAFE aims towards better assessment of the epidemiological risks based on real-time objective data, which is a strategic objective for public health policy and of potentially significant impact on the eHealth industry. The SAFE technical approach shown in Figure 1 will be promoted to the different actors of civil protection and epidemiological surveillance, in the context of readiness exercises. Its main components are as follows:

- *Network of expert centers* able to communicate by satellite and interoperable with other networks (e.g. gateways to Galileo[1] and GMES-RESPOND[2]);
- ***Coordination van*** equipped with DVB-RCS [5] capability and Internet access for communication with decision makers and expert centers. It has the role of the local coordination centre. Communication between the local coordinator and the mobile teams on the field is ensured via a local Wi-Fi network and Satellite phones outside the Wi-Fi coverage. Mobile teams are equipped with handheld terminals for data collection;
- *Field laboratory or lab kit* equipped with biological and biomedical equipment to identify microbial agents responsible for the threats to enable in-situ analysis;
- *SAFE information system* including a data collection sub-system and a Geographical Information System (GIS). Besides geolocalisation, the GIS will enable visualizing the evolution of the epidemic and monitoring the alarm levels associated with the different geographical regions. This system will be based on relevant standards and will be interoperable with existing information systems, i.e. national health information system, emergency response information system, epidemiological information systems, and others. It will facilitate monitoring of indicators and other measures potentially useful in modeling the transmission patterns. Dissemination of this data can be done with the Internet via satellite.

This general SAFE configuration can be adapted to the requirements of specific demonstrations or pilot studies. Satellite terminals and data collection points can operate without the coordination van. Data collection can be integrated to existing procedures with interoperability standards, cooperating with and complementing current data collection facilities.

Components of the SAFE architecture

The main components of the SAFE architecture as deployed in the post-crisis earthquake readiness exercise in Crete are: the mobile coordination center, the laboratory kit carrying analysis of biological samples, and the SAFE information system integrating the GIS, the Emergency Coordination System (EKAB), a public health information system, and a Health Observatory (HealthObs) carrying out epidemiological surveillance. A simulator will feed into the system medical cases including those of typhoid fever in a realistic fashion modeled along established readiness exercises with the involvement of WHO[3] and ECDC[4] [11,12].

Mobile coordination center

In the post-crisis demonstration scenario of SAFE, a mobile pre-hospital coordination centre will be set up following an earthquake disaster near a settlement. The coordination van will exploit satellite and radio technologies in accepting and registering rescue calls, in coordinating rescue teams, as well as in providing valuable input for health early warning.

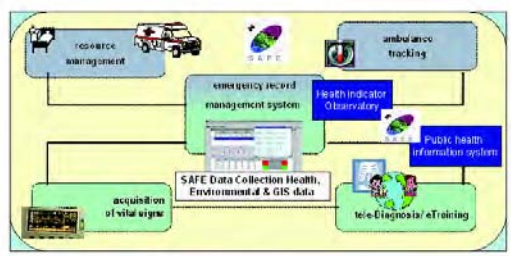

Figure 2 - SAFE adds value to the already advanced ICT infrastructure of EKAB-Crete.

The ICT infrastructure of EKAB-Crete is quite advanced [5,6]. Its components appear in Figure 2: (a) emergency record management system offering protocol-based triage for all episodes (in daily operation since 1997); (b) telemetry applications from ambulances transferring vital signs, 12 lead ECG, etc.; (c) resource management using a GIS combined with GPS-equipped ambulances for central ambulance tracking and route guidance; (d) teleconsultation subsystem, eLearning seminars/refreshing courses for different population groups including protocols for addressing BCRN (Biological, Chemical and Radionuclear Agents), biological threats, earthquakes (very frequent in the area), nuclear disasters, etc.

1 Galileo: European Satellite Navigation System: http://ec.europa.eu/dgs/energy_transport/galileo/index_en.htm
2 Global Monitoring for Emergency and Response,Humanitarian Aid http://www.esa.int/esaLP/SEM3B60DU8E_LPgmes_0.html
3 World Health Organization: http://www.who.int
4 European Center for Disease control: http://www.ecdc.eu.int/

The SAFE system adds value to the existing ICT infrastructure by making EKAB operational in minimal time and by connecting it with expert centres in other parts of the world. Existing management procedures and guidelines for health management in natural disasters that are already enforced, will be extended to demonstrate the role of SAFE and its added-value services.

The mobile coordination van will also provide all the equipment for epidemiological surveillance: (a) Local Wi-Fi network; (b) handheld terminals for mobile teams; (c) laboratory kit to perform analysis of biological or clinical samples; (d) GIS for geolocalisation of critical resources and visualization of the sanitary and epidemiological conditions; (e) links with expert centres, decision makers, or public health institutions according to the master preparedness plan.

Analysis of biological samples

A laboratory kit will be employed for the in situ-analysis of biological samples. Minimal analyses can be performed using mobile facilities (including microbial culture and optical microscope). Samples that will be analyzed for detection of the typhoid fever etiological agent may include water, blood, stools, etc. The lab equipment is connected to the SAFE information system for data collection and to microbiology experts for evaluation and interpretation of microscope images and results obtained from bacteriological culture and other biological tests.

GIS monitoring critical resources and the epidemic outbreak

The GIS application will facilitate monitoring of critical resources and visualization of the simulated evolution of the epidemic. The status of critical resources will be presented on a map to facilitate overview of the public health situation and epidemic evolution. The following aspects will be addressed in the readiness exercise: (a) real time localization on a map of mobile rescue teams and ambulances; (b) report on the status of critical resources (drinking water, excreta disposals etc.); (c) visualization of the public health situation; (d) follow-up the timeline of the simulated epidemic marking health alerts for verified and suspected clinical cases of typhoid fever.

Health indicators, data mining and health early warning

Health indicators associated with electronic health record systems linked to alerts for the onset of epidemics and appropriate use of data mining techniques will further demonstrate the value of effectively sharing and transparently processing health information. Three main information systems will be deployed and integrated in the post-crisis monitoring scenario: the SAFE information system, the EKAB emergency response information system, and a primary care/public health information system. The primary care/public health information system will record the health status of the people in the settlement. A simulator program will generate credible clinical cases for the purpose of demonstration. Finally, the HealthObs integrated environment will be connected to these systems [8,9]. HealthObjs is based on advanced data-mining and knowledge discovery operations and enables specific treatments to identify trends from the collected data and from other sources of data from external databases. HealthObjs supports discovery of interesting clinical associations and monitoring of crucial health and epidemiological indicators.

SAFE will adopt a unified approach towards collection of data from remote and heterogeneous clinical data sources. The general approach shown in Figure 3, is based on standardized medical data models and XML technology [9] as well as disease surveillance via the HealthObs integrated environment.

In essence, SAFE will demonstrate an active Electronic Health Record System, which through its link to HealthObjs raises epidemiological alerts worthy of further investigation and monitoring. HealthObs offers advanced data analysis operations towards investigation of population health dynamics. During an epidemiological investigation the query presented to the system should carry with it the health or epidemiological indicators of interest. In addition, discovery of clinical correlations (e.g. disease symptoms, or therapeutic treatment) enhances potential for evidence-based medicine since correlations, once validated, help to establish a rationale baseline for evidence-based medical decision making. Although this capability does not exist in the current system of EKAB, SAFE will demonstrate a proof of concept in the readiness exercise and possibly lead to its adoption as part of the daily practice of health surveillance in Crete.

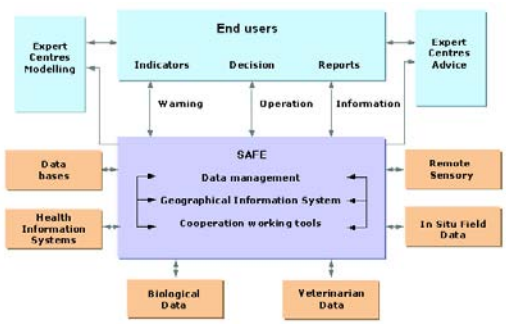

Figure 3 - Interface with external information systems.

Satellite connectivity for second opinion on simulated cases

Collaboration with expert centres and other laboratories for second opinion over the Internet will demonstrate the added value of seamless integration and in-context interpretation of simulated clinical cases of typhoid fever.

Video conferencing for coordination of mobile teams

Video-conferencing techniques using satellite technology will enable coordination of rescue teams and training of volunteers in the earthquake settlement. Teams of volunteers will be trained on site using satellite technologies before a vaccination campaign starts.

Results

The SAFE architecture will be validated in the post-crisis health monitoring section of an earthquake readiness exercise in 2007 by local authorities and WHO under a comprehensive scenario of a typhoid fever epidemic.

The proposed post-crisis monitoring scenario will focus on a simulated typhoid fever epidemic in a settlement of earthquake victims after the disaster. We assume that several critical buildings including that of the pre-hospital and emergency coordination centre of Crete (EKAB) have been destroyed. Thus, the situation calls for expert help from other regions, the set up of a mobile coordination centre, training of volunteers, and monitoring the onset of the epidemic. The emergency response system of EKAB will be restored using the capabilities of SAFE.

Network connectivity will be established using the DVB-RCS connection of the coordination van and a Wi-Fi network. The video-conference application will enable communication with expert centers, health authorities and the team members for a better coordination in support of Xenocrates, the master plan for earthquake preparedness. This application may also support the training of volunteers and possibly the education of the people in the settlement regarding health prevention or adoption of extraordinary sanitary measures. The videoconference capabilities will enable connection to expert centers and laboratories to meet the need for a second opinion on relevant cases of typhoid fever.

Epidemiological surveillance of the public health situation will be achieved with the rapid restoration and deployment of the SAFE information system. Handheld equipment will facilitate data collection in the field. It will be possible to make biological analyses in the field using the lab kit provided in the coordination van. The onset of an epidemic will be monitored using advanced data mining techniques in the integrated public health and prehospital emergency systems. Interoperability of the data collection subsystem with the national health information system and in particular public health/primary care information system and the emergency coordination center will facilitate health surveillance in HealthObs.

Although, the infrastructure at EKAB is particularly advanced, SAFE adds significant new capabilities demonstrating interoperability between traditionally diverse systems and additional functions. As the whole system will be evaluated in the context of the master plan for post-crisis management with user involvement in all levels of the hierarchy, we expect that user acceptance will be high. Furthermore, a formal user acceptance methodology will be applied to evaluate any bottlenecks that may come up due to the proposed revised master plan.

Evaluation methodology

During the various phases of the simulation, an evaluation of user acceptance will be carried out based on:

- Follow-up of the different simulation phases and the observation of the user attitudes during the simulation, and in particular at the experts centres, at the mobile pre hospital coordination centre, and during the training of the volunteers;
- Interviews carried out on representatives of stakeholders.

This evaluation approach attempts to identify the facilities and the constraints met by users in their practice during the post-crisis scenario, and to measure the suitability of the techniques and the interest of stakeholders. More generally, this study will contribute to the definition of tools and indicators to access user acceptance of health early warning systems.

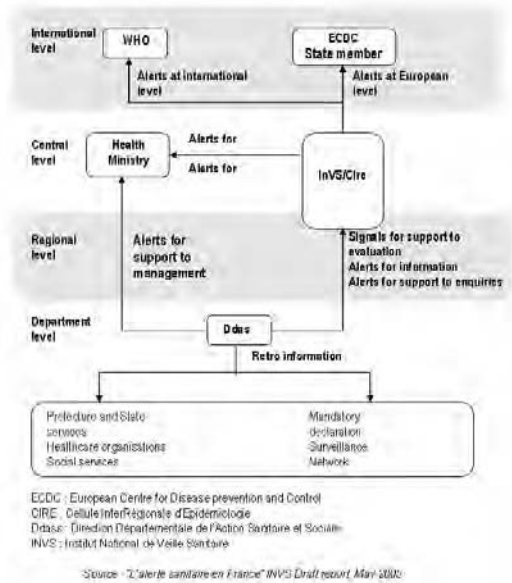

Figure 4 - Information flow in epidemic surveillance.

Discussion

At the European level, an Early Warning and Response System (EWRS) [12] has been established to alert public health authorities in Member States (MS) and the European commission (EC) on outbreaks with greater than national dimensions, where a coordinated EU action may be required. The EWRS is a telematic system focusing on infectious diseases and linking the designated authorities in MS and the EU. The system allows for immediate exchange of views on risk assessment and risk management that are crucial for timely public health action. The EWRS has already proven to be a useful tool during a number of outbreaks/incidents.

In fact, health warning systems are organized in different ways at the level of the MS. These systems include for example surveillance of indicators, health events, and animal diseases as:

- All declarations for mortality;
- Indicators of biological, chemical and physical exposures (pollution, water quality, air quality, radioactivity, aerobiological, meteorological etc);

- Indicators of infection and morbidity;
- Indicators of risky comportments.

Surveillance of events includes different types of networks:

- Networks of clinicians, civil and military;
- Networks of epidemiologists;
- Networks of public health agencies;
- Networks of civil security;
- European and international epidemiological surveillance networks (pharmacological, toxicological etc.).

Surveillance of animal diseases includes several types of networks and particularly surveillance ensured by veterinarians.

There are many organizations involved in epidemiological surveillance, from the regional to the national level. The information flow between the different actors on Figure 4 is based on the French system and provides an example of how information flow may proceed in the European context. A list of the main networks on communicable diseases at the European level can be found in [9].

SAFE will take into account the procedures and information flow reflected in the national preparedness master plan. Its focus will be on facilitating better coordination and cooperation among the actors involved e.g. civil protection and health authorities not only at the national, but also at the EU and international level. The exercise will be modeled along established exercises addressing the problems noted in their review with more effective communication tools and procedures.

Conclusions

The component-based interoperable architecture of SAFE addresses the communication and coordination needs of earthquake post-crisis health management. SAFE focuses on health early warning and monitoring the onset of epidemics emphasizing the value of satellite technologies in education, data collection, integration, processing, analysis, and notification. In particular, seamless workflows, collaboration with expert centres, geographic monitoring of rescue teams and critical resources, transparent data collection and analysis, as well as provision of health early warning will be highlighted in a scenario of typhoid fever epidemic outbreak in a settlement of earthquake victims.

SAFE is in line with the vision of ESA[5] to specify, develop, and demonstrate with support from WHO, a European health early warning system that will become a key tool for the national and European bodies in charge of epidemiological surveillance and especially ECDC.

5 European Space Agency: http://www.esa.int

Acknowledgments

The authors would like to thank all the members of the SAFE consortium for their input. The project SAFE is co-funded by the European Space Agency (ESA) and is part of the ESA telemedicine via satellite transition phase set up to pave the way for the creation of a European user-driven telemedicine via satellite program.

Remote Support for Stroke Rehabilitation: MyHeart's "Neurological Rehabilitation" Concept

Toni Giorgino[a], Paolo Tormene[a], Barbara Cattani[b], Caterina Pistarini[b], Silvana Quaglini[a]

[a] *Laboratory for Biomedical Informatics, Dipartimento di Informatica e Sistemistica, Università di Pavia, Italy.*
[b] *IRCCS Fondazione Salvatore Maugeri, Pavia, Italy.*

Abstract

Stroke is a serious neurological accident which accounts for a wide fraction of the healthcare costs in industrialized societies. Recovery from stroke and other neurological accidents usually include motor rehabilitation, maintained for several months, and logopedic training for the recovery of cognitive and speech abilities. The MyHeart consortium is addressing several aspects of cardiovascular diseases' management by combining clothes with embedded biomedical sensors and information technologies. One of the application areas is especially devoted to supporting Neurological Rehabilitation (NR). This article describes how MyHeart's Concept NR is structured and how technologies are leveraged to support both motor rehabilitation and speech/cognitive training. Information technology and garment-embedded sensors, combined, permit assisted training both at the clinic and at home, after discharge from the intensive care unit.

Keywords:

telemedicine, cerebrovascular disorders, stroke, rehabilitation, speech therapy

Introduction

Cardiovascular diseases (CVD) are among the principal causes of death and disability in industrialized countries; they represent a big social and economical problem and costs for their cure are going to increase with the growth of the mean age of population. CVDs are often correlated to a wrong lifestyle and to lack of prevention. Early symptoms detection, prompt intervention and efficient post-acute rehabilitation are necessary to properly address the problem [1].

Given the large impact of the problem and corresponding potential benefits to be gained from more efficient treatments, the *MyHeart* consortium was created. Its mission is to address various aspects of CVDs by means of information technologies (IT) and intelligent biomedical clothes (IBC). It currently includes 33 partners; the project's activities take place between December 2003 and September 2007. Research within MyHeart is partially funded by the European Union to promote advancement of the state of the art in fields such as automated remote monitoring, early symptom detection and innovative sensing technologies. It initially encompassed plans for 16 different applications of IBC to cardiovascular diseases: prevention, detection and treatment were diversely addressed among the proposals, which were named "Concepts". During the first project phase (16 months) each concept was asked to develop both technology and a relevant business model. In April 2005 each of the 16 concepts undertook an extensive evaluation phase to evaluate the corresponding potential market impact. Each concept sampled prospective acceptance of the product or service proposed by conducting standardized interviews with patients, medical experts and economic policy-makers, representing the three main stakeholders for the consortium.

At the end of the concept evaluation phase, the 16 concepts have been reshaped into four new "Product Concepts", namely:

Fitness Coach – maintenance of an healthy lifestyle
Take Care – monitoring people at risk of CVD events
Heart Failure Management – monitoring after an acute event
Neurological Rehabilitation – telemedicine and motion analysis as a support to post-event recovery.

Each Product Concept is partially independent from the others, and being a medium-sized sub-project itself, it develops the required technology and architecture. This paper provides an account of the Neurological Rehabilitation (NR) Product Concept.

Scope

Recovery from a neurological event begins in the acute unit and it is articulated into a series of intensive and extensive rehabilitation protocols which depend on the specific healthcare system in which they are inserted. Patient's needs and relative costs decrease with the progressive re-acquisition of motor and cognitive functions.

Product Concept NR's aim is to support patients in the performance of *speech* and *motor therapy*, both when they are still hospitalized, and after discharge, at home.

Eligible patients will be (1) hemiplegic patients in stable clinical condition (i.e. the problems related to the acute phase and possible complications must be over); (2) patients with mild motor and/or cognitive impairment (this criterion is essential if we want the patient to use the

system alone, or with a limited assistance from his/her caregiver); (3) aphasic patients with no other cognitive impairment that could impact on the system's use. Motor and speech problems may be present or not in the same person. The physician identifies the candidate patients and communicates the enrolment to the physiotherapy/speech therapy responsible.

Patients and their relatives are informed about the study through a meeting with the chief of the NR ward and they will be provided with a booklet with explanation about the goal and the use of the system. Their informed consent will be required.

When hospitalized, eligible patients are taught about the use of the system by the same personnel that administers the usual therapy. Organizational and liability constraints impose that IT-based rehabilitation does not replace conventional therapy hours. After hospital discharge, patients can bring the rehabilitation device at home (or long stay ward), and continue exercises with the help of their caregiver, relative or professional nurse. (The requirement of a caregiver is not imposed by the system. Often post-stroke patients are not self-sufficient.)

Patient stations are user-accessible devices which support the rehabilitation exercises (figure 1). Patients' identity is recognized via personal "check-in cards". Once inserted, the most recent exercise protocol and messages are downloaded automatically at the patient's site. For maximum accessibility, interaction with rehabilitation software, both for speech and motor therapy, takes place via a touch-screen.

Speech therapy is based on the EvoLing software developed by Dr. Hein GmbH [2]. It includes an extensive set of exercises, each promoting one ability: to recognize words, phonemes, graphemes, and pictures. Semantic and orthographic information is considered in order to build exercises with an adapting degree of difficulty.

Motor therapy is an innovative component of the system. When sitting at the patient station, patients can review an instructional movie about the exercise they are asked to perform. They are then asked with the help of the caregiver, to wear a special sensorized garment and plug it into a portable electronics box (see below). After a brief calibration phase, the motion recognition software is started; it provides real-time feedback on the progress and accuracy of exercises by means of clearly visible symbols such as colored bars and a smiling or frowning face. The movements have to be repeated until the assigned number of repetitions are performed correctly, or a timeout expires.

Motion recognition is based on strain sensor technology, directly printed on garments. Conductive elastomers (CE) are polymer-based materials which exhibit electrical conductivity [3]. Polypyrrole, for example, can be deposited in stripes on fabric [4]. After vulcanization the stripes present an electrical resistance around 10-100 k/cm, varying depending on the printed geometry but also on the stretch imposed to the fabric.

Sensing stripes of CE material are thin and can be printed by cheap industrial processes; they do not alter the mechanical properties of the material they are smeared on. After vulcanization they are stable and non-toxic. The same material can be used to realize connection wires between sensors and a portable readout electronics.

When the fabric is then used to sew appropriately-sized and shaped garments, a *sensorized garment* is obtained. For the motor rehabilitation application, Lycra was chosen as a substrate fabric, because it allows the realization of tight-fitting but comfortable shirts. Figure 2 shows an early prototype of a sensing garments. Sensing tracks are visible in black on the outer side. Current prototypes embed the sensing stripes between two layers of fabric, and therefore they are not visible. The sensor layout is presented in figure 6.

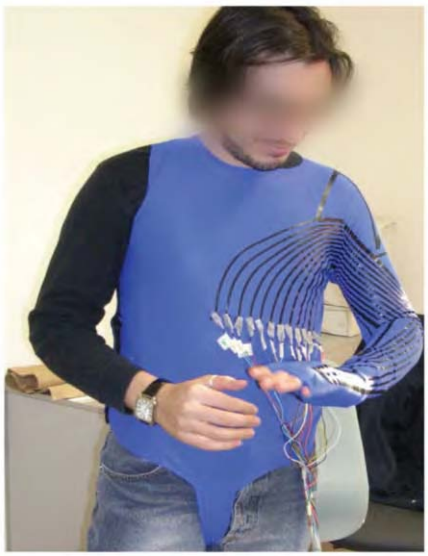

Figure 2 – Sensorized garment for motor rehabilitation. Picture of an early prototype whose CE tracks are visible.

Architecture

Figure 3 shows the telemedicine infrastructure underlying Concept NR. It is based on EvoCare, a solution adopted by Dr Hein GmbH, which is also a partner of the product concept [5]. The main components are one *server*, and a number of *therapist stations and patient stations*. The components are connected by a secure network which, depending on organizational constraints, may leverage the hospital's wired infrastructure, use wireless links, or based on public cellular network (GPRS) connections, as is the case when patient stations are used at home.

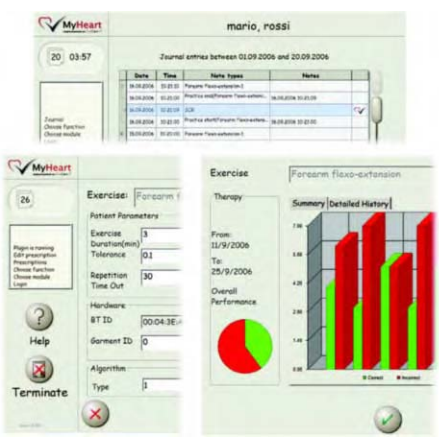

Figure 4 – Exercise prescription, configuration and results' review modes for the motor rehabilitation plug-in

Medical personnel (both physicians and physiotherapists) administer their assigned patients, prescribe exercises, and review their results using dedicated *therapists' stations*.

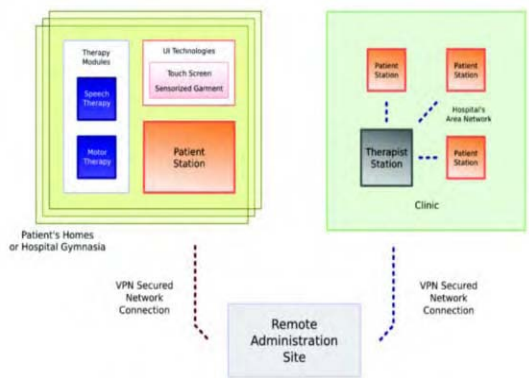

Figure 3 - Concept NR's telemedicine platform: simplified view of the architecture

The *server* acts as the repository for exercise prescriptions, results, and messages. Since session data is stored on the server, not the clients, patients can use one workstation or the other indifferently. Also, replacement of faulty workstations is straightforward.

The software architecture is based on a generic telemedicine framework which supports security and authentication, data storage and retrieval, and on-screen look-and-feel. Specific exercises, including speech therapy and motor therapy, are realized by a "plug-in" mechanism. Each plug-in implements all activities required by the specific type of exercise: it is responsible for providing configuration screens, support the execution of the actual exercise, provide appropriate feedback to the patient, and store the results. It also supports browsing and summarization of the results for the therapist to review. Figure 4 shows three views of the motor rehabilitation plugin.

CSEM (Centre Suisse d'Electronique et de Microtechnique) has realized the portable electronics required for sampling the strain sensors' resistance values (SEW, figure 5). The box, when used for the NR application, performs analog to digital conversion for 32 channels in 16 bit precision at 128 Hz, in parallel; digitized waveforms are packed and streamed in real-time over a Bluetooth connection [6]. Battery life of the current SEW prototype amounts to approximately 8 hours of continuous use.

When signals from body movement are acquired, they are processed in order to verify the correct execution of the rehabilitation exercise. Repetitions have to be counted and classified evaluating the similarity with a known "correct" or reference path. This is an important research topic by itself, because there is no direct correspondence between the fabric stretch values at various points of the garment and biomechanical parameters, like angles between limb segments. Also, strain sensors are affected by various sources of uncertainty which make the recovery of limb positions from sensor readings less than straightforward.

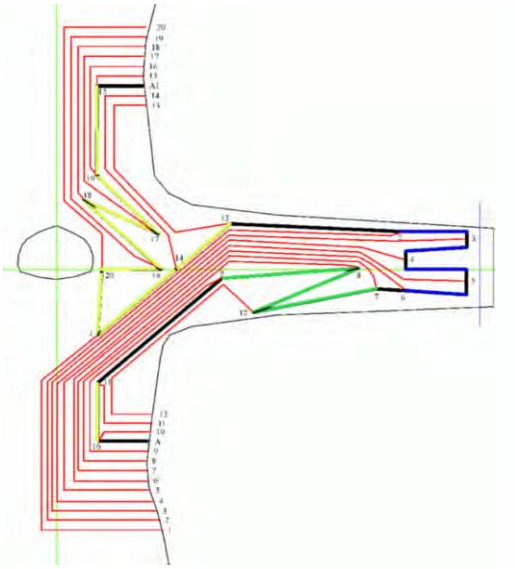

Figure 6 – CE mask in the garment. Thick lines are strain sensors; thin lines are wirelike printed connections

Classification algorithms were similarly applied for the actual posture detection. Although this strategy is partially successful, the accuracy of classification is affected by the dynamic nature of the task. On one hand, smeared sensors produce velocity-dependent artifacts; therefore, the recognition accuracy is impaired when limbs are moving. Also, one is interested in the closeness of a movement *path* to a reference, not just to detect a limited set of basic positions. For this reason, research is now ongoing to perform movement recognition on the basis of qualitative multivariate time-series analysis.

Results

The NR system is currently undergoing a small-scale study to assess user satisfaction and gather initial measures and feedback. It includes, as its last phase, 10 months of experience on the field, with real healthcare operators and at least 20 patients exploiting the different system functionalities. Results of the study will deal with the usability of the system (user-friendliness, lack of technical problems, comfort e.g. possible problems with the garment) and the users' satisfaction (perceived usefulness from the patients' and therapists' point of view).

Preliminary qualitative and quantitative results for speech therapy were obtained from the first four patients enrolled. One of them, recovering after a stroke accident, required only two training encounters to start using the logopedic software. He is now using the system three times a day. Although the amount of data is still limited, figure 7 shows the resulting trend: after the initial training phase carriedon with the speech therapist help (first two points), word recognition ability grows steadily.

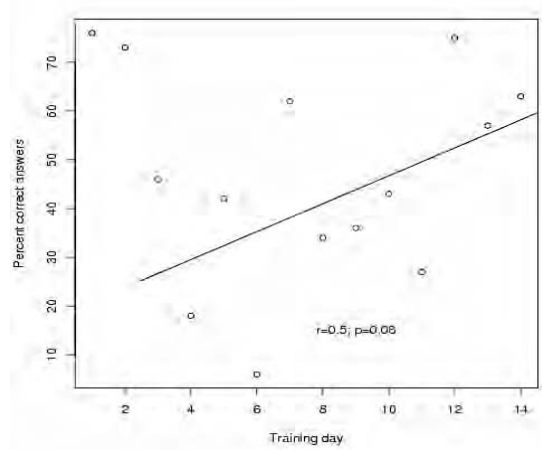

Figure 7 – Progress in speech training. During the first two days the patient was assisted. Linear regression for days > 2 indicates a positive trend (p=0.08)

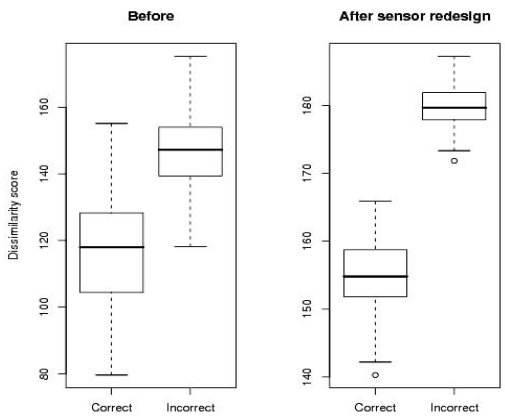

Figure 8 – Sensor layout affects recognition accuracy (exercise: sideways arm abduction)

The recognition algorithm used for the classification and real-time feedback on the exercises has been validated on several garment prototypes. The recognition is based on a "dissimilarity score" which is output by the recognition algorithm after a per-session calibration. A volunteer executed the rehabilitation exercises in sequence (table 1). Each exercise was repeated 10 times correctly, then 5 times mimicking the most frequent compensatory movements. Two distributions of "dissimilarity scores" were therefore obtained. The amount of overlap between distributions is proportional to the probability of a correct/incorrect misrecognition. Quantitative measures allowed redesigning the sensor layout in order to maximise the classifier margin (figure 8).

Conclusion

Development of the NR rehabilitation system followed an integrated approach which involved research on tissue-embeddable strain sensors, portable wireless electronics and ergonomic feedback, in order to be easy to use for patients which are often cognitively-impaired. Its most innovative component is the exercise recognition algorithms, which are able to provide feedback in real time, insensitive to several sources of noise stemming from the inherently noisy, multi-sensor approach taken.

The integrated nature of the NR system is now intended to support a multidisciplinary, telemedicine-based approach to rehabilitation. The benefits of this (and similar) IT-based aids are supported by current beliefs on rehabilitation, e.g. those expressed in the SPREAD guidelines [1]. First of all, long term rehabilitation programmes are considered beneficial for the recovery process[1]. However, their cost makes it unlikely support from insurances and national health-care systems. IT technologies are a promising solution for providing long-term rehabilitation at lower costs. At the same time, early discharge is recommended for patients with less severe degrees of disability[2]. The system allows for early discharge while still being monitored remotely.

Finally, the concept addresses a frequently-reported issue for rehabilitation professionals, i.e., lack of quantitative measures on the progress of rehabilitation. Standard functional scales, such as the FIM functional motor index, are in fact partially subjective. The diffusion of computerized monitored rehabilitation aids may increase the objectivity of practice and allow for quantitative progress evaluation and therapy comparisons.

Acknowledgments

Abstract:

A gap exists in cardiac care between known best practices and the actual level of care administered. To help bridge this gap, a proof of concept interface for a PDA-based decision support system (DSS) was designed for cardiac care nurses engaged in teletriage. This interface was developed through a user-centered design process. Quality of assessment, quality of recommendations, and number of questions asked were measured. Cardiac floor nurses' assessment quality performance, but not their recommendation quality performance, improved with the DSS. Nurses asked more questions with the DSS than without it, and these additional questions were predominantly classifiable as essential or beneficial to a good assessment. The average participant satisfaction score with the DSS was above neutral.

Keywords:

Teletriage, user-centered design, user interface design, mobile computing, decision support system

Introduction

As the number of Canadian cardiac patients increases and the length of hospital stay decreases, there is a need for expert care and evaluation once patients return home from the hospital. The current services of homecare agencies, community hospitals, and family physicians are inadequate to meet the needs of this growing patient base for two main reasons:

1. inadequate access to professionals (many patients may have to wait several weeks before seeing their family physician once they leave hospital) [1] and
2. limited professional access to up-to-date, best practice guidelines for cardiac care [2].

The Nursing Coordinators (NCs) at the University of Ottawa Heart Institute (UOHI) receive more than 2000 calls per year from patients requesting help and advice for cardiology and cardiac surgery concerns. Though teletriage is significant in the care of these patients, there is no standardized protocol in place to guide the advice-giving, nor is there any formal training for staff.

The purpose of this research was to design an effective Decision Support System (DSS) to help primary healthcare professionals field these calls. The final DSS will initially be used by the NCs, but aims to assist less experienced care providers in the future. The literature suggests that challenges lie both in the practice of teletriage [3, 4, 5, 6], and in the design and development of decision support systems [7, 8, 9, 10, 11]. To the extent that an inadequate design may rest on poorly defined user tasks, one would expect improved DSSs to result if that limitation were to be overcome. This research therefore explored the use of task analysis as part of a user centered design process aiming to produce an effective DSS.

In this study, cardiac best practice algorithms are introduced via a handheld DSS. Access to these best practices is expected to improve the quality of teletriage performance [1], provided that a) the best practices are sound, and b) the DSS delivers them so that they are easily used by NCs while on the phone with a patient. This research encompassed the design and evaluation of the DSS, but did not evaluate the best practice algorithms.

The hypotheses were: (1a) that nurses' performance in assessment of a patient's problem will improve using the DSS, and (1b) that nurses' performance in recommendations for the patients will improve using the DSS; and (2) that nurses will ask fewer questions with the DSS than without it.

Since there were many aspects to this research, this article will focus primarily on the results comparing nurses' performance with and without the DSS. The design process, and the design itself, will not be discussed at length here.

Materials and methods

Development of pain scenarios and standardized patient profiles

Two Subject Matter Experts (SMEs) developed four pain scenarios, based on best practice algorithms that were determined with a larger expert team. There was one scenario for each of the following types of pain complaint: non-urgent cardiac surgery, urgent cardiac surgery, non-urgent cardiology, and urgent cardiology. The following

specific ailments were chosen as common examples of each type of pain (see Table 1).

Table 1- Pain scenarios

Scenario	Cardiac care area	Urgent or non-urgent
1: Post Pericardiotomy Syndrome (PPS)	Cardiac surgery	Non-urgent
2: Ischemic Pain	Cardiology	Urgent
3: Cardiac Tamponade	Cardiac surgery	Urgent
4: Stent Pain	Cardiology	Non-urgent

Each pain scenario was developed with a standardized patient profile whose characteristics matched the algorithm for the pain complaint in question. These simulated "patients" were created by the two SMEs, based on the algorithms and their practical experience.

Baseline test – Nurses' performance without the DSS

Because some of the NCs participated in development of the algorithms and because there are very few NCs at the UOHI, the NCs did not participate in DSS prototype testing or the baseline test. Instead, participants were cardiac care nurses from the UOHI who work with hospitalized cardiac patients.

Twelve nurses completed the baseline testing, in which their performance was assessed without the DSS. During the baseline test, nurses used only pen and paper while on the phone with the patient, as these are the tools normally available to them. Seven of these nurses subsequently completed the DSS test, which scored their performance with the DSS prototype and helped the researcher evaluate the DSS interface. During both the baseline and DSS tests, an SME acted as the patient on the other end of the phone. This SME also acted as the UOHI attendant who transfers incoming patient calls to the NCs. The study did not use real patients as participants.

This baseline provided initial data for the number of questions asked by each participant in each scenario, and for performance scores on quality of assessment and quality of recommendations. "Quality of assessment" measured nurses' ability to ask the right questions in assessing the patient's condition. "Quality of recommendations" measured their ability to give the patient correct advice based on the presenting problem in each scenario. The scoring of the quality of assessment and quality of recommendations was done independently by the two SMEs after many practice sessions and iterations of the scoring sheet. For the four scenarios tested, the average inter-rater reliability (IRR) for quality of assessment was .94, ranging from .83 to .98. For quality of recommendations, average IRR was .97, ranging from .86 to 1.

The presentation of the four pain scenarios was randomized to avoid serial order effects. In all scenarios, the SME in the role of the patient made an effort to answer the nurse's questions in an appropriate way, neither volunteering more information than requested, nor being furtive and vague. For each pain scenario, the SME referred to the corresponding standardized patient profile during the call to ensure she was giving consistent answers. Each standardized patient profile listed, in logical order determined by the algorithm, questions that the NC would likely ask with corresponding answers for that scenario. The profiles also contained answers to questions not necessarily in the optimal flow of questioning. Throughout the baseline and DSS tests, if a participant asked a question that was not on the list, the SME gave an answer consistent with the cause of pain in that scenario. She then added the new question and answer to the list, ensuring that a consistent response would be given should the same question be asked by another participant. To preserve the SME's anonymity and increase semblance to a real telephone call, the SME was in another room and communicated via telephone throughout the test.

The researcher read an introductory script before the pain scenarios began, telling the nurse that they would be acting in the role of an NC, and that their task was to assess the patient's condition and advise them accordingly. To more closely mimic real-life use, nurses were asked to hold the telephone handset to their ear during the call even though the speaker phone was in use to record the session, enabling the researcher also to hear the "patient's" responses. Participants proceeded through the phone call using a pen and paper to record whatever they wished. The participant marked the end of the call by hanging up the telephone handset.

DSS Test – Nurses' performance with the DSS prototype

Seven of the original 12 participants were available and completed the proof-of-concept DSS test, on a mid-fidelity prototype. These sessions were scheduled approximately six weeks following the baseline testing. The same SME who participated in the baseline test acted again in the role of the patients for the DSS test. The SME did not personally evaluate the interface during the DSS test.

Apparatus was similar to the baseline test with the addition of a Palm Tungsten T3 PDA including stylus, and the DSS prototype running on a Toshiba Portégé M200 tablet PC. The T3 was presented with only the software that comes installed from the manufacturer. The DSS prototype incorporated best practice algorithms for cardiac pain into an interface that supported nurses in asking the correct questions while they were assessing the patient, and assisted the gathering of patient information. With the exception of the first participant in the trial, participants did not have access to a pen and paper for the DSS test. The pen and paper were removed to encourage participants to use the prototype rather than the paper. All interaction with the tablet occurred through the included stylus.

Tablet PC interaction exercise

Each nurse completed a short interaction exercise on the Tablet PC. This was not recorded and served only to give each nurse equal opportunity to practice interacting with the device via the stylus. All participants were first-time Tablet PC users.

Practice scenario

After the first participant, it became apparent that the nurses would likely benefit from some practice on the system before being asked to use and evaluate it in a simulated working environment. Therefore all subsequent participants received the following practice scenario. The researcher walked the nurse through a sample scenario, which was based on a fictitious patient with a chest cold rather than a cardiac pain concern. Then the researcher played the role of that same patient, and allowed the nurse to click through the tool on their own while asking questions of the patient. This gave them extra practice with the stylus, and with the prototype interface elements.

Pain scenarios

The pain scenarios proceeded exactly as in the baseline test, but the participants used the prototype DSS to assist in assessing the patient. Scenario order was randomized, and participants received them in a different order than in the first session to avoid order effects. Patient and physician names were changed from the baseline test.

As participants progressed through a patient call using the DSS, they saw questions on each screen (for example, "What makes the pain worse?") and could input patient responses through checkboxes, pick lists, and freeform fields. Participants had freedom to move about within the interface, and were not instructed to read each question in sequence. At the point just before the software would throw a "flag" based on the input so far, suggesting a possible presenting issue and a recommended course of action, the participant was asked to guess what the patient's problem was and give their own recommendations. The automated assessment flag was then revealed, and the participant was asked whether they agreed or disagreed with the DSS' suggestions.

Results

Quality of assessment

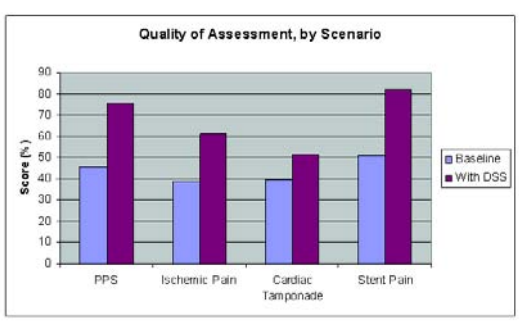

Figure 1 - Quality of assessment, by scenario

Figure 1 shows the quality of assessment scores for each scenario. While this figure suggests that performance scores improved substantially from the baseline to using the DSS in the case of Stent Pain and Post Pericardiotomy Syndrome (PPS) – the non-urgent scenarios, this improvement was less evident in the case of Ischemic Pain and Cardiac Tamponade – the urgent scenarios. A Wilcoxon Signed Ranks Test indicated that, statistically, quality of assessment did improve for every scenario with the DSS ($p < 0.05$). These results support one of the experimental assumptions, namely that that nurses' performance in assessment would improve using the DSS.

Quality of recommendations

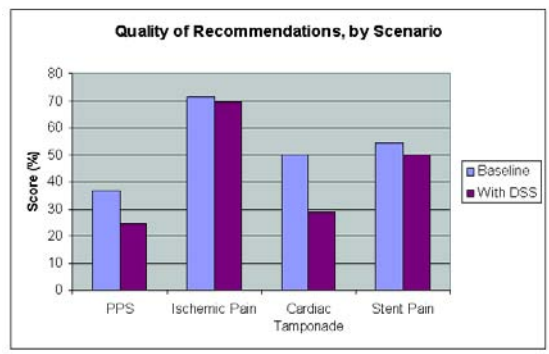

Figure 2 - Quality of recommendations, by scenario

Figure 2 suggests that recommendation performance declined at least slightly across all scenarios. This decline was most evident in the Cardiac Tamponade (urgent) and Post Pericardiotomy Syndrome (PPS) (non-urgent) scenarios. However, contrary to the predictions, the Wilcoxon Signed Ranks Test revealed no significant effect ($p > 0.05$). In seven cases out of 28, the nurse did not correctly guess the patient's problem, but they agreed with the automated DSS assessment. In these cases, recommendation quality might have improved in real life, had they seen the automated DSS flag before advising the patient – this assessment flag offered a possible condition, as well as recommended course of action.

Why was there no improvement in recommendation scores with the DSS? The nurses were provided with essential and beneficial questions to ask (contributing to the quality of assessment score), but they were not provided with the recommendations contained on the DSS. In clinical practice, telepractitioners would not be forced to advise the patient without seeing the DSS recommendations. Additionally, cardiac floor nurses would be expected to give good recommendations without assistance, so improvement may be observed more readily in a more novice user group. Nurses' lack of experience with the technology (PDAs and the tablet test platform) may have interfered with their ability to synthesize information during the phone call because a lot of their attention was devoted to trying to use the technology. Also, since this was the first time the pain scenarios were used, it is possible that these could benefit from further iteration. Finally, the floor

nurses participating in the study were not used to performing teletriage, which could have contributed to low recommendation scores both with and without the DSS.

Number of questions asked

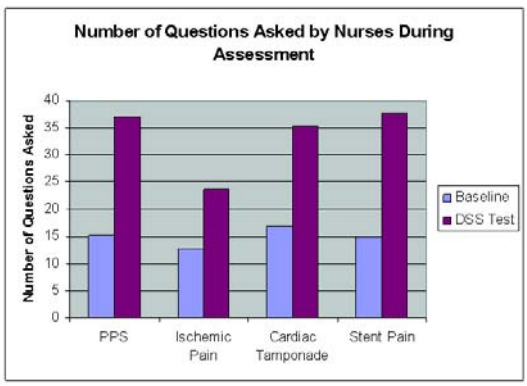

Figure 3 - Average number of questions asked by nurses during assessment

Hypothesis (2) predicted that nurses will ask fewer questions with the DSS than without it. A Wilcoxon Signed Ranks Test, comparing the number of questions asked in the baseline test and the DSS test, indicates that participants in fact asked significantly more questions with the DSS than without it ($Z= -2.31$, $p<0.05$). These results are illustrated in Figure 3 above, and they thus refute that hypothesis.

However, in addition to comparing the number of questions asked, the efficiency of questioning was also assessed. Efficiency was measured as a proportion of questions asked that were on the SME's list of essential and beneficial questions. These lists were agreed upon by two SMEs, and were iterated following the final test, before scoring was done. This iteration was deemed necessary because the nurses asked beneficial questions during the DSS test that were not on the original lists. The SME's lists of questions were not tested prior to using them for coding. Questions outside of these lists are purposely not called "bad" or extraneous questions, as it is possible that further iteration to the lists could be beneficial.

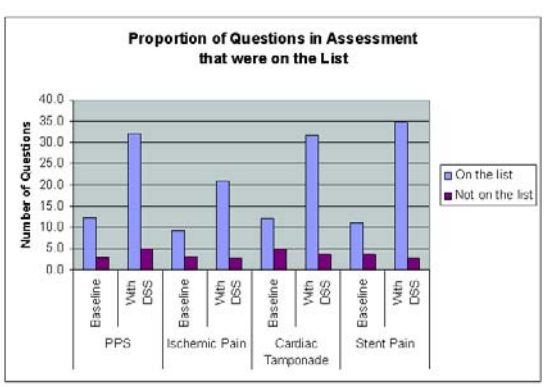

Figure 4 - Proportion of questions in assessment that were on the list of essential or beneficial questions to ask

Figure 4 shows the proportion of assessment questions asked that were on the list compared to not on the list. It suggests that most of the additional questions asked with the DSS were marked in the SMEs' list. Furthermore, the number of questions not on the list remained fairly constant across scenarios between the baseline and DSS.

A Wilcoxon Signed Ranks Test indicated that nurses asked significantly more questions on the list with the DSS than without, but there was no significant difference in the number of questions asked that were not on the list. Earlier, it was reported that assessment scores increased with DSS use. This supports the results we see here, since nurses asked more essential and beneficial assessment questions with the DSS than without it. So at the same time this figure refutes hypothesis (2), it helps confirm hypothesis (1) in that asking more essential and beneficial questions with the DSS contributed to participants' higher assessment scores.

On later discussion between the SME and an NC, it came to light that less experienced teletriage practitioners don't ask enough questions – this supports the literature [6]. In this respect, hypothesis 2 turned out to be misguided; it should have predicted an increase rather than a decrease in the number of questions asked, provided that additional questions asked could be shown to be relevant and beneficial to the final recommendation.

User satisfaction

User satisfaction was measured in a post-test questionnaire, immediately following the DSS test. Users marked their score on a 10-centimeter line scale, and these scores were translated to values between 0 and 10. Aspects that ranked most satisfying (average scores across all participants) included:

- "It was **easy to learn** to use this system" – 7.5
- "The **information was helpful** to me in completing the scenarios" – 7.5
- "**Overall, I am satisfied** with this system" – 7.5
- "I **could effectively complete the scenarios** using this system" – 7.4

Aspects that ranked least satisfying included:

- "Overall, I am satisfied with **how easy it is to use** this system" – 5.2
- "It was **easy to find the information** I needed" – 5.8
- "The **order of the screens** made sense" – 6.1

Summary

Cardiac floor nurses improved their assessment quality, but not their recommendation quality, with the DSS compared to without it. Participants asked more questions with the DSS than without it, and these additional questions were predominantly classifiable as essential or beneficial to a good assessment. This supports the literature where Wheeler found inexperienced teletriage practitioners often failed to obtain adequate patient history. Participant satisfaction with the DSS averaged above neutral.

Future research

One problem identified with the current Telepractice Record form – the paper form currently used by NCs during a patient call – was that NCs tend to fill them out incompletely. Though this is unlikely to make a difference in the quality of their advice or assessment, this tendency creates difficulties in record keeping and patient tracking. It would be interesting to study whether enabling NCs to enter patient information in the DSS affects how complete the records are when they turn them in. Since the DSS will be associated with a database collecting patient call information, the potential is there to significantly improve record keeping for patient calls.

Developing the prototype for the Tablet PC allowed us to see what users were doing during the test, and to give users a feel for stylus-based interaction with the screen. However, the form factor of the T3 handheld unit is considerably smaller, and this might therefore affect users' performance and acceptance. During the opportunity for informal feedback on the T3, none of the nurses indicated they thought it was too small to use. Despite this, testing the DSS in situ on the T3 would be advisable to discover if any interface elements are hindered by the reduction in screen size.

Finally, a computerized decision support system can only be successful if it is actually used. There will need to be a certain degree of motivation on the part of the NCs to try something new, as well as encouragement and support from the developers and researchers involved. Feedback from the NCs should be closely monitored during the implementation stages of the final DSS. Acceptance testing after the system is in place would provide helpful information for future iterations, as well as valuable insight for future nursing decision support systems. Ideally, this would incorporate longitudinal testing of participants on the DSS over a period of several weeks, rather than in a single session, to give a better impression of how performance would be affected by the DSS over time. Because the DSS will eventually be used by less experienced nurses, and because the tested group of participants did not improve their quality of recommendations with the DSS even though it helped their assessment, it is advisable that nurses receive training not only on the DSS, but also on teletriage in general before they are expected to take on a teletriage role.

Opportunities and Barriers for Mobile Health in New Zealand

Farhaan Mirza[a] and Tony Norris[a]

[a] *Centre for Mobile Computing, IIMS, Massey University, Auckland, New Zealand*

Abstract

Ownership and the use of mobile technologies greatly exceed those of personal desktop computer systems and countries throughout the world are beginning to understand how these technologies can enhance the delivery of healthcare (m-health). This paper reviews the opportunities and barriers for m-health and describes a study to understand its potential in New Zealand. A survey consisting of a questionnaire and in-depth interviews was used to reveal clinician and service provider attitudes to m-health. The general perception is that m-health will be an increasing component of future healthcare with many opportunities for empowering patients, delivering convenience care, and supporting carers as well as offering the potential for more effective public health and lifestyle broadcasting. Participants recognised several barriers to the acceptance and sustainability of m-health, identifying privacy of information and device form factor as major concerns.

Keywords:

mobile health, m-health, mobile phones, cell phones

Introduction

The world total of mobile phones currently stands at 2.5 billion and is set to reach 3 billion by the end of 2007 (1). New Zealand alone has 3.8 million subscribers (2) from a population of 4 million people emphasising that many users have multiple subscriptions. Evidently, ownership and use of mobile technologies greatly exceed those of personal desktop computer systems and the pervasiveness of mobile solutions (3) offers possibilities far beyond the expedient of simple communication. The next phase of smart phone development will further extend these possibilities as communication, computing, and multimedia elements (cameras, video recorders, music players) converge seamlessly in the same powerful device (4).

Countries throughout both the developed, and the developing, world are now beginning to understand how mobile technologies can enhance the delivery of healthcare (m-health) (5) and this paper describes a study of the opportunities and barriers to m-health in New Zealand. The ubiquity of mobile devices clearly offers the potential for more convenient communication between patient and physician, the transmission of clinical test results, rapid diagnosis in emergencies, and similar applications (5) but how acceptable are such interactions to the participants and what are the obstacles to their introduction? The paper discusses these issues and makes recommendations for the advancement of m-health.

M-health applications

A definition of m-health

We can define m-health as a rapidly developing area that uses small, portable, and wireless computing and communication devices to meet the information and service needs of healthcare providers and consumers.

From this definition, mobile devices are effectively transceivers that run healthcare applications over wireless (and wired) networks. The armoury of such devices is increasingly diverse ranging from (3) laptop computers, tablets, and PDAs to mobile and smart phones (4) and RFID (6) technologies. Short (< 50 m) and long-distance network protocols are similarly becoming more powerful extending their reach and reliability (7).

Mobile devices offer some obvious benefits (8) in addition to portability such as convenience (easy access), immediacy (any time) and context (location).

The providers in our definition include clinical and non-clinical practitioners whilst the consumers are the general public but in particular patients and, increasingly, their carers. This clinical/non-clinical distinction offers a useful way of classifying m-health applications.

Clinical m-health applications

Table 1 shows some typical examples of clinical m-health applications.

Table 1 - Clinical m-health applications

Web access to evidence-based databases
Medication alerts using mobile phones
E-prescribing for repeat prescriptions via mobile phones
Telemonitoring to transmit patient results to clinicians
Transmission of test results to patients via SMS messages
On-line electronic health records via computer or phone
Community nursing contact with clinical expert advice
Public health and lifestyle messages over mobile phones
Care of at-risk people, eg air-line pilots, military personnel
Emergency care for accidents, natural disasters

The critical feature of these examples is that they encompass the whole spectrum of healthcare demonstrating the central role that mobile technologies can play in wellness promotion and disease management according to:

Prevention: public health and lifestyle awareness
Monitoring: pre-disease screening and assessment
Treatment: providing efficient and effective care
Support: for patients and their carers

The seamless and integrating utility of mobile devices is also evident from these examples.

Non-clinical M-Health Applications

The smooth operation of any healthcare service also relies heavily on administrative and management functions that support the clinical imperative. Table 2 shows how some of these functions can be discharged using mobile technologies.

Table 2 - Non-clinical m-health applications

Efficient workflow via wireless communication
Rapid collection/sharing of current data via mobile phones
Optimal asset utilisation, eg hospital bed rostering
Patient or asset (eg clinical equipment) location using RFID
Patient appointment booking and alerts via wireless e-mail
Mobile phone support for patients and carers
Safety of staff checks with RFID or mobile phones/networks

This small sample reveals the ubiquity and pervasive nature of mobile technologies which make them so acceptable (but see later) as personal and lifestyle essentials.

Potential benefits of m-health

As frequently happens with the introduction and diffusion (9) of new technologies, the benefits are driven partly by the needs of the domain and partly by the capabilities and opportunities offered by the technologies themselves. This section identifies some of the benefits that, at least superficially, are the most likely to accrue from the introduction and uptake of m-health. We might label these as 'the promise of m-health'.

Healthcare drivers

Perhaps the most significant issue and driver in healthcare today is the ageing of populations in developed countries (10). For example, a frightening statistic for New Zealand (11) is that 25% (1.33 million) of the populations will be aged 65 or over in 2051 compared with 490,000 (13%) in 2004.

This trend has multiple consequences but the most apparent is the increase in the incidence of chronic diseases that demand continual rather than episodic care as patients age. As the applications in Tables 1 and 2 show, mobile technologies offer the possibility of managing non-critical care within the community (including telecare (12)) thus reducing hospitalisation, improving patients' quality of life and controlling costs.

The longevity that results from the success of modern medicine also increases the importance of preventing people from getting ill in the first place and maintaining this status through appropriate lifestyle and care. Frequently, public health interventions and campaigns have limited success because they emphasise the need for change when none is apparent and they fail to raise personal awareness. However, the pervasive nature of the mobile phone offers the opportunity for targeted marketing of the health message and its reinforcement by repetition and with incentives (13).

These examples of the potential heath benefits of applications represent two of the generic improvements, namely efficiency and effectiveness, that are sought from the introduction of new technologies. The third general benefit is increased access to services and resources and the pervasiveness of mobile technologies, particularly mobile phones, is set to have a major impact on how we think about the delivery of healthcare and the relationship between provider and consumer (14). It seems highly probable that the increased ease of communication between clinicians and patients will lead to higher workloads that will have to be managed by the involvement of intermediaries who add value for all participants. Whatever form the new services take, they can improve equality of access for disadvantaged communities.

Technology drivers

The most obvious benefit of mobility is convenience and mobile technologies offer the possibility of 'convenience medicine' more so than any other previous innovation. Instead of the patient receiving care where the medicine originates, much of the medicine will come to the patient wherever he or she is. This demand will be flamed by the fires of patient consumerism and expectation so that m-health truly forecasts a revolution in healthcare delivery.

Some of these changes may be of questionable benefit but patient empowerment and greater responsibility for their own health planning and care will be an inevitable result of more frequent involvement and demand.

We have already noted the efficiency that rapid communication can bring to service operation and the ease of data collection and exchange. This ease will in turn increase the value of data leading to improvements in their quality and longevity (15). These advances could be especially important in New Zealand which enjoys significant advantages from its national data collections. If data could be collected directly and effortlessly from people via their mobile phones then, with the appropriate management and analysis, the derived information could have an enormous impact on the quality and efficiency of service planning and operation.

A final value proposition (literally) of mobile technologies for healthcare is their apparent low cost. Certainly, unlike many medical innovations, the cost of mobile technologies to the consumer is very small and their cost-effectiveness very high. There are of course the capital and operational costs of the supporting infrastructure but such costs are shared over many markets and the expansion of generic

mobile services has produced dramatic falls in service costs; a trend that shows no signs of abating. Indeed, as the technologies become more powerful the introduction of more innovative and seamless applications will drive down costs even further. These effects will, as noted, also encourage enterprises that previously had no presence in the health sector to offer value-added products and services.

Barriers to m-health

The potential benefits of m-health should not blind implementers to the inherent barriers and challenges. From a healthcare standpoint, first and foremost amongst these problems are concerns over the privacy and security of personal healthcare information (16). Whilst these apprehensions are sometimes more perceived than real, the ethical issues surrounding the electronic storage and transmission of sensitive data and their misuse cannot be ignored. Wireless security protocols are improving rapidly but often it seems only fast enough to keep pace with the ingenuity of hackers and other intruders who wish to gain illegal access to information.

A further clinical, and perhaps more limiting, challenge to m-health is the acceptability of the technologies to both patients and healthcare practitioners. Consumer empowerment and convenience are likely to overcome patient concerns without too much resistance but clinicians are rather more traditional when it comes to alternatives to face-to-face delivery of medicine (17).

Several concerns present themselves to clinicians; the potential for automating diagnosis and clinical-related decisions concerning treatment, the multidisciplinary nature of care which means that all members of the care team must accept the technologies if treatment is to be seamless and integrated, and the impact that the wireless and mobile devices and services may have on the doctor-patient relationship (17). The involvement of commercial enterprises offering value-added services as mentioned above is an example of the last concern.

From a technology perspective, one aspect of m-health offers an interesting paradox. The acceptability of the mobile phone is based on the simplicity (some phones are no more simple to use than video recorders!) and the convenience with which they perform their main function - voice communication by telephone. However, as the technology and power of the devices progresses, their expanded functionality betrays them as examples of a disruptive technology (7, 18).

A disruptive technology is a technology that when introduced does not meet the needs of users. Thus, a desktop personal computer or a laptop meets the computing needs of users in terms of modelling (eg Excel), office applications, or web searches but mobile phones, some of which are as powerful as a 1960s mainframe, cannot satisfy these requirements. The main limitation here is of course the form factor. The demands of portability have not so far been matched by the release from the tyranny of small screens and cramped keyboards. Similarly, the reliability of mobile devices and their fault tolerance attributes do not meet the exacting requirements of the mission-critical applications found in healthcare. Even the item that makes the mobile phone portable – the battery – is a limitation. Computing technology doubles in power every 18 months or so; battery power has taken 30 years to achieve the same level of improvement.

A study of attitudes to m-health

The observations made in the previous sections are based on evidence accumulated across several disciplines and markets and many of the findings are applicable to healthcare. However, the health sector's central focus on the well-being of persons is a crucial differentiator from other sectors. The ethical priority of care often makes the health sector a slow adopter of novel technologies, particularly those that challenge long-standing practice and so it is dangerous to make too many inferences or extrapolations about the impact of mobile technologies from other areas.

With this constraint in mind, the authors carried out a survey of attitudes to m-health to determine the potential and barriers for its development and sustainability in New Zealand.

Methodology for the study

The study was a pilot investigation based on a structured questionnaire and semi-structured interviews with healthcare providers across the primary, secondary, and community divisions of healthcare delivery, and with wireless infrastructure and mobile service providers. No patients were interviewed directly in the preliminary study but the health providers reported and compared patient views together with their own responses.

A total of 18 interviews was conducted and the questionnaire was administered to a total of 34 respondents who were identified by role, personal acquaintance, referral from other participants, or by self selection by enclosing the questionnaire in the registration pack at an international conference on health informatics. These two instruments covered a range of health planners and technology strategists including CEOs, CIOs, managing directors, clinicians from all sectors, information managers, IT consultants and nurses. The health sector representatives amongst the interviewees were mainly from secondary care anticipating the finding that m-health was most evident in this area.

The questionnaire and interviews at a macro level concentrated on the m-health experience of respondents and how they saw the opportunities and barriers for its mainstream extension at local and national levels. The responses therefore sought and correlated individual and industry perspectives within and across health sector divisions as well as at delivery and policy and planning levels.

The questionnaire was structured to enquire about general m-health barriers and opportunities, integrated care, and the role of mobile health at a national level. The interviews were semi-structured, but the main focus was to learn from the interviewee about: the role of mobile technology in

New Zealand healthcare, the role of m-health across the different health sectors, the demands and need for customized mobile software, the role of m-health to achieve integrated healthcare, and lastly to discuss the privacy and security implications of m-health.

Full details of this study and a more detailed and quantitative analysis of the results will be published elsewhere (19).

Results and discussion

This section reports and discusses the results of the survey that are most relevant to the m-health benefits and barriers reviewed in the earlier part of this paper.

M-health impact on patients

The most frequently expressed view from the survey was the perceived impact that mobile technologies would have on patient empowerment. The convenience aspect, patients' greater access to information, and the more facile communication with clinicians were all seen as triggers for patients to become more involved with and responsible for their own care. Vital signs monitoring and the transmission of test results were recognised as increasingly important roles for mobile technologies and the simplicity and standard format of short message services (SMS) promoted them as backbone mobile phone services for the present and foreseeable future. SMS services could also boost the impact of public health and lifestyle messages if a suitable format or incentives (extra air time?) could be found.

M-health work to date has been mainly of a 'proof-of-concept' nature and participants were clear that much more systematic work was needed to develop m-health as a group of mainstream technologies. In particular, looking further ahead, all clinicians felt that patients should have mobile access to their electronic health records (EHRs) but many problems, operational, technical, and ethical, had to be addressed before this facility would be generally available (see later).

M-health impact on providers

Providers saw the use of mobile technologies to collect data in an electronic format as a major advance in increasing the utility of data and its value in both operational and strategic decision making. The focus will be on mechanisms for routine data collection and these should be as independent as possible of the nature of the data.

Secondary care providers were especially vocal about the value to them of mobile technologies as vehicles for communicating with colleagues, particularly members of the care team, and, obtaining access to clinical information. On a more mundane level, Auckland District Health Board had managed to reduce its missed appointments percentage from 18 to 9% over the last two years and was determined to exploit SMS to reduce this number even further.

A response, volunteered by many participants, identified a key element to the successful application of m-health technologies. This factor concerned the need for seamless use of these technologies whenever there were several stages in a communication or information sharing chain. The example of a community nurse collecting data from a patient manually or receiving instructions on paper and then transmitting the data or issuing the same directions electronically was viewed as something that would hinder rather than promote m-health. A holistic systems or business process re-engineering approach was needed to avoid such barriers to progress.

Privacy and security issues

A previous section identified privacy and security issues as potentially significant barriers to the uptake of m-health. Those who took part in the survey were keen to separate these issues. Participants felt that security was not the main issue since its governing parameters were mainly operational and technical. Privacy of information and consent to its use or to treatment (16), however, were more conceptual and philosophical matters with strong ethical overtones. Objections to the transmission of information using m-health would probably diminish over time as the technologies matured and the benefits and convenience were seen to outweigh the risks but privacy concerns were paramount and m-health (and e-health) protagonists must incorporate them in the new ways of working.

Interestingly, the privacy issue divided clinicians almost equally on the possibility of supporting EHRs on mobile devices. Everyone saw the merit of doing so (see above) but whilst some providers would alter the privacy requirements to make EHRs available, others said that they were unlikely to become available (if at all) until security improvements could guarantee privacy.

Technology issues

Some of these issues (eg SMS) have been referred to above and respondents generally had quite informed views on technical matters. The major concern was the form factor needed to ensure the portability of a mobile device and the necessary constraints it imposed on the small screen and keyboard size, particularly with mobile phones. Doctors felt that m-health applications should not require users to enter significant amounts of free-field data but rather they should be able to enter items into specified fields by accessing options from pick lists. Thus, keyboards are not the main problem but all responses pointed to the limitation of a mobile phone screen and felt that new technologies such as folding screens (20) would be needed before multimedia or web-based services could come of age.

Future projections by suppliers drew attention to voice recognition technology (clearly of some relevance to a mobile phone!) pointing to the advances that had been made over the last decade but clinicians felt that the science was yet not sufficiently reliable for a mission-critical activity such as healthcare.

A valid point made (over several years) by healthcare systems developers drew attention to the difficulty of achieving a critical mass of sales and the negative impact it had on software construction times and cost (21). Given

the pervasiveness of mobile technologies, this is potentially less of long-term problem but the short-term difficulty focused squarely on the proliferation of so-called standards and the need to port applications across multiple protocols and platforms.

Conclusions and recommendations

The survey generally painted an optimistic picture for the future and 'promise' of m-health and, whilst it was conducted in New Zealand, the implications and the results and conclusions can reasonably be extrapolated to most developed nations. The proliferation of m-health devices and technologies will continue (and is inevitable) and as applications mature we will learn more about what works well what does not. The convenience factors and the ease of communication with m-health will empower patients and when used appropriately improve both their capacity to remain well and, if they do become ill, their ability to cover quickly and enjoy greater quality of life.

A firm recommendation from this study is not to get carried away by the technology or the latest killer applications but to carry out considered and systematic research (22) alongside product and service development that extracts the principles of good practice and disseminates them to all who can deploy them.

Applying Mobile and Pervasive Computer Technology to Enhance Coordination of Work in a Surgical Ward

Thomas Riisgaard Hansen[a] **and Jakob E. Bardram**[b]

[a] *Department of Computer Science, University of Aarhus, Denmark*
[b] *IT University of Copenhagen, Denmark*

Abstract

Collaboration, coordination, and communication are crucial in maintaining an efficient and smooth flow of work in an operating ward. This coordination, however, often comes at a high price in terms of unsuccessfully trying to get hold of people, disturbing telephone calls, looking for people, and unnecessary stress. To accommodate this situation and to increase the quality of work in operating wards, we have designed a set of pervasive computer systems which supports what we call context-mediated communication and awareness. These systems use large interactive displays, video streaming from key locations, tracking systems, and mobile devices to support social awareness and different types of communication modalities relevant to the current context. In this paper we report qualitative data from a one-year deployment of the system in a local hospital. Overall, this study shows that 75% of the participants strongly agreed that these systems had made their work easier.

Keywords:

operating room information systems, awareness, communication, user-computer interface, software design, mobile phone, handheld computers, computerized medical record

Introduction

Ensuring a smooth flow of work in a operating wards requires efficient collaboration, coordination, and communication [1,2]. A considerable amount of time and energy is spent on getting information about where people are located, what they are doing, getting information about changes in plans, and ensuring that the right staff is present inside the operating room at the right time, including the patient. Large whiteboards and a constant flow of phone calls are some of the tools that clinicians use to communicate, to stay aware on the flow of the work, and to maintain a social awareness of one another.

Information posted on whiteboards are, however, only visible in one location. For example, the whiteboard that displays today's operation program is typically only visible from the coordinating central within the operation ward. Similarly, phone calls might be a useful tool for the caller to gain knowledge and coordinate his or her work, but phone calls may also be disturbing to the recipient because they are occupied with other activities [3].

This paper describes a set of pervasive computing systems called iHospital which are designed to support the intense coordination of work in an operating ward. The goal of these systems is to address some of the shortcomings of communication and awareness systems in use today, thereby increasing the quality and efficiency of operation coordination. The paper then reports from qualitative studies of a one-year deployment of the systems which demonstrates that the systems in general made work easier on the wards by helping clinicians to reduce interruptions, locate each other, get an overview of work, coordinate work, handle changes in work, communicate in and out of the operating ward, and to reduce the amount of traffic in and out of the operating room.

Systems design

The designed system was developed in close participating with doctors and nurses over a one-year period. Several workshops and early mockup and prototypes were used to test out early ideas and get instant feedback. The final developed and deployed system was comprised of three separate but tightly integrated sub-systems: (i) a location tracking system, (ii) the AwareMedia system, and (iii) the AwarePhone system.

Location tracking

The *location tracking system* was designed to get information about the activities and whereabouts of the clinicians. The location tracking system was a zone-based tracking system that only tracks clinicians inside predefined zones, like operation rooms, the patient wards, and the recovery department. Zone-based tracking was chosen partly due to the high cost of fine-grained indoor location tracking equipment, partly because this coarse-grained location was deemed sufficient for our purpose, and partly due to privacy protection of clinicians once outside of 'interesting' zones (see [4] for a survey of tracking systems ubiquitous computing). Clinicians were only tracked inside predefined zones and no logging was performed about how much time the clinicians spent in different zones.

In the pilot study, location tracking was done by tracing Bluetooth tags and devices (e.g. mobile phones) worn by

clinicians. Location information was displayed in the AwareMedia and AwarePhone systems.

AwareMedia

AwareMedia is a full-screen, touch sensitive system running on large and medium-sized wall displays. These clients are typically deployed in the coordination central of an operating ward, inside each operating room, in different patient wards, and in the recovery ward. AwareMedia presents an overview of what is going on in relation to the daily handling of surgeries. The display shows a list of operation rooms and a list of people at work, where they are located, and what their current schedule, according to their calendar.

AwareMedia displays a detailed view of the current and scheduled activities inside each operating room. It displays the current operation, its status, the people located by the tracking system inside the room, the patient being tracked, and a complete schedule of the surgeries scheduled for this room. This information provides an overview of the status and activities inside each operating room as well as detailed and updated information about the clinicians associated with the operating ward.

The program not only provides an overview of what is going on, it also supports different types of communication. A video link from each operating room provides a passive overview of what is going on in each operating room (these video links are also called media spaces [5]). The quality is adjusted so it provides an overview of what is going on the operating room without being privacy-invading for the patient. A chat function allows clinicians to send information between the system and the operating theatres, collaborating wards or mobile devices running the AwarePhone system.

Figure 1 - The AwareMedia System running on two large displays in use at the hospital (left), The AwarePhone System displaying a list of clinicians and their location (bottom) and at the top is a clinician wearing a small tracked Bluetooth chip (top)

AwarePhone

The AwarePhone system is an application running on mobile devices and it provides a similar functionality to the AwareMedia system. The mobile device has a smart phone book where each clinician and operating room is listed. Besides presenting the name the phone book keeps an updated list of the location of clinicians, their current booking in the calendar system and a self-reported status. Next to the operating rooms is listed the current surgery in that room and its status (patient arrived, surgery just started etc). By selecting a person or an operating room, the system presents the options to call the person/room or send a message. If a message is sent to the operating room the message is presented to the people in the operating room through the AwareMedia system.

Figure 1 shows an overview of the three systems. To the left is the AwareMedia system running in the coordinating central at the hospital, to the right is a clinician tracked with a Bluetooth chip, and the bottom picture shows the AwarePhone system. The developed systems are rather complex and the technical details of the systems are presented in depth in [6, 7, 8].

Methods

The suite of systems described above was deployed in January 2006 in an operating ward in a medium-sized Danish hospital. The operating ward is a centralized ward with nine operating rooms and supports three departments (organ, orthopedic, and gynecology/obstetric surgery). Around 150 clinicians were associated with the operating department.

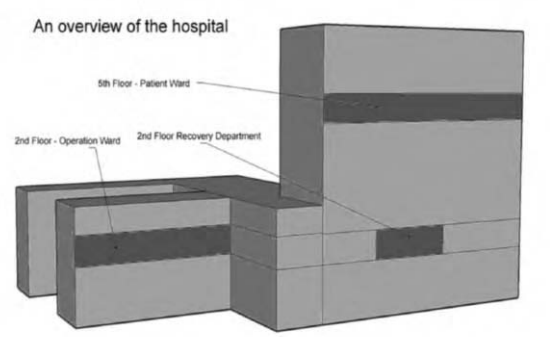

Figure 2 - A view of the hospital with the operating ward marked to the left on the second floor, the recovery department in the main building on the second floor and the patient ward at the fifth floor in the main building

For the pilot study, three operating rooms were equipped with the AwareMedia system (two orthopedic and one gynecologic), the coordinating central was equipped with a large wall-sized version of AwareMedia, and they recovery department and the patient ward for orthopedic surgery was also equipped with the system. For the tracking system 10 zones were defined and the system was able to track around 30 people (20 carrying mobile devices and 10 carrying tags). 15 mobile phones were distributed to clinicians, operation technicians, and nurses with coordination responsibilities.

Figure 2 shows a sketch of the hospital and presents the areas of the hospitals the system was installed in.

Table 1 - The Table shows ten of the forty six questions and the corresponding responses

How much do you agree with the following statements?	Strongly agree	Agree	Neutral	Slightly disagree	Disagree	Don't know	Not answered
9a. The system has lead to fewer interruptions	35%	30%	14%	0%	7%	12%	2%
9b. It has been easier to locate co-workers	42%	23%	21%	5%	5%	5%	0%
9c. I have a better overview of today's work tasks.	53%	23%	12%	5%	2%	5%	0%
9d. The system made it easier to coordinate work.	47%	21%	14%	0%	5%	5%	9%
9e. I save some steps.	49%	16%	19%	5%	7%	5%	0%
9f. It has become easier to handle changes in today's schedule.	35%	33%	23%	0%	5%	5%	0%
9g. There has been a better communication between the operating ward and the recovery department.	9%	16%	30%	0%	7%	30%	7%
9h. There has been a better communication between the operating ward and the patient ward.	23%	21%	21%	5%	7%	21%	2%
9i. The system has minimized the traffic in and out of the operating rooms.	30%	28%	14%	2%	2%	19%	5%
9j. The patient is getting a better treatment	7%	23%	37%	0%	9%	19%	5%

Results

Questionnaires

Questionnaires were given to a number of clinicians such as operation technicians, nurses, anesthesiologists, and surgeons. In total 43 questionnaires was handed out, 34 responses came from nurses and 9 from doctors and other medical personnel (approximately half the clinician working regularly in the operating ward filled out a questionnaire).

Being asked about the question, if the system in general made their work easier, 75 % strongly agreed with this statement. Only a single response stated that the system made it more difficult to use. Some other results from the questionnaires are presented in Table 1 which reveals that clinicians found that the systems helped them coordinate their work, led to fewer interruptions, helped them locate co-workers, saved them some steps, helped them handle changes in the operating schedule, helped improve communication in and out of the operating ward, and reduced traffic in and out of the operating room. The clinicians, however, reported that they did not find that the systems significantly helped improve patient treatment.

Interviews

Fourteen structured interviews were performed with doctors, nurses and supporting staff after the system had been used for three months. Each interview lasted approximately half an hour each.

The data material is huge, and in this paper we will only present very few of the statements. One of the findings highlighted by several persons was the ability to react to changes earlier than before. An operating nurse puts it this way:

[*With the system] people are starting to react earlier than before. We can see the surgery in operating room 9 is delayed so the last patient can be operated in room 4 instead. And that is a clear advantage because then the surgeon can just throw the gloves and move on to the next patient. That is a huge advantage because sometimes the last patient needed to be postponed to the next day.*

By monitoring the progress in the different operating rooms simultaneously, the coordinating nurse has a powerful tool to move patients to other rooms if the schedule is behind in one of the rooms.

Log data

The system logged all the interaction with the system. From the logged data we were able to analyze how the system was used, how many people that were tracked each day, how many messages sent, and similar data. For instance Figure 3 shows the number of surgeries created, modified, and deleted (canceled) using the system from January to September.

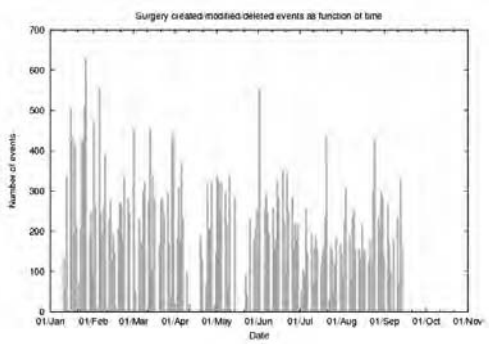

Figure 3 - The number of changes made by the AwareMedia system from January to September. A change can be a surgery being moved, a surgery being extended, the personal associated with the surgery being substituted. Some actions might result in a number of changes

Figure 3 shows that that the amount of changes made to the schedule each day is quite substantial – from 100-500 events pr. day, which correspond to approximately 10-20 changes to each operation. A small drop over time can be seen, but our analysis points to this drop being due to the clinicians getting more skilled in using the system and actually not less use. However, a larger drop can be found in the number of users being location tracked which will be further addressed in the discussion.

Discussion

Based on the study of the deployed set of systems, we will argue that there is some evidence that such mobile and pervasive computing systems may help enhance the work in an operating ward.

Efficiency

There is clear evidence that the system increased the efficiency in work at the operating ward. 67% of the clinicians agreed that the systems made coordination easier. 66% found that they could handle changes in the daily operating schedule easier and in the interviews the clinicians argued, that the systems increased the number of performed surgeries because it was easier to coordinate and gather resources to unscheduled surgeries. We are currently working on elaborating the findings by analyzing the number of surgeries carried out before and after the introduction of the systems.

The system was also designed to make communication between the operating ward and the patient ward and recovery ward easier. However, in the questionnaire only 44% and 26% respectively agreed to this. It was nevertheless in the interviews argued by the people using the system a lot[1] that the systems did enhancing cross-departmental communication and coordination. Many clinicians simply did not use this feature of the system, which also explains the large number of 'don't knows' in the questionnaire.

It is evident that the system helps clinicians locate each other and saves them many unnecessary steps. 65% agreed that it was easier to locate people and 65% agree that the systems save them some steps. Hence, critical time is saved.

Finally, the clinicians did not agree with the statement that the treatment of the individual patient had been improved based on the systems. However, the questionnaire was not handed out to people at the recovery and patient ward. At these ward they pointed out that they were able to give much more precise information to the patients and their relatives with the presented system than before. Secondly, the systems directly increase the *work quality* of the clinicians as such and hence indirectly provide better treatment of the patient.

Quality

Too much turbulence in the operating room can bring bacteria close to the surgical area and it is hence important to keep the airflow from the non-sterile areas to a minimum. Opening the door to an operating room in order to pass on a message, for example, is hence a safety hazard. It is hence interesting to note that 58% of the clinicians agreed that traffic in and out of the operating room has been minimized which clearly has improved the hygiene inside the operating rooms.

Especially, the chat messages were used as an alternative to passing messages between the operating room and the rest of the department. These messages were also mentioned as being far less interruptive than e.g. opening the door or calling the room for passing on shorter messages.

In particular from the interviews it became clear that the system could decrease errors or misunderstandings. A number of operation nurses pointed out that a number of misunderstandings previously arose simply because changes to the schedule were not passed on to all involved clinicians. As one of the operating nurses explained in an interview:

> *I remember once I was preparing for an operation. After I had finished preparing all the equipment, I was told that the operation was canceled. I had to return the equipment and start all over again, thereby delaying the flow of work. If I have had the system in that operating room it would have saved a lot of time for everybody.*

The nurses saw a significant decrease in these types of errors by using the suggested system.

1 This was typically nurses working as 'coordinators', i.e. the person in charge of coordinating the whole operating schedule for the whole operating ward. It was typically this person who was in charge of calling the patient ward and the recovery ward to ensure a smooth in- and out-flow of the patients.

Finally, we conclude that many of the interviewed clinicians found the system to make the work less stressful and overall strengthen the feeling of being ahead. Findings which are supported by the decrease in interruptions and easing of collaboration and scheduling pointed to by the questionnaires.

Challenges

While the results are promising a number of challenges exist. Interference is a highly controversial and debated area following the introduction of wireless communication technologies in hospitals. In some hospitals wireless equipment are used extensively whereas others have a complete ban on all wireless and mobile communication equipment and little research exists to guide the decisions. For our trial we got a research permit to try out mobile devices in the operation ward though with a safety distance of one meter to older medical equipment. A recently published paper in Mayo Clinic Proceedings concludes based on more than 300 tests that mobile phones do not pose the risk of interference [10].

A related problem with mobile and wireless technology is battery lifetime. While some systems can run for days, others need to be recharged regularly and managing the recharging process can be a burden.

Also privacy and local regulations pose a challenge. While the systems are designed to support quick overview and the ability to gather information by glazing at the displays while walking by, this easy access to information also pose a problem. Regulations are designed to ensure that sensitive information is only viewable by registered users. Logging of all interaction including viewing the data is often a requirement. Balancing easy to use information overview with the confidentiality of the information displayed is a clear challenge. In the trial we addressed this issue by only placing the displays in restricted areas, but even this approach might not correspond with the regulations in some countries.

Conclusion

The pressure on the health system is increasing. There is a constant demand for treating more patients with new techniques with the same amount of human and financial resources. New types of Ubiquitous Computing systems alleviate this fundamental dilemma by helping staff increase the level of treatment for the same amount of resources. Not by cutting the time spent talking to patients or increasing the overall speed, but by reducing some of the small time consuming problems encountered in everyday medical work. For example, the time spent searching for people, coordinating treatments, passing on information, being interrupted, or waiting for computers to log in [9].

In the presented set of iHospital systems we have found clear indications of how a system designed to support awareness and collaboration with the feedback from clinicians indeed can increase both the efficiency and quality of surgical treatment. The system was designed to run as a prototype for three months and currently it has been running for more than a year and clinicians call it an invaluable tool in their work. At the point of writing a new system is being developed based on the pilot study that is able to support the entire operating ward and collaborating activities.

Acknowledgments

This research has been supported by the Competence Centre ISIS Katrinebjerg. We thank the surgical staff at Horsens Sygehus who enthusiastically participated in this project as well as the management for daring this visionary project. We are also thanking Mads Søgaard, Christian Jonikeit, Martin Mogensen and Jonathan Bunde-Pedersen, who have made major contributions to the design, implementation and evaluation of the system.

Feasibility and Usability of a Home Monitoring Concept based on Mobile Phones and Near Field Communication (NFC) Technology

Jürgen Morak, Alexander Kollmann, Günter Schreier

Austrian Research Centers GmbH – ARC, Biomedical Engineering, eHealth systems, Graz, Austria

Abstract

Utilization of mobile information and communication technologies in home monitoring applications is becoming more and more common. The mobile phone, acting as a patient terminal for patients suffering from chronic diseases, provides an active link to the caregiver to transmit health status information and receive feedback. In such a concept the usability is still limited by the necessity of entering the values via the mobile phone's small keypad. The near field communication technology (NFC), a touch-based wireless interface that became available recently, may improve the usability level of such applications significantly. The focus of this paper is to describe the development of a prototype application based on this technology embedded in a home monitoring system. The feasibility and usability of this approach are evaluated and compared with concepts used in previous approaches. The high quantifier with respect to overall usability indicates that NFC may be the technology of choice for some tasks in home monitoring applications.

Keywords:

home monitoring, mobile phone, patient terminal, near field communication, usability

Introduction

Tracking health related parameters like blood pressure, heart rate, body weight, or blood glucose levels is part of many approaches in the treatment of chronic diseases like hypertension, congestive heart failure or diabetes mellitus. Such data are expected to show trends in the illness patterns and to help the physician in guiding the patient to the best possible health status by adjusting the treatment settings individually.

Using the conventional method of tracking data by hand written lists and diaries, however, often leads to poor patient compliance. Furthermore, interpreting such written records is difficult and time consuming [1].

Contemporary information and communication technology offers more appropriate home monitoring solutions. Instead of getting the patient's hand written diary once in a while in the course of consultations at the doctor's office, the patient and his/her doctor may use a home monitoring system to stay in contact.

A typical home monitoring system comprises of the following three parts:

- caregiver terminal – a PC with a secure Internet connection allows the caregivers to connect to the remote monitoring centre to view patient's data via a web - portal.
- monitoring centre - a web based system that hosts a central database to store, manage and process all data received from the patient and to show those data to authorized users. It may also offer automatic monitoring processes like continuously checking whether newly received values cross certain thresholds in order to notify caregivers.
- patient terminal (PT) - a PC or a mobile phone (MP) which enables the patient to feed the database with his/her self measurements and additional information via a secure Internet connection. The benefits of absolute mobility and high availability at low cost make the MP a very attractive PT to upload data and receive feedback.

One common way to transmit health measurements, for example blood pressure values, is to have the patients to transcribe the values from the meter's display into the MP using the keypad. Basically, this can be achieved in two different ways:

- **online** – Using the integrated micro-browser of the MP allowing the user to transmit data to the monitoring center via wireless Internet technology. The user enters the data into input-templates generated by Wireless Markup Language (WML) or the Hypertext Markup Language (HTML). Data is exchanged using the Wireless Application Protocol (WAP) [2].
- **on/offline** - values are entered by means of a stand-alone software application running on the MP (based on Java 2 Micro Edition J2ME technology) that stores the data locally and synchronizes afterwards [3] with the central database. A connection to the monitoring centre is not necessary during data entry.

However, the usability of both concepts is still limited by the necessity of dealing with the MP's small keypad and display. Fortunately, more and more health monitoring devices like blood pressure meters (BPM) already feature on-board communication interfaces. Those interfaces can be grouped by 2 different principles:

- **Wired solutions** based on universal serial bus (USB) or RS-232 cables: These interfaces are predominantly intended to communicate with a special software application running on the PC to receive and manage the data.
- **Wireless solutions** based on Bluetooth or Infrared Data Association (IrDA): They can easily be used to send measurement values to a MP which serves as a PT and facilitates automated data forwarding to the monitoring centre.

PTs based on those solutions are still not perfect. From the patient's point of view an adequate PT should feature the properties listed in the first column of table 1. These requirements can be met by technical features listed in the second column accordingly.

Table 1 – Properties of an adequate patient terminal

requirements	technical parameters and solutions
easy to learn and to use	high usability and automated methods
feedback	bidirectional communication between PT and backend system
single,integrated solution	flexibility and adaptability to various monitoring situations
privacy	data security by the means of encryption and user authentication
availability of service	on/offline data acquisition
reliability of service	error-handling, fault tolerant communication technologies
low cost	based on existing standards supported by MPs and/or PCs

All these requirements seem to be reachable by using MPs in combination with the Near Field Communication (NFC) technology. NFC technology provides an intuitive touch-based connection for automated data exchange between two devices. The present paper describes the development and initial evaluation of a home monitoring system based on NFC with the goal to assess the feasibility and usability of this method compared to concepts used in previous approaches.

Near Field Communication (NFC)

NFC is a short range communication technology for wireless peer to peer interconnections. It combines the benefits of radio frequency identification (RFID) and wireless communication technologies (Bluetooth, WLAN, IrDA) [3]. NFC is based on magnetic inductive coupling, adopted form RFID. The typical operating configuration of an RFID system is an active reader/writer device and one or more transponders as passive participants (e.g. RFID-tags or contactless smartcards). RFID technology is asymmetric in the sense that only the reader/writer device can initiate a data transmission. In contrast NFC, as the subsequent development allows bidirectional communication between two devices (similar to Bluetooth).

NFC operates in the unlicensed frequency band of 13,56 MHz and reaches a data transmission rate of up to 424 kBit/s within a short range of typically 5 to 20 centimetres. The analogue circuit for field generation and -detection and various digital components are combined in a single chip solution [4]. The NFC transmission module can operate as reader/writer unit to access tags and contactless smartcards based on ISO 14443 like MIFARE (NXP, Gratkorn, Austria) and FeliCa (Sony, Tokyo, Japan) products and additionally supports peer-to-peer communication between two devices in active and passive mode.

Basically, NFC enables data exchange just by bringing two devices close together. This is the intended purpose and the basic idea of NFC – to launch a communication session in an intuitive, easy to handle, and secure way. Literally touching NFC enabled devices, tags or contactless smartcards with a transmission device allows the user to access information and services and to run applications. Therefore, NFC is appropriate to be integrated in handheld devices like MPs and Personal Digital Assistants (PDA).

The first available MP that can be extended with NFC technology was the Nokia 3220 (Nokia Corporation, Helsinki, Finland) [5]. When equipped with a special NFC shell the MP enables users to read data from compatible RFID-tags, as well as to communicate with other NFC devices. When service instructions are provided, a build in software application (Service discovery) recognizes them and launches the appropriate MP functions like initiating a phone call, sending a text message (SMS), or connecting to a predefined web service.

Methods

Home monitoring system

We developed a home monitoring system consisting of:

Patient terminal

To enable a medical measurement device with NFC we developed an all-purpose NFC module equipped with various standardized interfaces. It consisted of a single chip NFC module (PN531, NXP, Gratkorn, Austria) [6] and an embedded microcontroller (PIC 16F88; Microchip, Chandler, AZ). We implemented this module using surface mounted device (SMD) technology to keep it small (30x35mm) and to case the integration into the UA-767PBT (A&D Company, Tokyo, Japan), a digital BPM (figure 1, a). This device offers a standardized interface and was originally connected to a Bluetooth module. Instead of the Bluetooth module we attached the NFC module and adapted the module's firmware to understand the proprietary protocol.

To fetch the measurement values from the NFC enabled BPM we utilized the Nokia 3220 which has been equipped with the special Nokia NFC shell (figure 1, b). To make the MP able to receive and forward the blood pressure value, we configured the firmware of the integrated NFC module to be compatible with the pre-installed application Service Discovery. The transmitted information consisted of:

- the measured values for systolic and diastolic blood pressure as well as the heart rate,
- a unique device identification number,
- a checksum to provide for transmission reliability,
- the web address where the data should be forwarded to by the MP.

In this configuration the BPM worked "out-of-the-box" without the need of any further settings or configurations by the user.

Figure 1 – NFC "pair": blood pressure meter UA-767PBT + NFC module inside (a) and mobile phone Nokia 3220 (b)

Monitoring center

We set up a three tier server architecture to receive, process and store the measurement values which was based on the following open source components:

- web server (Tomcat, Apache Software Foundation, Wilmington, DE) to receive data and to provide the information to the user via a web browser,
- application server (Zope 6.1, ZOPE Corporation, Fredericksburg, VA) to manage data and users (figures, statistics),
- database (Interbase 6.1, Borland, Cupertino, CA) to store the data persistently.

Caregiver terminal

The user was able to view the most recently transmitted blood pressure value or the scatter plot of all transmitted values (Figure 2) via web browser.

Evaluation of feasibility and usability

To evaluate feasibility and usability of the prototypically developed NFC based home monitoring concept we asked students in a health-care-management course to perform measurements and to transmit the values to the monitoring centre. The purpose of the survey was to quantify and compare WAP, J2ME, and NFC technology for MP based data acquisition and transmission in a controlled environment according to the following protocol:

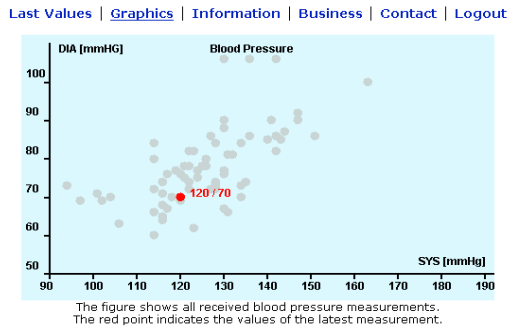

Figure 2 – View of the scatter plot of all transmitted values

- Prepare the MP for the use as PT. When WAP technology was used the web-address has to be entered and stored as a short-cut. In case a J2ME based software application was used, the software has to be downloaded and installed first. In case NFC was used, no further preparation is necessary.
- Put on the cuff and start the measurement by pushing the start button on the BPM.
- After completion of the measurement process, the displayed values have to be transferred to the MP by entering the numbers via the keypad (WAP and J2ME). When using NFC technology, the MP has to be moved close to BPM. Data transmission from BPM to the MP starts automatically and so does the software application that prepares sending the received values.
- In every case, data upload to the monitoring centre starts after pressing the "OK" button and is followed by an acknowledgement that the transmission was successful, reflecting the values that were written to the web-based database.

Each student was asked to transmit at least one dataset to the monitoring center using WAP, J2ME, and NFC. For each technology, the general user requirements as presented in table 1 were interrogated in the course of the survey. The participants were asked to weight and rate 20 predefined properties of an optimal PT concerning usability, technical feasibility, service and costs.

The requirements were weighted from 0 (not relevant) to 100 (very important) according to the individual appraisal of each student. Accumulated weight factors were normalized to a sum of 100. Thereafter the test person was asked to rate each requirement from 1 (don't agree) to 5 (strongly agree) for each method. If a certain method didn't feature a requirement it was set to 0.

The 20 requirements were merged (averaged weight and averaged rating) to the general user requirements as described in table 1. The overall quantifier for each requirement and method was estimated by multiplying the averaged weight value by the averaged rate value. Results were presented as mean +/- SD. To assess the significance of differences between the methods statistically, the

Friedman – Test was used. P < 0,05 was considered to be statistically significant.

Results

14 students (6 female, age 23,2 +/- 4,9 years) evaluated WAP, J2ME and NFC technology for the usage in MP based PT. 13 students returned duly completed questionnaires for further analyses. Overall, NFC was rated as the most suitable technology if compared to WAP and J2ME. The detailed results displayed in Table 2 indicate that general usability aspects (easy to use and learn) were weighted as most important (33% out of 100). Availability (21%) and Reliability of service (15%) were rated as second and third, respectively.

Table2 – Weighted comparison of WAP, J2ME and NFC; Bold values indicate the most suitable technology for a given requirement

requirement	weight [%]	quantifier			p-value
		WAP	J2ME	NFC	
easy to use and learn	33	99,6 +/-23,6	128,6 +/-21,0	**138,6 +/-37,9**	< 0,01
feedback	5	**16,1 +/- 4,8**	11,5 +/- 5,3	12,3 +/- 8,1	n.s.
integrated	12	35,0 +/-12,0	31,6 +/- 7,4	**38,9 +/-10,0**	n.s.
privacy	3	5,8 +/- 2,6	9,2 +/- 2,9	**10,2 +/- 2,4**	< 0,01
availabiity of service	21	59,5 +/-13,1	**80,8 +/-14,3**	78,1 +/-23,4	< 0,01
reliability in service	15	32,7 +/-11,6	48,2 +/-11,6	**58,5 +/-15,5**	< 0,01
low cost	11	**41,0 +/-13,1**	36,9 +/- 9,9	33,3 +/-12,9	n.s.
total	100	289,7 +/- 40,4	346,7 +/- 38,1	**369,9 +/- 82,8**	< 0,01

Comparing the quantifier for each method indicated that NFC was the most suitable technology in terms of general usability aspects (easy to use and learn). NFC was also found being the most suitable solution when a single, integrated system is needed, regarding privacy, as well as reliability of service, shown in table 2.

WAP was rated as the most suitable technology in terms of feedback and costs. J2ME was rated as most feasible in respect to the availability of service.

Besides the usability and feasibility test of NFC in a controlled environment the device was in use for a testing period of 11 month. Overall, more than 500 health parameters recorded by 10 different users were successfully received, mainly from Austria but also from Germany, Finland, and the U.S.

Discussion

After initial conceptual considerations on the applicability of NFC for Health Monitoring [7] the present paper provides the first report on results which had been obtained with a working prototype based on NFC technology.

Although the medical benefit of using MPs as PTs in home monitoring scenarios could already be demonstrated [8] (reduction of emergency cases and hospitalization, increase in patient therapy adherence, etc.), some patients reported a lack of usability using the conventional methods. In our experience the problems, mostly faced by elderly people, are in handling the small keypad and reading data from the display. This impression was confirmed by the mostly young test users who rated WAP technology lowest regarding general usability aspects. Moreover, using WAP technology requires an online connection to the network during data input; it is also lacking in terms of navigation and providing an intuitive user interface.

By using J2ME technology, which allows us to design much more user friendly graphical user interfaces, usability was found to be significantly better as indicated by an increase of this quantifier by more than 25% as compared to WAP (table 2). Additionally, validating the entered data using plausibility constraints is feasible for J2ME software applications resulting in lower error rates and increased reliability as compared to WAP. However, both technologies require at least basic knowledge in handling an MP which some - in particular elderly - people may not have.

Using NFC opens a new approach to simplify the health data acquisition process in home monitoring scenarios. It provides an intuitive and automated way to read out measurement values from medical devices. Compared to WAP und J2ME, NFC technology showed the highest quantifier regarding overall usability. The “bring-in-touch” paradigm of making two devices communicate provides an error-fuse way to assess the data without the need of cumbersome configurations or manual user interaction. Therefore, as compared to WAP and J2ME technology, the NFC based PT can be learned quickly without extensive training.

Another technical advantage of NFC, which was also recognized by the test users, is the fact that NFC provides an integrated solution. On the one hand existing measurement devices can be equipped with NFC modules, on the other hand NFC technology is compatible to certain parts of the existing RFID infrastructure. Therefore, RFID tags can be used to manage additional information. As an example, RFID tags could be attached to medication boxes or well-being icons. Simply touching those items with the MP would be enough to record medication intake or the well-being status.

Table 2 also indicates the main deficits of NFC technology. Because of limited availability of NFC enabled MPs the costs are relatively high at the moment. In the near future, however, NFC enabled MPs will penetrate the market leading to lower prices. The main driving force currently is the MP’s ability to act as a contactless smartcard for pay-

ment and ticketing applications. A forecast estimates that shipments of NFC enabled MPs will increase from less than 5 million in 2006 to nearly 500 million in 2011 (Figure 3).

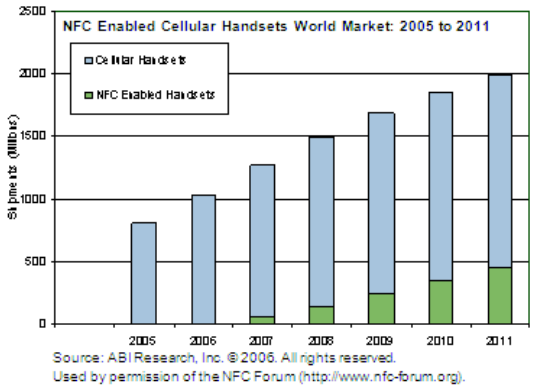

Figure 3 – Predicted shipments of NFC enabled MPs

At the moment the NFC prototype works as stand-alone-application based on the pre-installed service discovery software of the Nokia 3220 MP. Hence, only a single scenario (in our case blood pressure monitoring) is supported. To increase flexibility, we intend to develop a software-application running on the MP that will combine touch based data fetching with features provided by a J2ME application. The functions will include:

- automated fetching of measurements from medical devices and various parameters from RFID tags
- user authentication via RFID tag or RFID smartcard
- manually adding of information
- local storage of data and automated or manually synchronization with the monitoring centre
- increased data security by means of end-to-end data encryption

Additionally, we intend to redesign the NFC module to allow for integration into other medical devices like body weight scales and blood glucose meters.

Conclusion

The results of this limited survey obtained so far confirm the assumption that NFC technology does have the potential to bridge the gap between patients and the technical infrastructure in home monitoring scenarios. If similar results can be confirmed with patients in a real world home monitoring scenario, NFC technology may be established as a method that would ultimately enable more elderly and technically unskilled people to benefit from home monitoring.

Abstract

In order to facilitate knowledge transfer between specialists and generalists and between experts and novices, and to promote interdisciplinary communication, there is a need to provide methods and tools for doing so. This interdisciplinary research team developed and evaluated a decision support tool (DST) on a personal digital assistant (PDA) for cardiac tele-triage/tele-consultation when the presenting problem was chest pain. The combined human factors methods of cognitive work analysis during the requirements-gathering phase and ecological interface design during the design phase were used to develop the DST. A pilot clinical trial was conducted at a quaternary cardiac care hospital over a 3-month period. During this time, the DST was used by the nine nursing coordinators who provide tele-triage/tele-consultation 24/7. This clinical trial validated the design and demonstrated its usefulness to advanced cardiac care nurses, its potential for use by nurses less experienced in cardiac care, and for its potential use in an interdisciplinary team environment.

Keywords:

clinical decision support, personal digital assistants, cardiac care best practices.

Introduction

As the worklife of healthcare professionals becomes ever more complex, there is a need to provide them with decision support tools that enhance their practice. Providing the right information at the right time in the right format is a modern challenge that healthcare researchers, educators, and clinicians are currently struggling with. At present, even though there is a trend to increase the role of clinical nurse specialists in healthcare, there are a declining number of nurses with sufficient training to perform this role [1]. In addition, there continues to be very few computerized decision support tools for advanced practice nurses [2] [3]. Every indication, however, is that this is changing. Journal articles, best practice guidelines, drug guides and other forms of decision support tools for clinicians are readily available on the world wide web. Decision support can be thought of as any resource that provides guidance for making decisions regarding clinical care. The availability of decision support tools for downloading onto personal digital assistants has seen explosive growth in the last several years, and the rate of adoption has outpaced the evaluation of such tools [4]. Strayer, Reynolds and Ebell [5] provided a comprehensive overview of the various healthcare applications available for decision support on PDAs. The majority of applications available, however, do not provide targeted summary information in order to provide information to clinicians in an efficient manner. In addition to whatever evidence may be drawn upon in the literature, there is a window of opportunity to capture the clinical expertise of experienced clinicians before the first large wave of retiring healthcare practitioners leave practice. With the regionalization of healthcare services, there is also a need for innovative ways to support teamwork across professions and between hospital care and care in the community.

The intent of this project was to demonstrate the viablity and value of implementing a cardiac decision support tool on personal digital assistants to deliver standardized care to cardiac patients using a human factors approach to the design. PDAs are particularly suited to tasks where there is an urgent need to access the decision support tool and the user is mobile.

The University of Ottawa Heart Institute nursing coordinators (NCs) receive approximately 2,000 calls a year from patients. Of these 2,000 calls, about 20% of them are from patients experiencing chest pain. Therefore, the application chosen to be designed and developed was the cardiac teleform, which was the previous paper-based documentation form that the nursing coordinators used to document calls from patients. This documentation record was used to capture patient demographic information, a description of why the patient was calling in, the pertinent clinical history, the nursing assessment, a description of the advice and recommendations that the NC gave the patient, and documentation as to whether or not the patient agreed with the advice and recommendations. The intent of the PDA-based teleform was to provide a vehicle for documenting the information exchange between the nursing coordina-

Selected for best paper award.

tors and the caller, but also for embedding decision support.

Methods

Two human factors methods were used for this project. A cognitive work analysis (CWA) approach [6] was used for the requirements-gathering/task analysis phase and the ecological interface design [7] approach was used for the design phase. Other than the cognitive work analysis (CWA) that has been done related to hemodynamic monitoring [8], there has yet to be a cognitive work analysis performed to model the work that nurses do to design computerized systems that would facilitate the nursing process.

Although a full CWA has five levels of analysis that include an analysis of complexities, an analysis of tasks, strategies analysis, social-organizational analysis, and worker competency analysis, not all five levels are appropriate to conduct for all projects. For this project, we concentrated on the strategies analysis which included in-depth interviews with all eight of the nursing coordinators (NCs) at the University of Ottawa Heart Institute. In addition to the interviews, the NCs were asked to generate examples of the types of calls that they received. Twenty-five hypothetical calls were generated.

The hospital provides patients with a number they can call 24 hours a day, 7 days a week to talk with one of the nursing coordinators. An analysis of the types of calls received was performed on the paper-based cardiac teleform documentation for a one-year period from November 17, 2002 until November 16, 2003. During this period of time, 550 calls were received from cardiology patients and 1520 calls were received from cardiac surgery patients. For the cardiology patients, chest pain calls ranked second in terms of the numbers of calls received and for cardiac surgery patients, chest pain or incision-related calls ranked second. The only calls that were more numerous in number were medication-related calls. In order to support those type of calls, commercial software was downloaded onto the nursing coordinators' PDAs.

In order to embed more explicit decision support related to chest pain calls, we were interested in developing decision trees (algorithms). A brain-storming session was held with nine subject matter experts (SMEs), three of whom had previous experience developing chest pain algorithms for tele-homecare and interactive voice response systems. Three chest pain algorithms were developed: (1) Possible ischemic pain, (2) Cardiac surgery, incision not healing well and (3) Cardiac surgery, incision healing well. The algorithms were reviewed and approved by the cardiac surgeon and cardiologist on the team.

The decision support tool that was developed was a cardiac tele-triage/tele-consultation tool called the cardiac teleform residing on a personal digital assistant (Palm Tungsten T3) with companion desktop software for downloading patient files from the memory card. Feedback on the alpha version of the PDA software was received from the NCs as well as from participants of a family physicians conference and participants of a nurse practitioner conference.

Figure 1 provides an example of how visualization tools were incorporated into the cardiac teleform. OLDCAR is an acronym for onset, location, duration, characteristics, associated symptoms/aggravating factors and relieving factors. The 'T' for 'treatment' that is usually associated with the mnemonic OLDCART was not included, as the application focused on the nursing functions of assessment, consultation and triage of patients.

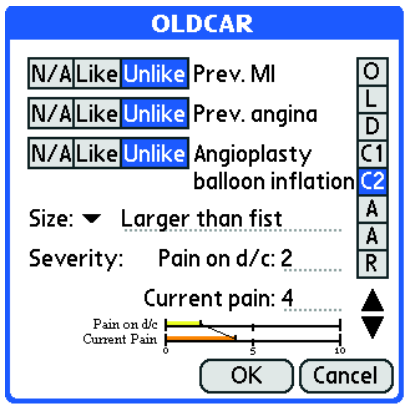

Figure 1 - Screen shot of one of the pages of the cardiac teleform decision support tool

Figure 2 is a screen shot of 1 of the 3 chest pain algorithms. The 'Cardiac surgery, incision healing well algorithm' is recommended for use if the patient's presenting problem is chest pain, they recently has cardiac surgery and the description of their pain does not sound as if it is ischemic in nature and their incision is healing well.

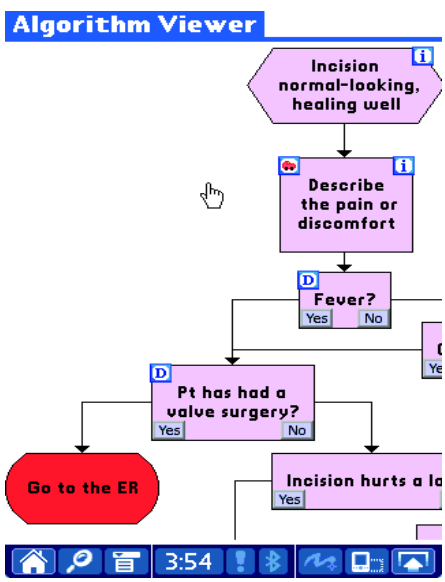

Figure 2 - Screen shot of one portion of the chest pain - incision healing well algorithm

The algorithm is meant to suggest questions that might be asked in order to help the clinician decide on a recommendation. The 'car' icon is an access point for OLDCAR data entry. The 'D' icon is an entry point to provide more information such as whether or not the patient had an aortic or mitral valve replacement, or a valve repair. The 'i' icon indicates points where more information can be obtained, such as a reminder of serious complications that can arise after cardiac surgery, the signs and symptoms of those complications, and any pertinent references.

Since a variety of pieces of information are gathered during a phone call from a patient, we provided a summary page that could be accessed at any time during the call by clicking on the 'S' icon at the top of the screen. The top of the screen also has shortcut icons to facilitate switching algorithms if you need to, going to the OLDCAR assessment page directly, or accessing the bibliography. The bibliography includes references to pertinent texts and articles but also to current related cardiac consensus guidelines from the Canadian Cardiology Society, the American Heart Association, and the American College of Cardiology.

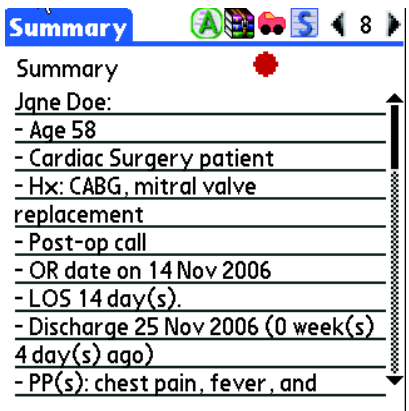

Figure 3 – Screen shot of the summary page which includes all the entered data elements from the previous teleform pages and algorithms

A 3-month pilot clinical trial was performed with the developed cardiac teleform. Outcome measures included evaluations of (a) appropriateness of the advice received as judged by the patient's physician, (b) satisfaction with how the call proceeded and the advice that was given as judged by the patient, and (c) satisfaction with using the tool as judged by the nursing coordinators A log analysis of navigation and data entry strategies was performed and all NCs participated in in-depth interviews at the end of the clinical trial.

Results

Themes from the interviews at the start of the project

Seven of the eight NCs employed by the Heart Institute at the start of the project were interviewed following a semi-structured format for between one and two hours. Although there were many areas of agreement among the NCs, the way in which the call proceeded and the types and number of questions that were asked differed. In terms of agreement, six of the 7 NCs thought that there were major differences in the way a call proceeded with a cardiology patient compared to a call from a cardiac surgery patient. Although initially the NC is assessing whether or not the patient is acutely ill (for instance, having ischemic cardiac pain, in which case the recommendation would be that they hang up the phone and call 911), the calls proceed differently if the patient recently had cardiac surgery or is being followed by cardiology. Many questions that are appropriate to surgery patients (for instance, questions related to the surgical incision) are not applicable to cardiology patients. Therefore, the first two check boxes on page 1 of the cardiac teleform have the NC choose whether the patient is a cardiac surgery patient or a cardiology patient. The subsequent screens then have items related to that subpopulation.

An example of where the call might be managed differently depending on the NC was illustrated by their answers to the following questions: "For cardiac surgery patients, do you always (or almost always) assume that the complaints have to do with the recent surgery? Would you be as likely to consider other possibilities (e.g., a new condition on its own) at the same time"? Four of the 7 NCs said that they almost always assume that the complaint has to do with the recent surgery if the patient calling was a cardiac surgery patient. The other 3 NCs said that they considered not only the recent surgery but other types of problems that might also affect cardiology patients. For this reason, in terms of the design of the teleform, a drop-down menu at the top of the teleform allowed for quick access to any of the 12 pages in the teleform and the NCs did not have to go through the teleform sequentially. The algorithms were designed so that they could be entered or exited easily from any location in the teleform and navigation within the algorithm was not constrained.

Feedback from family physicians and nurse practitioners

Although the feedback on the alpha version of the teleform received from the family physicians and the nurse practitioners at their annual conferences did not help with any design modifications, it did help validate the approach to decision support that we were taking. One family physician commented that it would be particularly useful in his clinical setting where he was the team leader for a number of nurse practitioners in a rural setting.

Results of the clinical trial

The final version of the cardiac teleform was evaluated in a 3-month pilot clinical trial. The NCs were given the choice of using the teleform on the PDA or their paper-based teleform when they received chest pain calls from patients over the 3-month period. Of the 61 chest pain calls, 46 of them were documented with the PDA software. The outcome measures used to evaluate the effectiveness of the cardiac teleform were:

- Appropriateness of the advice received as judged by the patient's physician
- Satisfaction with how the call proceeded and the advice that was given as judged by the patient
- The nursing coordinators' satisfaction level when they used the PDA teleform software on chest pain calls

An analysis of the NCs' navigation and data entry strategies was performed from the teleform log file.

Of the 61 chest pain calls, 46 (75%) of them were documented with the PDA software. The advice received by the patient from the NC was considered appropriate by the patient's physician in 59 of the 61 calls (97%). Thirty-four of the 37 patients who could be reached for feedback were satisfied (92%) with how the call proceeded with the NC and with the advice that they received. Two of the patients contacted did not answer the question. For the one patient who stated that they were not satisfied, the advice given was different from the recommended advice in the cardiac surgery algorithms in the cardiac teleform.

The median satisfaction rating of the nursing coordinators with using the PDA teleform on chest pain calls where 1 was 'not at all satisfied' and 5 was 'very satisfied', was 4.00. The navigation strategies revealed that despite the fact that power user features were built into the decision support tool to reflect the various strategies the NCs used during their calls with patients, they mainly used the cardiac teleform in a serial manner, going from page 1 to page 12 in order.

Themes from the interviews at the end of the clinical trial

Part way through the project, another NC was hired, leading to a total on 9 NCs to participate in the clinical trial. Each of the 9 NCs participated in an end-of-project semi-structured interview lasting approximately an hour. The features of the cardiac teleform that were considered the most useful and easiest to use were the pick lists, the drop down menus and the OLDCAR assessment pages.

The algorithms, which were developed with the help of the NCs and approved by them before the clinical trial, were generally liked for the same reason that the teleform and OLDCAR were liked – namely that it encouraged structure and reminded them to ask questions they might otherwise have forgotten to ask the patient. However, the algorithms were not as universally liked as the other parts of the teleform and the OLDCAR assessment pages. Any problems with using the algorithms appeared to be due to two reasons: (1) there were a small number of atypical calls related to chest pain that did not fit into any of the scenarios in the algorithm and (2) the NCs weren't using the flexibility built into the tool to exit the algorithms at any point and go to any page they wanted in the teleform from the short-cuts icons at the top of the screen.

The NCs saw the benefit of the teleform to be (a) that it provided a standard approach to patient assessment (b) that the documentation was more complete when they used the PDA teleform compared to the paper-based teleform, (c) that it produced a more professional document to send to the patient's cardiologist or cardiac surgeon and (d) that it was more legible than the paper-based teleform. Many of the comments related to improvements that could be made to the teleform were features that already existed but had not been used (for instance, the 'Go To' button at the top of each page where you could navigate to any page in the teleform from that drop down menu).

We investigated the accuracy of the NCs' perception that documentation was generally more complete with the P'DA-based teleform than it was with the paper-based teleform. We compared the documentation of the required data elements in the 46 PDA-based teleform records with a matched set of paper-based teleform records of comparable chest pain calls received immediately preceding the clinical trial. The documentation was more complete on the PDA-based record 68% of the time.

Seven of the 9 NCs thought that it was more time-consuming to use the PDA teleform than to use the paper-based teleform. There was also the fear that the information may get lost since the PDAs were stand-alone and not connected to a wireless network to be downloaded to the hospital LAN as the hospital does not currently have a fully functioning wireless network. The NCs also did not like the process of having to transfer the patient files from the memory card to the card reader and then onto the companion desktop software on the PC.

In terms of the design of the teleform and the algorithms, all of the NCs thought the DST supported their usual workflow and did not interfere or change the development of their mental models regarding the patient's condition. They all thought that the decision support tool would be particularly useful for novice nursing coordinators with the caveat that they also be encouraged to think for themselves in case the problems the patient is calling in with do not fit into the algorithms.

Discussion

The use of the combined human factors methods of cognitive work analysis and ecological interface design resulted in a decision support tool that closely matched the nursing coordinators' cognitive strategies and the mental models they develop during their tele-triage/tele-consultation sessions with patients. Feedback from the nursing coordinators and from nurse practitioners and family physicians at their annual conferences provided support for the approach being taken to develop a decision support tool that would facilitate knowledge transfer between specialists and generalists and between experts and novices while promoting interdisciplinary communication. Standardization of care based on available evidence and best practice guidelines was seen as a major benefit of such a tool, especially in a regionalized healthcare system comprised of many acute and primary care facilities and agencies. The 3-month clinical trial of the decision support tool further validated the design approach taken.

Logistically, the use of PDAs for healthcare applications are still limited by (1) the speed and robustness of the

device and (2) cumbersome data entry using graffiti or the keyboard.

Conclusion

The combination of decision support and personal digital assistants has seen explosive growth in the last several years [4] [5]. However, the majority of the applications available are generic in nature, providing information only or allowing for calculations of various sorts. The next generation of more clinically comprehensive interactive decision support tools for PDAs are only starting to emerge [9] [10]. The decision support tool reported here is another example of a next generation PDA application. The cardiac teleform application design was the cumulative result of a cognitive work analysis and ecological interface design human factors methods. The cardiac teleform and embedded algorithms for decision support provide a flexible, interactive tool which results in documentation of the nursing coordinators' tele-triage/teleconsultation session with the patient. Reference to the evidence, where it exists, to support the recommendations for questions to ask and suggested courses of action to take, are easily accessible in the tool. This type of application has the potential to be utilized in a multi-disciplinary team environment if it were to include scope of practice information for the professionals on the team. The approach taken here also provides a vehicle for capturing the expertise of specialists. Since many aspects of clinical recommendations are the result of expert opinion, this tool also demonstrates how the expertise of specialists can be captured to share with other healthcare professionals in a variety of clinical settings.

Acknowledgments

We are thankful to the NCs who have been so supportive of this project. Other supporting team members who have contributed ideas and discussion are Dan Pajek, Curtis Saunders, Dan Ho, Winnie Chen, and Jordanna Kwok. Special thanks to Whynne Caves for her clinical and PDA expertise, Yukari Enomoto for her design ideas, Vincent Ho for doing the bulk of the software development, and Katie Bush for data entry and analysis. We acknowledge the support of the Ontario Ministry of Health and Long Term Care Primary Health Care Transition Fund (Grant no.G03-05372).

Abstract

An aging population and an increase in chronically ill patients demand teamwork treatment models. To support these with information systems, interoperability is a prerequisite. Model-driven software development (MDSD) with special healthcare extensions can enable reuse of components and improve conformance to international standards. In this paper, a MDSD HealthCare Framework is proposed and demonstrated for homecare services. Using the framework, information systems will improve their conformance to international standards and the interoperability with other systems.

Keywords:

Medical Informatics, home care services, information systems, systems integration

Introduction

In healthcare, the disease burden is changing from acute to chronic care, 35,000,000 people died from chronic diseases in 2005, and 60% of all deaths are due to chronic diseases [1]. New ways of providing care are being evaluated, based on teamwork treatment – demanding support from interoperable information systems. Interoperability in healthcare has been identified as an important area of research and development by many organizations, including the European Union (EU)[1], the Object Management Group (OMG)[2] and other national organizations [2]. The ability to exchange information and share services across departmental, organizational and national borders can reduce the administrative overhead and costs [3], and as a result improve the effectiveness of healthcare provided. Consequently, more patients can be treated faster with the same amount of (care) resources. A sustainable healthcare infrastructure depends upon interoperable health information services [4, 5].

The treatment and management of homecare consumers, typically elderly, chronically ill and cognitive disabled, require a coordinated effort from healthcare and social welfare services. To effectively support these care services with information systems, interoperability of core information such as patient careplan calendar and medication-list is a prerequisite.

To improve interoperabity between systems, the leading standardization bodies in healthcare information, HL7, CEN TC251 and OpenEHR, have specified standards that address systems architecture and information exchange. Although these standards have been available to the Health Information Systems (HIS) vendors for some time, they have not fully adopted them into their products. Thus, the different HIS are not interoperable, requiring the development of software adapters to be able to exchange information about the patients. There is an urgent need for a standardized interface and method to realize this information exchange.

The standardization bodies provide limited tool support to the developers of health information systems. To incorporate standard healthcare concepts in the systems' design, an operational software engineering artefact that provides both semantic and syntactic interoperability functionality [6, 7] should be available for the system architects and developers [8-10].

In 2002, the Object Management Group (OMG) introduced the Model-Driven Architecture (MDA) [11], an approach focusing on using models (e.g., UML models [12]) as first-class entities in the development of software systems. In practice, this means that the models are used directly in the implementation of an information system, either as system blueprints or as input to code generation engines that produce executable code. MDA is the most known model-driven software development (MDSD) approach, and the overall idea is to separate business functions (in Platform Independent Models - PIM) from its technological implementations (in Platform Specific Models – PSM), enabling code generation and reuse of components. The overall benefit is improved interoperability and reduced development time and cost.

Using a MDSD approach in the development of healthcare information system services could facilitate the use of standards through specification of reusable standards-based PIMs. Advanced UML mechanisms such as Profiles

1 EU Life sciences, genomics and biotechnology for health website: http://cordis.europa.eu/lifescihealth/home.html
2 Object Management Group (OMG) website: http://www.omg.org

and Patterns could be used to further extend the expressiveness of the modeling language and force the use of standardized healthcare concepts. As a result, the developed systems will increase the level of interoperability, and at the same time development and maintenance costs will decrease.

With an aging population and a rapidly increasing number of chronically ill patients [1], the need for teamwork treatment is crucial. Healthcare Information Systems (HIS) can no longer be seen as standalone systems, but need to interoperate in a health network [10]. This leads to the problem statement: *How can health information systems development be improved to ensure that systems involved in a homecare teamwork treatment infrastructure can share information in an effective and sustainable manner?*

This paper proposes a model-driven software development framework with standards-based healthcare extensions as a tool to achieve interoperability between HIS. The healthcare focus is on homecare services although the healthcare standards discussed have general applicability. The paper concludes that MDSD with the appropriate healthcare information extensions can improve software's conformance to standards and thus also the ability for caregivers to share information in teamwork treatment.

Following next is an overview of the challenges that are associated with developing such a MDSD Healthcare framework, both from a software engineering and healthcare viewpoint. Then the framework is presented along with an example from the homecare domain, before the paper concludes with a discussion of the validity of our results and directions for future work.

Immature MDSD tools and need for evaluations

In a keynote talk at the 2006 ECMDA-FA conference in Bilbao (Spain), Bran Selic (IBM) advertised for rigorous scientific studies that investigate how MDSD can improve the development process[3]. Recently, the ModelWare project[4] conducted five different scientific MDSD evaluations. A summary of the evaluations is presented in [13] and concludes that by applying MDSD, a productivity gain of 20% can be expected and the quality of the software produced would increase.

Despite these and other reports, there is a considerable skepticism in the software engineering community about the performance and usability of MDSD. The skepticism is based on three main points: 1) the UML is too generic and is conceptually too far from implementation languages making it difficult to generate efficient and fully executable code [14, 15], 2) The maturity of MDSD tools: transformation tools are not complete enough to provide return of the investment put into developing reusable UML models. E.g., the Query/View/Transformation (QVT) standard [16] by OMG does not have good tool support and 3) standards are used in different versions, some of which are not interoperable.

4 MODELWare (FP6-IP 511731) project website: http://www.modelware-ist.org

Many systems, many standards

The use of information standards to improve interoperability between information systems in the healthcare domain is not straight-forward. In a single healthcare organization, there is a plethora of information systems, each based on one or more information standards. In the context of systems development, sharing of information and services between these systems need to address the following issues: 1) Many systems (such as patient administrative systems) are dated back to the late eighties, long before the specification of today's information standards, 2) Department specific systems developed to serve one specific purpose do often not use international standards nor follow best-practice in systems architecture, 3) The information systems themselves and the information standards used are continuously being upgraded [7].

A MDSD framework for healthcare

The work presented in this paper build upon three assertions presented in the following.

Assertion 1: Model-Driven Software Development with healthcare information standards support will improve interoperability between health information systems (compared to the traditional way of developing systems)

UML allows for extensions through the use of UML Profiles. A profile defines stereotypes, tagged values and constraints that can be assigned to modeling elements in the design process. The main purpose of a profile is to extend UML's expressiveness for a certain domain, e.g. healthcare. By providing healthcare specific UML profiles and patterns as a part of a MDSD framework for healthcare, concepts defined in international healthcare information standards can be automatically built into the information systems. A healthcare profile can be used by transformation templates and code generators to explicitly implement attributes, relationships, operations and objects that provide interoperability services.

Assertion 2: Healthcare Information Standards are appropriate as reusable model-driven development artefacts.

Standards from HL7, CEN TC251 and OpenEHR make use of UML class diagrams to specify concepts and relationships. However, parts of the semantics are described textually as constraints-comments to the formal UML models. To be able to correctly incorporate these standards into model-driven development artefacts such as UML Profiles, the complete semantics of the standards must be possible to represent formally. The correctness and reusability of the models created with the UML profile will depend on the mapping between the standard and the UML profile artefacts.

Assertion 3: Healthcare information services in the homecare domain can be reused across organizations.

The usefulness of a MDSD Healthcare framework for the development of interoperable homecare services will depend on the ability to define functional and coherent information services in the domain. The services need to be reusable beyond departmental and organizational bor-

ders, preferably also national borders as some healthcare institutions have rehabilitation and treatment centers abroad, often collaborating with the local healthcare services.

Results

Using a model-driven approach such as the MDSD Healthcare Framework enables rapid development of interoperable healthcare information systems. The framework includes a set of UML profiles, models and experience reports from the homecare domain, but with generic healthcare service applicability.

Example of MDSD healthcare framework in homecare

A trivial example is provided to demonstrate how a UML Profile for healthcare can be used in the development process to achieve interoperability between information systems.

The example service is a CarePlan service where a HomeCare Center System and a General Practitioner (GP) EHR HomeCare extension can access and update the homecare patient's careplan. Both systems will need to provide a defined interface for information exchange based on the same standard. A small subset of the "CarePlan" concept in the Continuity of Care (CONTSYS) [17] standard is used for demonstration (Figure 1). A "CarePlan" is applied by one or more HealthCare Professional and addresses one or more health issues that the Subject of Care has (relation not shown).

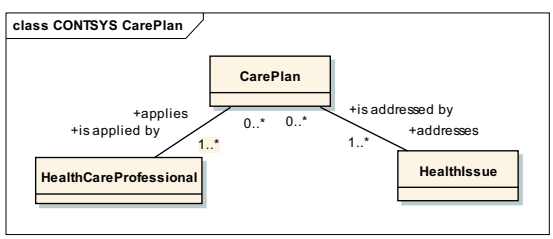

Figure 1 - A subset of the CONTSYS CarePlan concept

The goal is to develop Java based (sub-) systems that allow exchange of careplan information for the homecare patient according to the CONTSYS standard.

A simple UML profile for homecare

Based on the CONTSYS standard, the following UML extensions are specified: 1) UML Class Stereotype: SubjectOfCare: The person receiving treatment, 2) UML Class Stereotype: CarePlan: The treatment plan for one or more health issues (problem), 3) UML Class Stereotype: HealthCareProfessional: A caregiver entitled to provide care, 4) UML Association Stereotype: HealthCareProfessional_isResponsible: The healthcare professional (source element) is responsible for the target element and 5) UML Association Stereotype: SubjecfOfCare_Owns: Subject of Care (source) has owner right of the target element.

Two *tagged values* are defined: 1) Boolean: isShared: when used with a CarePlan, stating whether the careplan is shared or not and 2) Boolean: isOrganDonor: used with a SubjectOfCare to state if the person is organ donor or not.

The healthcare information systems

The two systems are being developed independently by different vendors using the same CONTSYS-based UML profile. The Care Center system platform independent model (PIM) shown in Figure 2 shows that the HomeCarePlan (stereotyped CarePlan) is related to the HomeCarePatient (owned by), the Doctor (under responsibility of) and the Visiting Nurse. All classes are stereotyped according to CONTSYS. As a result, the HomeCarePatient has a tagged value for "isOrganDonor" and the HomeCarePlan has an "isShared" tag.

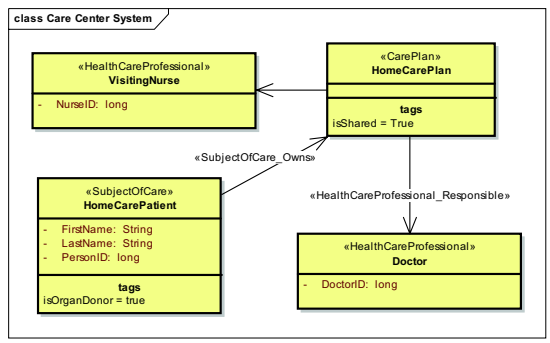

Figure 2 - The Care Center System PIM

The PIM for the GP EHR Homecare extension system (Figure 3) shows that the TreatmentPlan ("CarePlan") elements are related to one or more patient problems ("HealthIssue") according to a problem-oriented EHR [18]. This can be used to filter out treatment activities that are not related to the coordinated care of a homecare patient.

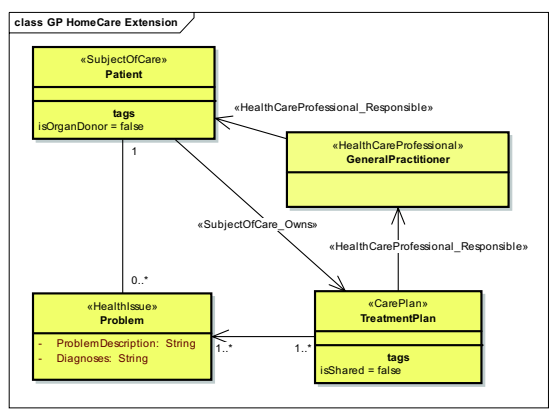

Figure 3 - The GP EHR Homecare Extension PIM

The two PIMs can be transformed to Java Platform Specific Models (PSM) using a CONTSYS-based transformation script for Java. This script utilizes the stereotypes and tagged values in the transformation process to add attributes and operations to ensure that the

required interoperability mechanisms are implemented. In this trivial example, only set and get operations for the tagged values and careplan elements are created. The Java Model for the Care Center system (Figure 4) and the GP EHR Homecare extension (Figure 5) show that during the transformation process, three operations have been created on the CarePlan-stereotyped classes. These operations, stereotyped with "CarePlan", enables exchange of CarePlan elements and retrieval of all HealthCare Professionals that are related to the CarePlan.

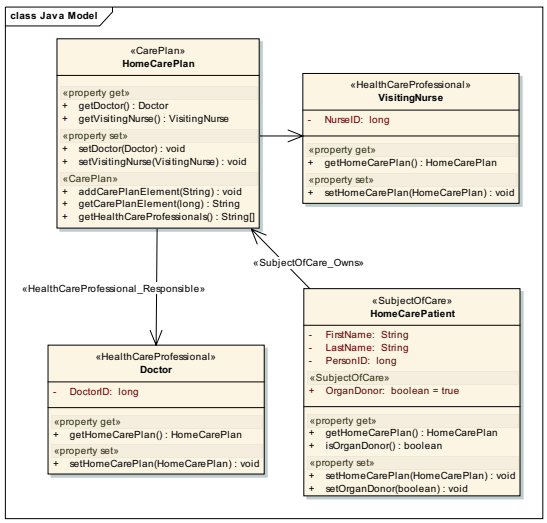

Figure 4 - Java PSM for the care center system

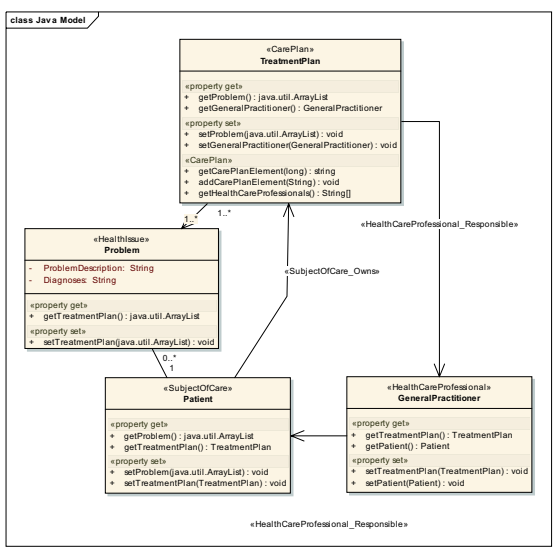

Figure 5-Java PSM for the GP EHR HomeCare Extension

From these Java PSMs, code can be generated using a standard code generation tool based on e.g. QVT [16].

To summarize: using the CONTSYS UML Profile in the design and development of the careplan service in the Care Center and GP EHR systems ensured that the services are conform to the standard and thus can exchange information correctly.

Discussion

The MDSD Healthcare framework proposed in this paper addresses the need to make information systems in the healthcare domain interoperable and sustainable. To achieve this, the framework provides tools and reusable components that incorporate international information standards into the information system design.

The effect this will have for the future healthcare information systems relies on the three assertions described in the first part: 1) the quality of artefacts artifacts produced from the framework, 2) the ability to map information standards to useful UML profiles and 3) the identification of reusable services.

The quality of the software produced by the framework will depend on the tool support and the developer. The main improvement compared to traditional software development lies in the built-in healthcare tool support, where use of healthcare UML profiles, reuse of existing platform independent models and use of code generation will reduce roundtrip time and improve the quality of the code.

The example showed a simple careplan service where a concept from CONTSYS was applied. More complex services will need more concepts, maybe from more than one standard. The MDSD framework will provide UML Profile support for the most used healthcare standards and patterns for the most recurring concepts. A modular design, in line with Beale's *archetype* concept (7), provides scalability and maintainability of the models as the standards are updated or extended. The *Archetypes* being specified in both CEN TC251 EN13606 [19] and OpenEHR, can be used by the MDSD framework as reusable models and patterns. An archetype is a model of a healthcare concept, and is represented formally using UML.

The specification of reusable services in the healthcare domain is in accordance with Service-Oriented Architecture (SOA) [20]. Many healthcare organizations are adapting SOA as the core enterprise architecture, using a message-oriented middleware with HL7 to exchange information between systems. The process of transitioning to a SOA architecture is expensive, but a fully interoperable healthcare infrastructure would reduce coordination expenses dramatically [3]. Homecare services are likely to be a part of this enterprise service architecture connected through a health network [5]. SOA-based homecare system services can enable independent development and deployment of new patient monitoring and surveillance services in the health network. A SOA based infrastructure will allow sustainable development of healthcare services.

A critical aspect when introducing new development tools and techniques is to evaluate its effect. Proper scientific methods must be applied to achieve rigor. A complete medical informatics solution should not only evaluate the artefacts isolated, but also study their effect in a real

environment [21]. The MDSD HealthCare Framework will be subject for two scientific experiments with real users in the M-Power project[5].

Future work

The framework proposed in this paper is a part of the work being done within the M-Power and Linkcare projects[6]. These projects will identify and develop reusable homecare services for the provision and coordination of homecare services. Using the first version of the HealthCare MDSD framework, some of these services will be evaluated in 2007 and 2008.

Conclusion

With an aging population and dramatic increase in chronic diseases [1], systems interoperability in the healthcare domain is of utmost importance in order to maintain the service level of today and support teamwork treatment. One way to improve interoperability is to ensure the healthcare information systems' conformance to international standards.

The Healthcare MDSD framework will incorporate standards into the development process of information systems, and as a result improve interoperability. The MDSD framework will be evaluated in two experiments in 2007 and 2008 as a part of the LinkCare and M-Power projects. These projects have a strong focus on treatment and management services for chronically ill, elderly and cognitive disabled. This will ensure the framework's relevance for the domain.

Abstract

Conformance testing has been studied extensively but the current state of the art varies very much in different software companies in the healthcare domain. In this paper we present findings of a survey of conformance testing of interface specifications in the healthcare domain. The survey was conducted among software companies and their customers, i.e. hospital districts, in Finland. The findings of the survey show that the quality of the applications should be improved, that there is a reluctance to use external interface testing services, and that software vendors do not adequately fulfill customers' requirements in relation to testing. However, conformance testing is considered to be very important and should be improved. The main contribution of this study is the analysis of the findings and we give some recommendations for healthcare organizations, software companies, and authorities to improve the conformance testing related to the interoperability of the applications.

Keywords:

Software Validation, Quality Assurance, Health Care, Conformance Testing.

Introduction

The challenges of integration, distribution, security, and interoperability complicate the software development and testing [1]. Fortunately, the challenges can be met by means of standards, conformance testing, and the certification of systems. Conformance is defined by the ISO/IEC as the fulfillment of a product, process or service of specified requirements [2]. The requirements or criteria for conformance must be specified in the standard or official specification. After traditional testing phases (e.g. module, integration, and system testing), conformance testing is needed. In relation to interoperability, the goal of conformance testing is to assure that applications follow interface specifications so that the application integration and introduction can be done without extra adaptation or development work. Conformance testing covers testing of the interfaces between the applications, and their conformity to standards, not testing of the inner parts of the application.

Software developers are encouraged to use common standards and implement open interface specifications. If the applications have open standard-based interfaces, their interoperability is improved, introduction and integration become easier, and less local adaptation work is needed. But, in order to successfully assure software interoperability of networked applications, such as in healthcare networks, requirements for testable specifications have to be developed, too [3].

Standardization, certification, and conformance testing have been studied extensively in the telecommunication domain [4] but the practices are not well-established in other domains. Only a few studies on conformance testing in the healthcare domain [5, 6] and certification of health information systems [7, 8] have been reported. No empirical studies on the level of conformance testing in the software companies and in their customers' organizations in healthcare have been reported. However, the current level of testing has to be studied and understood before it can be improved. Therefore, we conducted a survey to find out how much and how often conformance testing is performed in relation to the interface specifications in the healthcare domain in Finland. We also wanted to find out how customers perform testing in their organizations, and how they can influence conformance of the software they acquire. In addition, we wanted to study general testing practices and test process improvement in the healthcare organizations. The results of general testing practices and test process improvement have been presented earlier [9]. In this paper the focus is on conformance testing of open interfaces.

Health information systems (HIS) aim to support a high-quality and efficient patient care [10]. The healthcare domain and HIS in Finland face big challenges which will affect testing in the near future, such as the introduction of the national electronic patient records, and many old, monolithic legacy systems which have to interoperate with new applications in the network of organizations. The other special characteristics in healthcare are high quality requirements, the safety criticalness of the systems, and non-deterministic and non-predictable processes, which often cross organization borders. Thus, efficient quality assurance and improved conformance testing processes are needed.

The rest of the paper is organized as follows. First, the research method, sample, and questionnaire of the survey are introduced. Second, the results of the survey are pre-

sented. Then, we analyze the results and make some recommendations for the further development of conformance testing. Finally, conclusions and future work are discussed.

Materials and methods

Research method

The study presented in this paper is based on empirical and constructive research. Our aim was to study conformance testing and interoperability issues using a survey research method. In addition, we wanted to make interoperability recommendations based on the survey results. A WWW-based questionnaire, with open and structured questions, was used as a survey instrument. The WWW-based questionnaire was easy and cheap to deliver to many respondents. However, we were aware of the fact that people may report higher incidences of, for example, the use of standards in self-reports than when objectively reported by outside parties. Therefore, we asked that the questionnaire be passed on, if possible, to more than one person in the same organization. We sent the participants an e-mail and asked them to respond to the survey. After a month we phoned those who had not responded and reminded them to respond.

The main research questions for healthcare application vendors and their customers were:

1. How can customers, i.e. hospital districts, influence the conformance of the software they acquire?
2. How much conformance testing do software vendors perform and how often are standards used?
3. What are the main goals of, problems with, and opinions about external interface testing services?

Sample

Conformance testing procedures concern both software vendors and their customers. Customers can require standard-based applications in calls for tenders. The expected benefits from the use of standards include better interoperability and quality of software. On the other hand, vendors can prove customers conformity of software implementations to the standards. Thus, the survey was delivered to the both groups.

The sample covered all the Finnish hospital districts, covering geographically the whole country (except _land, a self-governing territory). In addition, the sample covered those healthcare software companies which belong to a Health and Welfare IT R&D cluster in Finland. The cluster covers most of the Finnish healthcare software companies. The questionnaire was delivered to chief information officers or other leaders of each organization, and they were asked to pass it on to those responsible of testing (testers, test managers, testing engineers, etc.).

The questionnaire was sent to 47 organizations, of which 27 were software companies and 20 were hospital districts (see Table 1). Responses were obtained from 29 organizations, of which 14 were software companies and 15 hospital districts. The response rates were 52%, and 75%, respectively. Companies completed on an average of 94% of their questions (completion rate), while customers completed on an average of 91% of theirs. The companies were operating mainly in the domestic market but eight had both national and international customers.

The respondents in the software companies (henceforth *developers*) were testing engineers, designers, project managers, managers, and consultants. In the hospital districts the respondents (henceforth *customers*) were chief information officers, project managers, and designers. In addition, one senior physician responded to our survey.

The non-respondents were asked by phone why they did not respond. In most cases the reason was busyness. The other reasons were outsourcing of testing, and testing not being in focus at the moment.

Table 1 - Statistics of the sample

	Sent	**Responded**	**Resp. rate**	**Compl. rate**
Companies	27	14	52%	94%
Hospital districts	20	15	75%	91%
In total	47	29	-	-

Questionnaire

The questionnaire was developed based on the literature and our own knowledge of conformance testing theory and practice.

The questionnaire consisted of three sections: general testing practices [9], conformance testing and standards, and the organization of interface testing services. The results of conformance testing and standards, and the organization of interface testing services are discussed in this paper. The conformance testing and standards part consisted of questions on the rationale for conformance to standards, use of specifications and standards, and conformance testing methods and practices. The organization of interface testing services dealt with the use of external testing services, questions on roles and responsibilities, and comments and ideas for organizing testing services. The questions are shown on http://www.cs.uku.fi/~ttoroi /questionnaire.html.

Results

In this Section we first present the results related to conformance testing of interoperability standards. Secondly, the organization of interface testing services is presented.

Conformance testing and standards

The developers were in small (fewer than 50 employees), medium (50-250 employees) and large organizations (over 250 employees). There were 8 small, 2 medium and 4 large organizations. All the customers were from large organizations.

All the customers had understood the term "conformance testing" correctly, while two developers misunderstood questions concerning conformance testing. They had understood that the questions dealt with the testing of inner parts of the applications, and not the testing of interfaces and interoperability.

It appears that new versions of the applications are installed and conformance retesting is needed between one and four times a year for each application. However, there were significant differences in conformance testing in different software companies. Some developers' the whole system and its specifications were based on standards, while others only tested whether two particular applications could be integrated. Customers had invested in testing, and used more rigorous methods than, for example, small companies did [9].

Some comments by the respondents display a "seller's market" situation. One customer said: "From time to time there is a "take it or leave it" situation and testing does not help much. We know there are errors but we have no other choice than to buy it".

Unfortunately, testing is not an exciting and fascinating topic in software companies at the moment. As one respondent said "We had many good test practices a little while ago but do not have them any more. Our company fired the testing engineers, and does not invest in testing anymore."

The results reveal that standards are widely used in healthcare applications in Finland. All respondents replied that their applications complied with standards (except one customer who did not know whether their applications conformed to standards). The most common standards and official specifications were HL7 (Health Level 7) messages, STAKES (The National Research and Development Centre for Welfare and Health), and IEC (International Electrotechnical Commission) standards. Increasing the use of standards and official specifications was also considered to be very important.

The most often used interface specifications in the healthcare domain are natural language specifications. However, we noticed that specifications based on UML (Unified Modeling Language) and XML (Extensible Markup Language) are needed, too. In addition, one developer wanted that requirements by the authorities should be in a format that could automatically be transferred into a requirement management system.

The main sources of information concerning the standards were information provided by standards associations and other public seminars. However, information was surprisingly often acquired by rumors and surfing the Internet, too.

Developers considered recommendations by authorities to be the most desirable means to promote the use of standards. The other means were customers' requirements, laws, and commitment by management. Customers considered recommendations by authorities, common agreements, laws, and certification to be the most desirable means. One customer stated that customers also have to be more active and demand the use of standards. The respondents were divided over whether laws are a good means. Some developers claimed that no standard is implemented without legislation. Others stated that excessive legislation only delays development and innovation.

The most common problems in the use of standards were the application and interpretation of standards, national specifics which differ between countries, and the laboriousness of implementing of standards. In addition, customers ordered applications which referred to incomplete or non-official standards. Some developers stated that, when interpreting standards common solutions should be made, not tailored ones, and it is a waste of time if standards are not international. Unclear responsibilities related to standardization on a national level were also considered problematic.

Organization of interface testing services

The respondents were suspicious of an external interface testing environment. Only 9% of the responses concerning willingness to use external testing services were 'yes'; the rest were 'no' (21%), 'maybe' (38%), and 'I do not know' (32%). No respondent was willing to pay for testing services.

Respondents were divided over the responsibility questions. They responded, almost evenly, that some national actor or separate software companies should be responsible for the external testing service, but the authorities should be responsible for interoperability certification. However, certification was not considered very necessary nor useful. This view was captured by one developer who stated that "Certification does not help. Software companies must be responsible for their own products." Another developer observed that external testing of medical devices in the test labs has been organized very well, but it does not function for software code.

Respondents considered that external interface testing services may not be profitable, and may become a bottleneck. In addition, the respondents thought that external testing services cannot help in integration, and applications can be truly confirmed only by integrating them in the real local environment.

It was very surprising that respondents were not familiar with the international development of conformance testing or certification of interoperability. Only one developer was acquainted with IHE (Integrating the Healthcare Enterprise) and CCHIT (Certification Commission for Healthcare Information Technology).

Discussion

In this Section we analyze the findings of the survey and make recommendations for healthcare organizations, software companies, and authorities to improve conformance testing, and compliance to interoperability standards.

R1: Perform interoperability conformance testing more rigorously

It was no surprise that too little time was allocated for testing both within the software companies and in the customer organizations. It is worrying that even though time is not allocated to testing on either side, and customers are not satisfied with the applications they acquire, still so little is being done. If the customers do not demand more reliable and interoperable applications, developers will not invest time and effort in quality assurance and testing. Software developers and their customers should both participate in the testing process as responsible parties and improve testing in mutual understanding, as equals.

Interoperability of applications requires various conformance testing activities. Besides interoperability standards, conformance testing can also be performed against any kind of specifications, for example, if the software processes are ITIL compatible or if the applications conform to the generic requirements of electronic patient record systems. It can be concluded that more conformance testing must be performed and it must be more diversified and disciplined.

R2: Utilize open interfaces and use interface testing services

Open interfaces promote the market penetration by small software companies. However, this can be against the interest of large software companies, because they try to protect their market positions. In healthcare applications, open external interfaces between different applications and different organizations are used increasingly. Proper interface testing services or environments promote cost-effective interoperability testing. When open testing environments are used, it is not necessary for everyone to develop their own test environments. Everyone can select the counterparts of the application interfaces they need, and the correct versions, from a well-established testing service, and interoperability testing can be performed against them, simulating the real environment. This is safe, cost-effective, and saves resources. However, it requires that a neutral or official stakeholder is responsible for the development and maintenance of the testing environment. In addition, organizing and keeping the testing service in balance should be subsidized by public resources.

R3: Provide proper skills and knowledge

Increasing the use of standards was considered important. To achieve this, customers must be provided with the knowledge and skills required to demand standard-based systems. They must be educated about the benefits of standard-based interfaces, as well as certified and interoperable software products. This does not prevent free competition: it promotes standardization in widely-used interfaces and reduces local “fixes”.

Conformance testing activities varied very much in different companies. All of the respondents reported that they test the conformity of the applications to interoperability standards, but by "conformance testing" some respondents actually meant code testing or introduction testing by customers. The relation of requirements specification and process descriptions to the conformance testing were not clear. This could be noticed from responses, such as "Conformance testing is done through checking and looking at the code" or "Conformity is tested in the customers' environment". The knowledge of conformance testing must be increased through open seminars and training. What conformance testing covers and what it does not cover must be clearly stated.

R4: Enforce the recommendations by authorities

Both vendors and their customers were in favor of official recommendations. These recommendations may be related to interoperability, usability, security, and appropriateness of the applications to the customers' workflow. From the results of the survey it can be concluded that official recommendations and laws are needed to promote interoperability and quality of the applications. Therefore, recommendations by authorities have to be introduced and enforced more actively. In addition, the implementation of the recommendations must be supported, facilitated with tools, and supervised.

R5: Organize neutral testing services

On the basis of our study, there were little market possibilities for commercial interface testing services. On the one hand, the low level of interest in interface testing services is understandable since it adds one extra layer to the testing process. This adds complexity, costs, and can become a bottleneck. On the other hand, versions of the applications can be changed several times a year, and conformance retesting is needed. Thus, conformance testing must be as automatic as possible.

Studies and projects are needed, in which interface testing services are organized in a neutral manner. The organization of testing and certification should be mandated to a national institute. Companies competing with each other cannot easily establish an external testing service. In Finland, the selection of the Social Insurance Institution as a national actor for health IT and the increased coordination by the Ministry of Social Affairs and Health may alleviate the confusion related to standards and conformance testing. The increasing standardization and use of open interfaces will also help in developing external testing services.

R6: Reuse testing experiences and information

Testing experiences and information should be transferred between organizations. One feasible idea is to share testers' tacit knowledge using testing expert groups, which work independently of software vendors. This is an extension of the mentor activity performed in hospital districts, in which the introduction of the applications has been distributed between different hospital districts and the experiences from one district are utilized in other districts.

R7: Improve the testability of specifications and standards

Testing against inaccurate and ambiguous specifications is impossible. Therefore, in addition to conformance testing, the specifications and standards also have to be improved,

and UML and XML must be utilized besides natural language, to achieve accuracy and consistency [3]. Successful utilization and testing of standards requires accurate technical implementation guidelines and constraints to generic standards, such as HL7 specifications, which can be complemented with IHE integration profiles.

Conclusion

In this paper we present a survey of healthcare software companies and their customers. The objective was to survey conformance testing related to interoperability in software companies and their customer organizations in the healthcare domain, and to identify necessary improvements.

Conformance testing and quality improvement require customer demand, investments, and standard-based applications. However, it appears that there are various necessary testing improvements, including attitude problems to be solved before applications conformity to standards and interoperability can be tested. In addition, it will take quite a long time before certification of the interoperability of healthcare software becomes common in Finland. This is due to resistance to change, a fair amount of work needed to introduce standards, the immaturity of standards, and difficulty in reaching a mutual understanding between different stakeholders.

The main contribution of this study is the recommendations based on the findings of the survey. They are meant for the organizations and authorities who aim to improve conformance testing activities of interoperability between applications. Among other things, the requirements by authorities have to be enforced more actively, customers must be educated to demand standard-based applications, and projects are needed to elaborate the idea of external interface testing services.

The timing of the survey in Finland was quite favorable in relation to the national Electronic Patient Record, which increases pressure for quality assurance. On the other hand, there is a slight downtrend in software business in view. In a downtrend it is important to increase turnover and quicken the deployment, whereas quality improvement and software testing are emphasized in an uptrend.

In healthcare, many different applications have to communicate and interoperate with each other. Processes cross organization borders and are often non-deterministic. In addition, many systems are safety critical. Since the study was conducted in the healthcare domain in Finland its results can not be directly generalized without considering domain and market differences.

This study provides empirical knowledge about conformance testing in healthcare. It also discusses the viewpoints of software developers and their customers and contributes to conformance testing research.

The recommendations of this study suggest improvements to the conformance testing of interoperability. They also highlight the need for the development of testing environments and collaboration models for conformance testing. The effects of the recommendations can be surveyed using a repeated survey.

Acknowledgments

This paper is based on research in the OpenTE and SerAPI projects, funded by the National Technology Agency TEKES, software companies and hospital districts. The authors thank all the participants involved in these projects.

Connecting Public Health and Clinical Information Systems by Using a Standardized Methodology

Diego M. Lopez, Bernd G.M.E. Blobel

eHealth Competence Center, University of Regensburg Medical Center, Germany

Abstract

To meet the challenge for efficient, high quality and sustainable care, health systems in developed and increasingly in developing countries require extended communication and cooperation between all principals involved in citizen's care. The challenge also concerns supporting information systems, which demand interoperation with public health, bioinformatics, genomics, administrative, governmental, and other sources of data. The paper describes an architecture development methodology for modeling the integration between clinical and public health information systems that harmonizes existent standardized modeling approaches and integrates HL7 domain knowledge. An integration-architecture for information sharing between public health surveillance and clinical information systems is derived demonstrating the feasibility of the proposed methodology. Predominantly, a harmonized process for analysis, design, implementation and maintenance of semantically interoperable information systems based on formal grammars is discussed in some detail.

Keywords:

information systems, public health surveillance, semantic interoperability, architecture, unified process, HL7

Introduction

To meet the challenge for efficient, high quality and sustainable care, health systems in developed and increasingly in developing countries are moving from organization-centered to process-controlled (diseases management) health systems. This process will continue towards person-centered care (favored homecare, patient monitoring, body area networks, etc.) in the future. Such inter-organizational collaboration requires extended communication and cooperation among all principals involved in citizen's care. By that way, health systems become regionalized, nationalized or even internationalized.

Such complex collaboration requirements concern the supporting health information systems (HIS) and in consequence also their development processes. Thus, HIS need to be analyzed, planned, specified, designed, developed, deployed and maintained, bearing in mind the current/future integration with public health, bioinformatics, genomics, financial, governmental and other sources of data.

In particular, information systems serving primary, secondary, tertiary and quaternary care must be interlinked with public health information systems (PHIS). While concepts and rules defining the actual policy in clinical care settings are predefined and rather stable, different policies in an integrated environment have to be contractually harmonized through policy bridging, including procedural agreements such as clinical pathways and public health protocols; applicable, e.g., to chronic and communicable diseases.

Regarding development methodologies, medical care information systems and public health ones are often developed independently, not considering specific information requirements for information sharing. Existing development methods support specification, analysis, design, implementation, maintenance of HIS, but they normally do not consider the complexity of integrated HIS when dealing with interrelated domains such as public health.

The aim of the paper is to propose a methodology for modeling the integration between clinical and public health information systems.

Materials and methods

A key success factor for any HIS development process (requirements analysis, design, implementation, evaluation, use, and maintenance) is the definition of the system architecture in structure and behavior.

At the moment, a comprehensive development methodology meeting all requirements of future proof integrated HIS, i.e., component and service orientation, model-driven approach, flexibility, scalability, semantic interoperability, trustworthiness, etc.; doesn't exist. Such methodology can only be realized by harmonizing existing architectural approaches in software engineering and health informatics.

In software engineering, architectural frameworks (e.g., Zachman Framework [1] and ISO 10746 Open Distributed Processing – Reference Model (RM-ODP) [2]), architectural models (Model Driven Architecture (MDA)[3]), architectural styles (Service Oriented Architecture (SOA)

[4]) and development processes (The Rational Unified Process (RUP) [5]) provide some guidance for software architecture specification. In the healthcare domain, examples for architectural approaches describing an architecture development methodology are the HL7 Development Framework HDF [6], the Service Oriented Architecture for HL7 (SOA4HL7) [7] and the former CEN ENV 12967 [8], which has recently been revised and is currently under balloting. Those approaches, however, are diverse in nature touching different aspects of the system and considering different architectural paradigms.

As an alternative, the Generic Component Model (GCM) [9], developed and enhanced at the eHealth Competence Center Regensburg is a generic framework able to harmonize different architectural approaches, considering all the architectural requirements and processes mentioned. The GCM -which has meanwhile been established in some ISO standards- defines three dimensions for system modeling: the domain, the system's granularity (composition/decomposition), and the system's viewpoints as defined in RM-ODP. GCM is the only approach which allows harmonizing different architectural paradigms through 1) managing different domains thereby allowing different domain languages; 2) starting from the computation-independent business perspective and separating platform-independent (logic) from platform-specific (technology and implementation) aspects; 3) being process-controlled and service-oriented to meet the users' needs; 4) considering semantics; and 4) following ontological principles.

Results

The Architecture Development Methodology

The Architecture Development Methodology for modeling integration in HIS is described in figure 1.

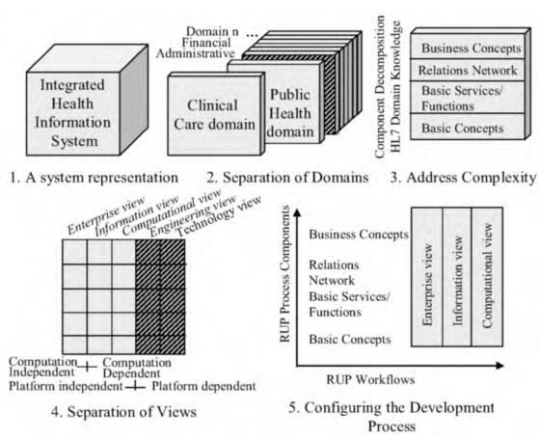

Figure 1 - The Architecture Development Methodology

The process is performed by progressively constraining the GCM. In step 1, the system to be modeled is identified. The real system under consideration is an "integrated health information system". In step 2, the GCM domain dimension is simplified by separating the domains of interest (clinical and public health domains) from other related domains (financial, administrative, security, etc). The third step in the methodology addresses the complexity dimension. All four levels of granularity defined in GCM are analyzed independently for each domain starting bottom up: basic concepts, basic functions, relation networks, and business concepts. This step intends to define the domain knowledge (reference models, reference information models, domain concepts, vocabulary) to enable semantic integration. HL7 domain knowledge was found the more comprehensive set of clinical and public health domain knowledge for the purpose of describing business concepts.

In step 4, the scope of the architecture is defined by restricting the analysis to platform-independent aspects of the system. After analyzing the enterprise architecture as well as describing the computation-independent aspects of inter-related businesses using the business viewpoint (clinical care and public health process), the platform-independent specification of the components' properties is performed considering the information and the computational viewpoint of every single component needed in the next phase of modeling. The resulting specification can automatically be transferred into platform-specific models using MDA transformations covering the engineering and the technology viewpoints.

Finally in step 5, a process guide for architecture development refining the aforementioned principles is defined. Considering that the RM-ODP specification does not prescribe any particular method for building the different viewpoints, the RUP framework is used as process guide. RUP counts as the more comprehensive development process for meeting the methodology requirements, being also configurable to integrate other development methods. An analysis of the concepts defined in the ODP standard was performed, identifying the more adequate RUP process components for inclusion into the method configuration of the Architecture Development Methodology. For each ODP perspective, a set of process components (roles, activities, artifacts ,tools) is identified in order to describe, at different levels of granularity, the HIS components. Figure 2 describes the process components configured for the Architecture Development Methodology.

Modeling the Integrated Colombian Health Information System

The Integrated Health Information System (Sistema Integrado de Información en Salud – SIIS [10]) in Colombia is used as a scenario to analyze the integration between public health and clinical information systems. The aim of SIIS is to manage virtually any kind of health information (administrative, clinical, public health) in a centralized way. In practice, SIIS deals only with administrative and financial information, however.

Health services delivery in SIIS is based on the division between personal and population- based health services, with the former controlled by public and private health

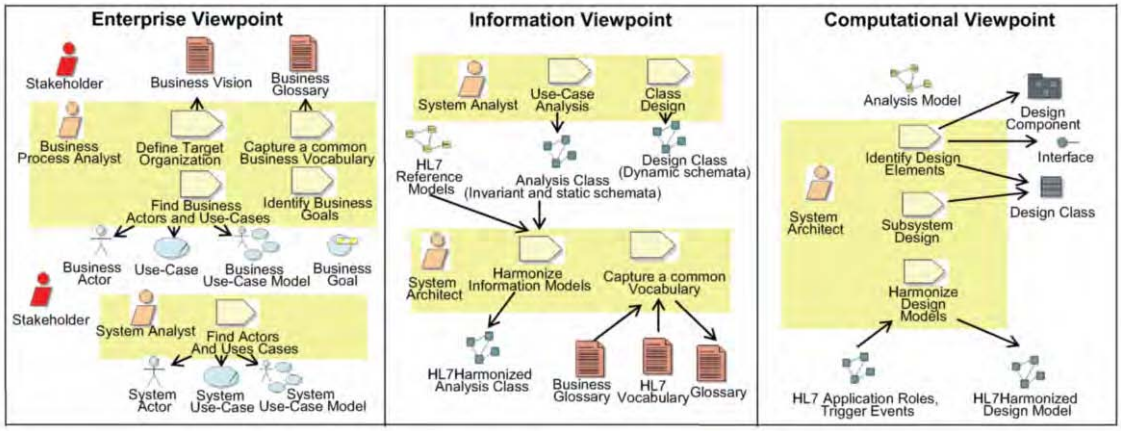

Figure 2 - Architecture Development Process details

care service providers and the latter managed by the government. This suggests the distinction of two groups of information systems: Hospital Information Systems for administrative and clinical information management and PHIS for public health information management (health surveillance, promotion and prevention). Both systems are obliged to share at least some administrative data, but at the moment they run completely independent one from the other. Occasionally they only share plain text files manually.

Figure 3 describes the proposed architecture for the Integrated National Health Information System, in which Public Health and Clinical Information Systems are integrated through an "Integration Subsystem". In the next subsections, the architecture, particularly the Integration Subsystem, is detailed according to the proposed Architecture Development Methodology.

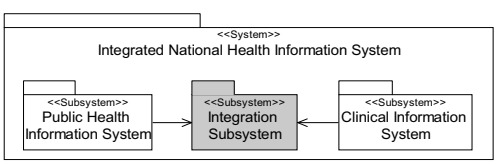

Figure 3 - The Integrated National Information System Architecture

Enterprise viewpoint

The enterprise viewpoint examines the information system and its environment in the context of the business requirements on the system, its purpose, scope and policies. The business process and the boundaries of all associated systems: Public Health and Clinical Information Systems and the Integration Subsystem are analyzed. For the sake of brevity, only two main artifacts in the methodology are detailed, the Business Vision and the Business Use Case Model.

Artifact: Business Vision

Public Health Information System. The target organization is the National Public Health Surveillance System (Sistema de Vigilancia en Salud Pública-SIVIGILA [11]). The system consists of health care institutions, protocols, norms and resources organized with the objective of supporting the systematic and ongoing collection, analysis, interpretation, delivery and evaluation of health events necessary to support health promotion and prevention programs. The system's external actors are: health services providers, health services administrators (EPS), and any other organization interested in public health information for decision making e.g. Pan-American Health Organization (PAHO):

Clinical Information Systems. The target organization is the health care service providers (IPS) network in Colombia. IPS are public and private institutions (hospitals, clinics, laboratories, primary care establishments) offering individual health care services including diagnosis, treatment, control, rehabilitation and even supporting promotion and prevention programs. The system's external actors are: Population, Ministry of Health, territorial public health authorities and EPS.

Artifact: Business Use Case Model

Integrated Public Health Information System. The business processes supported by the integrated information system are described in Figure 4.

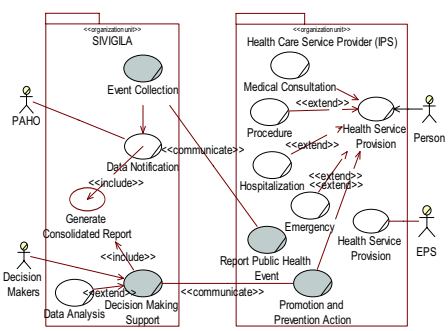

Figure 4 - The Integrated Public Health Information System Business Use Case Model

After analyzing and documenting the business process and rules of the two interacting systems; the interacting business processes are identified. The interacting use cases (colored in grey) constitute the business process identified for the Integration Subsystem.

Information viewpoint

The Information viewpoint describes the static and dynamic structure of information managed by the distributed information system to be specified, that is the "Integration Subsystem". The information components are derived from the enterprise viewpoint models and the functionality described in the national health systems policies. The process components below describe the system Analysis Class Model (RM-ODP Invariant Schemata).

Artifact: Analysis Model

Figure 5 describes the Integration Subsystem main informational components. The main entities are "Public Health Event" representing information about the SIVIGILA events, and "Person" representing the patient associated to that event.

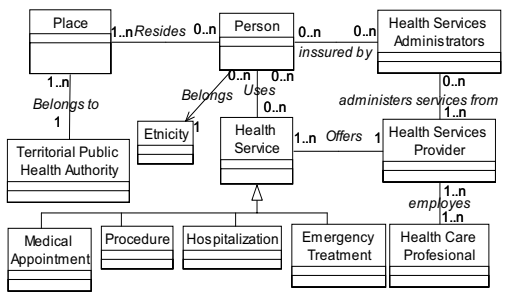

Figure 5 - The Integration Subsystem Invariant Schemata

Task: Harmonize Analysis Model

For supporting semantic integration, information models should be harmonized with reference models. Domain information models for supporting the informational components were identified in HL7 specifications. Concretely, the Public Health Reporting Domain Information Model (PORR_DM 180001) has been specialized [6]. An extract of the harmonized model depicting demographic data in the "Person" class is shown in Figure 6.

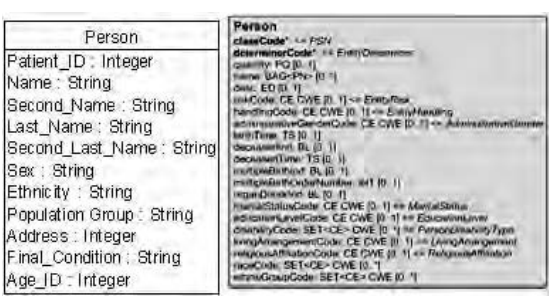

Figure 6 - Comparing the entity Person in the UML Analysis Model and the HL7 harmonized model.

Computational viewpoint

The computational view is concerned with the functional decomposition of the Integration Subsystem by specifying logical components and their interactions through interfaces. The architecture development methodology describes a top-down approach in which the computational components are derived from system use case descriptions in the enterprise viewpoint. The system Design Model is detailed below.

Work Product: Artifact Design Model

Figure 7 shows the structural diagram for the Integration Subsystem. The diagram is not exhaustive, but depicts the main components and interfaces. "Event_Look_Up", "Retrieve_Event_Data" and "Store_Event_Data" support the "Event Collection" business process presented in Figure 4. "Store_Event_Data" and "Notify Event" support the respective "Report Public Health Event" business process.

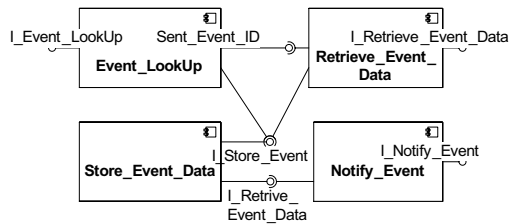

Figure 7 - The Integrated Public Health Information System Business Use Case Model

Task: Harmonize Design Models

In this stage, design components and interfaces are harmonized and refined with reference models. HL7 services, domains, application roles and CMETS serve as references for computational components and interfaces. In the scenario, the Entity Identification Service (EIS) and the Retrieve, Locate, and Update Service (RLUS) were used. As an example, figure 8 shows the operations defined for the interface "I_Event_LookUp". The semantic profile for the EIS is defined based on the "PublicHealthEntity" specified in the HL7 E_PublicHealthEntity CMET (COCT_MT840000) [6]. The interface implements the operations "Find Entities by Trait" defined in the EIS specification. The first allows for a search in the Clinical Information System for matching instances, where the attribute (traits) "ICD-10 code" is equal to one of the ICD-10 codes for notifiable diseases. Thus, a notifiable event can be retrieved from the Clinical Information System.

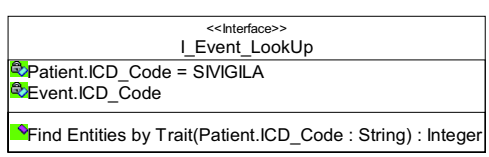

Figure 8 - "I_Event_LookUp" Interface definition

Discussion

There is not one unique methodology that can be applied to HIS architectural development; fortunately some architectural paradigms are in place to support this process. Also the resulting architectural models must include domain knowledge, which needs to be referenced when looking for semantic integration. The proposed methodology harmonizes advanced architectural approaches (RM-ODP, MDA, SOA, Component Based Development) and integrates HL7 domain knowledge into a comprehensive architecture development process.

HL7 specifications are partially reused because they are nowadays the richest source of reference to medical and public health knowledge. Furthermore, in addition to the information viewpoint, it is the only one that progressively supports enterprise and computational specifications. Nevertheless the methodology is flexible enough (through RUP configurations) to include other domain approaches, e.g. openEHR archetypes, CEN 13606 EHR Standard, CEN 12967, GPICs, etc.

The proposed methodology and the scenario architecture certainly follow very closely the HL7's SOA services specifications. Two services were reused (EIS and RLUS) as far as they are two of the three services included in the current HL7 specification [6]. Other services are under development within the HL7 SOA SIG. It is expected to integrate them into the architectural process. Policy Management, Authorization, Anonymization are some examples.

Regarding the proposed integration-architecture used to demonstrate the feasibility of the methodological approach, very important models were develop to address the necessary but not yet envisaged process of automatically interlinking the National Public Health Surveillance System in Colombia with emerging HIS.

The partially described integration architecture offers several possibilities to enhance the Colombian National Integrated Health Information System (SIIS) by providing efficient, high quality and sustainable health services. One possibility is that the architecture can be broaden and used as technical specification (platform-independent specification) to normalize all information systems developments in the country which are often autonomous projects not dealing with integration. Another possibility is to address the technical specification of the SIIS by transferring the architecture to platform-specific models using MDA, thus providing open software components and services that can be reused in local/regional developments.

Finally, the methodology and the derived architectures are an opportunity not only for Colombia but mainly for developing countries where relatively few systems are in place and resources are very short facilitating the adoption and adaptation of healthcare standards and advanced architectural approaches in use in the developed world.

Conclusion

The creation of semantically interoperable HIS including the integration of systems from other domains requires a comprehensive architectural methodology. Based on the GCM, different existing and heterogeneous architectural approaches have been adapted and partially reused in a harmonized way. The resulting architectural methodology has been deployed for integrating clinical HIS and PHIS. The feasibility of the derived architecture development process has been successfully demonstrated at the integration of clinical information systems into the National Public Health Surveillance System.

Acknowledgments

The authors are indebted to thank partners from HL7, OMG and other organizations for collegial collaboration. It's a pleasure to also thank "Dirección Departamental de Salud del Cauca" in Colombia for support and kind cooperation. This work was partially founded by the EU Programme Alban, contract E03D16197CO, and by the University of Cauca.

Clinical and Translational Science Sustainability: Overcoming Integration Issues between Electronic Health Records (EHR) and Clinical Research Data Management Systems "Separate but Equal"

Robert P. DiLaura

Cleveland Clinic and Case Western Reserve University, Cleveland Ohio, USA

Abstract

The use of health information technology (HIT) is growing rapidly for patient care systems required to test, diagnose and treat patients, and to bill for these services. Today's Electronic Health Record (EHR) systems are a response to this pressure, enabling feature rich computer-assisted decisions and communication. And even though EHR benefits dramatically outweigh the costs, required investments are nonetheless significant. Continuing to invest in HIT at a revolutionary rate is unsustainable given institutional financial constraints and continuing reimbursement cuts. Future improvements must come from new treatments, test methods, drugs and devices – from research. But data management information systems for clinical research receive less funding than patient care systems, and in less coherent ways. It is easy to imagine using the high cost, patient-based EHRs for clinical research data management, and thus accelerate the speed of translating new medical discoveries into standard practice. But taking this step requires thoughtful planning to overcome significant technology, legal/regulatory, policy, process, and administrative issues.

Keywords:

medical informatics, biomedical research, clinical research, information systems,
computerized medical record systems

Introduction

Although the challenge of defining an Electronic Health Record (EHR) with multinational agreement has vexed experts around the globe, several professional associations are now reaching consensus on a basic conceptual elements.[1-3] An EHR uses computer systems to enter, store and retrieve patient medical records with accessibility by various authorized individuals. Additionally and more importantly, an EHR's extended functionality and interoperability bring significant benefits to users, healthcare providers and payers across multiple EHR systems and geographic locations (the Integrated Care EHR). Primary benefits come from faster and better decisions and reduced errors, thus improving care and saving lives. But looking more carefully at the financial picture, EHR adoption rates internationally vary based on country, care setting and provider specialization [4-5], typically anywhere between 15-85%, compared to the U.S. norm of about 25% for large hospitals[6]. While costs for nationwide implementation are well known where full adoption is nearly complete (e.g., Sweden, U.K.), other countries can only estimate the full financial requirements of such large scale projects, albeit with increasing accuracy. For the U.S., with the world's largest annual healthcare expenditures of around US$2 trillion, the cost projection for full national implementation of an ambulatory and inpatient EHR over 15 years is $114.6 billion.[7] This same report also estimates a 548% return on these investments, with savings of nearly $627.5B. Clearly the global trend to adopt nationwide EHRs is underway and will continue into the next decade. Unfortunately adoption has been slow in countries with market-based economies and privatized healthcare since financial models don't show the anticipated savings actually being accrued by the organizations that make the investments. Some large scale adopters have created new associations to encourage collaboration and financial intermediation, like the Good European Health Record project [8], or the not-for-profit company behind Australia's National E-Health Transition Authority (NEHTA), whose mission is to deliver a secure, interoperable nationwide e-health environment.[9] Such mechanisms may inevitably be required in the U.S. since projected HIT spending (Figure 1), currently less than 1% of overall healthcare cost, is expected to climb steadily (averaged estimate from CMS, IDC, Gartner, Frost & Sullivan, BCC Research, Datamonitor, Kalorama).

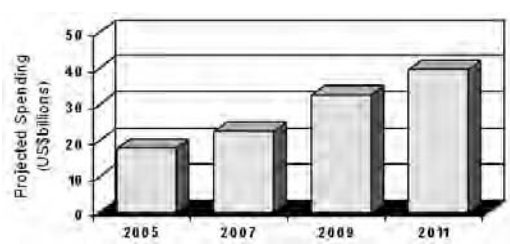

Figure 1 – Healthcare IT spending estimate for US ($billions)

U.K. national EHR implementation costs

To highlight the scale of coordination and funding required for national EHR implementation, The Lewin Group [10] summarized the U.K. National Health Service (NHS) in 2005 as:

> "…the largest organization in Europe and the third largest employer in the world, with more than 1.3 million workers. The agency is generally regarded as an efficient provider of high-quality health care to a large population. The state finances the NHS mainly through general taxes, administers the agency and makes executive decisions. Approximately 60% of U.K. primary practitioners use electronic health records. Recently, the NHS embarked on the world's largest civilian IT project, a plan to spend $11 billion on a national HIT system to replace existing local systems and paper medical records."

More recent reports have shown the size of spending in the U.K. may surpass US$20 billion before final goals are met, due partly from incorrect initial estimates and inflation, but also likely from scope creep for secondary uses of data.

Comparison with U.S. EHR funding

While the U.S. president has called for a national EHR to be available for most Americans by 2014, the necessary funding levels shown to be required in the U.K. haven't been provided thus far. And the FY2007 budget proposal recently submitted to Congress included only a request of $169M for EHR implementation, and $116M for the Office of the National Coordinator for Health Information Technology to coordinate and plan a national strategy and initiatives. The initial increase for the National Institutes of Health (NIH) in 2006, which saw a doubling of its budget over the past five years to approximately $28B, was virtually zero [11], although this was increased slightly by the NIH Reauthorization Act passed in December. But nearly two thirds of the NIH budget goes toward basic research, with only the remaining one third going to patient-oriented clinical research versus patient care; i.e., generally not for health information system infrastructure costs such as an EHR. Thus meeting the necessary expense for nationwide EHR implementation in the U.S. with such limited funding is unrealistic, with current efforts simply unsustainable.

Clinical research and its role in healthcare

Clinical research (CR) is defined by the NIH as human subject research involving an investigator that is patient-oriented including the study of – mechanisms of disease, therapeutic interventions, clinical trials (CT), and the development of new technologies. They may also involve epidemiologic and behavioral studies, outcomes research, be retrospective or prospective, utilize standard-of-care control groups or placebo comparisons, may randomize carefully selected samples of study subjects from larger groups or investigate specifically selected individuals because of their health circumstances.[12] Human subject research must follow strict ethical requirements that have been agreed to by well known international collaborations such as the World Medical Association Declaration of Helsinki, as well as regulatory requirements within, and sometimes between, national borders. Regulatory obligations typically mandate an independent Institutional Review Board (IRB) that evaluates all requests for research and ensures necessary policies and procedures are complied with. And since even large, well-known institutions can be involved with investigators who at times act inappropriately or who are not sensitive enough to study subjects special needs, especially for vulnerable populations (e.g., children, elderly, etc.), new positions and procedures have been created to independently review and endorse an institution's research enterprise and commitment to research integrity.[13]

EHRs and healthcare in general can be looked upon as vertical space in an overall strategic framework for biomedical science. The knowledge transfer that occurs from translation of scientific discovery in bench laboratories, to animal research, *in silico* research, pilot studies in humans, and all the way through large scale, multi-center, global studies into standard practice by healthcare providers was described by Sung et al [14] as the T1 translational block horizontally across these domains. Clinical research is the scientific domain prior to healthcare delivery, and upon which new standards of care depend. The need to improve the productivity and cost effectiveness of CR processes and data management systems is similar to healthcare, although on a smaller scale. The need to more tightly couple CR to healthcare, and move new discoveries forward across these domains quickly and inexpensively is also important.

Like healthcare costs, various reports [15-16] have studied the unsustainability of regulated clinical trials in particular as a subset of CR for drug and device discoveries to meet growing demands to control future healthcare problems and changing patient population demographics given the large expense and years required to get final regulatory approvals.

EHR/Clinical research integration

EHRs and CR data management systems (Figure 2) can exist as anything from independent, parallel technology platforms,

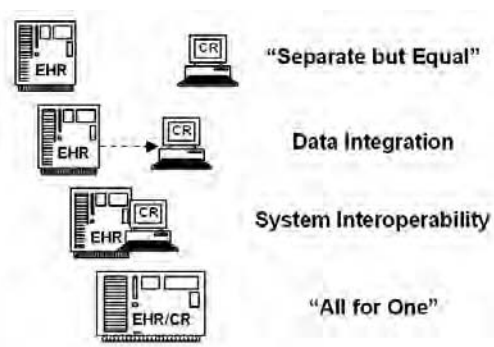

Figure 2 – EHR/CR Integration Models

to the CR system receiving a one-way data feed from the EHR, to some degree of two-way interoperability between the separate systems, to being completely integrated into

one system. This fourth alternative seems to be mostly theory at this point considering major EHR vendor products. An informal survey conducted during the 2006 HIMSS conference found only 20% with CR capabilities in current EHRs. This finding was similar to a more formal study by the American Academy of Neurology that found only 28.5% of mid-sized EHR vendors to be capable of conducting any level of CR in their current systems.[17] Usually a central IT organization governs the EHR. It also has certain budgetary or systems responsibility for CR systems, though whenever this is the case, the CR mission is almost always a very small part of the overall IT focus and funding.[18] In fact this study showed 60% of academic health centers do not even have a clear picture of how much is spent on IT for CR, and 49% have no central HIT-CR governance structure or cross-representation between these personnel. Virtually none have a strategic plan for CR. And while various attempts have been made to begin experiments to integrate EHRs with CR systems, or even to fully conduct a CR study completely within the EHR, most have been very small or ineffective due to the overwhelming issues that must be faced to make these connections work and leverage the significant investment in EHRs. Even demanding these connections through legislation in a national setting has proven futile.[19]

Issues in EHR/CR integration

As stated earlier there are many types of CR studies. All may not be appropriate to conduct directly within an EHR or via an integrated EHR/CR system, but it may be easily possible for some. The following are general categories of issues surrounding EHR/CR integration.

Technology

Most EHR products in the U.S. (other than for an OpenEHR) are proprietary technologies with vendor controlled code bases requiring certain operating platforms and network architectures. Interoperability with other information systems may be possible in some cases, but underlying data models, structure, format, vocabulary and transmission standards are certain to inhibit connectivity or data transfer without significant work.

Current FDA requirements for clinical trials of investigational drugs and devices specify that the data management system comply with system and software validation.[20-21] The steps to comply with these requirements are typically very expensive, and must be repeated whenever changes are made to the technology, which is unacceptable in a large EHR.

Legal/Regulatory

In the U.S. (similar to other countries), each patient obtaining medical treatment must be shown a Notice of Privacy Practice (NoPP) that informs them of their legal rights under the Healthcare Insurance Portability and Accountability Act (HIPAA). The notice requires "plain language", and a statement that information collected on the patients for standard care may be used for research (operational and outcomes) in addition to treatment, payment and quality purposes.[22] The use of patient data for future, unspecified research is ***not*** permitted. An assessment of the NoPP from the twelve winners of the new NIH Clinical and Translational Science Award (CTSA) for 2006 [23] indicates an average Flesch-Kincaid Grade Level of 14.3. Certainly most hospital patients are not college level readers. So even though the CTSA winners have been recognized for outstanding abilities to perform CR and to translate new science into the patient care domain, there will most likely need to be changes made in how they inform patients that research may be conducted on their data (possibly in the EHR) as normal care.

Conversely, whether a patient or not in a hospital, any person who is going to participate in prospective CR is required by regulation to be fully informed of all aspects of the study prior to making a decision to participate, and not to be coerced in any way, especially by any person in a position of authority (as is a physician-investigator when discussing a research study they are the principal investigator on with their patient). Typical informed consent forms for CR are 10-20 pages in length and can be quite complex [24] even though they should be written at less than a high-school reading level.[25]

Policy

A hallmark of an IRB is its ability to independently make ethical decisions that balance institutional interests in research against protecting human subjects involved in studies. Like criticism of the FDA because it receives money from drug companies as part of the drug approval process, the appearance of improper behavior or the potential conflict of interest is often enough to cause problems. At what point does an IRB, which may already be closely aligned with or supported by an institution, become too close and biased?

Revenues from research, whether federally funded or from industry sponsored sources generate a significant amount of income at large institutions. At what point does strict compliance with someone's interpretation of an SOP, or an unusual pattern of missing values, or delayed serious adverse event reporting require the institution to suspend or end a study (and revenue)?

How is time seeing patients as part of normal care accounted for by doctors when patients are also enrolled in a research study in the same visit? How are the costs separated, or insurance companies fully informed that the visit is for "research"?

Process

Fundamentally all CR processes are very similar, yet different enough that it has been easier to build required data management system from scratch every time a new study comes along. And since most funding for CR studies has been provided independently with little to no regard for centralized or reusable systems, investigators either received funding to build everything they needed from scratch every time, or they received little to no money for data management needs at all and thus had to cut corners in order to conduct an under-funded study in whatever way was possible within their institution. Standards for CR

(Figure 3) that improve operational consistency now exist however, especially where countries fund national EHRs.

Physicians are thus under increasing pressure to follow newly prescribed processes, especially in the case when an EHR is in place; often having 10 minutes or less to interact with patients. How can they provide the necessary additional time required to inform a patient fully about a new research study patients are eligible to participate in? Should they delegate?

Likewise, research studies have historically been statistically designed around strict visit schedules and data collection methods in order to ensure validity and significance. In many cases, these study schedules are not the standard-of-care that a physician would normally provide for their patients. So patients need

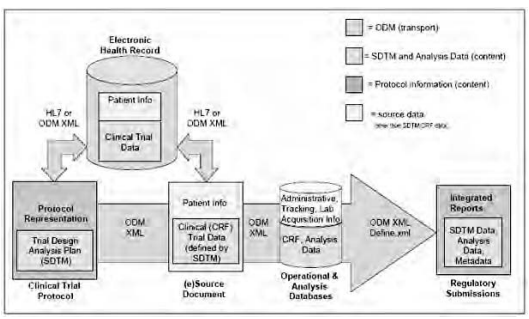

Figure 3 – Clinical Data Flow Using CDISC Std. [26]

to either come in more frequently than is normally necessary, or visit only when they are scheduled regardless of how they feel. Both situations are problematic.

Administrative

Security (i.e., confidentiality, integrity, accessibility, etc.) of a research subject's data is at least as important as a patient's data. Yet there are different rules that govern how data is managed and who can access what. Especially if CR data is collected as part of an EHR; consent forms often limit who can see study subject data to only people directly involved with the research, as opposed to anyone in the institution with general access to the EHR who is allowed to see patient records. How can this distinction be readily defined, and who will have the real-time responsibility to enter such permissions in an EHR as security administrator? Finally, healthcare data breaches are more commonplace than people want to know.[27]

EHR systems typically have well defined workflow components designed into the data collection screens for ease of use. Will new fields or special screens need to be designed for all research trials to enable complete and timely collection of relevant study variables (eCRF)? Will study subjects have the legal right to withdraw from research participation at any time for any reason without repercussion to their normal care, or to prohibit future use of their data for research purposes?

Recommendations for progress

The consensus from leading U.S. academic medical research centers at the Clinical Research Forum meeting in April 2007, as well as new dialog on this topic held at the 2007 HIMSS meeting with the EHR Vendor Association and pharmaceutical companies was that there are many issues to overcome, but none are impossible. Participation of all stakeholders is necessary to create sustainable success. There is no single "leader" or starting point to EHR/CR integration. Pick any spot relative to your unique environmental needs and just get started!

Regarding technology, if you already have an EHR, begin a dialog with your vendor on inclusion of CR into their functional design. Require this from them in the future. If you don't have an EHR, become involved in national associations that are beginning to hold these public discussions (e.g., AMIA) with mixed stakeholder groups. Require vendor involvement and compliance with nationally recognized standards. Pressure publicly elected officials regarding regulatory agencies to accelerate changes in outdated rules and guidelines in support of electronic source data collection and transmission.

Challenge legislators through efforts with national associations to harmonize the legal framework around patients and study subjects, thus lowering the burden associated with CR translational science. Rethink and revise plans and materials for patient and community awareness, and their involvement in CR including NoPP and informed consent document creation.

Form or re-energize institutional committees defining responsible research conduct, research integrity, or conflicts of interest. Establish policies for limits to IRB involvement in hospital operational research; budgeting and accounting for research activities and investigational staff effort reporting.

Investigate, then adopt or adapt a CR process model. Benchmark best practices, including sharing your work with others. And finally, continuously improve and regularly test your security model for patient and research data. It's never secure.

Conclusion

EHRs implemented on a national scale are inevitable over the next decade, but there must be significant financial support and coordinated collaboration among many stakeholders to succeed and overcome the unsustainability of sub-optimized approaches. Likewise CR data management systems have diminishing chances of existing on their own as separate source records because of the many issues identified in this paper. Integration of the EHR with CR systems, or better, enabling CR to be completely carried out within the EHR system itself, will take foresight and redesign work between central HIT staff, CR informaticists, and commercial and open source partners. In addition to the financial and quality-of-care benefits, future research will be able to leverage clinical data-CR repositories that will become available from regional and

national networks. Study subject enrollment may quickly increase and open a way to explore rare "orphan" and pediatric diseases that would have otherwise been financially or statistically unattainable.

The FA4CT Algorithm: A New Model and Tool for Consumers to Assess and Filter Health Information on the Internet

Gunther Eysenbach [a,b] **, Maria Thomson** [c]

[a] *Department. Of Health Policy, Management, and Evaluation, University of Toronto, Canada*
[b] *Centre for Global eHealth Innovation, University Health Network, Toronto General Hospital, Toronto, Canada*
[c] *Department of Health Studies and Gerontology, University of Waterloo, Canada*

Abstract

Background: eHealth-literate consumers, consumers able to navigate and filter credible information on the Internet, are an important cornerstone of sustainable health systems in the 21st century. Various checklists and tools for consumers to assess the quality of health information on the Internet have been proposed, but most fail to take into account the unique properties of a networked digital environment. Method: A new educational model and tool for assessing information on the Internet has been designed and pilot tested with consumers. The new proposed model replaces the "traditional" static questionnaire/checklist/ rating approach with a dynamic, process-oriented approach, which emphasizes three steps consumers should follow when navigating the Internet. FA4CT (or FACCCCT) is an acronym for these three steps: 1) Find Answers and Compare [information from different sources], 2) Check Credibility [of sources, if conflicting information is provided], 3) Check Trustworthiness (Reputation) [of sources, if conflicting information is provided]. In contrast to existing tools, the unit of evaluation is a "fact" (i.e. a health claim), rather than a webpage or website. Results: Formative evaluations and user testing suggest that the FA4CT model is a reliable, valid, and usable approach for consumers. Conclusion: The algorithm can be taught and used in educational interventions ("Internet schools" for consumers), but can also be a foundation for more sophisticated tools or portals, which automate the evaluation according to the FA4CT algorithm.

Keywords:

internet, consumer health informatics, information quality, information retrieval, education

Introduction

Searching for health information online is often said to be "one of the most popular activities on the Internet". Such sweeping (and only partially accurate) claims are mostly based on survey data, such as the Pew Internet Report, where people are questioned whether they have "ever looked online for" a certain category of information such as health, entertainment, or shopping. The Pew Internet Report 2003 [1] found that "fully 80% of adult Internet users, or about 93 million Americans, have searched for at least one of 16 major health topics online" and goes on concluding that "this makes the act of looking for health or medical information one of the most popular activities online, after email (93%) and researching a product or service before buying it (83%)."

In reality, the question "have you ever used the Internet for y" does not necessarily translate into the prevalence of day-to-day activities. To gauge these, one has to directly observe Web traffic or monitor what people are searching for. Several independent studies using these more "direct" methods to gauge online activities by tapping into the datasets from various search engines, have concluded that the actual volume of health-related searches on the Internet as a proportion of all searches conducted each day is "only" around 5% [2-5], with other areas such as entertainment, shopping, porn, research, places or business being much more popular.

In summary, survey and search data combined suggest that searching for health information is a popular, but relatively infrequent activity for most people (chronically ill people being a notable exception).

This usage pattern of health information has implications: While people may know where to go for reliable news, weather information, movie reviews, shopping, and business information, medical questions arise infrequently enough so that people not necessarily have a trusted brand names or portal in their mind. While people may be savvy and experienced enough to evaluate the credibility of a general news website or an ecommerce site, they may have insufficient experience and expertise with health websites. Consumers need to be "eHealth literate" in order to succeed in finding and filtering information. "eEhealth literacy" [6] consists of six literacy types (traditional, information, media, health, computer, and scientific literacy) which combined form the foundational skills required by consumers' to engage with electronic health information.

Several attempts have been made to create tools which can be used to educate consumers or which may assist consumers in identifying "credible" information. Most (if not all) previous tools are checklist-like instruments, designed to evaluate information on a webpage or website level.

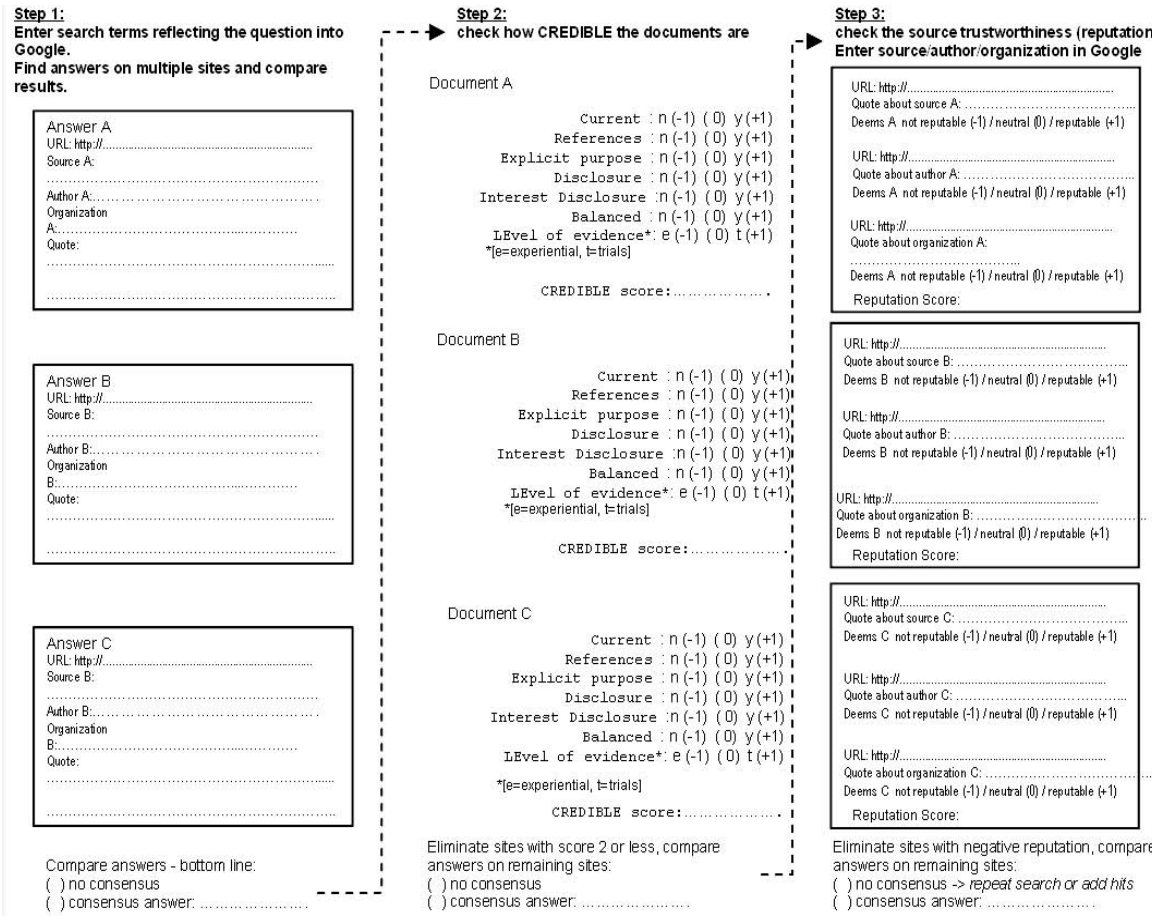

Figure 1 - The FA4CT Algorithm (Worksheet for Consumers)

A recent review of 273 instruments which can be used by patients and consumers to asses the credibility of health information has concluded that "few are likely to be practically usable by the intended audience" [7].

Many or all of today's tools are cumbersome and time-consuming checklists. They do not adequately take into account the unique features of a digital networked environment, but are still guided or influenced by our thinking about credibility in the "offline", printed world. The DISCERN instrument, developed for *printed* patient education brochures but advocated by its developers as an evaluation tool for web-based information [8;9] is a prime example. The claim of the DISCERN authors that "there's nothing radically different about information on the web" [10] illustrates a failure to recognize and to capitalize on the advantages of the Web to use the networked environment itself to assess the credibility of (health) information.

A second generation of educational tools – beyond checklists of authorship and content criteria of web documents – is needed, one that takes into account that consumers are in a *networked, digital* environment, and that credibility evaluation in this medium is a dynamic, interactive, and iterative process. Advantages of a networked environment, which should be exploited and utilized by educational and technological tools include the ability for users not to rely on only a single source, but to cross-check information on other websites and to check the credibility and reputation of the source using the Web itself. As Meola noted, rather than promoting a mechanistic way of evaluating Internet resources, a contextual approach is needed, which includes for example the possibility to corroborate information on the Web from other sources [11].

Methods

The FA4CT approach

In this paper we propose and pilot test a second generation educational model and approach which we call the FA4CT model. This educational model was originally developed in the context of an Internet school for cancer patients (I3MPACT project: Impact of Internet Instructions on Men with Prostate Cancer). FA4CT is intended for use by consumers to find and check medical facts on the Internet. In contrast to earlier approaches, FA4CT is not a checklist, but an intuitive process (or algorithm) which users are instructed to follow when assessing health information on the Web. The algorithm mimics the process expert search-

ers use for information retrieval and fact checking on the Web. For example, journalists use the technique of cross-checking facts from multiple sources to verify the credibility of their sources.

FA4CT (or FACCCCT) is an acronym for the three steps suggested in the algorithm: 1) Find Answers and Compare [information from different sources], 2) Check Credibility [of sources, if conflicting information is provided], 3) Check Trustworthiness (Reputation) [of sources, if conflicting information is provided].

The model also recognizes that consumers are usually not primarily interested in assessing the credibility of an entire "website" (or page, or document) as the unit of evaluation, but usually in the credibility of a specific health claim (fact). Thus, in order to use FA4CT, a consumer seeking information on the Internet is instructed to first formulate his factual question as clearly as possible, preferably in a way that allows a yes/no answer. He is then instructed to translate this question into search terms and to conduct an initial Google search query to locate three web sites that contain an answer to their specific medical question. The first key step (**step 1**) for making sure that the information found on the Web is "accurate" is to *compare* (cross-check) the information found on multiple websites. This is a major shift from previous approaches such as DISCERN, where checklists are used to check the credibility of the source and the information itself. In contrast, the FAC4CT algorithm suggests a source/information credibility assessment based on a checklist only as a second step, and only if there is no consensus in the three answers provided. In this case, **step 2** suggests to assess each web site using the *CREDIBLE* criteria [12]. The acronym CREDIBLE refers to Current, References, Explicit purpose, Disclosure of sponsors, Interest disclosed and no conflicts found, Balanced, and Level of Evidence. These criteria are based on empirical studies and reflect markers which have in multivariate regression models been shown to be independent predictors for accuracy [12].

Each of the seven criteria has three simple rating options "not fulfilled" (scored with -1), "neutral" (0), and "fulfilled" (+1) with a total possible credible score ranging from -7 to 7.

If after elimination of less "credible" web sites according to these criteria there is still no consensus among the remaining websites, users are in **step 3** asked to enter the name of the source into Google to check what others on the Web have to say about the source, arriving at a *reputation* score. To assess the reputation, for each web page in question the source, author or organization are entered into Google and three new sources commenting on the reputation of the source in question are identified and a quote commenting on the reputation of the source is recorded. Reputation is scored "+1" if there was an explicit statement of trustworthiness, "0" if neural or "-1" if there was an explicit statement of untrustworthiness. Figure 1 shows the algorithm as worksheet for users. In addition, a more detailed instruction sheet (not shown) is made available to users. It should be noted that the algorithm is designed for educational purposes or for implementation in automated tools assisting users. Users are not expected to go through these detailed calculations each time they check a fact, rather, they should - by applying the algorithm a few times with an instructor - develop and internalize the process on a more intuitive basis.

Formative evaluation and ROC evaluation of CREDIBLE checklist

As part of the formative evaluation of the FA4CT algorithm we had to establish 1) how many websites consumers should cross-check to arrive at a valid assessment on the accuracy of a fact, 2) what the optimal cut-off point of the CREDIBLE score from step 2 is, using a ROC (receiver-operating characteristic) curve approach.

Four questions related to a medical fact were used to pilot the FA4CT algorithm, for each question the first six websites resulting from a Google search containing the answer were assessed, resulting in a total of 24 evaluations.

The searches took place on March 3, 2006. The following are the four pilot questions used and their associated answers from gold-standard evidence based resources.

1) Do exclusively breastfed babies require vitamin D supplementation? The search terms entered were "vitamin D" "breastfeeding". The answer as derived from the CMA clinical practice guidelines developed by the Canadian Pediatric Society, which recommends that breastfeed babies be given a daily vitamin D supplement until their diet includes a reliable source or they are one year of age.
2) Does vaccination cause autism? The search terms used were "vaccination" "autism". According to the Cochrane database of systematic reviews there is no credible evidence of a link between the MMR vaccine and autism.
3) Does Echinacea cure colds? The search terms entered were "Echinacea" "colds". According to a review from the Cochrane database of systematic reviews there is no clear evidence that Echinacea prevents colds.
4) Should statins be taken for high cholesterol? This question was searched using "statins" "cholesterol". According to the recommendations of the CMA clinical practice guidelines people at high risk should be treated with the equivalent of 40 mg/d of simvastatin.

Pilot usability test with end-users

Eight participants were recruited using advertising posters distributed throughout three Toronto hospitals as well as the Consumer Health Information kiosk at the Toronto Reference Library. All participants attended an one hour session at the Centre for Global eHealth Innovation, University Health Network. The sessions were conducted from July 25-28, 2006. Computer sessions were held in a usability lab that enabled video, audio and computer recording, in addition to a one-way mirror for one observer to take notes. The session was recorded using Morae software and captured computer screen and key strokes as well as video and audio of the participant. Participants were

encouraged to speak out loud creating a narrative of their actions and decisions. Post session interviews were recorded with a simple hand held recorder.

Each computer session consisted of three tasks. Due to technical problems only five of the eight participants were included in the analysis of task two. All participants received a brief training at the beginning of the session.

Task One. This task was designed to test a "forced" step 2 of the FA4CT algorithm (regardless of whether step 1 would have triggered step 2). Participants were asked to rate three pre-selected websites using the CREDIBLE criteria. Each website provided an answer to the dichotomous question 'Do exclusively breastfed babies require vitamin D supplementation?' To retrieve these webpages the search terms "vitamin D" "breastfeeding" were entered into Google. Two of the three websites retrieved provided the 'correct' answer. This search took place on March 3, 2006. Each participant received a copy of the FA4CT algorithm and a list of the CREDIBLE criteria definitions.

To determine the reliability of the CREDIBLE criteria when used by multiple raters an inter-rater reliability score was calculated for each criteria. This measure was calculated using the Fleiss variation of the Kappa coefficient. Calculations were completed using SAS version 9.1 and the SAS MAGREE macro.

Task Two. Participants were asked to use the FA4CT tool for a health-related question of their own choice.

Both tasks were followed by a short semi structured interview and questionnaire to elicit participant feedback regarding the use of the FA4CT tool.

Results

Formative evaluation and ROC evaluation of CREDIBLE checklist

A total of 24 websites were assessed representing four different questions queried, 33% (8/24) of these web pages were determined to provide the "wrong" answer as compared to the evidence-based gold-standard, with "breastfeeding and vitamin D" having the most wrong answers at (3/6).

Although the FA4CT algorithm stipulates that step 2 (CREDIBLE evaluation) should only be carried out if there was no consensus among the first 3 websites, for this pilot evaluation a CREDIBLE score was calculated for all 24 webpages in order to determine the optimal cut-off point. The best cut-off point seems to be a threshold of 2 (sites meeting only 2 or less CREDIBLE criteria are considered not credible), where 87.5% of all web pages that contained the correct answer were correctly deemed credible and only 12.5% of web pages that contained the wrong answers were incorrectly labeled as credible.

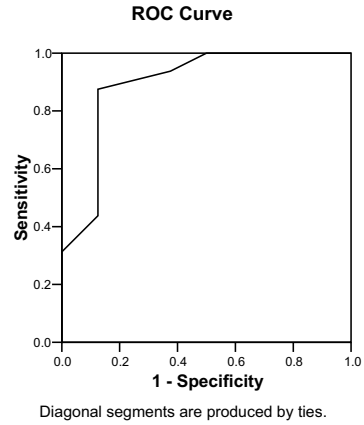

Figure 2 - ROC curve for CREDIBLE score of 24 webpages

Using 3 websites as a starting point, and a CREDIBLE score cut-off point of 2, the FA4CT algorithm performed well. Only 1/8 question sets did not result in a consensus answer at the end of the entire algorithm. Three question sets were correctly answered immediately in step 1 and a further four sets were correctly answered after employing the CREDIBLE criteria in step 2.

Usability test with end-users

The pilot user sample consisted of an equal number of males and females, with four participants aged 21-40, two participants aged 41 to 60 years and two participants over 61 years. In terms of education, three participants had completed post graduate training, four completed college or university and one completed high school. When asked about their level of confidence using the computer for the session, four reported feeling very confident, two reported that they felt confident and two reported to have some confidence. All participants had at least one year computer experience with six participants reporting more than ten years experience. All participants reported looking for health information on the internet.

Task one: The CREDIBLE criteria

All eight participants completed task one. On average the time to score one website using the CREDIBLE criteria was 10.25 minutes per page with a range of 5.1 to 18.1 min/page. Because two of the three websites provided a correct answer, it was of interest to identify whether participant criteria scores reflected this distinction. Three participants awarded final criteria scores that correctly classified all three websites therefore awarding passing scores to the two websites with the correct answer and a failing score to the website that provided an incorrect answer. Three participants correctly classified two out of three sites and two participants correctly classified only one site. The site that received the least correct classifications was the site that provided the incorrect answer, according to the gold standard.

Kappa statistics were calculated for each of the seven criteria scored on three webpages by eight raters. Generally the kappa results were satisfactory falling between k=0.52-0.79 (Table 1).

Table 1 - Kappa agreement scores from 8 consumers

CREDIBLE Criterion	Kappa Score
Current	0.62
Reference	0.62
Explicit purpose	0.79
Disclosure of sponsors	0.68
Interest disclosed and no conflicts found	0.68
Balanced	0.53
Level of **E**vidence	0.52

Task two: using the FA4CT tool

Five participants properly completed task two, using the entire FA4CT algorithm for their own health-related question. Each participant successfully asked a dichotomous medical question, completed a Google search and located three websites that answered their question. Upon evaluation of the three websites all five participants deemed a consensus answer to have been reached, i.e. no participant had to proceed to step 2 or 3. The average total time spent using the tool was 17.58 minutes with a minimum 10.1 and a maximum 27.2 minutes.

Participant search strategies may have influenced the outcome of the algorithm operation. Four out of five participants typed their medical question into Google using a full sentence complete with a question mark. Only one participant used keywords to search. This may have affected the retrieval of websites by listing first the websites that contained that specific sentence, as opposed to listing websites that contained the search key words without an exact sentence match.

Discussion

While the FA4CT approach still needs to be refined, the overarching model constitutes a major paradigm change from previous approaches. First, it is a *process*, rather than a mere checklist. While a checklist (the CREDIBLE criteria) is a part of the process, this checklist is only used as second step to eliminate less credible websites in case of lack of consensus among the first 3 sources in step 1, and is in practice rarely needed. Secondly, the approach teaches an evaluation on a fact-level, rather than a "website" or document level (though consumers could be taught to evaluate a couple of facts using FA4CT to arrive at a website/document rating). Thirdly, it takes into account the major advantages of information retrieval on the web, which is the ability to cross-check facts using different sources and to check the reputation of sources. Thus it reflects what experienced searchers do when they check the credibility of a (medical or non-medical) claim on the Internet. Consumers using the FA4CT approach are encouraged to check multiple sources and websites to arrive at an answer. They learn to eliminate clearly non-credible sources. In relatively rare instances, discordances will remain after elimination of non-credible sources, leading to the teaching point that in medicine there is often more than one answer, and sometimes even reputable sources contradict each other, which is often a sign of conflicting evidence in the literature.

Our initial experiments with the FA4CT approach have been encouraging. A caveat is that detailed instructions on how to formulate a search query in a neutral way should be part of the tool, to avoid that people enter preconceived opinions in form of full sentences into Google to find only one-sided answers. Initial findings from user testing also led to fine-tuning of the instrument, in particular related to the CREDIBLE scoring. Checking reputation (step 3) was rarely required in our initial experiments, as in most cases step 1 and step 2 already led to an accurate result, and will require further testing. Reputation checking on Google requires some more advanced search strategies, but might be facilitated by future tools specifically built for checking the reputation of sources (for some time, Google Labs offered such a feature, which is now disabled).

While the algorithm was initially designed to be used as part of educational interventions, it is conceivable that a similar algorithm based on a mix of cross-checking facts and checking of credibility markers and reputation could be part of future automated tools that help consumers to find trustworthy information on the Internet.

Abstract

Legal and technologic trends are making medical records progressively more patient-accessible. In the near future, information technology may make it even easier to provide patients a chance to review their records. One may wonder, however, about the practical use of this technology by patients. Understanding his/her own health record will certainly be one of the main concerns of patients. WRAPIN has been designed to provide patients and citizens with trusted health information. It will help to determine the reliability of documents by checking the ideas contained against established benchmarks, and enable users to determine the relevance of a given document from a page of search results. First, we present what is, in our opinion, the most original and important patient-centred WRAPIN characteristics and functionalities. Then, we compare these characteristics with those of representatives of two main trends in information retrieval: systems based on the popularity of web sites, and on the clustering of web sites. This comparison shows that, even though patients are tempted to use popular search engines, these are not sufficiently specialized in the medical domain to help them understand their own HER.. Finally, we discuss the complexity of medical readings over the Internet and the efforts that are still required in this domain.

Introduction

In a short note Dr PH Chew related a visit to one of his patients [1]. The patient said: "Doctor, I would like to inform you that for the past two weeks my *corpus spongiosum* has not been filling adequately (…) I read on the Internet that Metoprolol® can cause impotence." Dr Chew wrote: "I realised that the internet has provided this patient with the knowledge that his recently acquired impotence was drug-induced." It is true that it is now easy to log onto a web site and obtain this kind of information about Metoprolol. We learn from this account that Internet is currently an essential source of information for patients. It can also be used by patients to understand and check diagnoses and treatments.

Legal and technologic trends are making medical records progressively more patient-accessible. In the near future, information technology may make it even easier to provide patients a chance to review their health records. Studies of technology that allows patients to access their records over the Internet have already been conducted [2, 3]. In contrast to paper records, electronic medical records should be perfectly legible. Internet-accessible records can be viewed repeatedly and in the context of rich sources of medical information available on the World-Wide-Web, potentially increasing the potency of the intervention [4].

The Health on the Net Foundation Code of Conduct (HONcode) [5, 6] for medical and health Web sites addresses one of Internet's main healthcare issues: the reliability and credibility of information. The HONcode defines a set of transparency rules to: 1) hold Web site developers to basic ethical standards in the presentation of information; and 2) help ensure readers always know the source and the purpose of the data they are reading. **MedHunt** [7] is a dedicated, medical, full-text search engine, using a global database including HONCode accredited and selected Web sites retrieved by MARVIN, the HON's robot. The global database currently includes two types of documents: 1) the **accredited Web sites** which are updated daily and reviewed manually by the HON team; and 2) the **selected health Web sites** which have been automatically retrieved from the Web by the robot MARVIN.

WRAPIN has been designed to provide patients and citizens with trusted health information [8]. WRAPIN provides an entirely new facility allowing comparisons of health/medical documents with an interconnected knowledge base, in order to discover whether the information exists in the published literature and to provide a summary of the ideas contained. It will help to determine the reliability of documents by checking the ideas contained against established benchmarks, and enable users to determine the relevance of a given document from a page of search results. This will allow patients to gather information in a trustworthy environment. Moreover, the resources referenced in the WRAPIN database are indexed with MeSH key-words. That allows to provide end-users with trusted definitions of health concepts.

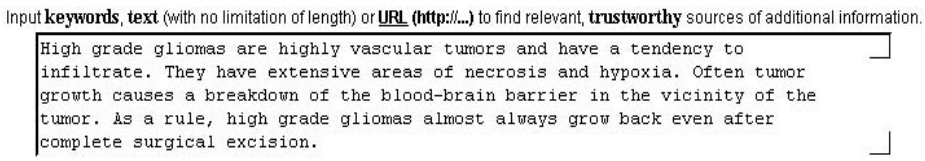

Figure 1.a. Copy and paste of a text submitted to WRAPIN for analysis.

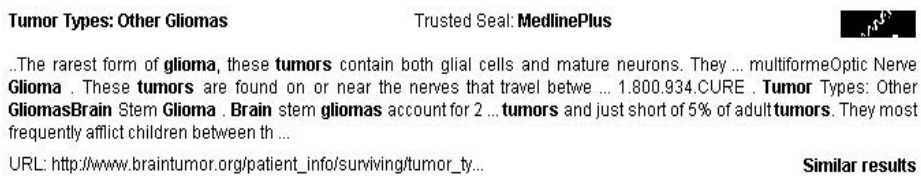

Figure 1.b. An example of a reference to a general public site related to the text submitted to WRAPIN in Figure 1.a.

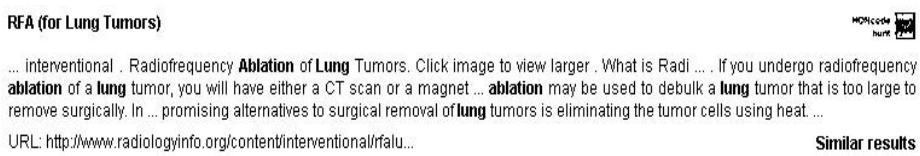

Figure 2.a - Extract of an answer to the query « ablation of a lung ».

A search engine for trustworthy health web sites

The main innovation of WRAPIN is to make available a tool to determine information reliability by automatically checking a document against matching sources from databases of known quality. Figures 1.a and 1.b respectively illustrate the submission of a text to be analysed and an extract of a related Web site of known quality. WRAPIN is fundamentally different from even the best medical search engines currently available, since an entire document may be proposed as the search query. A conventional series of search terms can also be used. A special effort has been made in the indexing process of health resources, since the extraction of MeSH terms from queries is guided by a component based on the UMLS knowledge sources [9].

Whereas other systems display search results in summary form, with bits of text extracted from matching documents, WRAPIN attempts to show how a document matches a query. To better define the results, MeSH terms (and synonyms) are highlighted in the results summaries and throughout the text of matching documents. Figure 2.a and 2.b respectively illustrate an extract from the answer to the question *ablation of a lung tumor*, and the display of a retrieved page where terms of the question are automatically highlighted.

WRAPIN is a multilingual search engine in the medical domain. If a request is expressed in a given language, French for instance, results are displayed in the same language. However, they can be adapted to another language, English for instance. Hence, a patient staying in a given foreign hospital could query WRAPIN and obtain information from data of his/her patient record expressed in his/her natural language. This is particularly significant in Europe where there exist numerous different natural languages, and where people move from one country to another, sometimes everyday, for work reasons.

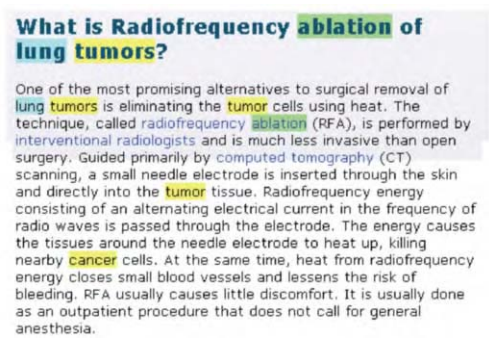

Figure 2.b - An extract of the page referenced in Figure 2.a where the terms of the query are highlighted on fly.

Another way to adapt the information retrieval process to patients' queries is to propose to rephrase queries. In the case of WRAPIN, this is done by suggesting a list of terms or relevant qualifiers, known as facets, aimed at making a query more pre- cise. This is illustrated by Figure 3.a in which the initial query is "glioblastoma". The list of terms used to rephrase a query is created dynamically with regards to the query content and is not predefined. These facets are based on the MeSH thesaurus. WRAPIN exploits other facets based on the medical domain. This kind of facet provides a useful way of helping citizens to better qualify their queries with pre-defined categories linked to a style of query. For instance, a query related to a disease activates categories such as "overview", "causes and risk factors", "screening and diagnosis", "complica-

tions", "treatment", and "prevention", as illustrated by Figure 3.b.

A last feature that WRAPIN exploits is the categorization of sources according to the complexity of the pages they publish. For instance, Medline is considered to be a complex source publishing technical information which is difficult to read by the general public.

Figure 3.a. Rephrasing the query « glioblastoma » by the means of facets.

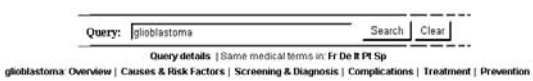

Figure 3.b - Use of pre-defined categories related to entities of the medical domain, here « disease».

A tool for patient empowerment within EHR

Figure 4 shows the general architecture of WRAPIN involving EHR. Extracts of an EHR may serve as a query to the system. Text is analysed, whatever its language (presently five European ones), by a multilingual sub-system represented in a grey rectangle. The result of this treatment is sent to the search engine which exploits an index of medical resources. Results of the query are sent to a module which displays them and suggests rewordings to render the query more accurate. If rewording is performed, a complete cycle is then processed until such time as the user is satisfied with the answers received.

On account of the above functionalities, WRAPIN constitutes an original Web search engine for the health domain. It will allow patients to involve themselves in their own care process, and to ask about and verify information related to their health care. If, for instance, a patient reads in his/her personal French EHR « … exérèse d'un gliome révélé par l'examen anatomopathologique associée à une radiothérapie … » (*…ablation of a glioma, diagnosed by a pathology exam, associated with radiotherapy…*), and if he/she wants more details in relation with this text, a copy-paste of it allows him/her to query WRAPIN and to obtain a list of trustworthy, related Web sites, as illustrated by Figure 5.

Traitement La chirurgie d'exérèse permet l'ablation de la tumeur quand celle-ci est particulièrement bien localisée. Ce traitement s'applique spécifiquement aux astrocytomes et aux craniopharyngiomes. Il existe néanmoins quelques risques de récidive dépendant de la localisation de la tumeur. Ainsi, le gliome et les tumeurs hémisphériques (situées dans chaque moitié du cerveau) sont parfois enlevées partiellement.

La radiothérapie se fait généralement complément du traitement précédent également dans le but de prévenir les récidives.

Figure 5.- French-language answer to the text « exérèse du gliome … associée à une radiothérapie » (ablation of a glioma … associated with a radiotherapy) copied and pasted from a patient EHR..

Facing the ever greater sharing of personal EHR, one may wonder what practical use patients can make of this system. Understanding one's own medical record will certainly be a major concern for patients. In Table1, we compare the WRAPIN features with those of representatives of two main trends in information retrieval: systems based on the popularity of Web sites (e.g., Google), and clustering of Web sites (e.g., Vivisimo).

Discussion

The World-Wide-Web is today probably the world's largest source of information. Among other functions, it enables patients and others to gather information about their health condition, to verify information they received and perhaps did not entirely take in, and to check the validity of their treatment. In short, it allows them to understand. WRAPIN is a tool they can use to query the health Web. One of the main features of WRAPIN is that it registers only certified quality sites. This allows it to convey reliable health information to patients and other users. Its wide-ranging features and its ease-of-use make it an unrivalled tool empowering the patient in his/her own health care process. Even if patients are tempted to use popular search engines, these are not sufficiently specialized in the medical domain to help them understand their own EHR. The comparison we made between features offered by other search engines shows that WRAPIN, as an instrument dedicated to the health domain, provides a better guarantee in terms of information quality and reliability of Web sources. Thus, thanks to its functionalities, it provides an easy-to-use search engine coupled together with EHR.

The WRAPIN search engine has been operational since 2005, having evolved from a prototype which was tested

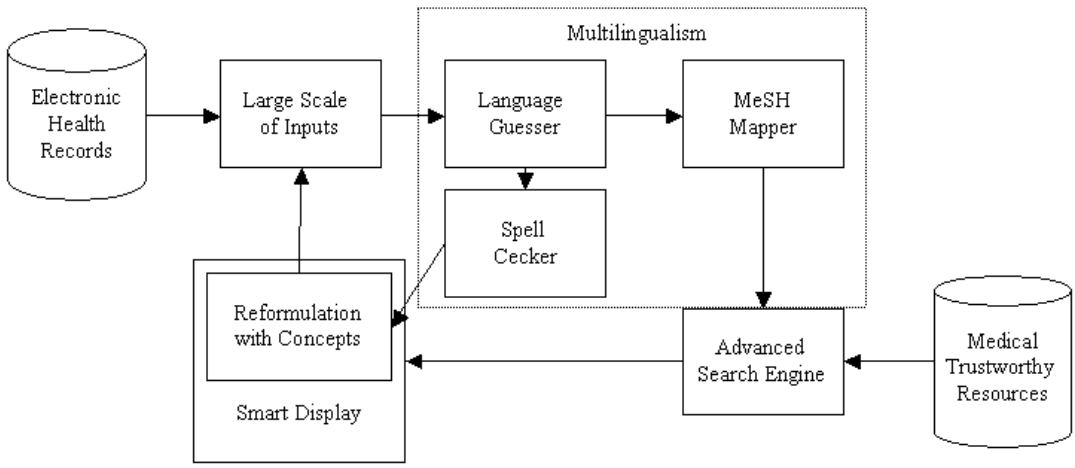

Figure 4 - EHR as an input to the WRAPIN search process.

Table 1 - Comparison of WRAPIN features with those of Google and Vivisimo.

	Google	**Vivisimo**	**WRAPIN**
Querying facilities	Limited in length	Limited in length	Copy and paste a part of a patient record
Quality of information	Related to page ranking only	Related to page ranking only	Related to trustworthy sources

Legend :*number of answers to the "health" query, Nov 26, 2006; ** e.g., the ability of a patient to query his/her health record from a foreign country; *** English, Spanish, French, Italian, Portuguese, German; **** access to easy- to-read information

and improved by evaluation outcomes [8]. The goal of this evaluation was to assess if WRAPIN really met to the user needs and particularly to know if it can help patients and individuals to judge information available on the Web. The analysis of the results made clear the important impact of WRAPIN to meeting needs expressed by great number of users. There were three types of questionnaires: technical, satisfaction and ergonomic. The evaluation was online and compared WRAPIN with another Web search engine.

There were four types of queries: free and pre-formatted questions, and free and pre-formatted URL for more than thirty medical specialties. The use of WRAPIN has, on he whole, been perceived as informative, reliable and trustworthy. Yet in a number of cases, the replies given by the system were irrelevant, but it was also true for the other engine. The rate of irrelevance/impertinence should be scientifically reckoned, and finally reduced. It seems the upfront lexical analysis of the queries, as well as the ergonomic of the reformulation leave room for improvement. In the view of the testers, WRAPIN is over-performing other engines when the replies are pertinent. By providing a synthetic and reliable reply to a query, or an assessment of a document further to the submission of an URL, WRAPIN goes beyond the other engines and brings a valuable tool to users seeking medical and health care information. It has been felt helpful that humans reviewed Web sites for appropriateness and correctness.

Usually, when citizens look for health information they look for it on the Internet with search engines like Google. It is obvious that, in order to have a more complete information related to various unclear issues of their medical health record, citizens will rush to Google again and try to clarify them. In this case, unfortunately, their search will not worry the reliability of found information. In this paper, we have presented several criteria which show that WRAPIN can be used by citizens in this context and represents a good and interesting alternative to existing non-specialized search engines. However, a more detailed evaluation should be performed in order to validate the relevance of WRAPIN for such a task and to identify more precisely appropriate functionalities needed within an EHR-oriented perspective.

To facilitate understanding of personal medical information by health consumers, the use of accessible, non-technical language is essential. Information complexity is often quantified on the basis of the complexity of words and sentence formulation, for instance, the number of words in a sentence or syllables in a word [10]. In a domain as specific as health, lexical knowledge is of paramount concern. Today, WRAPIN informs users about the *a priori* complexity of information sources. For instance, Medline is categorized as a technical source compared to Medhunt, since the presence of specific medical terms increases the level of complexity for the general public. Hence, a complexity measure based on the use of a lexicon seems promising.

Moreover, a major effort is still required if patients and non-patients are to have efficient access to health-related information. As noted by McCray in a thorough study into reading cability and the understanding of health-related documents [11], patients need to interact in a variety of health care settings, including doctors' offices, clinics, and hospitals. They also need to interact with a broad range of health-related information, including treatment instructions, patient education materials, prescriptions, bills, and insurance forms. In addition, they are being asked to take increasingly greater responsibility for their own health-care and disease management. The role of the Internet in the health-care system is just beginning to be understood. Still needed are better tools to assess and modify the comprehensibility of health materials as well as methods for improving access to information. McCray's conclusion, to which we totally subscribe, is that "health informaticians, developers of health information, and health care providers all need to work together to ensure that everyone has an equal opportunity to access, understand, and use health information".

Acknowledgments

The WRAPIN project, IST-2001-33260, has been supported by the European Commission. The authors have a special thought for Pr Jean-Raoûl Scherrer who was the originator of WRAPIN and passed away during the project. The authors wish to acknowledge all the members of the WRAPIN consortium, especially Michèle Thonnet, Anne Strauss (MISS, Mission d'Informatisation des Systèmes de Santé), Robert Baud (HUG, Hôpitaux Universitaires de Genève), Patrick Weber (NICE Computing), Pierre Uziel (XR Partner Information Systems), and Juan Bonal (Thales Information Systems). They thank Mr George Morgan who revised their English.

How do Clinicians Search For and Access Biomedical Literature to Answer Clinical Questions?

Annie Y.S. Lau, Enrico Coiera

Centre for Health Informatics, University of New South Wales, Australia

Abstract

This paper presents a retrospective data analysis on how 75 clinicians searched for and accessed biomedical literature from an online information retrieval system to answer six clinical scenarios. Using likelihood ratio measures to quantify the impact of documents on a decision, and a graphical representation to model clinicians' journeys of accessing documents, this analysis reveals that clinicians did not necessarily arrive at the same answer after having accessed the same document, and that documents did not influence clinicians in the same manner. A possible explanation for these phenomena is that people experience cognitive biases during information searching which influence their decision outcome. This analysis raises the hypotheses that people experience the anchoring effect, order effects, exposure effect and reinforcement effect while searching for information and that these biases may subsequently influence the way decisions are made.

Keyword:

evidence journey, information retrieval, cognitive bias, decision making, likelihood ratio, clinicians

Introduction

Increasingly, information searching plays an important part in health consumers' decision making [1] and clinicians' practice of evidence-based medicine [2]. Decisions are improved by better access to relevant information, and searching for documents on the Web is increasingly an important source of that information [3]. Yet, studies have confirmed that clinicians do not always achieve optimal results when using information retrieval systems [4]. While much research focuses on the design of retrieval methods that identify potentially relevant documents, there has been little examination of the way retrieved documents then shape real-life decision making [5]. To develop information retrieval systems that actively support decision making, it is necessary to understand the complex process of how people search for and review information when making decisions [6].

To understand how people search for and use information to make a decision, it is important to understand the "journey" in which people undertake to arrive at the decision. Taking the definition of evidence to be "the body of observed, reported or research-derived data that has the potential to inform decision making" [7], an "evidence journey" is the process that describes an individual accessing different pieces of information retrieved from an online information retrieval system to make a decision. The notion of the evidence journey is similar to Bates' *berrypicking* metaphor, or *bit-at-a-time* retrieval, where "a query is satisfied not by a single final retrieved set, but by a series of selections of individual references and bits of information at each stage of the ever-modifying search" [8].

There is a body of literature looking at how people use information retrieved from search engines to inform their decision making. An example from the information science literature is the model of document use proposed by Wang and colleagues [9,10]. Based on a longitudinal study of academic researchers' use of documents retrieved from online databases during a research project, they proposed that document use is a decision making process and people do not necessarily use the same criteria to select, read or cite documents. Gruppen and colleagues, reporting in the medical decision making literature, suggested that information gathering and selection are more problematic than information integration and use [11]. Based on a study examining how first year house officers select information to make a diagnosis, they found that subjects selected the optimal information in only 23% of the cases but were able to use the selected information to make a diagnosis over 60% of the cases. They suggested that physicians appear to have difficulties recognising the diagnostic value of information, which results in making decisions based on diagnostically weak information.

This study analyses the evidence journeys that clinicians undertake to answer clinical questions. It graphically models the way clinicians searched for and accessed biomedical literature to make clinical decisions and identifies factors in the evidence journey that may have influenced the decision making process.

Methods

Data description

A retrospective analysis was constructed on a dataset of 75 clinicians' search and decision behaviours (44 doctors and 31 clinical nurse consultants), who answered questions for 8 real-life clinical scenarios within 80 minutes in a con-

Selected for best paper award.

trolled setting at a university computer laboratory [12]. Scenarios were presented in a random order, and subjects were asked to record their answers and level of confidence for each scenario. Subjects were then presented with the same scenarios and asked to use an Internet search engine to locate documentary evidence to support their answers.

Subjects recorded their pre- and post-search answers to each question, their confidence in these answers and their confidence in the evidence they had found using the search engine. There were four options to answer each question: yes, no, conflicting evidence and don't know. Confidence was measured by a 4 point Likert scale from "very confident" to "not confident". In addition, subjects recorded any change in answer or confidence from their pre-search response and identified which documents influenced their decision. They were asked to work through the scenarios as they would within a clinical situation and not spend more than 10 minutes on any one question.

Data from only six scenarios for which a correct answer could be identified were analysed (scenario questions are described in Table 1). The unit of measure used in the analysis is a search session, which is "the entire series of queries by a user" [13] to answer one question.

Table 1 - Clinical questions in the scenarios presented to subjects [12]

Question (scenario name)	Expected correct answer
Does current evidence support the insertion of tympanostomy tubes in child with normal hearing? (Glue ear)	No, not indicated
What is the best delivery device for inhaled medication to a child during moderate asthma attack? (Asthma)	Spacer (holding chamber)
Is there evidence for the use of nicotine replacement therapy after myocardial infarction? (MI)	No, use is contraindicated
Is there evidence for increased breast and cervical cancer risk after IVF treatment? (IVF)	No evidence of increased risk
Is there evidence for increased risk of SIDS in siblings of baby who died of SIDS? (SIDS)	Yes, there is an increased risk
What is the anaerobic organism(s) associated with osteomyelitis in diabetes? (Diabetes)	Peptrostreptococcus, Bacteroides

Document likelihood ratio

Since a document may be influencing some subjects to answer in different ways, a quantitative measure is needed to model the impact a document may have on a decision. One simple method is to associate a document with the frequency of correct and incorrect decisions made after having accessed the document. This leads to the idea of using a likelihood ratio (LR) to calculate a ratio of the frequency that accessing a document is associated with a correct answer rather than with an incorrect answer, *P(AccessedDoc|Correct) / P(AccessedDoc|Incorrect)* (Equation 1). The LR thus measures the impact a document has in influencing a subject towards a specific answer. Documents with a LR > 1 are most likely to be associated with a correct answer and a LR < 1 with an incorrect answer.

To calculate the likelihood ratio, the sensitivity and specificity of a document with respect to an answer are calculated. The *sensitivity,* or true positive rate, of a document is the frequency with which the document being accessed correlated with a correct answer being provided post-search (Equation 2). The false negative rate, the frequency with which access of a document correlated with an incorrect answer, was also calculated. The *specificity*, or true negative rate, is one minus the false negative rate (Equation 3). The sensitivity and specificity values were calculated based upon the frequency with which a document was accessed for each scenario.

$$\text{Likelihood ratio} = \frac{\text{P(Accessed Doc} \mid \text{Correct)}}{\text{P(Accessed Doc} \mid \text{Incorrect)}} = \frac{\text{Sensitivity}}{1 - \text{Specificity}} \quad (1)$$

$$\text{Sensitivity} = \frac{\text{No. of correct post-search answers where document was accessed}}{\text{Total no. of post-search correct answers}} \quad (2)$$

$$1 - \text{Specificity} = \frac{\text{No. of incorrect post-search answers where document was accessed}}{\text{Total no. of post-search incorrect answers}} \quad (3)$$

Results

Overall, subjects made 1761 searches and accessed 1873 documents across the 400 search sessions for six scenarios. In a search session, subjects took on average 404.75 seconds (standard deviation (SD): 590.824), made 4.32 (SD: 4.002) searches and accessed 4.65 (SD: 3.670) documents to complete a question.

Across the six scenarios, most subjects improved their answers after searching. There are subjects, as reported in [12], who had a wrong answer before searching and a right answer after searching, wrong-right (WR: 37%), followed by those who never answered correctly, wrong-wrong (WW: 30%), then those who answered correctly before and after searching (RR: 26%), and those who went from right to wrong (RW: 8%).

Since some documents were accessed on only a few occasions, it was not possible to calculate meaningful sensitivity and specificity measures for all documents. Thus, LR was only calculated for the subset of documents that had been accessed by at least five subjects (each document was accessed by 4.7 subjects on average). A total of 725 documents were accessed across the 6 scenarios, with a range from 78 to 138 documents per scenario. After culling, 88 documents were kept in the pool of influential documents (i.e. accessed by more than 5 subjects), with a range from 10 to 19 documents per scenario.

Did clinicians who accessed the same document arrive at the same answer?

Analysis of different evidence journeys taken by study participants reveals that subjects did not necessarily arrive at the same answer after having accessed the same document. In one scenario (MI), around 25% of WW subjects (i.e. 10 out of 39 subjects) cited the same source as WR subjects to support the opposite post-search answer. Across the six scenarios, subjects often produced different answers to questions despite having accessed the same document. The majority of frequently accessed documents were seen *both* by subjects who answered a question correctly after searching as well as those who answered incorrectly (Figure 1).

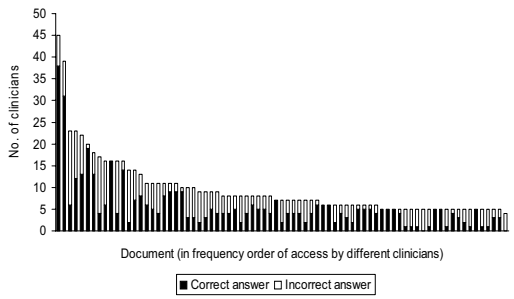

Figure 1 - Frequency of subjects answering a question correctly or incorrectly for each document accessed [14]

In addition, Figure 2 shows that documents accessed were almost equally distributed between those more likely to be associated with a correct answer (51% of accessed documents had a LR > 1) or incorrect answer (49% of accessed document had LR < 1). There was a clear variation in the likelihood that accessing different documents was associated with a subject providing a correct or incorrect post-search answer.

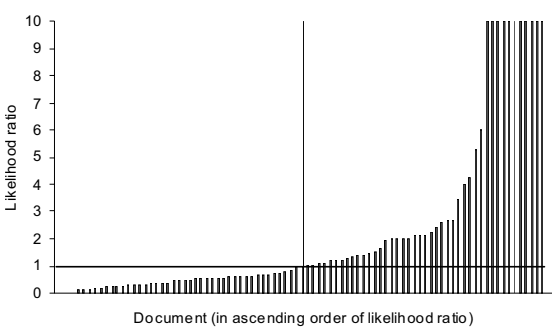

Figure 2 - Variation in influence of accessed documents in obtaining a correct post-search answer, as measured by likelihood ratio (Note: Likelihood ratio = 10 refers to documents having a likelihood ratio ≥ 10) [14]

Are there typical patterns in the evidence journey?

To better understand the way that accessing a sequence of documents might have influenced an individual in making a decision, a qualitative analysis was conducted to look for typical patterns amongst the dataset. In a search session, a *positive document* is a document with LR > 1 and is represented by a closed circle; a *negative document* is a document with LR ≤ 1, represented by an open circle; an *indeterminate document* is a document with a LR that cannot be established and it is represented with a strip-patterned circle; and each query submitted to the search engine is represented with a line.

The following examples demonstrate the evidence journeys of subjects in four different categories: RR, RW, WR and WW.

Figure 3 - Example of a subject with a right answer pre- and post-search (RR)

The subject in Figure 3 was correct before and after searching. This subject expressed being very confident in the pre-search answer. The subject made only one search and accessed one document, which is a positive document (a). One possible interpretation of this evidence journey is that the first document confirmed the subject's pre-search answer; hence, the subject stopped searching and provided the correct answer.

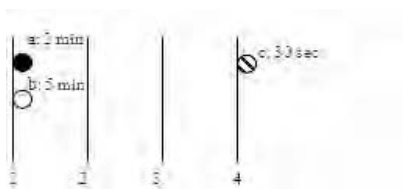

Figure 4 – Example of a subject with a right answer pre-search and a wrong answer post-search (RW)

The subject in Figure 4 gave a correct answer before searching but changed to an incorrect answer after searching. The subject made four searches. On the first search, the subject accessed two documents; the first document was a positive document (a), followed by a negative document (b). The subject then performed more searches, viewed the titles and summaries of documents retrieved on the results pages but did not access any document until the last search, which was a document with an indeterminate likelihood ratio (c). One possible interpretation is that as the subject spent more time on the negative document (b: 5 min) than the other two documents (a: 2 min, c: 30 sec); the extra time spent on the negative document may have contributed to the subject giving an incorrect answer

after searching. (Note: Time spent on a document was measured as time elapsed between the commencement of accessing the document and the subject's next action).

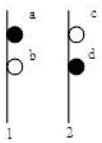

Figure 5 - Example of a subject with a wrong answer pre-search and a right answer post-search (WR)

The subject in Figure 5 gave an incorrect answer before searching, made two searches, accessed four documents and answered the question correctly after searching. The first document was a positive document (a), followed by two negative documents (b and c), and then a positive document (d). One possible interpretation is that the first and the last documents, which are positive documents, influenced the subject to change opinion and make a correct answer.

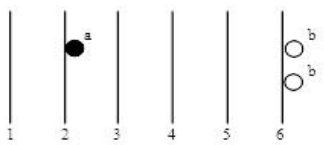

Figure 6 - Example of a subject with a wrong answer pre- and post-search (WW)

This subject in Figure 6 answered the question incorrectly before and after searching. Although the subject only accessed two documents, a positive document (a) and a negative document (b), the subject accessed the negative document twice (b). Perhaps, revisiting the negative document (b) led the subject to retain an incorrect pre-search opinion and provide an incorrect answer after searching.

Discussion

This study provides a snapshot on how clinicians searched for and accessed online biomedical literature to answer clinical questions. The likelihood ratio analysis shows that clinicians did not necessarily arrive at the same answer after having accessed the same document and that documents did not influence clinicians in the same manner. The graphical representation of evidence journeys illustrates that people take different journeys to arrive at an answer to a question and that the way documents were accessed and interpreted collectively may influence the way decisions are formed. It also reveals the possibility that the following components of an evidence journey influence the shaping of a decision outcome:

- an individual's *belief and confidence before searching,* e.g. Figure 3: RR
- the *order* of accessing documents, especially the first and last accessed documents, e.g. Figure 5: WR
- the amount of *time* spent on the documents, e.g. Figure 4: RW
- the *number of visits* the searcher made to the same document, e.g. Figure 6: WW

Each of these phenomena has been identified in the general decision making and information retrieval literature in different guises. Specifically, the literature identifies the existence of *cognitive biases* in the way people use information to make decisions [15-18]. For example, decision makers are biased by their prior beliefs and the order of information presentation when making decisions and forming impressions [19, 20].

The concept of decision biases may provide us with a theoretical model with which to understand search behaviours. Different subjects have different knowledge and levels of confidence before searching; their evidence journeys are different in search length, number and types of documents accessed; the way documents were accessed and how these documents may have interacted are possible elements that influence the way people process and use information to make decisions. Specifically, subjects may be experiencing the following cognitive biases in their evidence journeys:

- *anchoring effect*: the phenomena where one's prior belief exerts a persistent influence on the way new information is processed and subsequently affects the way beliefs are formed [21]
- *order effects:* the way in which the temporal order that information is presented or accessed affects the final judgement of an event [22]
- *exposure effect:* the phenomenon where the amount of time exposed to the information affects the final judgement of an event; e.g. [23]
- *reinforcement effect:* the phenomenon where the level of repeated exposure to information affects the final judgement of an event, which is best related to "mere exposure" discussed in [24]

Impact of these biases have been tested in a preliminary analysis that uses a Bayesian model to predict the impact of information searching on decision making [14]. The Bayesian model that predicts decision outcomes most accurately is the one that incorporates all the above-mentioned cognitive biases during information searching (without biases: 52.8% (95% CI: 47.85 to 57.59); with biases: 73.3% (95% CI: 68.71 to 77.35)).

Analysis limitations

The assumption that subjects read a document based on having accessed the document was a potential limitation in the study. Subjects may not have read documents they accessed, or only partially read them, modifying the likelihood that the document influenced them. Similarly, subjects may have been influenced by documents without accessing them, e.g., looking at the title or the abstract of the document only on the search engine results page, but not accessing the document itself.

Conclusion

This study presents a retrospective data analysis on how clinicians searched for and accessed biomedical literature to answer clinical questions. The analysis suggests that people take different journeys to answer questions, and that the way documents were accessed could contribute to different interaction effects between pieces of information, which influences the way evidence was evaluated and subsequently the decision making process. It also raises the hypotheses that people may experience cognitive biases during information searching that influence their decision making, and calls for further investigation to test these hypotheses.

Acknowledgements

The authors would like to thank Professor Johanna Westbrook, Dr Sophie Gosling and Miss Nerida Creswick for providing the data in this retrospective data analysis. Annie Lau was financially supported by the Australian Research Council during this research.

Blogs, Wikis, and Discussion Forums: Attributes and Implications for Clinical Information Systems

Jacob B. Weiss, MS and Thomas R. Campion, Jr., BA

Department of Biomedical Informatics, Vanderbilt University Medical Center, Nashville, Tennessee, USA

Abstract

Informaticians increasingly view clinical information systems as asynchronous communication systems instead of data processing tools. Outside of health care, popular web technologies like blogs, wikis, and discussion forums have proven to be platforms for effective asynchronous communication. These popular technologies have implications for improving the coordination of clinical care and social support. In order to appropriately evaluate these web-based tools for use in clinical information systems, it will be essential for the informatics community to formally identify the distinguishing attributes of these communication methodologies. The authors propose seven interpersonal and informational attributes to compare and contrast the purposes of blogs, wikis, and discussion forums. This attribute-based approach to analyzing emerging web technologies will lead to a better understanding of the design choices involved in web-based information systems. Two case studies demonstrate how informatics researchers and developers can consider these attributes in the design and evaluation of clinical information systems.

Keywords:

communication, blogs, wikis, social support, medical records

Introduction

Healthcare delivery is a social process, hence the informatics community's perspective on clinical information systems has shifted from that of data processing to an emphasis on asynchronous communication [1]. To coordinate care in a fragmented health system, information systems that promote collaboration between providers and/or patients are necessary. Emerging collaborative technologies may support the communication needs of clinical information systems.

Blogs, wikis, and discussion forums are asynchronous web-based technologies that facilitate the creation and exchange of text, pictures, and other digital media among individuals and groups. The technologies are easy to use and require no knowledge of computer programming. To create content, users typically login to content management systems, which provide straightforward ways to edit and make content available to peers via a web browser. The intended purpose of the technologies differ: blogs facilitate individual expression, wikis facilitate document creation, and discussion forums facilitate group dialog. Applications of the technologies in medicine are beginning to appear in the literature, but references to these concepts sometimes are misidentified or treated interchangeably [2]. Comparisons of the general advantages and disadvantages of the technologies exist, but little has been done to suggest methods for comparing the technologies' socio-technical characteristics [3].

For the medical informatics community to design and evaluate clinical information systems using aspects of emerging web technologies, the attributes of these tools must be distinguished. In this paper, we propose seven defining attributes of blogs, wikis, and discussion forums and assess the value of each attribute with respect to each technology. We present two case studies applying these attributes to clinical information systems: one evaluates a "problem list" in an electronic medical record, and the other explores online social support for cancer survivors. This paper is intended to stimulate discussion of these promising technologies and their attributes.

This paper is written for individuals and organizations that are developing or evaluating health communication software. For those trained in medical informatics, gaining an understanding of blogs, wikis, and discussion forums can provide insight to improve clinical information systems. For those trained outside medical informatics, viewing clinical systems through the lens of popular social software can illustrate the unique communication challenges of health care to which they can apply their knowledge and experience. With a better understanding of both collaborative software and the socio-technical underpinnings of informatics, informaticians and their industry partners can improve the design and evaluation of clinical information systems.

Analysis

In the following sections, we define blogs, wikis, and discussion forums in terms of the attributes presented in Table 1. In all three technologies, we refer to "entries" as content that is novel and discrete. "Responses" are replies or modifications to entries. We refer to creators of entries as "authors" and creators of responses as "respondents."

Selected for best paper award.

Table 1 - Seven attributes of blogs, wikis, and discussion forums

	Attribute	Blogs	Wikis	Discussion Forums
1	*Publication model*	**One-to-many**	**Many-to-many**	**Many-to-many**
2	*Display of entries*	**Reverse chronological**	**Topical**	**Chronological within topics**
3	*Response to entries*	**Append**	**Change**	**Append**
4	*Display of knowledge*	**Fragmented across entries and replies**	**Synthesized into a single document**	**Fragmented across entries and replies**
5	*Participant emphasis*	**Author > respondent**	**Author = respondent**	**Author = respondent**
6	*Visibility of author/ respondent identity*	**Strong**	**Weak**	**Strong**
7	*Tone of voice*	**Informal**	**Formal**	**Informal**

We define "identity" as a user's real name/credentials or as a persistent online pseudonym.

Blogs

A blog (an abbreviation for "web log") is a website that facilitates individual expression using a one-to-many publication model, in which a single author creates entries that any number of readers can access (attribute 1) [4]. Blog software displays entries in reverse chronological order (i.e. most recent at the top) (attribute 2). In a blog, a response is called a "comment" and consists of a text reply and respondent's name. Comments are appended to entries and do not replace the original content of the entry (attribute 3). Knowledge, the interpreted understanding of information, is fragmented across the various entries and responses; blogs lack a formal structure for the synthesis of information contributed over time (attribute 4). The blog interface places greater emphasis on the author's entry than the respondents' comments (attribute 5). For example, the interfaces for commenting often have fewer options compared to the interface for writing original entries. Comments frequently are displayed with a smaller font and sometimes are visible only by visiting a page separate from the main page of entries. Furthermore, the blog author has control over the privacy levels of the entries, and the author also has the ability to delete comments submitted by others. The identity of each individual contributor is visibly labeled for each entry and comment, except in the case where authors permit respondents to be anonymous (attribute 6). Related to the purpose of self-expression, the tone of voice in blogs is informal and spontaneous. Examples of existing health care related blogs include physicians and medical students sharing experiences and discussing clinical topics [5, 6], as well as patients updating family, friends, and/or the general public about treatment, recovery, and healthcare experiences [7].

Discussion forums

A discussion forum is a website that facilitates group dialog using a many-to-many publication model; each user can author entries that any number of readers can access (attribute 1). When an author creates an entry, called a "topic," the intent is for dialog to occur on a subject specified by the author. Users freely respond to the topics of their interest. The discussion forum interface lists topic subject lines together on one page, separating the dialog of each topic to individually accessible sub-pages. Forums also can include hierarchical categories and sub-forums akin to folders in a file system for organizing topics (attribute 2). Each topic page displays responses in chronological order (i.e. most recent at the bottom), such that new responses are appended to existing ones (attribute 3). Despite the topical and chronological arrangement, knowledge still can be fragmented across entries and responses over time (attribute 4). The typical discussion forum interface provides the same formatting for all responses in a topic so that all appear equal. Additionally, the creator of a topic and all respondents have the same abilities to include text, images, and other media when they contribute content (attribute 5). The discussion forum interface displays a user's identity alongside each topic or response he or she contributes (attribute 6). The tone of voice in forums is informal and conversational, often with the use of the first-person speaking voice (attribute 7). Discussion forums are a mature technology, and healthcare researchers have studied them extensively in terms of online social support for cancer patients and other purposes [8].

Wikis

A wiki is a website that facilitates document creation using a many-to-many publication model; any user can be an author by creating entries that any number of users can view (attribute 1). In a wiki, an entry is the creation of a page about a specific topic (attribute 2), and a response is modification to an existing entry (attribute 3). Wiki entries can link to other entries, as well as to other web resources. Because an entry's content is updated and/or replaced with new information, knowledge pertaining to a given topic is continually synthesized and displayed in a single cohesive document (attribute 4). The wiki interface provides no easily visible connection between individuals and their contributions (attribute 6). The interface also de-emphasizes any distinction between the original author and the respondents in favor of stressing the entry's content (attribute 5). Because the purpose of a wiki is to create documents, authors and respondents tend to write in a formal tone (attribute 7). Examples of healthcare wikis include Wikicancer, a social support resource for cancer patients and their families [9], and Clinfowiki, a growing

encyclopedia of medical informatics concepts sponsored by the Informatics Review [10].

Case studies

The authors present two case studies that demonstrate a systematic approach to analyzing the design of clinical information systems in terms of the attributes defined in Table 1. The first case study evaluates a "problem list" in an electronic medical record, and the second assesses online social support for cancer survivors.

"Problem list" in an electronic medical record

StarPanel, a web-based electronic medical record (EMR) developed at Vanderbilt University, contains a "problem list" for quick viewing (Figure 1) and/or updating (Figure 2) of a patient's current diagnosis, medications, and related clinical information [11]. Many aspects of the problem list resemble a wiki. All providers can create and access the problem list content (attribute 1), as well as modify the information (attribute 3). The interface presents information by clinical topic—"significant medical conditions, significant procedures, allergies and drug reactions, current medications, health maintenance, social and family history" (attribute 2) [11]. An advantage of this system attribute is that information stored by topic in discrete fields can be reused in other parts of the EMR [11]. Only the most recent version of the list is displayed; the chronology of individual updates is not immediately visible, although the user can access the previous versions of the problem list to look for changes. The interface provides a single, patient-centered source for quick access to the most recent and most relevant clinical information (attribute 4). The original author's entries are not presented differently from or emphasized more or less than each respondents' changes, although the most recent respondent is highlighted at the top of the page (attribute 5). The interface does not clearly identify each provider's contributions to the problem list (attribute 6), which may interfere with the ability of providers' to coordinate care. This example of clinical documentation features a tone of voice that is straightforward, objective, and formal (attribute 7). However, the tone of voice in the text can also be considered informal due to sentence fragments and piecemeal thoughts, which make the entry somewhat more blog-like (attribute 7).

This case study illustrates how the proposed attributes can be used explicitly to evaluate a clinical information system. For the most part, the StarPanel problem list has the attributes of a wiki. A disadvantage of the current implementation is that users cannot easily determine the individuals who contribute specific parts of the problem list. As personal health records and patient portal systems begin to give patients the ability to update portions of their own medical records, the system interface must clearly display the identity and role of the person responsible for each specific update. Rather than viewing this complication as a reason against using a wiki-based approach for the problem list, one can instead determine which of the wiki-like attributes is problematic. Simply switching to a discussion forum or blog model would not be satisfactory because this shift might alter other attributes that reduce the effectiveness of the problem list. The developers therefore can focus on redesigning the application with respect to the visibility of a contributor's identity (attribute 6) rather than redesigning the entire interface.

The attributes defined in this paper do not offer a specific design solution for each problem, but the interfaces of existing blog and discussion forum software may provide inspiration for different ways to identify the author of a specific entry. Informaticians also can study wiki-like software to learn how these applications have addressed similar challenges. The proposed attributes should be used as an objective guide to support the subjective judgment of the developers and researchers in making design choices. A possible resolution for this problem list implementation might be to display the role of the individual who entered each item by displaying each portion of the text with different background colors that represent "primary care physician," "specialist," "nurse," and "care tech."

Figure 1 - Problem list view

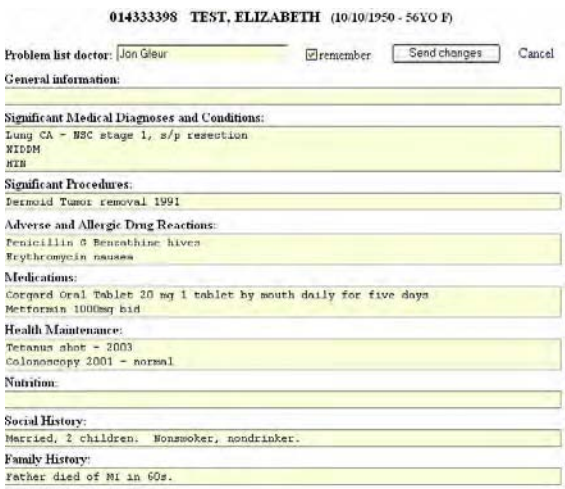

Figure 2 - Problem list edit

Case study: Online social support for cancer survivorship

An estimated 10 million individuals treated for cancer are living in the United States today [12]. Improving the qual-

ity of life of these individuals currently is a clinical challenge and priority research goal [13]. The literature includes a growing number of studies that address the use of online cancer support groups by patients and/or their informal caregivers [14, 15]. Social support is a complex concept and includes dimensions of informational support as well as emotional support [16].

Online social support interventions in health care have focused on discussion forums, newsgroups, chat rooms, and email listservs [14]. Online support groups only recently are beginning to include online communication technologies with blog and wiki functionality [9, 17]. Cancer patients and caregivers have used discussion forum software to facilitate both informational and emotional social support. Messages in online cancer support groups often include the sharing of information, encouragement, humor, and prayer [18]. Researchers have not fully considered when discussion forums might or might not be the most appropriate asynchronous collaboration tool for online social support

Independently addressing each aspect of social support might better address the advantages and disadvantages of discussion forums, blogs, and wikis. Blogs may be a powerful interface for informal, personal expression related to cancer diagnosis and survivorship (i.e. emotional support). Additionally, blogs may be a good format for providers to inform patients of timely announcements, such as new clinical trials or fundraiser events (i.e. informational support), as they present information in a reverse chronological fashion (attribute 2). A discussion forum might be appropriate for the process of discussing information that involves a variety of opinions, such as advice on certain types of alternative treatments. However, the information and knowledge created through these discussions will be fragmented in messages over time. A wiki might be an appropriate tool for creating an information resource that summarizes the collective knowledge of cancer survivors, family, friends, and providers on certain topics [17], such as what to expect during the initial period following chemotherapy and radiation treatment [19]. Adjusting the interface to clarify the identity or role of the individual who contributes each part of the document could improve the credibility of the information, as discussed previously in terms of a collaborative problem list. These examples indicate that interactive health collaboration systems may need to offer a variety of communication technologies to facilitate both the emotional and informational social support needs of cancer survivors.

Discussion

Developers of clinical applications create interfaces that inherently have attributes representative of wikis, blogs, discussion forums, or some combination of the three. These choices will fundamentally affect the way in which providers and patients use health information systems [20]. For example, if a patient, her providers, and her family members can all update a personal health record, should entries by the patient be emphasized more than the others, or should the patient, doctors, and family members all be emphasized equally in the interface design? Different sets of attributes may be appropriate for different medical or social contexts. These choices have implications for patient-provider relationships, information ownership, information filtering, social support, and other socio-technical aspects of clinical care.

By breaking down each technology into its fundamental elements, developers can select the desired properties of blogs, wikis, and forums to create interfaces that better match the goals of certain information system components. Several authors have suggested that further research is needed on how communication tools can effectively work in parallel and how they can be combined to create new technologies [3, 21-23]. For example, a “bliki” is a term that describes the combination of blog and wiki functionality [21]. The attributes proposed in this paper represent a first step toward a formal method of generating new ideas for system design by combining specific properties of emerging web collaboration software. The method could apply to health care applications as well as web-based communication applications in other domains.

This study has limitations that warrant discussion. As seen in the evaluation concerning tone of voice in the problem list case study, it is not always clear which attribute value is the most appropriate description for a given interface. Further refinements to the attribute definitions by the authors and the informatics community will be needed. The attributes are based on the literature and the authors' personal involvement in design and use of web technologies, and experimentally validating the effectiveness of these definitions on existing software applications is planned for future studies. We have excluded podcasts, newsgroups, instant messaging, and other popular technologies from the current discussion because they do not meet our inclusion criteria of primarily text-based, asynchronous web-based software. Additional analysis should extend the attributes defined in Table 1 to address these technologies as well.

Conclusion

Formally analyzing the attributes of emerging web technologies will support the creation of improved design approaches for health communication. The authors define seven attributes for researchers and developers to use in the design and evaluation of clinical information systems. Two case studies illustrate the application of the proposed attributes to improve the coordination of clinical care and social support.

From Intermediation to Disintermediation and Apomediation: New Models for Consumers to Access and Assess the Credibility of Health Information in the Age of Web2.0

Gunther Eysenbach [a,b]

[a] *Department. Of Health Policy, Management, and Evaluation, University of Toronto, Canada*
[b] *Centre for Global eHealth Innovation, University Health Network, Toronto General Hospital, Toronto, Canada*

Abstract

This theoretical paper discusses the model that, as a result of the social process of disintermediation enabled by digital media, traditional intermediaries are replaced by what this author calls apomediaries, which are tools and peers standing by to guide consumers to trustworthy information, or adding credibility to information. For apomediation to be an attractive and successful model for consumers, the recipient has to reach a certain degree of maturity and autonomy. Different degrees of autonomy may explain differences in information seeking and credibility appraisal behaviours. It is hypothesized that in an apomediated environment, tools, influential peers and opinion leaders are the primary conveyors of trust and credibility. In this environment, apomediary credibility may become equally or more important than source credibility or even message credibility. It is suggested to use tools of network analysis to study the dynamics of apomediary credibility in a networked digital world. There are practical implications of the apomediation model for developers of consumer health websites which aspire to come across as "credible: Consumers need and want to be able to be co-creators of content, not merely be an audience who is broadcasted to. Web2.0 technology enables such sites. Engaging and credible Web sites are about building community and communities are built upon personal and social needs.

Keywords:

internet, consumer health informatics,
information quality, credibility

From disintermediation to "apomediation"

The debate on quality and credibility in the digital age is a result of a social process of disintermediation through digital technologies, and the health industry is no exception: Just as in many other areas of life (e.g., travel industry), information and communication technologies empower consumers and enable them to cut out the middleman or intermediary (travel agents, real estate agents, librarians, pharmacists, health professionals) to access pertinent information or services directly, whenever they need it and where they need it. For instance, on the Internet, consumers can now not only access an unprecedented amount of health information, but increasingly also personal information from their electronic health record [1]. With direct and convenient access to an abundant amount of health information on the Internet, consumers now bypass the expert intermediary and gain direct access to unfiltered information [2]. In this situation, consumers have to assume new responsibilities for assessing the credibility of the information, and intermediaries sometimes defend their role as "gatekeeper" using quality arguments.

As the role of "human" intermediaries diminishes or changes, consumers and patients are finding new ways to arrive at relevant and credible information. This can be human beings (peers) and/or technology (e.g., collaborative filtering tools).

In this paper, the author proposes to refer to these new intermediaries as "**apomediaries**", because they mediate without standing "in between" consumer and services or information. Rather, they "stand by" and provide added value from the outside, steering consumers to relevant and high-quality information without being a necessary requirement to obtain the information or service (Fig. 1). While intermediaries provide "upstream filtering", apomediaries enable and facilitate "downstream filtering" [3]. Apomediaries can help to navigate through the onslaught of information, give additional credibility cues, and provide metainformation. Examples for apomediaries are consumer ratings on Amazon or epinions, technologies like PICS or MedPICS labels and their semantic web successors [4;5] enabling the machine-processable dissemination of such ratings, collaborative filtering and recommender systems such as StumbleUpon.com, and other second generation (sometimes called Web 2.0) Internet-based services that let people collaborate and share information online in a new way - such as social networking sites, wikis, communication tools, and folksonomies.

Disintermediation not only takes place on a society level in health care and other industries, but there are also parallels to the individual emancipation process that takes place for example during puberty, when adolescents strive to become more autonomous and have the desire to reduce the influence of the intermediary (parents), with peers

(apomediaries) partly taking over the role of the former intermediary.

The disintermediation/apomediation model is useful because it allows us to analyze and discuss the implications of the disintermediation process at the societal level, for example for consumers of entire industries (ehealth), and to draw analogies to what is happening at the individual level during adolescence due to the emancipation process from traditional authorities and the use of digital media. These observations are free of judgment – it is not implied that the disintermediated / apomediated model is always better than the intermediated model. Rather, which model is "better" depends on the individual and the respective situations. In the following, the author will first discuss general implications if disintermediation takes place, and will then consider credibility implications.

Table 1 - Dichotomies in the intermediation versus apomediation model.

Intermediation Model	**Apomediation Model**
Dependency–Paternalistic System–Acute Illness–Pre-adolescent Kids–Illiterate Consumers	Autonomy–Net–Chronic Illness–Adolescents–Literate Consumers
Traditional	Digital
Centralized	Highly Networked
Managed environment	Autonomy, emancipation
Dependence on Intermediaries (physicians, parents)	Guidance by Apomediaries (peers, Web 2.0 technology)
Credibility of Authorities/Experts	Credibility of Peers
Power held by intermediaries	Empowerment of consumers/youth
Source expertise = traditional credentials (seniority, professional degrees etc)	Source expertise = first-hand experience, peers
Message credibility: professional language, message "length is strength", comprehensiveness signifies expert status	Message credibility: Understandable language, "street cred"
Top-down	Bottom-up
More formal learning	More informal learning
Static hubs	Dynamic hubs
Source credibility more important than message credibility	Message credibility and credibility of apomediaries more important than source credibility

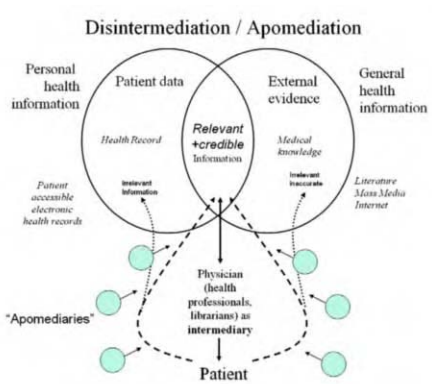

Figure 1 - Disintermediation and apomediation (circles = apomediaries assisting in "downstream filtering")

General implications of disintermediation

Decreased reliance on the intermediary

Disintermediation enabled or enhanced through technology changes the role of the recipient (consumer, patient, youth), who now has the choice to determine whether, when and how they choose to use the intermediary. The better informed the recipient is (or perceives to be), the better he knows what information or services he needs, the less likely he will need an intermediary. For example, a consumer with a chronic condition (e.g., diabetes) will have a greater knowledge and self-efficacy to critically appraise information found on the Internet than a consumer with an acute illness, and will not need an intermediary. Similarly, an older adolescent eager to learn about sexuality is less likely to rely on an intermediary such as a parent or teacher as filter than a younger child.

With increased literacy (including the ability to distinguish different types of information) and knowledge, i.e., when the receiver is knowledgeable about message content, the effects of source expertise will be attenuated, i.e., the credibility of "experts" and other authorities decreases [6], leading to an interesting positive feedback loop, where consumers learn to rely less and less on experts or intermediaries, preferring apomediation instead (Fig. 2). Again, there are parallels to what is happening during adolescence when youths learn to emancipate themselves from traditional authority figures.

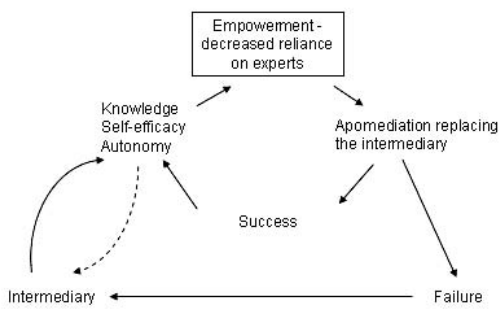

Figure 2 - Dynamic Disintermediation/Apomediation Model: Information is initially mediated and filtered by an intermediary. Once a critical threshold of knowledge, self-efficacy and autonomy is exceeded, apomediation can replace the traditional intermediary, while the recipient still has the option to choose the intermediary in case of failure.

Power shift

As a result of disintermediation, the power-relationship between recipient and intermediary changes. This may create conflicts. For instance, a significant minority of health care providers see their authority challenged, perceive a deterioration in the physician-patient relationship, and fear a negative impact on the quality of health care or health outcomes, although most embrace the shift from a paternalistic to a partnership model [2;7-12]. Parents may be equally irritated when the youths are searching for information on birth control on the Internet rather than discussing these issues with them or a physician.

Concerns have been expressed that more information does not necessarily translate into more knowledge or better

quality (self-)care, in particular as some of the quality and credibility of health information on the Internet clearly does not live up to professional standards. This view fails to recognize apomediation as an alternate mechanism to filter information.

Interestingly, the model presented above (Figure 1) also helps to explain some of the perceptions and frustrations intermediaries (health professionals, parents) often have with the disintermediation process, as they tend to see predominantly the "failures", for instance patients having found irrelevant information on the Internet.

Interpreting the message and filtering for relevance

It is interesting to note that when physicians express discontent about patients bringing stockpiles of "low quality" Internet printouts in the doctor's office, the primary complain is not so much the low quality or credibility of that information in an objective sense, but its *irrelevance* for the specific patient. In one survey 73.8% of General Practitioners said about this information that it was "accurate", and 65% of physicians even said the information was new to them, but many thought that the information often does not apply to that particular patients' condition – in the same survey, only 44.7% said the patient correctly interpreted information [13]. Another survey found that those providers who thought much of the information was often irrelevant also had a more negative view on how the patient-physician relationship was affected [11].

To what degree apomediaries actually succeed in the same way as intermediaries such as physicians or parents to filter information is largely an unexplored area. While there have been data on the "self-corrective" nature of digital media, to the effect that for example inaccurate statements on mailing-lists are corrected by peers [14], relatively little is known to what degree "apomediation" helps to filter *relevant* information and to contextualize information.

Credibility implications

The shift from intermediaries to what the author proposes to call apomediaries has implications for credibility constructs. Some credibility implications and research questions arising from the disintermediation/apomediation model are discussed in the following.

Explaining group and situational differences

Disintermediation usually means that people can, but must not use the intermediary, leading to groups of people who (or situations where people) continue to use intermediaries, trusting a more central authority, and others where people use apomediaries, relying on more decentralized, "networked" mechanisms to infer credibility (reputed, tabulated etc.). Reviewing audience factors in Web credibility research, Metzger [15] reminds us that "credibility is highly situational" and that "demographics, Internet use and reliance, and issue involvement have been found to influence perceptions of the credibility of Web-based information". The disintermediation/apomediation model hypothesizes that factors such as self-efficacy and perceived or desired autonomy (freedom from authority and capacity to make an informed decision) play a critical role in information seeking and credibility assessment behaviour. In other words, autonomous individuals are more likely to choose an apomediation model, and apomediation in turn increases autonomy. Navigation in the digital world requires and at the same time enables a high degree of *autonomy.*

As mentioned above, there are parallels between certain groups of consumers who prefer a more paternalistic patient-doctor relationship and pre-teen dependent children on one hand, and empowered consumers and teenagers striving for autonomy on the other hand. For example, a chronically ill patient is more autonomous than a traffic accident victim, and will be more likely to seek out information from peers. A pre-adolescence teenager is more dependent on parents and other authority figures than an older teenager, who deliberately seeks autonomy and questions authority – in this developmental stage, apomediaries such as peers and peer-to-peer technology gain in attractiveness and relevance.

Teenagers, people with chronic illnesses, educated people all share a common desire and capacity for autonomy, hence their credibility assessment heuristics are more on the right side of Table 1 above. On the other hand, younger kids, seniors, incapacitated people, people with acute diseases etc. are more likely to willingly submit themselves to a system in which they are dependent on intermediaries. The model proposed here theorizes that the desire for autonomy or perceived autonomy are predictors for differences in the interpretation of credibility cues (e.g., formal professional credentials versus "street cred") and differences in information seeking and verification behaviours, and explains differences between pre-Internet and Internet generation, information seeking strategies of chronic versus acute patients, pre-teens versus teens, and illiterate versus literate consumers.

What is argued here is that variables like *autonomy, self-efficacy and knowledge* (thought to be predictors for embracing disintermediation) are presumably correlated with *motivation* (issue involvement, including knowledge and personal relevance of some topic) and *ability* (e.g., cognitive abilities, literacy, time), which, according to the elaboration likelihood model (ELM) of persuasion [16], affect message processing and, thus, influence message effects and credibility judgments. The ELM theorizes that higher issue involvement (motivation) and ability (which together affect what is here called autonomy) will lead to more effortful processing of a message (central route to persuasion), while lower motivation and ability will favour a peripheral route, where environmental characteristics of the message, like the perceived credibility of the source, presentation, or the attractiveness of the source are the primary credibility cues. An extension of this model has been proposed (though not empirically tested) by Fogg and Teng, who hypothesize that people with lower motivation and ability (those who are persuaded through a peripheral route) are more likely to adopt a binary evaluation strategy (credible or not credible), whereas people with higher motivation and ability employ a spectral evaluation strategy [17]. Thus, if we accept that in

most cases autonomy is highly correlated with general motivation and ability, and if we accept that these variables also predict whether or not somebody chooses to emancipate themselves from a gatekeeper, and if we believe the predictions made by the ELM and its extensions, then the line of argument presented above becomes clear.

Boosting credibility through disintermediation

"Direct", unmediated information is often is perceived as more credible because with "greater apparent mediation comes greater opportunity to impute motives and intentions of the communicator" [18], which is one of the most cited reason for why (live) television is perceived as more credible than newspapers [15]. In other words, disintermediation has the potential to increase the credibility of information. This is particularly true the health care field, where many consumers have a "healthy" (and sometimes not completely unjustified) mistrust in a system where doctors are paid per service, and where payers are under considerable cost-pressures leading to a perceived rationing of publicly available services. In addition, many consumers view the traditional health care system as being biased against alternative medicines [19], as health care professionals are incentivized to offer expensive therapies for which they are reimbursed more generously, as opposed to therapies which are "natural" but for which they cannot charge much. Such mistrust creates the desire to bypass the intermediary, and boosts trust in information which can be received without intermediaries.

While youths will rarely rationalize their mistrust against traditional intermediaries in a similar way, questioning and mistrusting traditional authorities is a natural part of adolescence, and information mediated through traditional authorities is often perceived as biased.

Reinstating trust in the intermediary

It can also be hypothesized that transparency confirms the trustworthiness of intermediaries who "step aside" allowing and perhaps even facilitating direct access to information and transparency. In other words, once disintermediation has taken place, disintermediation has the potential to reinstate trust back to the intermediary if information provided through more direct channels proofs to confirm the information the intermediary used to provide. For example, health professionals who allow and actively encourage patients to access their own electronic health records help to reinstall patients' trust in the medical system. If however the information now obtained from other channels is perceived to contradict information from the former intermediary, then the trust-relationship will be undermined. For example, youth accessing information on issues of sexuality through the Internet will loose trust in parents and teachers if this information contradicts the information these intermediaries have provided.

Experiential credibility

While traditional wisdom from credibility research suggests that perceived "accuracy" is a hallmark for message credibility [15], it would be a mistake to assume that "accuracy" means evidence-based information based on scientific studies and that evidence-based information based on research would automatically have more credibility for consumers than anecdotes. In a focus group analysis with patients using evidence-based health information, Glenton and colleagues found that "participants described how they often made treatment decisions in a context of great pain and despair. Under such circumstances, they often had little energy to seek out written information and were sometimes too desperate to care what the research might have to say. Instead, they often gathered information about treatments through the personal anecdotes of friends and neighbors, and, in most cases, this experience-based information was considered to be more relevant than the evidence-based information" [19]. Not only is experiential information from apomediaries and peers more *relevant* for patients, it is hypothesized here that it often is also more or at least equally credible as information based on research.

Similarly. the notion of "source expertise" as being communicated primarily "through the comprehensiveness of a web site's information, its professionalism, and its sponsor's credentials" [15] is questionable in the health care context and perhaps in many other apomediated environments used by "autonomous" individuals. Here, "expertise" is not only expressed by credentials such as professional degrees and qualifications, but also first-hand experience. *Experience-based credibility* can be seen as one additional dimension of source credibility. Past research has identified that similarity in attitudes with the speaker as well as liking positively influences credibility perceptions. What might be added is that similarity of *experiences* (in the health care context: similarity of symptoms, diagnoses etc.) adds to credibility perceptions. In the context of youth, this is expressed by the term "*street cred*", which has been defined as "commanding a level of respect in an urban environment due to *experience* in or knowledge of issues affecting those environments" [20].

Applying network theory to apomediaries: credibility hubs

Apomediaries can be seen as highly complex networks of individuals and tools guiding consumers to credible information. While "networked" tools are often seen as a more equitable, democratic structure (as opposed to a system with intermediaries, who hold most of the power), network theory [21] teaches us that credibility networks are scale-free networks, where a rich-gets-richer phenomenon leads to the emergence of highly influential hubs, which in our context could be called *credibility hubs*. That is, not all apomediaries are equal, there are some apomediaries which have more influence than others. In the networked, apomediated model, some "nodes" (players or tools) become (or cease to be) credibility hubs in a more dynamic and fluid fashion than in the traditional model, where there is usually one intermediary whose credibility is influential and relatively stable.

In a "networked credibility" model with apomediaries as nodes, former intermediaries do not disappear completely, they are just one of many apomediaries, with a seemingly equal chance of becoming a "credibility hub", but in reality, they are more connected and have a better chance in ending up as a credibility hub,

For instance, a professional medical organization has a pre-existing social network which leads to other organizations linking to their website, leading that website to appear on top of Google, leading to more people linking to it, etc.

An interesting psychological phenomenon is that people attribute statements they believe to credible sources. For example, participants of an experiment who were exposed to a statement many times (and hence believed it) were more likely to attribute it to Consumer Reports (a credible source) than to the National Enquirer (a not so credible source) [22]. Such mechanisms may further increase the trustworthiness of credible sources, leading to a further rich-gets-richer phenomenon.

Conclusion

This paper discusses the idea that as a result of disintermediation, traditional intermediaries are replaced by what this author calls apomediaries, which are tools and peers standing by to guide consumers to trustworthy information, or adding credibility to information. It is hypothesized that in such an environment, tools, influential peers and opinion leaders are the primary conveyors of trust and credibility. In this environment, *apomediary credibility* may become equally or more important than source credibility or even message credibility. It is suggested to use tools of network analysis to study the dynamics of apomediaries in a networked digital world.

There are practical implications of the apomediation model for developers of digital media such as websites for consumers. Governments and other "authorities" – while certainly having credibility due to brand name recognition - do not typically do a very good job of creating "credible" Web sites – they always look and sound like government Web sites, and they lack the "edge" and the "street cred" that consumers and in particular youths are looking for to keep them engaged.

Good Web sites allow consumers to share their voices and connect with others in a safe, positive, supportive, possibly moderated, online community. Consumers need and want to be able to be co-creators of content, not merely be an audience who is broadcasted to. Engaging and credible Web sites are about building community and communities are built upon personal and social needs.

Abstract

Rising concern over the poor state of chronic disease management led to the user-informed design and development of a home tele-monitoring system. Focus groups with patients and primary care providers guided the research team towards a design that would accommodate the workflow and concerns of the healthcare providers and the low use and comfort with technology found among the patient population. The system was trialed in a before-and-after pilot study of 34 patients with diabetes and hypertension. Findings demonstrate a significant improvement in systolic and diastolic blood pressure. An RCT beginning in 2007 is being conducted to confirm these findings. It is hypothesized that this user-centred approach, utilizing focus groups, iterative design and human factors methods of evaluation, will lead to the next-generation of home tele-monitoring applications that are more intuitive, less cumbersome, and ultimately bring about greater patient compliance and better physician management.

blood glucose self-Monitoring, self care, mobile phone, computers, handheld

Introduction

Chronic disease presents a growing challenge to the health and social care systems around the world. In 2005, chronic diseases accounted for 72% of the total global burden of disease in the population 30 years and older. [1]

Although many chronic conditions are preventable or can be controlled with proper treatment, evidence is mounting that current chronic disease management practices are falling short. The prevalence of type-II diabetes is expected to rise to 4.4% of the worldwide population by 2030, for a total of approximately 366 million people globally. [2] Additionally, 40-50% of type II diabetics also have hypertension, which confers a 2 to 3-fold increase in the risk of morbidity and mortality for diabetics, and is a major risk factor for both renal and cardiovascular disease (CVD). [3-5] Despite being treatable, less than 15% of these patients have reached the widely accepted goal of 130/80 mmHg. [4, 6]

This research discusses the development and testing of a novel approach to tele-monitoring for improved chronic disease management. The primary objective of this study was to determine if a hypertension tele-monitoring support system, designed to enhance patients' self-management and provide reliable information to clinicians for decision-making, will markedly improve blood pressure control in a primary care setting.

A user-centric design approach was taken to the development of a mobile phone based remote patient monitoring system for the control of hypertension in type II diabetics. The system was developed (Phase I) using affordable devices and iterative gathering of user feedback to ensure high usability and low disruption to lifestyle and workflow of patients and providers.

The system concept would start with the regular home monitoring of blood pressure (BP) by the patient. BP readings would then be automatically transmitted by a mobile phone to the central data repository. A clinical rules engine would then check the data and the patient and family physician would be notified if the readings were outside of the desired range for a period of time. Given this alerting, the system would theoretically facilitate timelier follow-up of the patient's care. Additionally, the availability of the home monitored data at patient visits may provide more information for assessing the patient's condition.

A pilot demonstration (Phase II) was undertaken to determine whether the system lowers the risk of dangerous complications for diabetic patients with high blood pressure. The study outcome was measured by assessing change in the measured blood pressure of study subjects.

Phase I - Requirements Gathering and Design

Methods

Before any development of the system began, a consultative phase was initiated to investigate the problems with the existing management of hypertension in diabetics and gather patient/physician impressions of the system concept. From these sessions, conclusions were drawn to inform iterations of the system development.

Two sets of focus groups were held. The patient set consisted of 24 type-II diabetics with hypertension, interviewed in small groups in one of four focus group sessions. The physician set consisted of 18 family physicians, also interviewed in small groups in one of four focus group sessions.

Results

Patient reaction to the concept was generally favourable, with patients showing a high regard and interest for the self-care aspects of the proposed system. Although patients were interested and intrigued by the use of a mobile device for the transmission of their BP data, they appeared to be more comfortable and familiar with the use of a mobile phone than a PDA. Surprisingly, there was little concern towards the security of the proposed electronic transmission of personal medical data. An additional significant finding from this group was that their level of Internet use was below expected. Although many had used the Internet in the past, their current use would be described as infrequent and simplistic, such as the occasional email. Many accessed the Internet through a proxy, such as a family member. These findings resulted in significant changes in the planned design of the system architecture.

The physician findings were in contrast to that of the patient group. Physicians were skeptical that patients would adhere to regular measurements of BP. Their most serious concerns were around compensation and disruption of workflow. There was concern that they would be accountable to address alerts in a timely fashion. As well, they would not be compensated for their work related to addressing alerts and reports, since it was not tied to a face-to-face patient visit. Physicians insisted that the reporting of data be tied to a patient visit. Like the patient group, physician use of computers and the Internet in the office setting was minimal and could not be seen as a means to communicate patient reports or alerts.

Design principles

Based on the findings of the study groups, the following design principles were formed:

- Personal computers are not to be used for information input, retrieval, or review by patient or physician.
- Phone and fax are the only means available to disseminate alerts and reports to physicians.
- The mobile phone or PDA is the information hub for the patient with the following considerations:
  - Data gathering will require no user-intervention.
  - User interface will consider visual and physical impairments.
  - User interface will consider limited or no previous knowledge of the operation of a mobile device.
  - Messages to the patient will be in lay terms.
  - Communication is secured via SSL connection to signed client-server applications.
  - Messaging to the patient will not be done via SMS due to usability problems. Messaging will be done via the client application, or by automated voice messages sent to the patient's home phone.

The strict adherence to these principles in order to simplify the use of the system for the end-user made the development and implementation more complex. The description of the realized system follows.

System overview

Bluetooth-enabled medical devices (BP monitor, weight scale and glucometer) are used to transmit physiological data automatically to a mobile phone. A custom application running on the mobile phone acts as a personal medical diary of the patient's test history. The application also relays data securely back to a central data repository where clinical rules are applied and alerts generated. These alerts are sent to the patient's physician by fax (in the absence of any other electronic means of communication) and to the patient by automated text and phone messages. The system is designed to remind patients by text and voice message to take their home readings if they fail to adhere to the prescribed schedule.

From the patient's point of view, the measurement of their BP is as before, with no additional steps needed for the transmission of data. The original design goal of the system was to be as unobtrusive as possible, and to require no manual intervention on the part of the patient. If desired, the patient can simply plug the mobile phone into an electric outlet to maintain battery charge and leave it unattended as it automatically relays data back to the central repository. More technically inclined patients can use the diary and reporting features of the device to review all previous measurements taken in the home, summary reports, or view a graph of historical trends in their data. Since all device interaction is optional (beyond the standard measurement procedure), no technical acumen is required of patients in order to benefit from this system.

Technical architecture

The monitoring system consists of three main components; the patient components, the back end data repository and decision support system, and the alerting and physician-

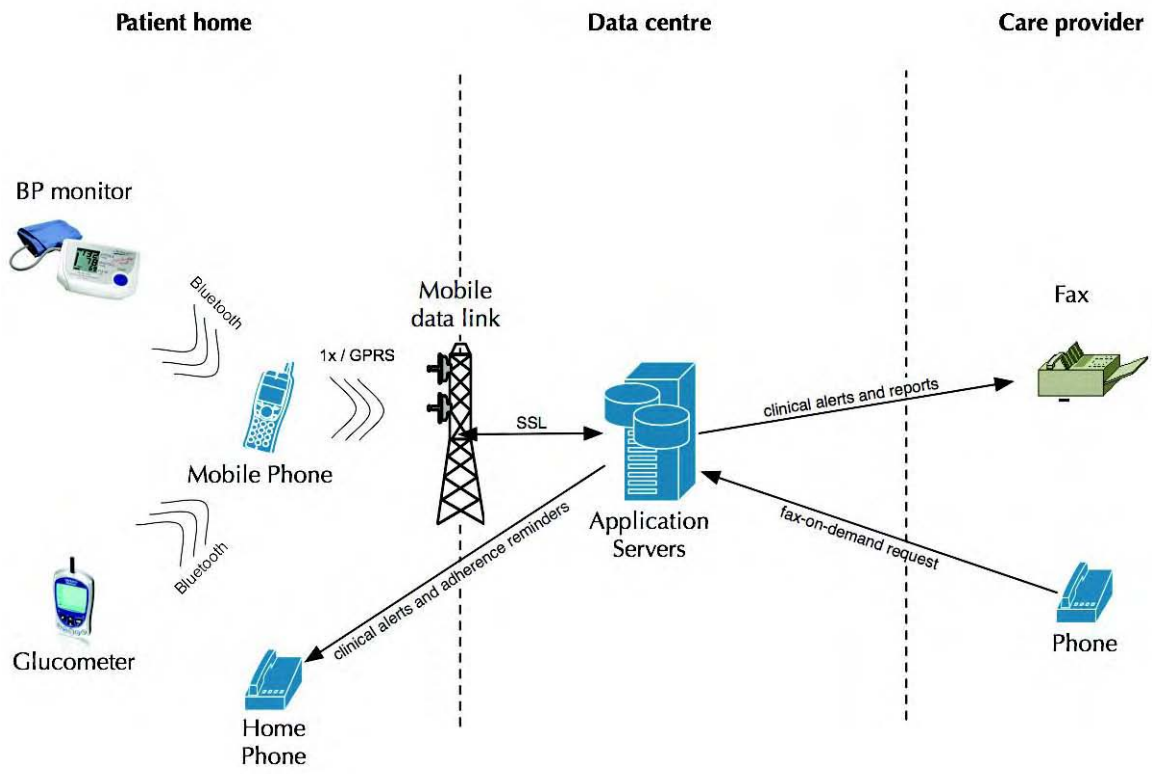

Figure 1 - Mobile Phone Based Remote Patient Monitoring System

reporting component. The data flow between these components is shown in Figure 1.

The patient component of the system comprises the medical devices themselves and the mobile phone used to relay results to the server. There is also an interface for patients to review previous readings on the device itself, in tabular, graph, and summary formats (see Figure 2). Progress messages are sent from the central server onto the mobile device after every reading, allowing for reminders and other coaching messages to be delivered automatically to the patient.

Figure 2 - BP Client Application

The back end of the system comprises a web based server application, which gathers results from client devices, a database to store the results, and a set of clinical rules, which are applied to the data as it arrives. These rules trigger events handled by the alerting and reporting component of the system.

The alerting and reporting system provides secure web, email, voice, and fax gateways into the data stored for each patient. Certain conditions (such as non-adherence to scheduled measurements) may trigger alerts to be sent to the patient via an automated telephone message to the patient's home phone number. The thresholds for these alerts can be set by the physician, on a patient-by-patient basis. Physicians can also request a fax (via an interactive telephone system) of the patient's readings to date displaying averaged readings over the past 30 days, as well as a chart of the patient's historical data measurements. These are also available online for providers who prefer to use the web for reviewing patient information.

As substantial portions of the monitoring system operate in an uncontrolled environment, measures to ensure the confidentiality of patient data were a paramount concern in the design of the system. The initial transmission of data from the measurement device to the mobile phone is done via Bluetooth, providing strong encryption of patient data during transmission, and also ensuring the authenticity of received data. Data stored on the mobile phone has no readily individually identifiable information stored with it,

as results are only tied to a specific patient at the server. This mapping associates patients to the unique numeric Bluetooth ID of the patient's medical device, and is known only to the system server. Nonetheless, in the event a device is lost or misplaced, a 'kill' message can be sent to the device from the server, causing all stored data to be permanently deleted from the device. Data is sent from the mobile device to the server via a secured SSL web connection, providing an industry standard level of confidentiality in addition to the security offered by the underlying cellular network.

Use of the interactive telephone system to request a fax report requires the physician or patient to input a valid numeric user id and password. The information is validated and authenticated against the information in the database before access is granted to the patient record. Fax-based transmission of patient results is only permitted to pre-programmed physician office fax numbers.

Phase II - Pilot study

Methods

A thirty-patient trial of diabetic patients with hypertension in the Toronto area began in December 2005 and concluded in November 2006. Patients monitored their blood pressure at home for four months using the aforementioned system. Patients had mandatory visits with their physician at baseline, two and four months. (Other visits may have taken place due to patient health factors and/or the alerting system requesting that the patient go see the doctor because of elevated hyper or hypo-tension.)

Main outcome measures of this pilot study are changes in BP compared to pre-trial baseline measurements, patient adherence, and technical and clinical feasibility of the system.

Results

Shown in Table 1 are the results. Significant results were found in all cases.

Table 1- Pre and post trial, ambulatory (24hr) and 2-week home measurement averages

	Pre (SD)	**Post** (SD)	**N**	*P*
$Systolic_{24hr}$	**143.3** (14.05)	**133.3** (12.56)	27	0.001
$Diastolic_{24hr}$	**81.4** (10.74)	**76.2** (10.70)	27	0.000
$Systolic_{2wk}$	**140.8** (16.50)	**131.8** (13.88)	32	0.001
$Diastolic_{2wk}$	**81.7** (11.70)	**78.3** (10.40)	32	0.006

Of the 34 patients that were enrolled in the study, 32 remained at the end of the four-month trial. One physician withdrew their patient, and another patient withdrew due to a confounding health problem that affected their ability to home monitor.

Discussion

The first outcome measure looked at pre and post trial ambulatory and 2-week home blood pressure averages. In both cases the results were significant. Ambulatory monitoring is currently the gold standard for measuring blood pressure, and the study patients experienced an average improvement of 10 mmHg systolic and 5 mmHg diastolic. These results show great promise as the health benefits of lowering BP in a diabetic population are well documented. [7-9] However, this was only a pilot study with 30 patients, a full clinical trial is required in order to confirm the generalizability of these results. (see "Current and Future work")

The second outcome measure was patient adherence. The success in adherence experienced in the pilot may be partially attributable to the automated phone calls to the patient's home, reminding them to continue to monitor. These phone messages were generated by the system when it was detected that the patient was not regularly monitoring their BP. The upcoming clinical trial will investigate the affect of these alerts on adherence. A comparison of the intervention group with the control arm of the study will demonstrate if adherence drops off without the adherence reminders.

Finally, the study demonstrated the technical feasibility and readiness of available and affordable technology to be applied for the purpose of home tele-monitoring (outcome measure three). Patients with the technology encountered only minor problems. Certain features of the mobile phone proved to be a challenge for some users with low dexterity or visual impairments. The small joystick for navigating on-screen menus, and the narrow power button were features that caused frustration. Additionally some patients had trouble viewing the screen when the backlight was off. The fax-back system proved to be a simple and efficacious method of providing data to the family physician, without changing their workflows significantly.

Current and future studies

An additional thirty-patient trial in the northern Ontario community of Chapleau began in July 2006 and adds glucometry in addition to home blood pressure measurement. The care model also differs in Chapleau. A nurse practitioner is the main primary care provider for diabetics in the area. Based in the local hospital, staff members have easy access to computers in the clinic, and prefer a workflow model where records and alerts are retrieved through a PC, rather than fax. A web-based application to accommodates this workflow, displays all data, reports and alerts, as well as allows patient parameters to be adjusted, such as measuring frequency, BP and glucose goals, and alert thresholds.

A randomized controlled trial (RCT) will be conducted in the greater Toronto area beginning in 2007. The control group will perform regular home monitoring of blood pressure, and the intervention group will utilize the tele-monitoring system.

Conclusions

The intent of a user-centric approach was to lead to the development of a system that was more intuitive, less cumbersome, and would ultimately bring about greater patient compliance and better physician management. The intent is to demonstrate a technology that is applicable to a wide variety of chronic diseases and conditions such as congestive heart failure and asthma and builds on the demand for new and more effective ways to improve chronic disease management. A secondary benefit of this study is the validation of the use of commodity hardware, which promises to provide significant cost savings in the delivery of the management tool.

Results from the pilot study indicate the potential efficacy of the system at reducing hypertension, which we will attempt to confirm in an RCT.

Acknowledgments

This research was funded through the Primary Care Health Transition Fund of the Ministry of Health and Long Term Care of Ontario. The clinical trial in Chapleau, Ontario is funded through Project Chapleau, a joint initiative of Bell Canada and Nortel to research the impact of advanced technology on rural and dispersed communities. The RCT is funded by the Heart and Stroke Foundation of Canada.

Abstract

For improving quality and efficiency of health delivery under the well-known burdens, the health service paradigm has to change from organization-centered over process-controlled to personal health. The growing complexity of highly distributed and fully integrated healthcare settings can only be managed through an advanced architectural approach, which has to include all dimensions of personal health. Here, ICT, medicine, biomedical engineering, bioinformatics and genomics, legal and administrative aspects, terminology and ontology have to be mentioned. The Generic Component Model allows for different domains' concept representation and aggregation. Framework, requirements, methodology and process design possibilities for such a future-proof and meanwhile practically demonstrated approach are discussed in detail. The deployment of the Generic Component Model and the concept representation to biomedical engineering aspects of eHealth are touched upon as essential issues.

Keywords:

Personal health; system architecture; Generic Component Model; biomedical devices

Introduction

Healthcare systems in industrialized countries, and increasingly those in countries in transition, are faced with the challenge of ensuring efficient and high quality care independently of time, location and local resources, utilizing advanced knowledge and technologies. This challenge must be realized despite demographic developments, the growth of multi-morbidity, demands for health services and expenditures for diagnostic and therapeutic procedures, and decreasing contributions to health insurance funds. To meet this challenge, the systems have been changing from an organization-centered towards a process-controlled care paradigm, which is also called shared care, managed care or disease management. This development is combined with extended cross-organizational communication and cooperation between all of the healthcare establishments involved in patient care. This process has to be supported by deploying advanced information and communication technologies (ICT) in health, connecting primary and secondary care. Regarding the need for prevention and the integration of social care in an aging society (addressing citizens before becoming patients, and so moving the focus from healthcare to health) this process-controlled strategy is no longer sufficient. Health, nowadays provided by organizations such as hospitals, primary care offices, policlinics or medical centers as well as, has to move closer to the citizens' environment.

Observing the citizens' health status, context and conditions for providing person-centered (personalized) and dedicated health services implies the need for a new health paradigm: *personal care*, which completely integrates all of the *principals* involved in the care process. According to the definition of the Object Management Group principals are any actors in the domain in question such as persons, organizations, systems, devices, applications, components or even single objects. This does not mean that there will no loner be acute care and ambulant service, but that such services will be tailored to relevant personal care needs,.

Materials and methods

To realize patient care at any location in an individualized way, three technological paradigms have to be managed: mobile computing, pervasive computing and autonomous computing (Figure 1). Mobile computing enables the permanent accessibility of the principals involved, providing, for example, teleconsultation services. Pervasive computing allows for location-independent service provision, established as telemedicine services. For providing personalized care, services have to be flexible and cannot be rigidly predefined. Such adaptive

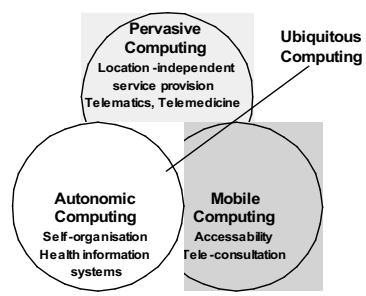

Figure 1 – Computing paradigms deployed in the personal care context (after Kirn and Müller (2005), changed [1])

health information system design, towards a self-organizing environment, draws on current challenges in the research and development for autonomous computing.

Another aspect which is characteristic for personal health (pHealth) concerns the distance between the physical and the informational world. In the traditional ICT environment, this gap is mediated through human users. Introducing advanced technologies, this gap is getting closer to the real integration of the health subject (patient) in the health system, and even becoming a part of the information system environment (Figure 2).

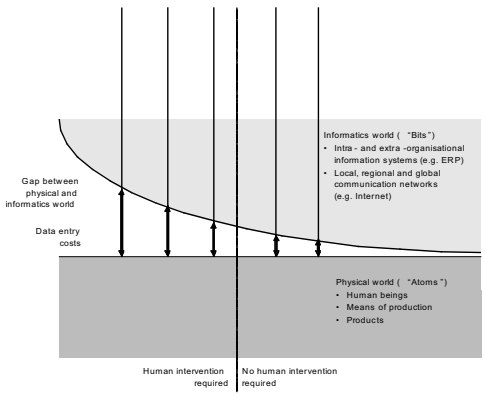

Figure 2 - Closing the gap between physical and informational world (after Kirn and Müller (2005), changed [1])

The process to be supported has to be properly described, abstracting from reality by using appropriate grammars for modeling it. A model is a partial representation of reality. It is restricted to attributes the modeler is interested in. Defining the pragmatic aspect of a model, the interest depends upon the intended audience and the reason and the purpose for modeling the reality. The resulting model is used for a certain purpose and time as a proxy for reality. Therefore, the model (which is the result of an interpretation) must be interpreted itself.

The simplification of systems through formal models can be provided in three dimensions according to the Generic Component Model [2] (Figure 3). The first level of simplification concerns the restriction to the domain of interest. Examples for such domains are the medical domain, administrative domain, technical domain, legal domain, etc. Within this domain, the system considered can be decomposed or composed for analyzing or designing it. This results in different levels of granularity or complexity, respectively, using specialization or generalization relationships. In the Generic Component Model, the following granularity levels have been derived: business concepts, relations network, basic services/functions and basic concepts. The third dimension of a generic system architecture touches different aspects of the system according to the ISO Reference Model – Open Distributed Processing [3]. Here, the business process is expressed by the Enterprise View, the informational expression of this process is expressed by the Information View and the functional aggregation of algorithms and services is expressed by the Computational View. These are described through platform independent models of the system expressing the system's logical content. Platform-specific implementation details are described by the Engineering View, and the Technology View represents technology (or implementation) aspects. The system's architecture (i.e. the system's components, their functions and relationships) is characterized through the components' concepts and their aggregations. The representation of concepts and association rules is provided by constraint models, which are derived from reference models.

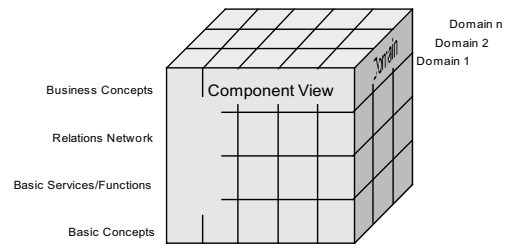

Figure 3 - The Generic Component Model [4]

The resulting pHealth information system is characterized by openness, flexibility, scalability, portability, user friendliness and user acceptance, service orientation, distribution at Internet level, being based on standards, semantic interoperability, lawfulness and trustworthiness. Organizational, contextual, rule-related or other constraining aspects of the system and its components are expressed by binding policies to the components and by ruling the component aggregation by policies .

Following the Generic Component Model approach, the pHealth information system architecture needs to combine the following paradigms: distribution; component-orientation; separation of platform-independent and platform-specific modeling, i.e. separation of logical and technological views; specification of reference and domain models at meta-level; interoperability at service level (concepts, contexts, knowledge); enterprise view driven process-controlled design; multi-tier architecture; appropriate multimedia GUIs; common terminology and ontology; unified design, development and deployment process; trustworthiness provided by appropriate security and privacy services, all as an integrated part of the design.

Results

The architectural approach of the Generic Component Model has to be applied for pHealth information systems covering health telematics aspects, telemedicine concepts, biomedical engineering solutions and bioinformatics problems in a harmonized way.

The knowledge representation is performed using meta-languages. For ensuring semantic interoperability, reference terminologies and ontologies have to be defined, using the aforementioned methods for knowledge representation in the Generic Component Model's context.

In this way, different systems deploying different modalities, belonging to different domains and different business areas, using different domain languages, can be harmonized and bound to policies. From this modeling, the specification of invocation calls and the development of XML messages can be derived as is shown in [5]. The connection of biomedical devices for patient monitoring and care is provided using the CEN ISO/IEEE 11073 standards set (which is based on ENV 13734/13735 "VITAL" and IEEE 1073-x) [6] as well as CLSI (formerly NCCLS) POCT-1A [7]. Thereby, biomedical devices can be aggregated and replaced like any other component. This is especially true for future mobile, modular, personal systems for individually caring patients. Such systems can be deployed in clinical settings and in homecare. In that way, a patient's transfer between both settings can be facilitated. Typical system components, at different levels of development and accentuation, are:

- Highly integrated sensor and human-machine interface components at the body or wearable in clothing (e.g. intelligent wireless sensors; wearable devices; PDAs);
- Components and infrastructure enabling communication between the aforementioned systems and components on the one hand and stationary systems and services on the other (e.g. Body Area Network; mobile phone/mobile network; wireless LAN; workstation with gateway function in patient's home; appropriate middleware);
- Distributed functions for sensor signal processing, state recognition and state monitoring up to person- and situation-related information and interventions offered (e.g. qualified management of emergency calls; cumulated multi-parameter records, processing and presentation using PDA or workstation);
- Information and expert systems for recognizing and managing emergency cases, for informing the patient as well as decision support for healthcare professionals (e.g. localization of principals; access to reference data; person-specific support for interpretation of data, secure access to patient's personal information/Electronic Health Record).

The system functions must realize proper escalation strategies, while the system components next to the patient must be relatively autonomous to minimize communication and maintenance effort, energy consumption and, on the other hand, communicating autonomously with external stationary system components in certain cases (exceeding of thresholds, recognition of exceptional situations, emergency cases, alerts, but also for routine communication).

Advancing the modeling approach towards the Generic Component Model methodology, biomedical device components can be designed to provide the same structure and behavior as all other system components in the sense of adaptive, self-organizing systems. In the IHE Patient Care Device Technical Framework, the eHealth technology domain is considered to have defined structural and functional requirements for semantic interoperability. Starting with an ISO OSI based layered model, the interoperability requirements have been defined by ENV 13735 Health informatics – Interoperability of patient connected medical devices. This specification, combined with others, has been moved up to ISO/IEEE 11073 "Health informatics – Point-of-care medical device communication", e.g. defining the underlying medical package model (Figure 4). The containment tree consisting of Medical Device System, Virtual Medical Device, Channel, Metric and reflecting the granularity levels, as well as its combination with the process management aspect, are consistently in line with the Generic Component Model.

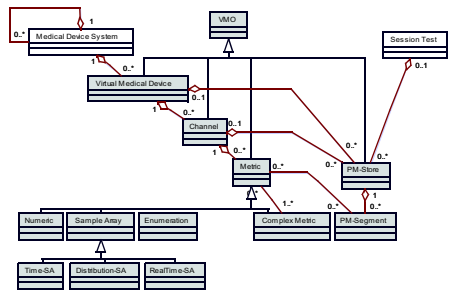

Figure 4- ISO/IEEE 11073 Medical package model

Some of the standards specifying the integration of medical devices in health information systems for enabling personal health systems, are presented in some detail below.

Standards for medical device interoperability

Unlike other clinical communication standards, the CEN ISO/IEEE 11073 family of standards provides real-time "plug-and-play" interoperability to facilitate the efficient adding and swapping of acute and continuing care devices, such as patient monitors, ventilators, infusion pumps, ECG devices, etc in critical environment settings.

To fulfill real-time requirements, a highly efficient "Medical Device Encoding" scheme is used. Conversion to alternative XML encoding reduces real-time capabilities, but enables use of XML-specific concepts and tools [8] promising dramatic cuts of development time and effort for interoperability component implementation. "Plug-and-play" practically means that all a clinician has to do is making the connection – the systems automatically detect, configure and communicate without any subsequent human interaction, maintaining both functional and semantic interoperability.

Health informatics and clinical communication standards are often generally interpreted as relating to ISO/OSI Level 7 based on the assumption of a generally available LAN-infrastructure to build upon. A prominent example for this approach is the HL7 communication standard

(appropriately named with a seven) [9]. For medical devices, interoperability explicitly implies all ISO/OSI Levels. While 11073 defines/modifies standards in ISO/OSI levels 7 – 5, it chiefly references other standards (such as 802.x, IrDA, Bluetooth, etc.) in levels 1 – 4.

For systems in homecare, and even more for mobile systems providing personal health services in dynamic environments, equivalent considerations apply. In order to enable functional interoperability using different (wired, IR and RF wireless) network technologies, CEN ISO/IEEE 11073 provides standards for internetworking in the 11073.5 branch of the 11073 standards family. In that context, the 11073 specification for "Agent Device", e.g. an infusion pump, pulse oximeter, or ventilator, and the corresponding 11073 specification for "Manager System" – a patient monitor or device manager shall be mentioned. Both are situated in different sub-networks using different network technologies. Other typical applications are wired-to-wireless transport gateways or LAN/IR access points. Based on CEN preparatory work [10], CEN ISO/IEEE 11073-60101 defines an 11073/HL7 "Observation Reporting interface" (ORI) enabling device-to-HIS-level interoperability. It is the first standard in the 11073.6 "Application Gateway" branch of the 11073 standards family which is intended to provide interoperability among different application protocols. The 11073 coding scheme has been a registered HL7 Coding Scheme since 2003, permitting its use in HL7 messages.

Body area networks

The Body Area Network (BAN) concept specifies wireless communication between several miniaturized, intelligent Body Sensor (or actuator) Units (BSU) and a single Body Central Unit (BCU) worn on the human body. It is characterized by a maximum range typical for human body dimensions, e.g. 2 meters. The BCU concentrates the BSU-originated data streams, performs intermediate storage and processing as well as communication to the outside world using standard wireless technology like DECT, WLAN or Bluetooth. The Network Access Unit (NAU) can be implemented as a medical gateway hosting an embedded web-server.

Both NAU and BCU provide standard interfaces, particularly implementing ISO/IEEE 11073 "Agent" functionality. From a communication perspective, a BAN can thus be regarded equivalent to an 11073-compliant modular medical device, implying semantic interoperability between BAN and remote professional or clinical systems.

IMEX – a micro-system perspective for interoperability

As the development of micro-sensors and micro-systems, particularly for homecare and pHealth-related applications, is progressing, the acquisition of multiple biosignals (for instance blood pressure (BP), ECG, respiration, urine flow) can be performed by means of miniaturized patient-worn equipment. Utilizing the BAN concept for collection and communication of data to enable multi-parameter monitoring, micro-sensors can also be integrated into BSU units.

The German IMEX project [11] aimed at communication between micro-systems and with external device systems, analyzing possible interfaces and their communication requirements. A Micro System Data format (MSD) was defined to enable the use of standard health telematics coding schemes for semantic core elements on the micro-system-level, minimizing the processing overhead for preparation of micro-system-generated data for external standard-based communication [12]. Thus the "semantic interoperability chain" is extended to the micro-system level. Figure 5 shows smart micro-systems as the other end of the healthcare interoperability chain.

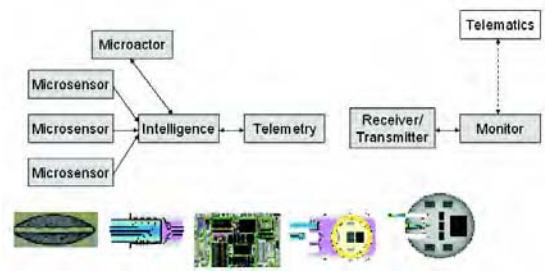

Figure 5 - Smart micro-systems as the other end of the healthcare interoperability chain

Specification and implementation process

To select the right components, aggregation rules and policies (in the broadest sense of the term policy: legal, social, organizational, ethical, functional and technical) in order to guarantee semantic interoperability, agreed constraints or profiles can be introduced similar to OMG's approach and similar to the process IHE is performing with its integration profiles.

For describing a unified process, the Rational Unified Process [13] or the HL7 Development Framework can be used. For domain-specific specializations, existing models such as HL7 Domain Message Information Models (D-MIMs), HL7 Refined Message Information Models (R-MIMs), HL7 Common Message Element Types (CMETs) [14], and also *open*EHR Archetypes [15] can be reused as demonstrated in [16]. Also other knowledge representation means can be deployed [17]. The future advanced eHealth architecture for individualized healthcare with region-crossing or European characteristics has been defined in the eHealth Action Plan of the European Commission and the EU Member States. The Electronic Health Record (EHR) is the core application of any eHealth platform; different countries are approaching this differently. The variants cover a medication file as starting point for eHealth in The Netherlands and the UK, the Sharable Record approach in Finland, right up to a comprehensive record architecture modeled and implemented within the national programme.

Discussion

Interoperability implies a number of different concepts, e.g. functional interoperability and internetworking, semantic interoperability and application gateways. Health information integration (eHealth) has established a demand for interoperability between clinical and health-care-related stakeholders, systems and processes or workflows. Domain-specific communication and interoperability standards are well established, but have to be supplemented for trans-domain use. Interoperability concepts for medical devices and for personal or mobile systems need to involve all 7 ISO/OSI reference model layers, more properly advanced to the Generic Component Model, including terminology/coding aspects.

The advanced concept of pHealth extends eHealth by the inclusion of smart sensors, body-worn mobile systems and situation-specific activation of applications and human health professionals, thus providing personalized ubiquitous health services. Body Area Networks and micro-systems are building blocks of future personalized health telematics infrastructures, and extend existing interoperability concepts. Another important eHealth pillar is the field of bioinformatics and genomics. As personal health requires personalized process models for optimal care, the underlying diagnosis and therapy has also to be individualized. This can be achieved by developing and deploying advanced bioinformatics and genomics as mentioned earlier.

The transfer to pHealth information systems with process-controlled, service-oriented, context-sensitive, semantically-interoperable information and communication architectures requires open, highly flexible individually tailored application systems for the cared for and the caring parties. Such applications cannot be pre-manufactured any more, but must be dynamically created and adapted to the actual requirements and needs. In that way, besides the well-established technology paradigms of Mobile Computing for realizing accessibility (e.g. teleconsultation) and Pervasive Computing for realizing independency of location when providing services (e.g. telemedicine), the paradigm of Autonomous Computing for realizing self-organizing systems can be introduced. The combination of the aforementioned technology paradigms leads to Ubiquitous Computing, which is bound to other paradigms and trends such as health grids. Personal health also requires an adequate legal framework and the new orientation of traditional organizational patterns.

Developing Information Technology Attitude Scales for Health (ITASH)

Rod Ward[a], Katherine Pollard[a], Dr Margaret Glogowska[a], Dr Pam Moule[a]

[a] *Faculty of Health and Social Care, University of the West of England, Bristol. UK*

Abstract

This paper reports on the ongoing development and testing of a set of scales designed to elicit the attitudes of United Kingdom healthcare staff towards Information Technology. The scales were developed in the light of existing literature. Testing included a test-retest completion by over 100 staff from various disciplines in three National Health Service Trusts and a comparison with an existing scale. Exploratory principal components factor analysis identified three components, with a loading of > 3.1. This pattern of item grouping could be understood and interpreted as representing 'efficiency of care', 'education, training and development' and 'control'. The three scales comprise the Information Technology Attitude Scales for Health (ITASH). The results suggest that the developed scales together comprise a measure that can be used to establish staff attitudes towards IT use in the healthcare sector. Those undertaking research in this area might consider employing the scales to measure the factors that influence attitudes towards IT. Additionally, employers might usefully draw on the scales as they aim to support staff in IT use and embed IT systems within the healthcare workplace.

Keywords:

attitude, computers, health personnel, United Kingdom

Introduction

The introduction of Information Technology (IT) in the National Health Service (NHS) in the United Kingdom (UK) has a long history, although the use made of IT varies widely between different geographical and practice areas [1]. Since the publication of the Information for Health Strategy [2], and more recently the 'National Programme for IT' (NPfIT), the use of computer applications within the NHS has been increasing. One of the barriers to successful implementation and use of IT in the NHS is believed to be the attitude of staff to IT use, however there is limited research on this topic and no validated instruments for measuring NHS staff attitude to IT could be found in the literature.

There are several models and tools used elsewhere in the world and in other sectors. These include the Technology Acceptance Model (TAM) [3, 4] as extended by Dixon into the Information Technology Adoption Model (ITAM) [5, 6] and the Rogers' Innovation-Diffusion Model [7] as explored by Lee [8] when examining nurses' attitudes in Taiwan. All of the studies in this area show that attitude is an important predictor of the use of IT. However, none of the tools that have been employed in the UK have been validated, and those from elsewhere are not necessarily appropriate in the UK context.

Stronge and Brodt [9] over 20 years ago, studied this area in the United States of America (USA) with their Nurses' Attitudes Towards Computers (NATC) questionnaire. Others have continued this work [10-12]; however none of the resulting measures were considered appropriate, valid and reliable for use in the NHS, because of the different healthcare systems and/or the use of American phrases.

The primary aim of this study was to develop and test a scale which can be used to examine the attitudes of NHS staff towards Information Technology (IT), both in general and specifically in the workplace.

The main objectives of the research were to:

- Review existing IT attitude measurement tools
- Develop a health care specific attitude measure
- Test reliability, uni-dimensionality and validity

Methods

Development of scales

The research team collaborated in the design of the ITASH scales. Statements on issues identified from the literature [13-16] and practice were generated. Specific items were included identifying factors known to influence staff IT attitudes. The scales were incorporated into a questionnaire which also asked for demographic data, which included age group, gender, professional specialty, qualifications and current level of computer use at home and work.

The topic areas in the attitude scales included:

- Quality of care/ Communication
- Benefit to the organisation
- Confidence/anxiety/interest
- Dependability issues
- Training issues
- Professional role
- Feelings about change/control

Ten to 15 questions were written for each topic and checked for duplication and relevance. The questions were re-ordered to reduce bias and question fatigue [17]. A pool of 79 items was assembled about IT use in health care, respondents were invited to agree/disagree, using a 4 point Likert scale, as it was assumed that respondents would have an opinion. Following completion the statement values were reversed where necessary. The item pool was then used in two different ways - with NHS staff in a test-retest format to investigate reliability; and secondly with Faculty staff exploring validity.

Ethical approval was obtained from appropriate Local Research Ethics Committees.

Paper questionnaires were delivered, as online mechanisms would have biased the results by excluding those without Internet access and those with negative attitudes to IT.

Between November 2005 and January 2006, 816 questionnaires were distributed via managers/matrons/professional leads. Trust 1 (Mental Health) – 470, Trust 2 (Acute Hospital) – 200, Trust 3 (Primary Care Trust) – 146. Follow up questionnaires were sent to all respondents who included their contact details between December 2005 and March 2006.

To test for concurrent validity, copies of the questionnaire and the Stronge and Brodt [9] scale were distributed to UWE Faculty members. The questionnaire data from NHS and UWE staff were entered into SPSS for Windows (Version 13.0) and exploratory factor analysis was carried out.

Results

Response rates

Response rates are detailed in Table 1.

Table 1 - numbers of completed questionnaires

	Trust 1	**Trust 2**	**Trust 3**	**Total**
Round 1 (test)	78	35	38	151
Round 2 (re-test)	57	28	36	121

NB – Six questionnaires were returned anonymously and therefore these respondents could not be sent a second round questionnaire.

Establishment of the scales

The scales were constructed using exploratory factor analysis, a standard technique in attitude scale development [18] This process identified three components, with statement loadings >3.1, as recommended by Watson and Thompson [19]. This pattern of item grouping could be understood and interpreted as representing:

- Scale 1 'Efficiency of Care'
- Scale 2 'Education, Training and Development'
- Scale 3 'Control'

17 items were included in each of scales 1 and 2, while 14 were included in scale 3. The three scales comprise the Information Technology Attitude Scales for Health (ITASH).

The cumulative value of the responses to the statements in each scale becomes the respondent's score for that scale. For the first and second scales, the minimum score is 17, while the maximum score is 68. Scores from 17 to 34.99, 35 to 50.99 and 51 to 68 indicate negative, neutral and positive attitudes towards the use of computers in health care, respectively. For the third scale, the minimum score is 14, while the maximum score is 60. Scores from 14 to 28.99, 29 to 41.99 and 42 to 56 indicate negative, neutral and positive attitudes towards the use of computers in health care, respectively.

Reliability of the scales

To assess the stability of the scales, a test-retest administration of the scales was sent to 145 respondents, of whom 121 completed the scales a second time, over a period of 2-3 weeks. Pearson's correlation coefficients for the scores on the three scales were found to be r=.88 ($P < 0.01$), r=.75 ($P < 0.01$) and r=.83 ($P < 0.01$) respectively. The internal consistency of each scale was assessed by means of Cronbach's alpha coefficients. The coefficients obtained were =0.88 (n = 150), =0.70 (n = 150) and =0.77 (n = 150), indicating a satisfactory degree of internal consistency [17]. These results indicate that the ITASH scales are reliable.

Validity of the scales

A publicly available tool [9] appeared to measure similar constructs to one of the three scales – effectiveness of care. In total 34 members of staff of the Faculty of Health and Social Care at the University of the West of England, Bristol completed both the newly developed questionnaire and the existing scale from Stronge and Brodt [9]. The results were compared to examine the concurrent validity of the new scales.

Pearson's correlation coefficient was calculated for each of the 3 scales developed: 'Efficiency of Care', 'Education, Training and Development' and 'Control'. Scale 1 (Efficiency of Care) correlated adequately with the Stronge and Brodt [9] scale which looked at similar issues (r = .73). Scales 2 (Education, Training and Development) and 3 (Control) looked at different areas to those covered in the Stronge and Brodt [9] scale and therefore did not demonstrate correlation. It has not been possible to find measures suitable for establishing concurrent validity of the second and third scales at this time.

Analysis of scale scores and demographic factors

For each of the three scales, ANOVA was used to analyse raw scale scores on the basis of demographic variables and those relating to patterns of computer usage. The significance level for the study was set at p=0.05 [21]. 120 is accepted as a reasonable sample to provide a reliability coefficient of 0.8 with a confidence interval of +/- 0.1.[22]

Responses to each of the three scales were compared on the basis of various demographic characteristics of the respondents. The type of trust (ie community, mental health and acute) showed differences on the 'Education,

Training and Development' and 'Control' scales (F=7.23, p = 0.001; F=3.11, p=0.05 respectively). This suggests that the organisation in which the respondents worked influenced the extent to which they felt prepared for computer use and to which they felt they were able to influence their own working environment. Age revealed no differences, suggesting that age did not significantly influence attitudes toward computer usage. Gender differences were found on 'Efficiency of Care' and 'Control' scales (t = 2.92, p = 0.004; t = 3.28, p = 0.001), suggesting that men showed a significantly more positive response than women in these areas

No differences in responses to any of the scales were found based on the frequency of computer use at home. However, raw scores for each of the three scales according to frequency of PC use at work revealed significant differences (F=4.21, p=0.017; F=5.93, p=0.003; F=5.69, p=0.004 respectively). Those using the computer more frequently at work appeared to display more positive attitudes

Differences were observed for all three scales (t=2.03, p=0.044; t=2.70, p=0.008; t=2.93, p=0.004 respectively) when they were compared with the level of computer training respondents had received. Respondents with a formal computer qualification displayed more positive attitudes on each of the scales. Similar differences were found when examining experience of computer use. Respondents were asked to rate their experience from 0 (none) to 10 (extensive). Those who rated themselves as 0,1,2 and 3 were grouped as "low experience", 4,5 and 6 grouped as "medium experience" and those who rated themselves 7,8,9 and 10 as "high experience". A Kruskal-Wallis H-test of responses to each of the three scales was conducted on the basis of degree of experience. Differences were found on all three scales. (Scale 1 $K^2(2)=13.52$, $p<0.001$; Scale 2 $K^2(2)=15.63$, $p< 0.001$; Scale 3 $K^2(2)=35.99$, $p<0.001$). Those who rated their experience of computer use more highly generally showed more positive attitudes on all three scales.

Similarly, respondents were asked to rate their confidence in computer use from 0 (none) to 10 (very confident). Those who rated themselves as 0,1,2 and 3 were grouped as "low confidence", 4,5 and 6 grouped as "medium confidence" and those who rated themselves 7,8,9 and 10 as "high confidence". A Kruskal-Wallis H-test of responses to each of the three scales was conducted on the basis of degree of confidence. Differences were found on all three scales. (Scale 1 $K^2(2)=17.12$, $p<0.001$; Scale 2 $K^2(2)= 19.16$, $p< 0.001$; Scale 3 $K^2(2)=47.48$, $p<0.001$).

Discussion

Attempts were made throughout the study to reduce potential bias and accurately represent the responses of the population; however, the sample size was small when compared with the total population of the NHS in the three trusts, each of which employs around 5000 staff.

The low response rate may be due to the distribution methods. Often unit administrators/ managers left the questionnaire in staff areas for individuals to complete. As a result of the UK Data Protection Act [23] lists of names and details of individual staff were not available, which would have allowed a more targeted approach. Respondents were not randomised and were self selecting and there may be a difference between those who completed the questionnaire and those that did not, possibly reflecting their attitude towards the subject area. The respondents were from three NHS trusts, within one Strategic Health Authority therefore local initiatives and factors, such as IT training may have influenced the results

Representativeness is not claimed but the study secured a range of participants from different NHS organisations. It is not known how closely the demographics of the respondents match the make-up of the wider NHS workforce. However, a wide range of staff from various settings within the three NHS trusts participated in the study.

During attitude scale construction, the use of exploratory factor analysis is designed to reduce multiple indicators of attitudes etc. by explaining the relationships between potential scale items. It must be remembered, however, that there is always a subjective element in this process [22].

The test-retest results confirmed that the ITASH scales developed in this study correlated adequately between the first and second application and also demonstrated a level of internal consistency commonly regarded as satisfactory for attitude scales (Oppenheim, Spector) . In addition, the 'Efficiency of Care' scale showed concurrent validity with a scale [9] which has been in use in several countries for many years. Since no available measures appear to be suitable for establishing the concurrent validity of the other two scales, further work is needed to establish their validity through other means.

Nevertheless, despite their lack of established validity, the results produced by Scales 2 and 3 were consistent with the body of literature relating to healthcare staff's attitudes to IT, which show that previous experience and exposure are major determinants of attitude formation [24]. The role of the individual in an organisation and the way in which IT are introduced, along with the purpose of the introduction are also known to be relevant to attitude formation [25].

As the pace of implementation of electronic records systems and other initiatives under the NHS's NPfIT increases, the involvement of staff in the use of IT will increase. IT will become vital for both organisational objectives and individual patient care, therefore it is important to be able to identify factors which will influence staff use and evaluate the effectiveness of strategies designed to change attitudes amongst the staff.

Several interesting findings have been obtained through the administration of the scales. Those respondents who had undertaken computer training, with or without obtaining formal qualifications, showed more positive attitudes towards IT. Greater use of a PC at work was associated with more positive attitudes, although there was no such association with the amount of PC use at home. There is also some indication that the type of organisation influ-

enced the extent to which staff felt prepared for computer use. The age of respondents in this study did not have any significant effect on attitudes towards IT. However, men showed more positive attitudes than women in relation to the 'Efficiency of Care' and 'Control' scales. Attitudes on all three scales correlated positively with the respondents self reporting of their experience and confidence in computer use.

These initial results suggest that in the female dominated NHS workforce, consideration needs to be given to strategies which will influence the attitudes of staff towards IT, which may include training provision and supported exposure to computers.

The development and testing of the scale was the primary purpose of this study. The main task for the research team is now to establish the validity of Scales 2 and 3.

Conclusion and recommendations

The results suggest that the scale offers a measure that can be used to establish staff attitudes towards IT use in the healthcare sector. Those undertaking research in this area might consider employing the scale to measure the factors that influence attitudes to IT. Additionally, employers might usefully draw on the scale as they aim to support staff in IT use and embed IT systems within the healthcare workplace.

All three scales have been shown to be reliable; however only scale 1 'Efficiency of Care' has validity when compared to established instruments. Further research is needed to examine the validity of scale 2 'Education, Training and Development' and scale 3 'Control'. It would also be useful to see further research into the relationship between the different professional groups and their attitudes towards IT.

The results obtained while developing and testing the scale give a snapshot of a selection of the NHS staff in three different types of NHS trust which show fairly frequent use of IT at work, primarily for word-processing, but to a lesser extent for patient records and communication. When this is compared with the demographics of the population, including the levels of IT training and qualification, and the factors demonstrated to influence attitudes to IT, it would be useful for NHS organisations to investigate ways in which a predominately female workforce can be helped with IT use.

Acknowledgments

This study was funded by the UWE Faculty of Health and Social Care, School of Adult Nursing, Research and Staff Development Scheme.

The research team is grateful to UWE staff including Dr Jon Pollock and Dr Nikki Coghill for statistical advice and to Leigh Taylor in the Faculty Research Office for administrative support. We would also like to thank the R&D Directors, managers/ professional leads/matrons in three NHS Trusts for permission to distribute questionnaires to their staff. The contribution of all those who completed the questionnaire and attitude scales was vital in this project which could not have been completed without them.

Abstract

A novel Virtual Organization framework which incorporates wireless technology support is presented in the research work. The Virtual Organization is designed for a clinical environment to provide better patient information management and enhanced collaborative working of multi-disciplinary care teams. The analysis studies the current clinical practices and looks at the general patient information resource structure currently in use for patient care. Based on this problem analysis and current requirements of the multi-disciplinary care team members, we propose a generic and sustainable Patient Centric Virtual Organization (PCVO) framework to complement the functionality of the existing infrastructure by incorporating wireless technologies support for improved patient information provision at the point of care. The preliminary results of the study identify and classify the specific point of care tasks suited to appropriate information resources needed by the care team members. This paper concentrates on the patient information management aspects brought in by incorporating wireless technologies at the point of care using patient information resources in a decentralized and distributed computing environment. This applied research is carried out in the secondary and tertiary care sector in the cancer domain. For the analysis and results of the pilot project, we have used a case study of a local NHS Cancer Hospital.

Keywords:

Patient Centric Virtual Organizations, Sustainable Patient Centric Framework, Patient Information Management, Patient Centered Care, Wireless Point of Care System

Introduction

The aim is to determine the functional requirements of multi-disciplinary care team members and provide a better infrastructure for the provision of relevant patient information at the point of care from existing information resources in an effective and efficient way by using a Virtual Organization (VO) framework. In the literature, Virtual Organizations (VOs) don't have an exact definition, as their functionality varies depending on the context of the organization, application and the way they are used. In general, VOs are formed by organizations or individuals who collaborate and work together to perform certain organizational objectives by accessing and sharing resources utilizing communication and information technologies [1], [2]. The team members in a VO might be separated by time or space. In the clinical environment, the healthcare professionals collaborating with a common objective of caring for a patient may form a VO. Some of the features which are basic for a VO can be described as: 'working for certain organizational objectives together; formation of teams for accessing and sharing resources; trust, collaboration and cooperation among team members; and usage of computer and communication technologies' [3]. In our VO, we are using wireless technologies as a means of information access and sharing among care team members due to their mobility. These technologies play an important role as a building block in a VO and serve as the backbone for all the processes within it. Looking at the nature of clinical environments with a VO context, we find a similar environment as the work practices in the clinical environment can be diverse; healthcare professionals with different skills might be caring for the same patient while working from different locations and at different times; and patient resources may be heterogeneous [4]. In our context, a VO is defined for the team members who might be dispersed physically or temporally but work to achieve a common goal using wireless technologies support in a novel way linked to traditional methods [5].

We describe how Patient Centric Virtual Organizations (PCVOs) can be developed in a clinical environment for better management of patient information using decentralized and distributed resources. PCVOs are supported by wireless technologies which play an important role in the patient treatment process at the point of care. This care is carried out at the secondary and tertiary care level by different multi-disciplinary care team members involved in the patient treatment. The care teams consist of different medical professionals having varied skills working together. In our study, the healthcare stakeholders considered are: clinicians, nurses and therapists, who access information from a variety of medical resources during a patient's treatment. Looking at the structure of secondary and tertiary care, these team members are the key players directly involved in the patient care. Since a VO provides a flexible framework, more healthcare professionals can be added or removed from the team according to patient care requirements. The analysis shows the existing information

resources used for patient treatment in the current patient care structure and reveals the issues faced by the care team members in this domain. This is used to suggest an approach of a PCVO at the clinical level which harmonizes well with the clinical settings and will utilize the existing information resources in a structured development. It will organize the patient information and support integrated working of the care team members for improved patient care. For the case study, the pilot project with anonymised data was carried out at Clinical Information Unit at Velindre Hospital, South East Wales Cancer Centre working at secondary and tertiary care level.

Motivations and problem analysis

Healthcare is a major industry and has continually evolved over time. Lack of timely information, medication errors and unavailability of centralized resources for shared information are some of the current challenges faced by hospitals [6]. Real time information at the patient bedside, which leads to better decision making support at the point of care, shows the importance of wireless devices in patient treatment. Existing computerized systems have limited capabilities as they cannot always provide appropriate information to patient care team members as required at the point of care. Current practices still involve use of manual and paper based work, which create problems such as storage of information in a suitable repository, manual data entry of the information into computerized systems, delays in system updates and mismanaged structure of patient information. One of the major concerns identified during the study was the provision of required patient information from decentralized / distributed resources to care team members at the point of care. Some of these problems can be addressed by using wireless technologies [5].

In general, the structure of resources at the secondary and tertiary care level is similar to other clinical environments. During the study, it was found that although clinical information systems contain most of the patient information required, they are not the only information resource used in patient treatment. Patient information is also stored in other information resources such as nursing notes and patient notes. Usually, at the point of care, nurses / patient notes contain most of the basic manual information about patients. So, although some of the patient notes information is stored in clinical information systems, care team members still have to refer to the manual patient notes during a patient interaction.

This highlights the need for a sustainable information infrastructure which is capable of managing the patient information resources and dealing with the patient information provision issues at the point of care. These issues are addressed by the proposed PCVO framework, which is based on a patient centric approach utilizing the power of wireless technologies at the point of care.

Related work

A VO and ad-hoc virtual team formation approach in a telecare project is discussed by Grootveld [7], in which different healthcare professionals work for the stroke service and access patient records in the emergency room for better diagnosis. It describes the stroke service which is a regional network of healthcare professionals as a VO. A VO and virtual clinic creation strategy for distributed clinical consultations is described in a case study of a prison telemedicine program which connects an academic medical centre to a prison hospital [8]. A concept of dynamic virtual collaborative healthcare teams dealing in homecare domain of cancer patients using fixed computers, mobile phones, PDAs and internet telephones for the provision of medical records is presented in enterprise project DITIS [9]. A virtual institutional infrastructure which includes different healthcare services and a linked structure of national networks is identified by a project for the integration of Cuban healthcare service market [10]. Some other papers have described work done to develop virtual communities, virtual teams and virtual systems. These cover the social context and issues of building these virtual environments in healthcare [11]–[13].

This related work has shown the benefits of virtual infrastructures and VO formation in different telecare and homecare projects, but no work has been done to analyze the potential benefits of a VO development with a Patient Centric approach at the clinical level particularly at the point of care. The potential of a VO as the patient information management infrastructure and its role at the point of care for patient information provision has not yet been investigated. Most of these environments utilized computerized systems as a communication channel, but the importance of wireless technologies in these environments at clinical level has not been utilized yet. The concept of a PCVO with wireless technologies support for patient information management as required at the point of care in clinical environment is the novel aspect presented in this paper and this area needs to be explored further.

Context analysis of existing patient information resources

This section covers details of common decentralized and distributed information resources available in an organization and through internet respectively for patient information and treatment at secondary and tertiary care level as shown in Figure 1.

Organizational resources

Clinical Information Systems most commonly provide a patient summary and the information required for patient diagnosis and treatment. This may include clinical trial information, surgery, radiotherapy, chemotherapy and home care. *Patient / Nurses Notes* are usually used by care team members for capturing the patient's vital signs, clinical workflow and bedside charting processes. Most of the information which is not available in clinical information systems is stored in patient notes. *Patient Administration*

Systems include the demographic details and patient waiting time. *Local Protocols* contain local care procedures e.g. care pathways and clinical trial protocols. In Figure 1, the highlighted area shows the Shared Information required for the purposes of patient diagnosis and treatment contained by Clinical Information Systems and Patient Notes which is obtained from Patient Administration Systems and Local Protocols [14]–[16].

Distributed resources

The distributed domain has a variety of resources for patient treatment and care like *Evidence Based Medicine (EBM) Resources, Pharmacy / Medical Information Resources and other Hospital Intranet Resources*, providing information from clinical evidence, medicine libraries, e-text books and bibliographic databases [15], [16].

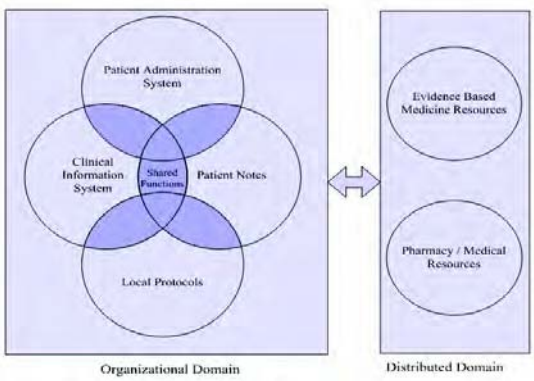

Figure 1 - Patient Information Resources Structure

Proposed approach and framework

This work presents PCVO as a Patient Centric approach at the organizational level with wireless technologies support. Looking at the building blocks of a VO, our approach is based on the functionality and tasks needed at the point of care in a clinical environment where different multi-disciplinary care team members work together in an integrated way to achieve a common goal, i.e. improved patient care. The Patient Centric approach shows that patient information is the central entity of the paradigm and a PCVO shows how each patient's data is used in different and improved ways. It aims to provide patient information at the point of care platform, which will be derived from different data sources like patient databases, other organizational resources and the internet. The PCVO framework shows only most commonly used organizational resources which are Clinical Information System and Patient Notes, because they also include the required patient information shared by the other organizational resources like Patient Administration Systems and Local Protocols, as represented by Shared Functions shown in Figure 1. Each PCVO is based on a single patient's information, so different care team members treating that patient become a part of that particular PCVO. They might be at different physical locations but will always work in a coordinated and common way for patient treatment under the same platform because the common patient information structure remains the same.

Considering the problem domain, our suggested approach presents the PCVO as an environment which works on top of existing information resources and incorporates a wireless system which is required to overcome some of the current point of care issues. It shows how a PCVO identifies and classifies the point of care tasks with respect to the information resources for care team members by using the support of a Wireless Point of Care System (WPoCS). Figure 2 shows the categorized tasks which are 'existing tasks', 'transferable tasks' and 'added tasks' or 'automated tasks' determined by classification for the appropriate information provision with respect to patient information resources. A WPoCS covering 'transferable, added or automated tasks' should play an important part in providing the needed functionality for care team members as shown in Figure 2, by capturing and providing the appropriate patient information at the point of care using PDAs.

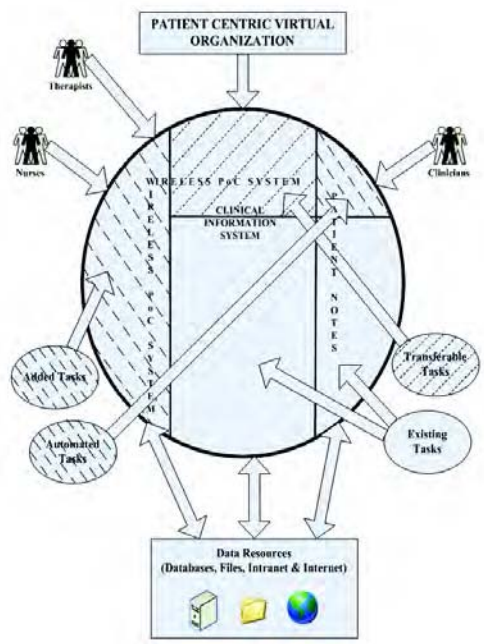

Figure 2 - Patient Centric Virtual Organization Framework

Study results: Point of care tasks classification

The results of this classification given below in the form of tables were achieved by analysis, direct observations, structured and semi-structured interviews and questionnaires conducted at various levels with different care team members, Information Analysts and IT staff in our case study conducted at the Velindre Hospital. The iterative process of this analysis and design covered the interviews, discussions and feedback from these stakeholders throughout all the phases - problem discovery, framework

approach, suitability and usefulness of task classification, development and modelling of test cases, and is still continuing in the prototype development and evaluation phases as well. The point of care tasks of the care team members are divided into three categories.

Point of care tasks suited to existing computerized clinical information system

Table 1 identifies examples of the point of care tasks which are better suited to a clinical information system. The tasks identified present a general level of usability compatible with information systems working in different environments.

Table 1 - Point of Care Tasks suited to Clinical Information System

Care Team Members	Point of Care Tasks suited to Clinical Information System
Clinicians	Data entry / order entry involving time consuming and detailed keyboard input
	Patient's detailed referrals and complete reports
	X-Ray and other large image analysis including MRI
	Looking at the case notes of the patients for detailed information
	Searching and comparing the cases for best EBM
	Searching the pharmacy resources for selection of medicines
Nurses	Data entry / order entry involving time consuming and detailed keyboard input
	Previous medical notes in dates format
	Looking at the text reports of X-Ray
Therapists	Previous medical notes in dates format
	Data entry / order entry involving time consuming and detailed keyboard input
	X-Ray and other large image analysis including MRI

Point of care tasks transferable to WPoCS

Table 2 shows examples of the suitable point of care tasks that can be transferred from Clinical Information System to a wireless system to provide easier access of relevant patient information. The framework doesn't exclude these tasks from Clinical Information System, but should provide a better interface for improved task accomplishment using wireless devices.

Table 2 - Point of Care Tasks transferable to WPoCS

Care Team Members	Point of Care Tasks transferable to WPoCS from Clinical Information System
Clinicians	Checking the laboratory test results
	Accessing summary disease history
	Accessing summary treatment history
	Checking current treatment status of the patient
	Checking current disease status of the patient
	Looking at current location status of the patient
	Checking the complications of treatment
	Checking the clinical summary of the patient
	Patient record retrieval by scanning barcode through devices
Nurses	Checking current treatment status of the patient
	Checking current disease status of the patient
	Looking at current location status of the patient
	Patient record retrieval by scanning barcode through devices
Therapists	Checking previous therapy records / past history
	Knowing the last examination of the patient, action measures taken and current status
	Checking the current location of the patient
	Patient record retrieval by scanning barcode through devices

Point of care tasks added or automated by WPoCS

Table 3 shows examples of new tasks that can be achieved using a wireless system at the point of care to assist care team members in the patient care process. It also includes the tasks that can be automated using handheld devices at the point of care instead of using a paper based approach. It must be remembered that WPoCS do not replace all the paper / patient notes but can only be utilized to automate suitable tasks which are better suited to wireless devices.

Table 3 - Point of Care Tasks added / automated by WPoCS

Care Team Members	Point of Care Tasks added / automated by WPoCS from other existing manual resources
Clinicians	Consulting reference notes / guidelines for decision making like blood pressure classification readings and average pulse rate for age-wise children and adults
	Accessing physical / vital signs like temperature, pulse rate, respiratory rate, blood pressure, body weight etc
	Looking at previous vital signs for comparison
	Recording of ward handover notes
	Accessing the trial protocols
	Accessing the treatment protocols
	Accessing the clinical pathways
	Consulting the cases for best EBM
	Consulting the right pharmacy / medical information for clinical use of medicines on the basis of symptoms
Nurse	Electronic data capture / recording of patient's vital signs like body temperature, pulse rate, respiratory rate, blood pressure, body weight etc
	Checking previous vital signs to compare
	Comparing the patient temperature and other vital signs using graphs
	Checking drugs details and timings of dosage given to patients
	Alerts and reminders for checking patient status and treatment
Nurses	Right identification of the patients and knowing their current status and details
	Step by step workflow process recording, for example, patient's check-in / position status, physical / vital signs notes etc
	Recording of ward handover notes
	Consulting actions and rationale for the specific nursing protocols
	Accessing the treatment protocols
	Right identification of the patients and knowing their current status and details
	Accessing the clinical pathways
	Accessing the trial protocols
	Accessing medical device / patient safety alerts
	Electronic bedside charting
	Pre-defined screens for data capturing
	Checking the drug prescription
Therapists	Consulting reference notes / guidelines for decision making like blood pressure classification readings and average pulse rate for age-wise children and adults
	Checking the social history / living conditions of the patient
	Knowing the last examination of the patient and action measures taken
	Accessing the treatment protocols
	Accessing the clinical pathways
	Accessing the trial protocols

Research limitations and challenges

This paper focuses on generic patient information management aspects at the point of care in the clinical environment. It concentrates on the point of care functionalities that can be achieved using organizational resources within hospital environment by a PCVO framework. We have not covered other distributed patient information resources aspects in this paper. Looking at the big picture, some of the challenges and issues must be considered if this framework is to be adopted in practice. These include the administrative,

control, management and other aspects of PCVOs. On the other hand, with regard to WPoCS working in a wireless network, security and bandwidth issues for the distributed information access must be considered. Finally, these PCVOs will not replace the current patient care infrastructure but take on suitable point of care functionalities with wireless technologies support using existing information resources in a novel and improved way.

Conclusions and future directions

This paper has discussed PCVOs development and its potential benefits in the clinical environment. The PCVOs will harness the power of wireless technologies through WPoCS, hence providing patient information management by timely information access at the point of care. The classification of care team tasks with respect to information resources shows how the PCVOs may provide a better approach for using patient information resources at the point of care without changing the current infrastructure of the existing clinical environment. The outcome of the pilot study results show there is a broad acceptance of the pilot project findings. The positive feedback from care team members received in discussions and interviews show the suitability of these tasks in addressing issues faced during their routine tasks.

So far we have designed and modelled the test cases for WPoCS. The next step is the development and implementation of a WPoCS prototype using a Pocket PC Emulator and PDA is in progress. This will determine its practical usage in the healthcare spectrum. To evaluate the pilot project we are working on qualitative measures with the healthcare stakeholders. We will also be improving and enhancing the system using feedback from care team members. The study suggests the real and tangible benefits that may be achieved with our framework. The ongoing work is likely to prove the usefulness and practical benefits to patient care in the secondary and tertiary care of cancer.

SPIRS: A Framework for Content-based Image Retrieval from Large Biomedical Databases

William Hsu[a], L. Rodney Long[b], Sameer Antani[b]

[a] *Medical Imaging Informatics Group, University of California, Los Angeles, CA, USA*
[b] *National Library of Medicine, National Institutes of Health, Bethesda, MD, USA*

Abstract

With the increasing use of medical images in clinical medicine, disease research, and education, the need for methods that effectively archive, query, and retrieve these images by their content is underscored. This paper presents the implementation of a Web-based retrieval system called SPIRS (Spine Pathology & Image Retrieval System) at the U. S. National Library of Medicine that demonstrates recent developments in shape representation and retrieval from a large dataset of 17,000 digitized x-ray images of the spine and associated text records. Users can search these images by providing a sketch of the vertebral outline or selecting an example vertebral image and some relevant text parameters. Pertinent pathology on the image/sketch can be annotated and weighted to indicate importance. This hybrid text-image query yields images containing similar vertebrae along with relevant fields from associated text records, which allows users to examine the pathologies of vertebral abnormalities. Initial experiments with SPIRS have demonstrated the potential for this system, particularly on a large dataset of clinical images.

Keywords:

medical informatics applications, information storage and retrieval, content-based image retrieval, visual access methods, web-based systems

Introduction

Medical imaging is an increasingly important and versatile tool for acquiring information about a patient and disease. Image features (e.g., shape, color, or texture) have been used to diagnose a variety of conditions. Hospitals have been adopting technology such as Picture Archiving and Communication Systems (PACS) and Hospital Information Systems (HIS) to assist in the digital collection, organization, and storage of patient data. The goal of these systems is to make patient data more accessible; in reality, the amount of data that is entered and stored in these systems have created a new challenge for effective information indexing and retrieval. Historically, PACS have limited users to query by certain keywords (e.g., unique patient identifier, fields in the image header). However, these keywords often do not capture the richness of features depicted in the image itself. Over the past two decades, content-based image retrieval (CBIR) systems have been researched to address the problem of indexing and retrieving visual data in a variety of domains [1]. Rather than limiting queries to textual keywords, CBIR users provide a query sketch/image, which is then used to find similar images of the same modality, anatomical region, and disease along with the associated text records.

The goal of this work is to develop a retrieval system that implements recent developments in shape representation, efficient indexing, and similarity matching; supports whole and partial shape matching, which enables a wide range of meaningful queries to be posed; and utilizes a distributed framework, which is customizable to the needs and constraints of healthcare environments. The result, Spine Pathology & Image Retrieval System (SPIRS)[1], provides a Web-based interface for performing image retrieval on a database of digitized spine x-rays using the morphological shape of the vertebral body. A query editor enables users to pose queries by sketching a unique shape or selecting or modifying an existing shape from the database. Additional text fields enable users to supplement visual queries with other relevant data (e.g., anthropometric data, quantitative imaging parameters, patient demographics). These hybrid text-image queries may be annotated with pertinent pathologies by selecting and weighting local features to indicate importance. Query results appear in a customizable window that displays the top matching results and related patient data. SPIRS provides a working proof-of-concept that demonstrate the capability of accommodating large amounts of imaging data expected in the near future.

Background

The problem of retrieving information based on image content has been researched by various groups since the early 1990's resulting in the development of tools such as QBIC, Virage, and Blobworld [2]. CBIR in medicine has been an active area of research [3], but only a small number of proposed systems such as ASSERT [4] and IRMA [5] have been demonstrated in the clinical environment. In addition, although many large image databases exist, such

Selected for best paper award.

as the National Cancer Imaging Archive (NCIA) or the Lung Imaging Database Consortium (LIDC) created under the aegis of the Cancer Imaging Program[2] at the U.S. National Cancer Institute (NCI), these efforts have concentrated on data collection and transmission but have left development of applications to the research community. Lack of CBIR adoption is attributed partly to the difficulty of integrating current implementations with existing healthcare systems [3]. SPIRS addresses this issue by (i) utilizing open standards to communicate among components, which can be extended to support data encryption to meet privacy regulations, and (ii) using modular open source software components. Much work has been done in the past on visual querying paradigms, as reviewed in [6]. Building upon these paradigms, SPIRS combines visual and text queries to provide users with greater flexibility in retrieving relevant results.

Biomedical database

At the U.S. National Library of Medicine (NLM), the focus of CBIR research has been to develop systems capable of performing a range of queries on large medical multimedia databases comprising various biomedical images and patient health data. Such a database in current use contains digitized spine x-rays and associated metadata from a large nationwide survey, the National Health and Nutrition Examination Survey (NHANES), conducted regularly by the National Center for Health Statistics in the United States. The goals of NHANES include estimating prevalence of selected diseases, monitoring disease trends, and studying the relationship between nutrition and health. The Lister Hill National Center for Biomedical Communications, a research division of the NLM, maintains data from the second survey, NHANES II, which was collected between 1976 and 1980 and featured over 20,000 participants. Each participant's record includes 2,000 textual data points such as health questionnaire answers, anthropometric information, and results from a physical exam. This textual data is stored in a relational database (e.g., MySQL). Supplementing the textual data is a collection of 17,000 cervical and lumbar spine x-rays that were taken from patients aged 25 – 74. These images were originally on film and subsequently digitized using a 146 dpi scanner resulting in 140 Gigabytes of data. The collection is considered valuable to radiologists, bone morphometrists and researchers interested in osteo-arthritis, and medical educators. Domain experts reviewed a sample of the data and identified 23 key biomedical features exhibited in the x-rays. Of these, anterior osteophytes, subluxation/spondylolisthesis, and disc space narrowing were determined to be frequently occurring and reliably detectable.

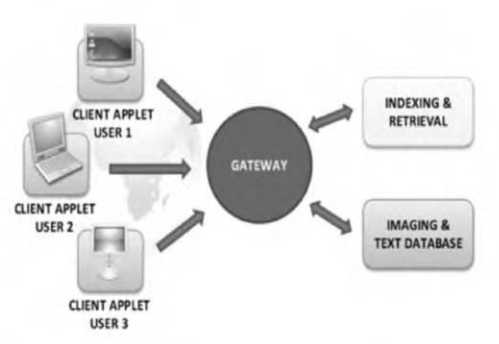

Figure 1 - The distributed architecture of SPIRS

Each of these key features may be identified by examining the boundary shape of the vertebra. However, identifying images that exhibit particular types and severities of these pathologies is extremely tedious for such a large collection. SPIRS and related tools [7], developed to analyze the images and populate the database, automate many tasks and enable retrieval of the images using sketches of the vertebral boundary with the desired feature. Furthermore, SPIRS may be used to determine what features (e.g., protrusion on the anterior edge of the cervical vertebra) are consistently associated with a certain symptom (e.g., neck discomfort) or whether a certain feature is a precursor to more serious illnesses (e.g., arthritis). Illnesses may be documented in the text of the patient record as a survey response or in the medical diagnoses.

System framework

The system's distributed architecture, shown in Figure 1, consists of four components: (i) the client applet, which provides a front-end for users to pose queries and interact with results, (ii) a gateway that acts as an mediator between client and server-side components, (iii) the indexing and retrieval server, which performs the feature representation and similarity matching, and (iv) the databases containing images and associated text data.

Indexing and retrieval

In our continuing research, we have explored and implemented various algorithms to extract, index, and retrieve shapes of vertebral bodies from x-ray images. Extraction of vertebral shapes is accomplished using manual and semi-automated algorithms such as active contour segmentation, active shape modeling, and hierarchical segmentation [8]. These algorithms have been implemented with the intention of applying them to a variety of image features; therefore, the system can be extended to a wider variety of images and text data. The resulting vertebral shape boundaries are then treated as closed polygons and represented in a variety of forms, such as Polygon Approximation, Fourier Descriptors, or geometric shape properties that help uniquely identify and characterize

2 http://imaging.cancer.gov/

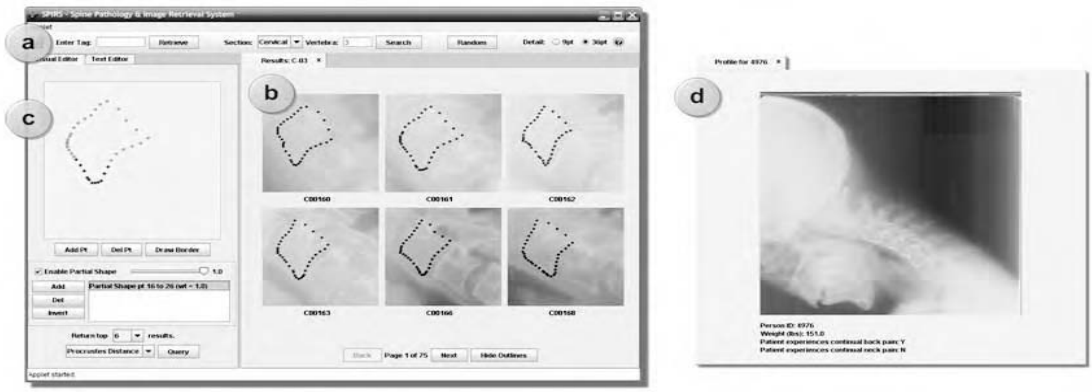

Figure 2 - A screen capture of the SPIRS client applet left) and a cropped screen capture of the overall results view tab (right)

them [9]. Traditionally, these representations are stored as a feature vector and compared individually with the query. However, for large image archives, this linear comparison approach would be impractical. SPIRS therefore uses a coordinate tree to efficiently index shapes and optimize retrieval time. Embedded with the indexing process are appropriate distance measures which identify matching shapes [10].

Client applet

The client, shown in Figure 2, is a Java applet that runs in a Web-browser and provides the user with the necessary functionality to query for particular shapes of interest and interact with the results. The applet (i) is a thin client that provides the look-and-feel of a standalone application but uses minimal computing resources, (ii) does not require installation of files onto the local drive, (iii) is easily modifiable without affecting core-CBIR functionality, and (iv) is platform independent.

Query toolbar

The query toolbar (Fig. 2a) supports query-by-example by allowing users to find vertebral shapes or spine x-ray images that match descriptors stored in the text database, such as image tag or vertebra type and number. A query vertebral shape can be selected from the returned x-ray images in the Overall View or from the selection of vertebral image crops in the Cropped View shown in Fig. 2b.

Overall view

The Overall View (Fig. 2d) displays the entire patient x-ray and allows the user to examine and select any of the segmented vertebral shapes. In addition to the unprocessed version of the scanned image, two forms of enhanced images are also available for improved visualization of subtle detail, viz., one processed with unsharp masking to enhance edges, and the other an adaptive histogram-equalized image which improves contrast. The user may use the mouse hover over and view the vertebral outlines as image overlays. A mouse click on the desired shape selects and transfers it to the query editor.

Cropped view

The Cropped View (Figure 2b) allows a user to inspect multiple vertebral shapes at once. Each displayed vertebra is cropped from the original patient x-ray using the boundary information associated with its shape. The crops are then normalized so that each vertebra is facing in the same direction, which simplifies the comparison between various vertebrae.

Query Editor

The query editor (Figure 2c) enables the user to pose queries using query-by-sketch, select text fields, and supply information pertaining to health history, anthropometric data, quantitative imaging parameters, and demographic data. The visual query component of the editor is a canvas where the user may choose to draw an entirely new shape or edit points that have been imported from an existing shape found using the query toolbar. The query editor also supports multiple partial shape query specification. This feature provides the functionality to select parts of the vertebral shape enabling the algorithms to focus on these boundary intervals, which may exhibit significant pathology. Partial shape querying is shown in the figure as the highlighted interval along the vertebral boundary. Finally, the user can configure the query execution parameters by selecting the retrieval algorithm and limiting the number of results.

Results view

The Results View offers two displays. The Cropped View (Figure 2b) shows returned matching vertebrae while the Overall View (Figure 2d) appears when a user selects one of the resulting vertebral shapes. In the Overall View, the entire x-ray of the patient is shown with the matching vertebra highlighted. Relevant text fields from the text database are displayed alongside the image and may be customized by the user. A unique feature of this system is the ability to use resulting shapes as queries. This can be considered as a form of relevance feedback through the use of iterative querying. More advanced relevance feedback methods have been explored [12] as standalone MATLAB programs and are under development for use with the Web-based system.

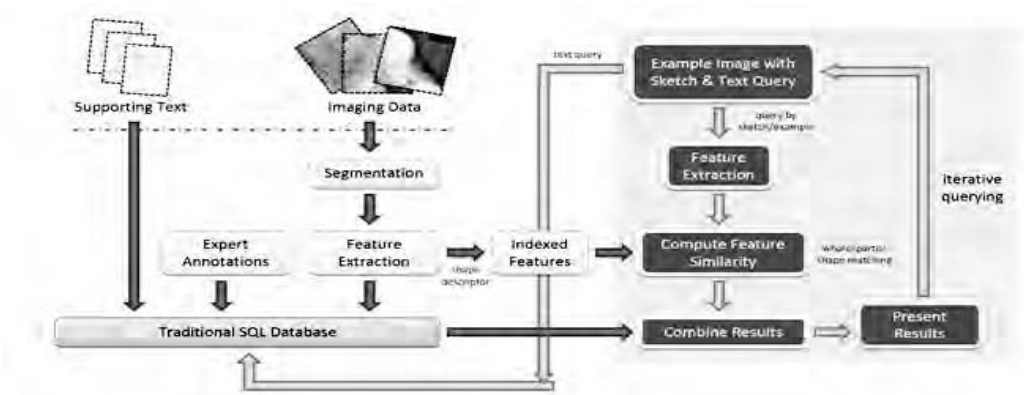

Figure 3 - The query handling process (shaded region) in the context of the overall retrieval system

Gateway

SPIRS utilizes standard Web communication interfaces to enable interaction with its components. The gateway is a Java servlet that acts as a mediator between client applets and server-side components. It manages multiple simultaneous connections (users) as separate session and queues requests to the core CBIR engine. The servlet translates text components into SQL query syntax for interacting with a MySQL database. In addition, the core architecture of the gateway makes interaction with other geographically distributed CBIR systems possible. An example is the interoperability between IRMA [5], which is a system located in Germany for CBIR of medical images using overall image intensity features, and SPIRS. While IRMA's interface provides shape query support for subtle localized pathology, it utilizes the SPIRS server located at the NIH in the USA for computing shape-similarity of spine x-rays.

Query handling

Although much CBIR research has focused on overcoming technical challenges such as developing accurate and efficient retrieval algorithms, in order for widespread CBIR adoption and use, systems need to provide users with the ability to exploit the capabilities of these algorithms in managing large biomedical multimedia databases. With this goal, we believe that SPIRS allows users to pose meaningful queries that have both clinical and research applicability.

Partial shape matching

A problem with many current CBIR approaches for medical images is that they operate on the image as a whole. Whole shape matching methods have been demonstrated to be more effective in identifying shapes with gross similarity because these algorithms operate over the entire shape. They are ineffective, however, in matching subtle shape characteristics, which may have critical pathology. It has been observed that pathologies of interest on a vertebral outline are often localized along a short interval on the boundary. For example, osteophytes are only expressed along the "corners" on the vertebral boundary as seen in the sagittal view. Partial shape matching (PSM) [7, 11] has been implemented in SPIRS allowing users to sketch or identify only the local interval of interest on the vertebral boundary. For instance, consider a user interested in identifying patients in the NHANES II data with a claw anterior osteophyte, which occurs when a spur of triangular shape rises from the vertebral rim and curves toward the adjacent disk. In the query editor, the user would highlight the subset of points that comprise the spur, weight these points greater than the other points in the shape, and execute the PSM query. Initial experiments have shown that PSM can be used to automatically classify the severity of a pathology depicted in the query shape such as whether the claw osteophyte is *slight*, *moderate*, or *severe* depending on criteria defined by domain experts [13].

Query execution

Figure 3 illustrates the process of query execution and how it integrates with the overall CBIR system. When the user formulates a hybrid text-image query, the query is separated into its visual and textual components. Relevant features and annotations are extracted from the visual component and matched against the indexed features using specific similarity computation methods. Parameters from the textual component are executed against the database containing survey and patient data. The results of these individual searches are then combined before the results are presented to the user. For example, a user who is researching the correlation between certain shape features and the degenerative spine disease spondylosis may be interested in the intersection of results between a visual query depicting, for example, a traction spur and patients who have been diagnosed with spondylosis.

Interaction with results

The standard method of reviewing the outcome of a query is through the Results View, which displays the whole patient x-ray with the matching vertebral shape highlighted and relevant text descriptions displayed alongside the image. The retrieval algorithms have been evaluated to 68% relevance (precision and recall) when querying for specific osteophyte type (claw or traction) or severity [13]. An additional 22% performance improvement is observed through use of relevance feedback methods [12, 13]. The shortcomings in the performance are linked to (i) erroneous determination of the query semantics and (ii) limitations of the shape matching algorithm. To overcome these problems, SPIRS allows users

to select a matching result as the basis of a new query. Traditionally, user interactivity has helped in minimizing similar problems with text retrieval, and user feedback has often been analyzed and employed to improve retrieval relevance. By allowing users the option to iteratively query and refine results, SPIRS implements a basic form of relevance feedback, which will be enhanced with a novel advanced weighted hierarchical feedback method using short-term memory [12] and other approaches as they are migrated from laboratory prototype routines.

Discussion

Image management and pathologically sensitive content-based image retrieval systems are increasingly necessary to interact with the growing volume of biomedical imaging data. In spite of their acknowledged importance, shortcomings in current approaches have prevented their widespread acceptance into medical research, practice, and education. We believe that a biomedical CBIR system should be easily accessible, extensible, and capable of supporting a rich set of segmentation, validation, indexing, query, retrieval, and visualization methods developed using open software and standards. It is difficult for individual systems to support unique requirements of different biomedical images. This can be addressed by providing the capability to combine this system with others (possibly geographically distant) that have complementary features. The SPIRS framework is capable of interacting with and retrieving relevant information from large databases of image and patient data using hybrid image and text query methods. It implements novel shape representation and similarity matching embedded with an index tree that allows efficient retrieval. It aims to capture query semantics through support of advanced mechanisms like multiple partial shape matching and iterative querying that provides simple yet effective relevance feedback to the system. SPIRS is built using open standards and is simultaneously developed as a service, which enables its integration with other complementary information retrieval systems. Although SPIRS focuses on shape-based queries its framework is extensible to adopt features particular to other biomedical image and data collections, e.g., its core architecture is being extended to include color, texture, and spatial location in uterine cervix images from the National Cancer Institute [13].

Future work

Future goals for the project include (i) data collection, assimilation, and validation, (ii) system feature enhancements, (iii) improved retrieval quality by learning from user feedback, and (iv) improved user interaction and visualization. Extracting and validating vertebral shapes is an ongoing process which will (at regular intervals) add to the 8,000 shapes indexed currently. In addition, three board certified radiologists are validating the segmented shapes and identifying relevant pathology on them and on the spine. Planned feature enhancements include integration of a generalized shape segmentation toolbox, which is a currently a standalone application, incorporation of additional similarity, relevance feedback, and visualization algorithms, and development of a formalized XML specification for integrating other local and global information systems (or resources) such as WebMIRS and IRMA with core SPIRS services. A multi-user comprehensive qualitative study of the interface is also planned.

Acknowledgements

This research was supported by the Intramural Research Program of the National Institutes of Health (NIH), National Library of Medicine (NLM), and Lister Hill National Center for Biomedical Communications (LHNCBC). The authors thank Dr. Alex Bui at UCLA for his valuable feedback.

The Quality of Reporting of Health Informatics Evaluation Studies: A Pilot Study

Jan Talmon[a], Elske Ammenwerth[b], Thom Geven[a]

[a]*Dept of Medical Informatics, Maastricht University, Maastricht*
[b]*Institute for Health Information Systems, UMIT - University for Health Sciences, Medical Informatics and Technology, Hall in Tyrol, Austria*

Abstract

The quality of reporting of evaluations in Health Informatics is considered to be open for improvement. STARE-HI provides guidance for improved reporting. This study aims at establishing the quality of reporting prior to dissemination of STARE-HI. All evaluation papers in three leading Medical Informatics Journals published in 2005 have been assessed with the aid of STARE-HI. A total of 48 papers have been analysed with respect to title, abstract, keywords and study context. Main results indicate that the type of study is seldom reported in the title, that the structured abstract contains more information than an unstructured abstract, that important keywords are often forgotten. Also important information about the system assessed is often not mentioned explicitly. Our conclusion is that there is room for improvement in the reporting of evaluations in health informatics. STARE-HI can be helpful in suggesting a structure for evaluation papers in Health Informatics and issues that should be included in such papers.

Keywords:

STARE-HI, quality control, evaluation studies, medical informatics, publishing

Introduction

Quality of reporting of studies has been a concern in medicine in the past. It has led to the development of several statements with guidelines for proper reporting of randomized controlled trials – CONSORT (1), diagnostic studies - STARD (2) etc.

A few years ago, it was recognized during a workshop on evaluation in Innsbruck that the quality of reporting of evaluation studies in health informatics was not optimal. Improvement of reporting was considered to contribute to establishing a more solid evidence base for health informatics (3).

In 2006, the authors (JT and EA) coordinated the development of STARE-HI (STAtement on the Reporting of Evaluations in Health Informatics). With input of several researchers with expertise in the evaluation of health informatics applications a draft version of STARE-HI was developed in an iterative way. Currently a draft is made available on the internet for comments (4). Based on comments from the scientific community, a final version of STARE-HI will be prepared and submitted for publication in one or more Medical Informatics scientific journals.

It has been demonstrated that CONSORT has resulted in improved reporting of RCTs (5, 6). As to be able to prove that STARE-HI has resulted in improved reporting, a baseline measurement on the completeness and quality of current reporting practices is needed. The objectives of the current study are a) to test first how well the current version of STARE-HI can be used to assess the completeness and quality of reports on evaluation of health informatics applications and b) to test whether the selected assessment approach is feasible for application in a larger baseline study on the quality of current reporting in relation to the proposed STARE-HI.

STARE-HI

The scope of STARE-HI is to provide guidelines for the reporting of evaluations in Health Informatics. We consider as the object of evaluation the health informatics application that is assessed. This assessment can cover the technical artefacts as such with its functionality, but also the effect the artefact has on the surrounding organizational environment, the working procedures and social and psychological issues.

Table 1 presents the issues that are considered relevant in STARE-HI to appear in a report on the evaluation of a health care IT application together with the results of this pilot study.

Materials and methods

For the purpose of this study, all issues of the International Journal of Medical Informatics (IJMI), Methods of Information in Medicine (MIM) and of the Journal of the American Medical Informatics Association (JAMIA) that appeared in 2005 were hand searched for articles that would fit the purpose of STARE-HI.

Based on title and abstract two of the authors (JT, EA) identified candidate papers independently of each other. Discrepancies among the identifications were discussed as to define more precisely the scope of STARE-HI.

Next, for all selected papers the full text version was obtained. Each paper was assessed by TG with respect to the following aspects of the STARE-HI guideline: Title (item #1 of table 1), abstract (item #2), keywords (item #3) and study context (item #5.1 and #5.2). For this pilot we wanted to restrict the analysis to a number of key items. The four items listed above were selected because a) title, abstract and keywords help in identifying relevant papers for reviews and systematic analyses and b) study context plays an important role for assessing whether a paper is applicable for the setting of the reader. In addition, as editor and reviewers for several Medical Informatics journals we had the feeling that this item in particular is often not well addressed.

In STARE-HI for each item several aspects are being specified that should preferably be included. We counted how many aspects were dealt with for the items title, abstract and keywords in the papers and compute average score across the papers.

In the title, we expect to find the type of system assessed, the study question and the study design being mentioned.

For the abstract, we assume that the following aspects are being addressed: objective, setting, participants, measures, study design, major results, limitations and conclusions.

For keywords, we looked for the term “Evaluation” or equivalents, and for descriptors for the type of system, the setting of the study, the outcome measures and the study design.

For the study context, we scored on a three point scale (0=missing, 1= partially described, some issues unclear, 2=satisfactory description) the degree in which the organisational setting was described (#5.1) and to what extent system details were reported (#5.2). In case of non-compliance of a paper with those items the identified shortcomings were recorded as to be able to provide more detailed suggestions how reporting can be improved.

In each paper we counted also (#5.2) whether the phase in the lifecycle was mentioned, whether the intended or real usage of the system was presented and whether the relation of the researchers towards the system assessed was described (e.g. developer, user or independent).

Results

Table 2 gives an overview of the number of papers that were considered eligible for inclusion in this study.

While doing the detailed analysis of the selected papers on the basis of the full text, one paper has been considered as not belonging to the scope of STARE-HI. It described an evaluation of an algorithm, although that was not clear from the abstract. Hence this paper has been excluded from further analysis. Results are reported for the remaining 48 papers.

Table 2 - overview of number of papers selected for inclusion in this study

Journal	# of publ. Papers in 2005	Selection JT	Selection EA	Initial Agreement	# of papers after consensus
IJMI – regular	27	11	7	7	11
IJMI – special issues	74	13	9	8	11 (1 excluded later)

Journal	# of publ. Papers in 2005	Selection JT	Selection EA	Initial Agree-ment	# of papers after consen-sus
MIM – regular	37	4	0	0	3
MIM – Special issues	71	4	2	1	1
JAMIA	74	23	19	16	23
Total	282	55	37	32	49

In table 3 we give an overview on the average score for each item.

Table 3 - Average scores for the various items assessed

Item	Possible range	Average
Title	0 - 3	2.2
Abstract	0 - 8	5.0
Keywords	0 - 5	2.0
Organisational setting	0 - 2	1.6
System details	0 - 2	1.6
Lifecycle, usage, and relation between evaluators and system.	0 - 3	1.2

STARE-HI suggests to include also limitations in the abstract. None of the papers addresses this in the abstract. Also other aspects are not consistently addressed as can be seen from the average score.

One of the journals does not include keywords. Papers of that journal have not been taken into account in the analysis.

It was disappointing to see that phase in the lifecycle, the usage of the system and the relation between those involved in a study and the system studied are poorly reported. In the latter category only three papers have make the relations explicit. In the other papers, the relation remains unclear or has to be deduced by careful reading of the text.

Discussion

Scope of STARE-HI.

The scope of STARE-HI is defined as: […]to provide guidelines for the reporting of evaluations in Health Informatics (4). The object of evaluation is defined as the health informatics application. However, while selecting papers that could be considered as falling within the scope of STARE-HI we also noted a number of studies that dealt with perceptions of (potential) users of a particular health informatics application or even of health informatics applications in general. We have also considered those papers that deal with potential user perceptions of particular applications, but not of health informatics applications in general. A total of 60 papers were selected by at least one of us, resulting in an initial agreement on 53% of these selected papers. After a discussion by email we obtained agreement to include 49 papers (81%). Papers we decided to exclude dealt with applications in education, a presentation of the main results of various studies, the evaluation of the content of webpages, the evaluation of methods without the real application in practice.

Still, the scope of STARE-HI is not rigid. The excluded papers could equally well be assessed along the lines of STARE-HI but some aspects may not have been applicable.

In summary we have initially included papers, based on their title and abstract, that have assessed some aspect of a health informatics application in a real user environment.

Completeness of current reporting

Title

It is clear that titles are not yet fully descriptive for the paper. In particular the study design is often missing. Only 14 of the selected papers mention the study design in the title.

Abstract

STARE-HI promotes structured abstracts. In our corpus, 37 papers have a structured abstract and 11 have not. When we compare the scores for these two groups of papers, we have an average of 5.5 for papers with structured abstracts and 3.2 for papers with an unstructured abstract. It is clear that structured abstracts provide significantly more information about the study than unstructured abstracts ($p<0.01$). It has been proposed by others to include in a structured abstract also a section on the limitations of the study (7). It is clear that our community has not yet adopted such a strategy since no abstract addresses study limitations. Other aspects that are poorly reported are the participants (46%) and outcome measures (58%).

Keywords

Also in this area reporting is far from optimal. Excluding the papers in JAMIA, which do not have keywords, on average only less than 2 of the 5 types of keywords are listed. In particular keywords addressing study design are seldom listed (only in 2 cases). Also the term evaluation (or equivalents) is listed only 3 times.

Organisational setting

We made a subjective assessment whether the organisational setting in which the study took place was described in an appropriate way. STARE-HI proves a quite extensive description of what could be included here. It does not define "mandatory" items, but presents a list of possibilities that could be addressed. We observe an average score of 1.6 (from a maximum of 2), which indicates that there is room for improvement here. We also noted which aspects were considered to be missing in the description. In particular the duration of the usage of the system is often missing.

System details

The description of the system description was assessed in a similar way as the organisational setting. The objective was to assess whether the reader would have a proper view on the functionality of the system and how it was used. We left out an assessment of the system details like name, commercially obtained, self developed etc., assessment of such details is only useful for particular type of studies. In 8 papers there were no details on the system used. Only the type was mentioned.

Lifecycle, usage and relation information

These aspects were assessed because it will allow the reader to weight the relevancy of the paper of their situation. When you consider purchasing a particular type of system, it doesn't make sense to have a look at studies that have assessed the quality of prototype systems in an experimental situation. So lifecycle information as well as usage patterns are relevant. We also think that providing information about the relation of the authors and the object of study is relevant. It makes a difference whether the evaluators are the developers of the system or an independent party. Details on lifecycle and usage were reported in about 50% of the papers. Only in 3 papers there was explicit mentioning of the relation between the evaluators and the system.

Quality of reporting

Quality of reporting is difficult to assess. Often, quality is equated with completeness. Without completeness, it is difficult to make a quality statement. When we equate quality of reporting with ease of finding information in the papers, it is our experience that papers that follow the IMRAD (Introduction, methods, results and discussion) structure are easier to analyse that papers that don't follow this structure. For a proper assessment of the relevancy of studies in Health Informatics, contextual information is of relevance as well. That aspect is not properly covered in IMRAD, since it may appear in all 4 sections.

The feasibility of STARE-HI

This is the first attempt to apply STARE-HI as a means for assessing evaluation papers in Health Informatics.

We noted that it is difficult to define precisely the scope of STARE-HI. In our set of selected articles there are many that fall within the scope of STARE-HI. However, there are a few for which it is less clear that they fit within the scope of STARE-HI. In particular for papers that evaluate not a single application or system, but assess, for example, the impact of IT in general on workflow, certain items are not applicable. Still the global objective of the various sections may still be applicable.

We applied only a few sections of STARE-HI. In particular the sections on title, abstract and keywords are clear and provide good guidance. The section on study context defines quite some aspects that may be important to report. However, when those issues are not reported, it is often difficult to assess whether they could be relevant or not. Additional guidance on how to use STARE-HI for assessment of papers is needed. Development of a uniform scoring approach is necessary.

Feasibility of the approach

The items addressed in this pilot study can be applied to assess the quality of publications. We have selected a broad scope of manuscripts that not only included the evaluation of a specific type application in a restricted (e.g. hospital) setting. We also included more survey type of papers where for example a larger group of patients has been interviewed about their perceptions and use of the internet for searching for disease specific information. When we consider the general objective of each item of STARE-HI as the guiding principle for the assessment, STARE-HI is broadly applicable. It may be difficult, however, to make statements about the quality of reporting in general when a broad spectrum of papers is taken into account.

Limitations of study

This study focussed only on a few items of STARE-HI. Results of the application of all items of STARE-HI will be reported during the meeting.

This is only a pilot study, mainly to assess the feasibility of STARE-HI as an assessment tool and to have a first indication of the completeness of reporting of evaluation studies in Health Informatics.

We included papers from only three Medical Informatics Journals that appeared in one specific year. Although one may assume that the results presented are generalisable to papers in these journals over a longer period of time, generalisation towards all papers on evaluation in Health Informatics is not yet possible. The editorial process and journal guidelines play an important role. An extensive study including more Medical Informatics journals as well as general and specialised medical journals is needed. Such an extensive study will set a baseline value for comparative studies in the future after STARE-HI has been disseminated on a larger scale and possibly adopted by several (Medical Informatics) journals.

Conclusion

There is room for improvement in the reporting of evaluation studies in health informatics. Even the sections that are often used to assess the relevancy of papers (i.e., title, abstract and keywords) score far from optimal. The fact that the completeness of structured abstracts is much better than that of unstructured abstracts is an indication that STARE-HI as a guideline for reporting on evaluation studies can contribute to quality of papers in our field.

A study covering all papers on evaluation in Health Informatics in Medical Informatics journals as well as general and specialised medical journals is indicated to have a baseline measure on the completeness and quality of publications from our domain.

Abstract

This paper summarizes the foci, activities, methods, and results of a three-year research project. Using a mixed methods approach, the Physician Order Entry Team has identified and categorized the unintended consequences of computerized physician order entry (CPOE). After analyzing 380 examples of unintended adverse consequences, the team described in detail nine major types and conducted a national survey in the U.S. to discover how hospitals recognize and deal with unintended consequences. With the assistance of a panel of experts, the team identified strategies for managing unintended adverse consequences and outlined contents of a toolkit for CPOE implementers for addressing them.

Keywords:

attitude to computers; hospital information systems; user-computer interface; physician order entry

Introduction

The Physician Order Entry Team (POET), a group of researchers based at Oregon Health & Science University in Portland, Oregon, U.S.A., was conducting a study of success factors for implementing computerized physician order entry (CPOE), defined as direct entry of orders into the computer by physicians or others with the same ordering privileges, when we began noticing unintended consequences (UCs), such as physicians entering orders for the wrong patient. Colleagues doing similar qualitative studies in Australia and The Netherlands were discovering these UCs as well, and a collaborative effort in 2002 produced a general description of kinds of adverse consequences caused by clinical information systems (CIS) [1]. This was a rather startling revelation at a time when CPOE was being touted as the "leap" that hospitals should take in the interest of patient safety [2] and little attention was being paid to problems caused by CPOE. With funding from the U.S. National Library of Medicine, POET has been able to conduct an in-depth study over the past three years utilizing both qualitative and quantitative methods to discover more about these UCs of CPOE. Data were gathered via two expert panel conferences, fieldwork at a total of six sites (one outpatient and five primarily inpatient), and a national telephone survey of all CPOE sites in the U.S. The aims were to identify types of UCs and strategies for preventing, managing or overcoming them, and to provide tools to help implementers address them. The following presents a summary of the research foci, methods, and results.

Methods

Sample selection

The main criterion for site selection for fieldwork was a reputation for excellence in using clinical information systems. Excellent organizations learn from their mistakes [3-4]. We found that personnel in these organizations are willing to 1) describe surprises they have experienced and managed, and 2) be observed during the order entry process. In addition, sites represented a geographic distribution, different types (e.g. teaching and community hospitals) and ownership, varying lengths of experience with CPOE, and both commercial and locally developed systems. Kaiser Permanente Northwest in Oregon, selected for excellence in outpatient CPOE, uses EpicCare (Epic Systems, Madison, WI), and is a health maintenance organization. Other sites included: Wishard Memorial Hospital, a county hospital in Indianapolis, IN using the locally developed Regenstrief system; The Brigham and Women's Hospital in Boston, MA, which uses a locally developed system; Massachusetts General Hospital, Boston, MA, which uses a newer version of the Brigham system; Faulkner Hospital, a community hospital in Boston, MA, that uses the commercial MediTech system (Westwood, MA); Alamance Regional Hospital in Burlington, NC, which uses the Eclipsys commercial system (Boca Raton, FL); El Camino Hospital in Mountain View, CA, which also uses Eclipsys; and Providence Portland, which utilizes McKesson's Horizon Expert Orders (San Francisco, CA). We received human subjects approval from each site and from the researchers' organizations. Within each site, informants for interviews were selected based on their knowledge of what had occurred during CPOE implementation and use and their representative roles (physician, nurse, pharmacist, implementer, champion, skeptic, etc.). We observed clinicians entering orders in all areas of the hospitals and clinics. Experts for the expert conferences were selected based on hands-on experience with CPOE implementation and included clinician implementers from a variety of hospital types and vendor organizations.

Selected for best paper award.

Figure 1 - PET Research Overview 2003 - 2006

Data collection

Figure 1 illustrates the progression of data gathering, analysis, and reporting of results that occurred between 2003 and 2006, starting with a transition period at Kaiser Permanente Northwest between the success factors study and the UC study. We gathered data at Kaiser on an ongoing basis between the spring of 2003 and winter of 2004, developing refined semi-structured interview and observational techniques during the transition to studying UCs. In the spring of 2004 we held a conference of invited experts at the Menucha retreat center near Portland, OR to gather stories about UCs from the experts and to gain guidance about questions to ask and what to look for in the field. We then spent three to four days at each site with four to six investigators. Observations were documented with extensive field notes. Taped oral history interviews probed the history of surprises that occurred over time at each site. Realizing that it is hard to know when consequences are indeed unintended, we developed a short survey instrument to assess what clinicians being impacted by CPOE expect, and administered it to groups at three sites. Once we had identified the major types of UCs, we developed, piloted, and administered a telephone survey instrument designed to elicit information about the nature of UCs from all U.S. hospitals reporting that they have CPOE. A second conference of experts was held in May of 2006 to help interpret our results and to plan dissemination strategies, including a set of tools that implementers could use for identifying, managing, and overcoming UCs in their hospitals.

Data analysis

We first reviewed data gathered at Kaiser [5] during the transitional period between projects to gain an overview of UCs and developed a general schema that included positive as well as negative UCs [6]. Data collected during the expert conference and at the remaining five field sites yielded 750 pages of field notes and transcripts. The POET team reached consensus on each description of what seemed to be a UC, approximately 80 from the Menucha conference and 300 from fieldwork. As we analyzed them in detail, we realized that the initial UC schema we had developed [6] was too broad and superficial and that we would need to develop a more sophisticated taxonomy. Using a card sort method [7] and grounded theory approach [8], we iteratively developed a taxonomy of nine major types of adverse UCs into which all 380 instances

fit, thus reaching saturation [9]. Using an axial coding approach [10], we then found subcategories within each of the nine. Finally, we held another Menucha conference of experts to verify that these results made sense to the experts and to plan dissemination of tools to help implementers address each kind of UC.

Results

The initial schema

The initial broad schema of consequences related to CPOE included categories of intended and unintended consequences, desirable and undesirable, direct and indirect, and "two sided" consequences that could be either desirable or undesirable depending on one's point of view [6]. This schema provided a valuable framework for fieldwork because it assured that we would not limit our foci to adverse consequences. While most informaticians are interested in undesirable consequences because they need careful management, it is also heartening to know that serendipitous, beneficial surprises occur as well.

The nine types of unintended adverse consequences related to CPOE

Using the card sort method, we developed a "short list" of nine categories based on the larger list. The categories were validated as we analyzed the full complement of UCs. We have published a paper summarizing overall results [11], as well as specific papers about changes in the power structure resulting from CPOE [12] and emotions related to CPOE [13]; a paper about impact on workflow is under review [14]. As we conducted our analysis, we discovered that a large number of consequences, over 20% of the total, emanated from issues with clinical decision support (CDS). Briefly, the categories, in descending order of frequency, are:

More / New Work Issues: Physicians find that CPOE adds to their workload by forcing them to enter required information, respond to alerts, deal with multiple passwords, and expend extra time.

Workflow Issues: Many UCs result from mismatches between the CIS and workflow and include workflow process issues, workflow and policy/procedure issues, workflow and human computer interaction issues, workflow and clinical personnel issues, and workflow and situation awareness issues.

Never Ending Demands: Because CPOE requires hardware technically advanced enough to support the clinical software, there is a continuous need for new hardware, more space in which to put this hardware, and more space on the screen to display information. In addition, maintenance of the knowledge base for decision support and training demands are ongoing.

Paper Persistence: It has long been hoped that CIS will reduce the amount of paper used to communicate and store information, but we found that this is not necessarily the case since it is useful as a temporary display interface.

Communication Issues: The CIS changes communication patterns among care providers and departments, creating an "illusion of communication," meaning that people think that just because the information went into the computer the right person will see it and act on it appropriately [15].

Emotions: As outlined in the paper by Sittig et al. [13], these systems cause intense emotions in users. Unfortunately, many of these emotions are negative and often result in reduced efficacy of system use, at least in the beginning.

New Kinds of Errors: As noted by Koppel et al. [16] and Ash et al. [1], CPOE tends to generate new kinds of errors such as juxtaposition errors, in which clinicians click on the adjacent patient name or medication from a list and inadvertently enter the wrong order.

Changes in the Power Structure: The presence of a system that enforces specific clinical practices through mandatory data entry fields changes the power structure of organizations. Often the power or autonomy of physicians is reduced, while the power of the nursing staff, information technology specialists, and administration is increased [12].

Overdependence on Technology: As hospitals become more dependent on these systems, system failures can wreak havoc when paper backup systems are not readily available.

The national survey

We had already determined that the UC categories list was both useful and easy to understand and use, so we operationalized most of the categories by asking questions about UCs in a national survey. Those surveyed were to answer these questions as yes or no, and if yes, to rate the importance of this issue from 1 (not very important) to 5 (very important) (no = 0). The questions are shown in Table 1. We surveyed the entire population of acute care hospitals listed in the 2004 HIMSS Analytics^{SM} Database as having reported that they have CPOE in place (N = 448). Since that database did not include U.S. Veterans Affairs hospitals, which we feel are important models of CPOE use, we also surveyed VA hospitals (N = 113). We conducted interviews with staff at 176 hospitals, discovering that a large number listed as having CPOE did not in fact have functioning CPOE systems. We also found that a number of hospitals have policies against doing surveys.

The survey results verified the existence of these UCs, and analysis of comments offered insight into the nature of the consequences. All types of consequences are indeed widespread. Our informants did not consider two of them, power shifts and new kinds of errors, as important as the others, however. We verified that there are positive as well as negative unintended consequences, and often the same consequence can be viewed in different ways by different people, depending on their perspectives. We can only speculate about why power shifts and new kinds of errors were not considered as important as other types: those answering the questions were generally information technology professionals who may not realize that power is

shifting in their direction. They may also believe that the new kinds of errors are not of a serious nature. A paper reporting results is under review [17].

The anticipation survey

To find out if the "unintended" or "unanticipated" consequences that we had identified were perhaps already known by others in the field and therefore actually anticipated during CPOE implementations, we designed and piloted an "anticipation survey." It was designed to determine what end user clinicians were expecting to happen in organizations that were about to implement CPOE. The questions, which were asked in person, are shown in Table 2. The survey was administered as a short interview survey to 83 clinicians at three community hospitals at common gathering spots such as the cafeteria. Results from each hospital were fed back to the implementers at those individual sites. The research team conducted a comparative analysis across sites. Briefly, end users and others affected by CPOE were usually aware that CPOE was coming and that their workflow might be disrupted for a certain period of time, but they were optimistic that in the long run it would be of benefit. Other UCs were rarely mentioned. Results are summarized in a paper under review [18].

Table 1 - Phone survey unintended consequences questions

Workflow (process)
Question 1: We have noticed in our research that when CPOE systems are in use, this alters how people do their work. Have you seen this, how important is it, and could you comment?
Communications
Question 2: Communication is really important in clinical care. Have you seen any alterations in communication patterns because of CPOE, how important are these alterations, and could you comment?
Over-dependence on technology
Question 3: As we become more dependent on technology, we've noticed that people may have a hard time when the CPOE system is not available. If your computer went down, would this be an issue for your organization, how important would it be, and could you comment?
Power
Question 4: We have noticed the balance of power may shift when CPOE is used. Have you noticed that at your organization, how important is it, and could you comment?
More work, new work
Question 5: We think of computers as labor saving devices, but we all know that sometimes they're not. Are there examples in your institution of new kinds of work that you didn't do before, how important is this, and could you comment?
New kinds of errors
Question 6: CPOE has been proposed as a solution to patient safety issues, but may have created others. Have you seen new patient safety issues with CPOE, how important are they, and could you comment?
Never ending demands of technology
Question 7: The information system typically needs a great deal of support in terms of maintenance, training, updating order sets, etc. Has this been an issue in your organization, how important is it, and could you comment?
Emotions Question 8: We have seen many emotional responses to the system. Have you seen users express strong feelings about CPOE, how important is this, and could you comment?

Table 2 - Short interview survey about anticipation of CPOE

About you:
What is your role in the organization? If clinician, continue.
• Have you heard about Computer-based Provider Order Entry being implemented here?
• If no…This is a new system that would allow the physicians to enter their patient orders directly into the computer system.
• Have you been trained on it, tested it, and/or actually used it?
• What effect do you think it will have on you?
• Do you have experience with the clinical information system now available?" How do you think the new CPOE system might compare to the current paper system? Advantages? Disadvantages?
About the organization:
• What effect do you think CPOE will have on other clinicians within the organization?
• Do you think it will be more positive or negative? In what way?
• What does this mean for patients?
• Do you think it will be more positive or negative? In what way?
• What effect will the system have on the hospital as a whole?
• Do you think it will be more positive or negative? In what way?

Affirmation and dissemination

The results of our fieldwork and the survey were disseminated to the experts prior to the Menucha conference held on May 4 and 5 of 2006. The experts affirmed our categories of UCs and recommended that we develop three tools for the UCs toolkit to be widely disseminated. These include a best practices guide for implementation to help avoid UCs, a checkup tool to help hospitals assess how well they are managing UCs, and a dashboard tool of recommended metrics that can help hospitals track their progress [19].

Discussion

In this team's earlier research on success factors for implementing CPOE, we cast a wide net because little was known at that time about factors leading to success or lack thereof. A rigorous yet open-ended grounded theory [8] approach was deemed most appropriate. As research questions became more focused, however, our qualitative methods became more structured. To investigate UCs of CPOE, we started with a broad schema of types and iteratively refined the schema by consulting experts, interviewing, and observing in the field. Once a taxonomy of types was defined, we were able to craft survey questions and administer a national telephone survey. Because such a large number of adverse UCs relate to CDS, our attention is becoming even more focused in that arena.

As the team and expert consultants develop tools for helping implementers avoid, manage, or overcome UCs, we have realized that all of the success factors identified and published in the past [20] are actually UC avoidance

mechanisms. In addition, there are other strategies for addressing UCs, and a more complete list is under development.

Conclusions and recommendations

While it is hard summarizing results of an intense three year study of UCs, we can draw some general conclusions about both methods and UCs. First, the selected methods served us well for this study. The more structured and rapid techniques such as the anticipation survey efficiently augmented other kinds of fieldwork. Second, development of a taxonomy of types and subtypes not only allowed us to craft survey questions, but was also useful in structuring an approach for addressing management of UCs. One key in prevention of UCs is to pay attention to success factors for implementing CPOE in the first place. Since so many UCs are related to CDS, it seems that a fruitful area for future research would be identification of success factors for implementation of CDS.

Impact of Health Care Information Technology on Hospital Productivity Growth: a Survey in 17 Acute University Hospitals

Rodolphe Meyer[a,b], Patrice Degoulet[a], Louis Omnes[c]

[a]*INSERM- U729 and Hôpital Européen Georges Pompidou, Paris, France*
[b]*Centre de Traitement de l'Information Médicale des Armées, Saint-Mandé, France*
[c]*Assistance Publique Hôpitaux de Paris, Paris, France*

Abstract

The quantification of the added value of information technologies (IT) in the health sector is a major issue for decision-makers and health care professionals. This paper relates the application of an economic production function in hospitals with different integration levels of their clinical information systems (CIS).

The study concerns 17 university hospitals within the Assistance Publique Hôpitaux de Paris group that were followed from 1998 to 2005. Using an extended Cobb-Douglas production function, yearly incomes (Y) were correlated with three inputs: capital (K), labor (L) and IT expenses (T).

The results indicate that incomes are significantly and positively associated with the three input variables with elasticity coefficients: α, β, and γ of 0.81, 0.17, and 0.09 that appear to be in the range of values found in secondary and tertiary sectors. The IT elasticity coefficient (γ) is higher in the subgroup of 6 hospitals that integrate, or started to integrate, a complete CIS within the study period than in the 11 reference hospitals.

In a general production function, hospital costs appear to be positively connected to the level of IT expenses, capital and labor. Calculations in two subgroups of AP-HP hospitals divided according to the importance of the IT integration level seem to indicate that the more the clinical information system is integrated, the more its influence is positive in hospital production. The results of this first survey are sufficiently encouraging to try to refine them (better granularity) and to spread them in time (over a longer period) and space (to other hospital structures).

Keywords:

Information technologies, Production function, Cobb-Douglass, Productivity, Integration level.

Introduction and objectives

Since the 18th century, it has been common to link the growth and productivity of an enterprise to the elements, or production factors, used to generate products or services. The explanation of the economic growth by the combination of production factors led to the notion of production function, a mathematical relationship established between the production (output) and the factors put together to obtain it (inputs). A major step in this field was achieved by the American economist Paul Douglas and the mathematician Richard Cobb [1], who proposed a non-linear function linking yearn (Y), capital (K) and labor (L). The initial studies with this function undertaken in 1930 particularly concerned the industrial sector, and since then have spread to all economic sectors seeking efficiency. In 1956, Robert Solow [2] enhanced the function by introducing a new factor known as the Solow residual that is related to the technology level. In the 1970s, information technologies (IT) became tools capable of influencing capital and labor in a direct way. Since then, they have represented important investments and led to changes to workers and their organization; therefore, IT efficiency needed to be evaluated [3].

In the health care domain, the development and spread of the first hospital information systems (HIS) also began in the 1970s [4,5]. After a slow implementation and acceptance phase, their installation has accelerated due to political and economic encouragement. HIS had high strategic and economic importance, in particular after studies emphasized its possible role in improving the quality of care or reducing medical errors [6]. However, HIS constituted a new expenditure line that did not bring proof of its profitability, and this raised the problem of justifying the associated investments.

In addition, classic economic analysis models applied to hospitals must be adapted to integrate health care specificities. Economic studies in the medical information domain raise theoretical and practical issues such as the definition and measurement of hospital production, efficiency or productivity [7,8]. Yet, it is essential in the health domain to be able to estimate the impact of technology investments on hospital activities.

This study had two main goals:

1. To show that a classic econometric production function is adaptable to the health care world.
2. To compare the share of IT in the production function between two sets of hospitals split on an IT integration level basis.

Materials and methods

Hospitals

The study concerns 17 of the 38 Paris university hospitals within *Assistance Publique Hôpitaux de Paris* (AP-HP) (Table 1). These hospitals were selected according to their size (more than 350 beds) and activity (acute and short-term care). Data used in this study range from 1998 to 2005, and give a total of 136 complete annual observations. The 17 hospitals were split into two groups according to their IT integration level. Group 1 consisted of 11 hospitals having mainly administrative and ancillary department management systems (i.e., laboratory, radiology and pharmacy). Group 2 consisted of 6 hospitals that installed or had started to install an integrated clinical information system (CIS) during the study period. Hospital H12 began the installation of its CIS in 1998, H13 in 2000, and H14 to H17 throughout t 2003.

Table 1 - Sample of data from the 17 hospitals, 2005

Hospital	Nb. beds	Y(*)	K(*)	L(*)	T(*)
Group 1					
H 1	468	129.6	29.4	78.8	3.45

(*) Y = yearn, K = capital, L = labor, and T = IT in millions					

Production function

Using an aggregate Cobb-Douglas function (1) [9,10] the links between hospital production (Y) and three different inputs –capital stock (K), quantity of labor (L), information technologies (T) – and the Solow residual (A) were evaluated assuming the constant elasticity of substitution of the inputs (i.e., $\alpha+\beta+\gamma=1$) [11].

$$Y = A.K^{\alpha}.L^{\beta}.T^{\gamma} \quad (1)$$

Knowing the value of the output (Y) and of the inputs (K, L and T), the value of the α, β and γ elasticity factors were calculated to estimate the importance of each input in the explanation of the observed output.

Output and inputs

For each hospital, the value of the production **Y** was assimilated to the yearly incomes of the hospital in millions of Euros.

K regroups the financial assets owned by the structure during the study period. The capital at year *t* is defined as the accumulated assets and real estate investments of the previous years, modulated by a depreciation factor depending on the nature of the investment. This depreciation varies between 3 to 10 years depending on the French Government's guidelines in use [12]. Capital stock is defined as the capital accumulated by the hospitals from past and current investments, adjusted with depreciation. Capital stock represents the capability of hospitals' productive assets, whereas annual investments only reflect assets acquired during a particular year. Hence, productive capital stock in a hospital is measured by the following depreciation formula [13]:

$$K_t = (K_{t-1} + NK_t) - D_t \quad (2)$$

The assets of the studied year (K_t) are equal to the value of the assets of the previous year (K_{t-1}) added to the value of the new investments (NK_t) decreased by a factor of calculated markdown (D_t) [14]. In this study, the K variable excludes IT investments.

The annual measurement of labor input **L** in Euros was delivered by hospital's budget records and it involved medical as well as non-medical hospital employees during the past years excluding IT workers.

T is the aggregation of IT-specific expenses including salaries, hardware and software expenses with their depreciation (i.e., T = IT capital + IT labor) [14–20].

Statistical analysis

Data collected in our survey has been retrieved from the financial systems of the 17 hospitals and were computed via scripts using the Eviews® 5 econometric software. The results for the R2 coefficient and Durbin-Watson's statistics were given by Eviews®. These statistics have then been cross-checked with Statistica® 7.

Results

Output and inputs

The values of Y, K, L and T increased constantly since 1998 (Table 2). Between 1998 and 2005, Y increased by 47.1%, K by 69%, L by 28.4% and T by 37%.

IT expenses represented 2.8% (5.8 millions ¤) of the global expenses (205.3 millions ¤) in 2005.

Table 2 - Average output and inputs values (17 hospitals 1998–2005)

Year	Y(*)	K	L	T
1998	161.4	32.1	113.1	4.3
1999	166.4	37.2	116.1	4.6
2000	172.4	42.4	121.0	4.9
2001	182.7	48.8	125.0	5.3
2002	197.3	51.2	131.4	5.3
2003	201.8	55.2	138.1	5.6
2004	226.2	56.7	140.6	6.2
2005	237.5	54.3	145.2	5.8
(*) Y=yearn, K=capital, L=labor, T=IT (millions ¤)				

Share of Input Factors

For the 17 hospitals, the share of capital, labor and IT were respectively 0.168, 0.766 and 0.085 (Table 3). All coefficients were statistically significant ($p<0.05$). The Solow residual is 0.81. Durbin-Watson's statistic is between 1.51 and 2. The value of the R2 is highly significant (0.97, $p<0.0001$).

Table 3 – Share of factors (17 hospitals - 2005)

	Value	Std. Error	t-Statistic	p
A	0.8146	0.0430	18.935	0.0300
	0.1686	0.0509	3.3086	< 0.0001
	0.7657	0.0555	13.791	0.0216
	0.0853	0.0361	2.3643	0.0094
R2 : 0.9701			**Durbin-Watson** : 1.5772	
A = Solow residual = share of capital = share of labor = share of IT				

The value for IT is in the range of results [0.03 to 0.16] from other studies performed in secondary and tertiary economical sectors (industry and services) [14, 16–20] (Table 4).

Table 4 - Share of factors in industry and service studies

Studies [14,16-20]				R2
Hitt – 1994 [16]	0.2280	0.6860	0.0307	0.9510
Hitt – 1999 [17]	0.1300	0.7300	0.1100	0.9400

= share of capital = share of labor = share of IT				

CIS integration level influence on elasticity coefficients

Table 5 compares the inputs' (K, L, and T) elasticity coefficients values in the two groups of hospitals. All elasticity coefficients remain statistically significant, and is higher in group 2 (integrated CIS) than in group 1 (0.103 vs 0.072).

Figure 1 shows that in both groups, the IT coefficients () increase from 1998 to 2005, and there is a higher slope from 2003. The difference between group 1 and group 2 has also increased since 2003.

Table 5 – Share of factors for the two groups (2005)

Group 1 (n=11) – no CIS				
	Value	Std. Error	t-Statistic	p

Discussion and conclusion

The economic approach of capital efficiency is generally represented by the informal ratio of production divided by capital expenditure [21]. The larger the ratio, the better the capital efficiency is, and thus leads to greater output. Long-term economic models, and especially growth accounting analysis [22], use the capital stock per worker ratio to study the impact of capital expenditure and capital stock increase on long-term output growth (e.g., the Robert

Solow model completed by different endogenous growth theories [23, 24]).

The common use of production functions described by Cobb and Douglas began in the 1930s, but it's only since the mid-1990s that researchers used its mathematical properties to isolate the share of IT in the production of various factories and business enterprises [15–20].

In the health care domain, numerous studies have measured the indirect earnings (quality and continuity of care, satisfaction of the users, etc.). However, very few studies have attempted to measure the direct earnings deriving from the integration of the different HIS components. The contradictory results of these studies frequently drive hospital managers to make decisions only on expected indirect benefits.

This study started with two goals: to try to use a classic econometric function on French hospitals data to isolate the share of IT in the hospital production, and to compare the share of factors between two sets of hospitals split on an IT integration level basis.

The first results show that using a function traditionally employed by economists in their analyses of the business world is possible within the health care world. In addition, the elements brought by the Cobb-Douglas production function stress the importance of the human factor in explaining the hospitals' production results. With a coefficient of 0.76, share of labor in the hospital is slightly superior to what is generally admitted in the industrial or service sector in France (0.70) [25].

If we compare the two groups, our results tend to show that the share of IT explaining the production observed is about 1.7 times more important in structures having a higher level of CIS integration than in the low-level ones. It is also important to notice that the share of IT explaining the production is measured between 0.07 (group 1) and 0.10 (group 2) and that the share of capital is measured between 0.17 (group 1) and 0.16 (group 2). When we know that IT investments represent only 11% of capital investment in the two groups, this may be a sign of the importance of IT in hospital production. It also shows that, in the end, a high level of IT integration is not necessarily more expensive than a low-level one.

The introduction of the IT input (**T)** in the production function takes into account the place of high technology in the hospital and its importance in modern health care activity. Numerous studies [18–24] emphasized their T input to smooth the differences observed with the global assets. They multiplied the IT labor value by a determined factor ranging from two to seven according to complex depreciation rules. Using the same approach in our work returned less pertinent results And therefore we didn't adopt it. The creation method of the T variable could be changed by extending it to workers and materials also closely related to the HIS-like image producing systems (i.e., scanner) and laboratory automatons that could be considered as acquisition peripherals. We limited ourselves strictly to the HIS officially assigned material and workers, having in mind that the border separating pure computer science from the techniques involving its presence is growing thinner.

A postulate known as the productivity paradox describes IT more or less like a victory that costs more than it achieves. Several authors [26, 27] analyzed this paradox in various industrial sectors to attempt to decide on its reality. The results are still contradictory. However our data seem to confirm the positive impact of IT on the studied hospital production during an eight-year period of follow-up. This global analysis needs to be completed by an individual analysis of hospital productivity before and after the introduction of their CIS since the different HIS implementation starting years in our study might have hidden some production that could appear just after the introduction of a CIS.

Since we showed that the initial production function could be enhanced using its mathematical properties, we can suppose that other constructions could be imagined that focus more specifically on one point or another (like the share of non-medical labor versus the share of the medical labor).

Information technologies are a composite mix of hardware software, knowledge, integration level, operational support and infrastructures. Our study showed us that IT investments are bringing value and contribute in positive way to hospital production. The separation of the hospitals into groups based on various other criteria (such as activity or volume) could sharpen the analysis of IT impact on hospital activity and production. Extension of this work to other hospital structures on a longer period of follow-up could also prove interesting.

On a methodological level, the econometric field is a vast area possessing a large quantity of mathematical functions that could prove useful to try on our data. These functions are either instantiations of the Cobb-Douglass function or new approaches born from mathematic research used by economists worldwide (Box-Cox, Box Tidwell, regression spline or stochastic borders analysis for example) [28, 29]. Considering the colossal increase in IT expenses and the size of IT costs in hospitals, this kind of analysis could permit hospital managers to obtain tools to aid decisions and enable the enhancement of IT governance in the health care business [30-33].

Acknowledgments

The authors would like to thank all the AP-HP staff who participated to the collection of this survey data, particularly J.P. Lefort, G. Pichaul, M.P. Ferec, D. Heudes and V. Woszto.

Risk Management and Measuring Productivity with POAS - Point of Act System

Masanori Akiyama [ab], Tatsuya Kondo[b]

[a] *Sloan School of Management, Massachusetts Institute of Technology, Cambridge, MA, USA*
[b] *International Medical Center of Japan, Tokyo, Japan*

Abstract

The concept of our system is not only to manage material flows, but also to provide an integrated management resource, a means of correcting errors in medical treatment, and applications to EBM through the data mining of medical records. Prior to the development of this system, electronic processing systems in hospitals did a poor job of accurately grasping medical practice and medical material flows. With POAS (Point of Act System), hospital managers can solve the so-called, "man, money, material, and information" issues inherent in the costs of healthcare. The POAS system synchronizes with each department system, from finance and accounting, to pharmacy, to imaging, and allows information exchange. We can manage Man, Material, Money and Information completely by this system. Our analysis has shown that this system has a remarkable investment effect – saving over four million dollars per year – through cost savings in logistics and business process efficiencies. In addition, the quality of care has been improved dramatically while error rates have been reduced – nearly to zero in some cases.

Keywords:

POAS (point of act system), hospital management, ERP (enterprise resource Planning), financial management, risk management

Introduction

There has been a tendency in medical care to give low priority to management and the improvement of efficiency; medicine has been regarded as a sacred area exempt from such moves. However, in September 2001 the Ministry of Health, Labor and Welfare made public a draft plan of medical system reform because of the need to seriously review the country's medical services. This was brought about both by the harsh economic conditions existing after the collapse of the asset-inflated bubble economy in the early 1990s and the aging of society accompanied by declines in the birthrate. The plan, which not only visualizes reform of the medical insurance system but also pictures an ideal system of medical care for the future, is a comprehensive draft for institutional reform. In concrete terms, the plan calls on medical professionals to respect their patients' points of view and allow patients to take responsibility for decisions regarding their own care, to improve the environment within which information is supplied, to provide high-quality, efficient medical care, improve the quality of medical service, regional medical care security and to introduce the use of information systems in providing medical services. The point of these suggestions is to foster respect for the options chosen by patients, to provide the information necessary for informed decision making, to establish a system that provides high quality, efficient medical service and to build a foundation for public confidence. Because of these proposals, economic efficiency in medical care is becoming an important public issue. In this context, information technology (IT) can serve as a helpful tool. When the improvement of efficiency is stressed, the quality of medical care may tend to be sacrificed.We have developed a system that, utilizing IT, can accurately calculate costs, in a bid to maintaining a balance between efficiency and quality. At the same time, the system can also be used as a yardstick for the measurement and improvement of efficiency.

Materials and methods

Points that need to be addressed

The traditional hospital information system (HIS), built by connecting order entries and the medical clerical system, takes in information about orders and outputs medical payment requests via a medical accounting system, which is actually a payment system. However, this kind of system has the following problems: 1) Although physicians are supposed to enter correct payment information, the information is often incomplete (occurrence of uncollected balance). 2) The data terminals within divisions and those at the HIS are not integrated. As a result, duplicate entries are required, resulting in unnecessary extra work. 3) While data held in the HIS can be sent to the medical financial system, divisional data necessary for payment cannot be entered due to inconsistencies in the master system. 4) It is difficult or impossible to search the information held by the medical financial or divisional systems via the order systems. 5) A most important problem is that the existing systems have been used primarily for preparing medical payment requests. As a result, data on clinical activities, which have nothing to do with medical insurance, are not received (and could not be handled anyway) by the existing systems.

In these circumstances, when certain expenses are not covered by medical insurance, it has not been possible to make accurate assessments of expenses for materials and person-

nel through cost calculations based on the data held in the medical financial systems.

Outline of the system

To deal with these problems, we have designed a three-tier model. The middle-tier application server is located at the center. Each divisional system manages data that has resulted from that division and its clinical work processes[1,2]. Each division manages and preserves detailed data, including its reports, and provides only the "outlines" of the data to the application server. Thus, the actual data are not sent to or preserved in the application server. Since only outlines of data are held in the central application server, the volume of data stored there will not increase dramatically. Each client communicates with the others via the application server, and a graphic user interface (GUI) is provided for each occupational category.

Calculating medical care costs

Calculating medical care costs, which had posed difficulties that needed to be resolved, has now become possible. POAS, which stands for the Point of Act System, is a design feature of this comprehensive medical information system. Its characteristics are as follows. 1) Information on all medical activities is collected as detailed data at major "action" points, from the time orders are issued on through to their implementation. 2) The system is organically linked to various medical devices, such as medical diagnostic instruments, X-Ray equipment and equipment in the pharmaceutical division. It records information about medical activities, and their results, in a general-purpose database in various forms such as images, numerical values and text. 3) It uses a general-purpose data description method that enables flexible incorporation in response to advances in IT technologies. 4) It has a data warehouse structure, which collects and permits the analysis of detailed data at the level of individual medical activities. 5) It helps prevent medical errors – including mistakes at the stage of implementation – by making it possible to cross-check such data as patient identification, ongoing medical activities, medicines to be used and what personnel carry out the medical activities, each time an activity is executed. 6) It can be used to calculate profits and costs, based on orders. It will total them by medical fees, sectors or patients. These figures can be utilized as management information.

Mechanisms for data collections and structure of order item

Data on medical activities at the points of action listed below can be collected centrally by direct connections to the order systems and the medical equipment in each division. Order is input, received, changed or cancelled, implemented (contact is made with the accounting section), and completed. Necessary units of data recorded by the system, based on the idea of 6Ws and 2Hs , are as follows: Who-the implementer (the person who placed an order, or the person who carried it out); to Whom - the patient; How - medical activities and changes in them; What - materials used (pharmaceuticals, medical materials and others); How Much - amount of materials used and the number of applications; For What - name of the disease subject to these medical activities; When - date when the order was placed, when it was implemented, and when it was discontinued; and Where - place of implementation (department, hospital ward, and equipment used). We have made it possible to calculate the costs related to each type of disease by entering the name of the disease along with each order.

Results

Operational track records

The underlying concept of this system is POAS, which enables records of "who did what to whom, where, when, using what, and for what reason" [1]. In short, real-time input becomes possible at the point of action. Logs, including inventories, are created. It becomes possible to reduce to a minimum the difference between expenses from medical activities and the amount claimed as lost by adopting the "accrued basis of corporate accounting" concept. In short, the management of divisions and their work, using a corporate financial/accounting system, has become possible by identifying the divisions that are incurring losses. The system operates continuously at the International Medical Center of Japan, handling 100 transactions per second, or more than 360,000 transactions per hour. It has been in continuous operation for four years.

Linking the hospital information system (POAS) with the management information system

The hospital information system concerning diagnosis and treatment (POAS) and the management information system, centered on accounting, are separate systems. Data collected as described above are compiled at midnight each day in the clinical database and then sent to the management information system. It calculates all costs in the early morning, using batch processing. As a result, management information from the previous day is available by 6:00 a.m.

Positive management analysis

1. The use of POAS makes possible management analyses based on objective data. The following kinds of analyses can be performed.
2. Profit-and-loss calculations for medical treatment departments/divisions
3. Profit-and-loss calculation by patient category
4. Calculating cost by disease
5. Profit-and-loss calculation by physician

Risk management

Characteristics

The difference between POAS and conventional systems is that POAS is not based on orders but on actions. Essentially, traditional systems were expanded versions of the medical accounting systems that were brought into nurse stations and outpatient departments. This means they were only capable of processing orders by day. As a result, these systems can cause time lags of anywhere between 10 minutes and up to several hours, posing a major problem for the medical workplace. To shorten the time-lag to meet the requirements of medical workers at the patient's bedside - about 2 to 3 seconds- data granularity must be based on

single vials. It is important to recognize at the outset that the Medical Affairs Section and the sections responsible for executing actual medical actions require different data granularities. If a system's granularity were to be based on single items to begin with, its data could be easily compiled to derive the data required by the Medical Affairs Section as well. This is the reason why conventional systems have not been useful for improving productivity, gathering clinical data or improving management efficiency. While manufacturers conduct production control on their drugs and medical supplies by single types, by the time these products reach the hospital through the wholesaler, they are batched together into units of boxes or purchase orders. As a result, conventional material flow systems process these items by the shipping slip and not by single types. Even if these products were checked by shipping slip or per day, once an accident occurs, it would be too late to prepare electronic medical charts. To prevent accidents, these products must be controlled as single items from the outset. When the shipment is received, POAS controls these items as single types, not by shipping slips. This helps prevent accidents since it allows hospital operators to implement the same level of quality control as the manufacturers.

Effects

According to a survey of injection prescriptions previously conducted at the International Medical Center, changes were ordered for 20% of these prescriptions at one time or another. Since then, the average hospital stay has been halved to 15 days, and we used POAS to calculate the rate of injection instruction changes for a one-year period ending October 2004.

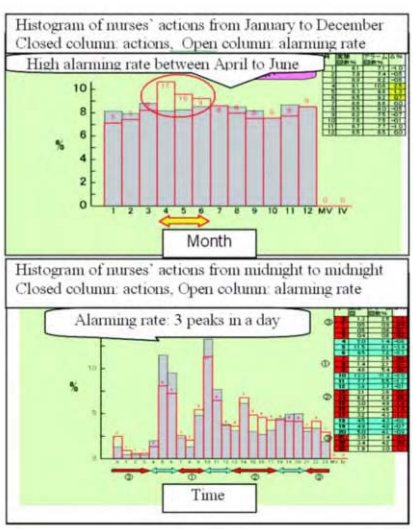

Figure 2 - Basic analysis: the frequency distribution of variables

Changes were ordered for 24% of the ﾒ injection prescription ﾄ between the time they were issued and the ﾒinjection mixingﾒ step. In addition, changes were ordered for 15% of the instructions after "injection mixing" (Fig.1).This shows that changes were ordered for a total of about 40% of the instructions. These changes should have doubled the amount of work for nurses and pharmacists, but their actual workloads did not increase. There was a reduction in nurse overtime and the number of accidents fell to zero. Similar improvements were seen at the Morioka Red Cross Hospital after they began using POAS. This was because automation eliminated tasks such as filling out and transferring slips, which previously took up most of the nurses' time.

Figure 1 - The effects of making injection action entries (calculated from performance data)

The figure 2 shows a map of nurses' actions from midnight to midnight. POAS also records nursing and care procedures. The logged records are 400 thousands / month, then about 80 million logs and 18 million records accumulated over two years. We can see that a variety of workloads are concentrated in the 9:00 AM to noon timeframe. This is because the morning shift starts at 8:30 for types of work. Most of the important medical actions are carried out before noon and 40% of the prescription instruction changes also procedures during this time. This is a hazard-prone timeframe that produces the most accidents and incurs the most wasted.

Injection accidents are most likely to result in personal injury. Therefore, here we analyze the causes of injection alarms. The horizontal axis shows the total number of injections performed and the vertical axis shows the alarm rates (Fig.3). Each point corresponds to a single sample with duration of 30 minutes each. The values are for the entire hospital for a period of one year. It shows that alarm rates were lower during time segments in which a large number of injections were performed and were higher during time segments in which fewer injections were performed. This indicates that accidents do not necessarily occur because nurses are busy.

Fig.4 shows the number of errors and error rates in 30-minute increments. You can see that the alarm rate increases immediately after a shift change. Additionally, you can see that the execution of instructions that were specified for 6:00 a.m. were scattered over several hours between 4:30 and 7:30. Conventional electronic medical chart systems will show these as being administered at 6:00 a.m. and there will be no way of getting a picture of the actual situation.

With the POAS system, users can not only track this information, but also analyze the effectiveness with pharmacokinetics and blood kinetics, as well as efficacy for different administration times.

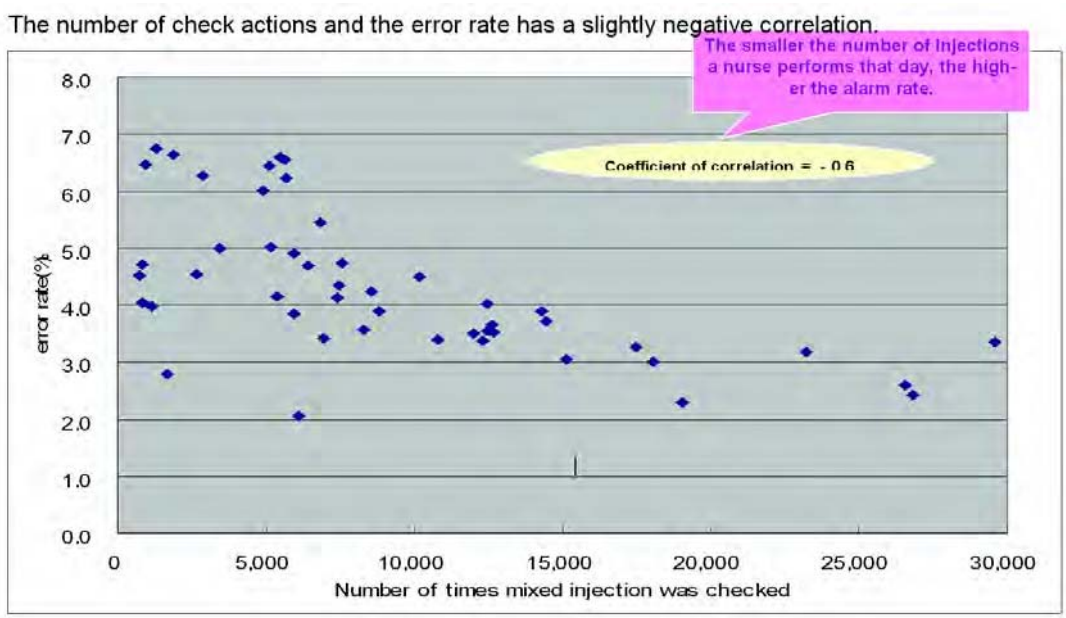

Figure 3 - Comparison of the number of times mixed injections were checked and error rate (%)

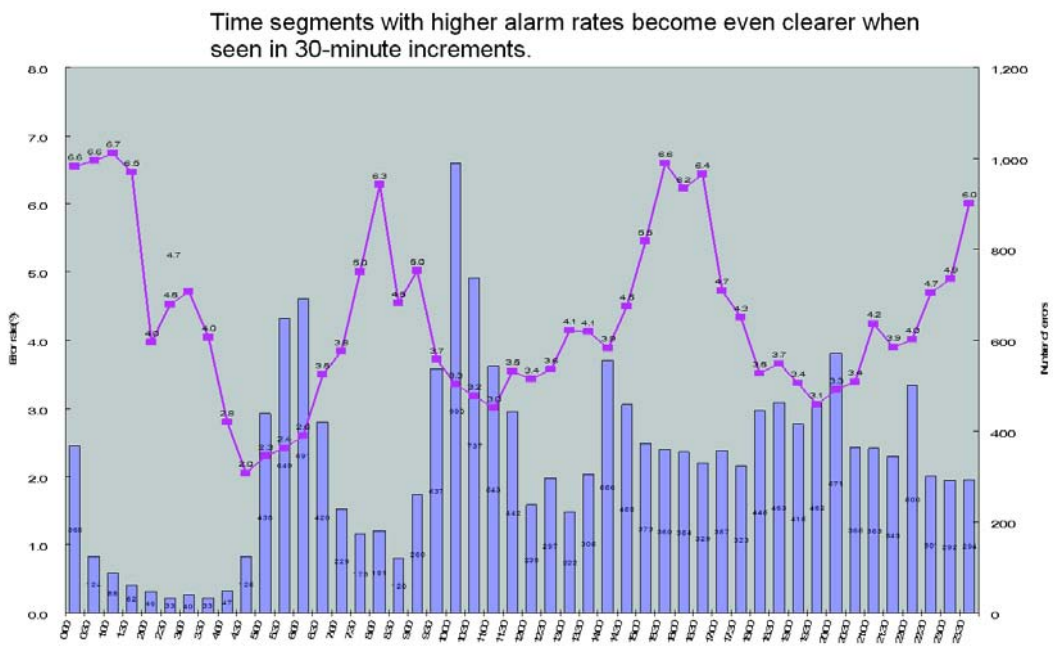

The height of the curve becomes progressively lower for the second, third and fourth injections and the dispersion become more evident. This is likely due to the fact that the first injection is started at around 6:00 a.m. and the second and later injections are IV replacements performed in response to nurse calls. The important point here is that the timeframe before 10:00 a.m. is potentially extremely hazardous. This is the timeframe during which powerful drugs are used the most often, with a corresponding spike in the number of incident and accident reports.

Discussion

Conventional hospital information systems are typically linked to other divisional information systems through the order entry system vendor [3]. However, such centralized

systems do not necessarily conform to the actual state of affairs within which the front line of medical care functions, led by the separate divisions. Linkage between divisional systems has become easier, thanks to recent distributed object technologies that have made it possible to design an order entry system centering on the divisions. With this system, on-site units not only output images and medical payment requests, but also record "where and when who did what to whom, using what, and for what reason." In short, it becomes possibleto enter the sources of events which generate logs that are useful for healthcare management.

As a result, it also becomes possible to assess each admission. Appraisal and review of clinical paths themselves is also made possible. We have found that there is no point in comparing the profits and losses of medical treatment departments and wards uniformly, since actual analyses of profit-and-loss indicated that each medical treatment department/ward has different characteristics. Therefore, we found it better to focus our efforts at improvement using comparisons of time series data from the same medical treatment department/ ward [4]. Losses are inevitable at some medical treatment departments and wards for institutional and political reasons. In this context, we concluded that money-losing divisions should be asked to make efforts to reduce their losses by setting goals, rather than to attempt to turn uniformly profitable.

This system not only aims to provide risk and logistics management, but also comprehensive oversight of management resources, means of preventing medical errors and the application of medical execution records to evidence based medicine (EBM). The system can also conform to a package payment system. Conventional systems could manage logistics in the central materials division, but it was difficult to manage materials accurately at the point of consumption in each division and department. The POAS system incorporates an online barcode check via newly developed portable terminals. It firmly establishes an efficient business system that records the relationships between materials use and work – which had not previously been recognized – and it eliminates waste. Simply stated, POAS enables users to relate medical activities to materials accurately, even though they are not listed on medical payment requests, and to confirm the real-time movements of materials and patients, after eliminating duplicate inputs and reducing clinical labor. Material on data that accrues within each division's system is transferred simultaneously to the management control system.

In conventional systems, prescription changes made by a physician would take several minutes to several hours to be reflected on terminals used by nurses or the pharmacy. Hospitals have experienced accidents even when barcodes were scanned during a procedure because no alarm sounded at the time. In POAS, all the information including prescription changes made by the physician, as well as confirmation points for nurses and pharmacists are on a shared database, so the information is reflected in 2 to 3 seconds. This eliminates injection accidents. The displays also reflect the use of a shared database. While displays for physicians, nurses, pharmacists and co-medical staff all have a different appearance, any shared data content is queried from the same database. POAS uses a single set of data for controlling processes. This is because data duplication results in inconsistencies and accidents.

You can imagine that an accident occurs. Is the physician responsible for the accident? The relation between a sequence of processes is crucial for preventing accidents. It would be impossible to reproduce the situation in conventional systems, but POAS makes this possible. By analyzing the actions of the person in question as well as those of the people connected with this person, hospital operators can establish systems and organizations that are robust in terms of accident prevention.

Conclusion

Since our focus was to develop a system based on data capture at the point of action throughout the hospital, this system is designed to be able to unitarily analyze data for better healthcare management. Our analysis has shown that the cost savings effect alone is over four million dollars per year. The quality of care and improved outcomes has shown equally significant improvement.

Abstract

The prevalence of Methicillin-resistant Staphylococcus aureus (MRSA) and Vancomycin-resistant Enterococci (VRE) continues to increase dramatically worldwide. Successful programs to reduce infection rates of resistant organisms require regional or national compliance with strict infection control measures and feedback on implementation and reduced rates. We partnered with local infection control professionals (ICPs) and leveraged our existing electronic network to create a comprehensive citywide network to track and uniformly respond to patients admitted with a history of MRSA or VRE. We successfully standardized and included electronic data from four out of six of the major healthcare systems within Indianapolis. We created tailored abstracts to deliver key infection control data to ICPs when a MRSA patient is admitted to a participating hospital. We created web-based data entry forms for ICPs to modify and enter new infection control data. This paper describes our design and initial implementation of a working electronic regional infection control network.

computerized medical tecord dystems, infection control, MRSA, VRE, antibiotic resistance

Introduction

Rates of colonization or infections with drug-resistant organisms are steadily increasing [1]. Patients infected with MRSA suffer increased morbidity and mortality and have significantly increased lengths of stay and health care costs [2]. Delay in correctly detecting these infectious patients and implementing measures to prevent transmission represents a danger to patients and providers who come in direct contact with these patients without appropriate precautions [3].

Some countries, notably Denmark and The Netherlands have successfully controlled rates of MRSA by instituting nationwide policies for prompt barrier isolation of MRSA positive patients and controlling antibiotic prescribing practices [4,5]. Within the United States, a network of hospitals demonstrated that sharing best practices between multiple hospitals significantly reduced rates of nosocomial infection and colonization [6]. Evans et al. at LDS hospital in Utah successfully created a system-wide surveillance system for MRSA patients and demonstrated the itinerant nature of MRSA patients [7]. Samore et al. successfully applied electronic clinical decision support to improve appropriate antimicrobial use across two states [8]. However, such success is the exception, and in most countries, including the United States, MRSA rates continue to steadily increase.

Indianapolis is well positioned to merge the benefits of inter-institutional collaboration and the efficiency of electronic data exchange and build upon the published experience. Investigators at the Regenstrief Institute created the Indiana Network for Patient Care (INPC) in 1994 with the goal of improving the care of patients [9]. The INPC is an *operational* community wide electronic medical record. The system currently includes data from 17 hospitals in five health systems, the Marion County Health Department (MCHD) and various physician practices.

Here we describe our rationale, design and initial implementation of an electronic infection control network paired with a standardized infection control approach to reduce the transmission of MRSA across a city.

Materials and methods

Background

Creating a citywide infection control network involved a concerted effort to build consensus among various stakeholders, and depended on a number of prior developments and studies.

In 1994, researchers at the Regenstrief Institute created the INPC to improve the care of patients across multiple institutions. Today, the INPC connects almost all major health care institutions within Indianapolis spanning over 95% of all inpatient care. When a patient registers at an INPC institution for emergency department care or admission to the hospital, a paper abstract prints which includes key clinical data on that patient from any INPC institution. The

core set of data currently received from all participants includes demographics, laboratory data, ED and inpatient encounter data including chief complaint, coded diagnoses and coded procedures [9].

Prior work within one of the participating INPC institutions highlighted the potential for the timely delivery of accurate data on MRSA history to improve the care and efficiency of patients [10]. In this study, computerized reminders to barrier isolate patients with a history of MRSA increased barrier isolation rates from 33% to 91%. Despite this success, rates of nosocomial infection did not significantly change. One suspected reason for this apparent paradox was the known itinerant nature of patients. A previous trial linking patient registrations across multiple INPC institutions demonstrated that up to 60% of all patients within the Indianapolis area are treated at two or more healthcare institutions within a single year [11]. Currently, information on positive cultures from prior institutions is not readily available. Based on our experience and models of community and hospital spread of MRSA we concluded that effective infection control requires efforts beyond the reach of a single institution [12,13].

Scope of the problem

To quantify the extent of this problem of itinerant patients spreading MRSA within our population, we conducted a retrospective analysis to determine how often patients with a history of MRSA known at one institution presented to an institution where they were not known to be MRSA positive. We obtained lists of patients with a prior history of infection or colonization with MRSA from the infection control departments of three health care systems within central Indianapolis, as of January 2006. The INPC has a tool to link patients with different hospital numbers (within or across systems) who are the same. It uses a number of patient attributes including name, birthdate, and gender to identify matches. Studies conducted on a test population resulted in a 92% sensitivity and 100% specificity for true matches [14]. We matched the common global identifiers from each institution's MRSA list to those on the MRSA lists of the other two in order to determine the subsets of patients held in common on each list, and to determine patients that were only on the list at one institution.

Within a subset of three centrally located INPC institutions we identified 8,895 patients with a history of MRSA based on the infection control lists against the registration lists of patients presenting to three participating institutions. Over a single year, these patients accounted for 4.4% (5,244) of the estimated 120,000 admissions for these three institutions. More concerningly, a subset of MRSA patients not known to have a history of MRSA (i.e. never showed up on the receiving institutions MRSA lists) generated 594 admissions with an average length of stay of 7.2 days. This accounted for an additional 11% of total admissions of MRSA patients over one year.

Addressing the problem: building consensus

With these results in hand, we approached the members of the INPC steering committee and successfully garnered support. We approached the individual hospital ICPs to raise the possibility of an electronic information sharing network for infection control data, and to elicit feedback, we conducted a survey of ICPs to determine their information needs and preferences to guide our subsequent design. Eight ICPs representing four INPC institutions responded to our survey. All respondents preferred electronic notification and web access for both storage and retrieval of infection control data.

With support from both the INPC steering committee, the local ICPs, and the approval of multiple institutional IRBs, we successfully competed for national funding to support further development work.

Through weekly teleconferences the researchers met with ICPs representing all participating institutions and together crafted a standard document and goals. An informatician was present to determine how standard practice could be captured and delivered electronically to ICPs.

We created a secure website using a commercially available software package [15] to coordinate the many participants and provide a common ground for the exchange of documents.

Partnering for organizational change

A key component of our design acknowledges that simply knowing a patient's MRSA status does not necessarily translate into action. We realized that for long term success, we needed to implement organizational change and drive implementation from the lowest level possible from within the frontline staff of an organization.

Lean is a quality improvement methodology based in Systems and Industrial Engineering techniques. These techniques have been shown to be highly effective for continuous quality improvement within manufacturing environments and there is evidence to suggest that appropriately developed and optimized Six Sigma and Lean techniques are effective within healthcare settings[16,17,18]. We partnered with faculty from the Regenstrief Center for Healthcare Engineering and the Purdue School of Engineering and Technology at IUPUI to identify and remove operational barriers present within the processes used to respond to the MRSA positive patient across all institutions. We focused on three processes: hand hygiene, barrier isolation compliance, and active surveillance cultures.

At each institution we identified a Project Team and a Process Owner for each of the three processes. We worked within the current quality improvement framework (e.g. Six Sigma, Model for Improvement) for each institution to clearly define the problem, the project goal and scope, and define metrics to measure success for each Institution's Project Team. Additionally, we worked with front line staff teams in application of Lean tools to identify and remove operational barriers within each of the three processes.

Results

Design and implementation

Based on our weekly meetings, and review of the data collected individually by ICPs at each institution we created seven standardized vocabulary terms to document potential infection sites, and study status (Table 1). To preserve

as much of the original descriptive data stored by ICPs we opted to maintain culture site as free text data. All observations are date and time stamped at the time of data entry, and stored in the individual institutions standardized medical record file.

Table 1 – Standardized infection control terms

Term	Type
MRSA Culture Site	Free text
MRSA Culture Infection Status	Coded
VRE Culture Site	Free text
VRE Culture Infection Status	Coded
Study Action Status	Coded
Barrier Isolation Status	Coded
Infection Control Comments	Free Text

To date we have standardized the data for 12,253 patients with a known history of MRSA, spanning four out of the six major health care institutions within Indianapolis. When a patient with a history of MRSA is admitted to an INPC hospital, we can deliver a printed or electronic abstract containing the standardized infection control data securely to the institutions ICP and admitting office (Figure 1).

We created web-based data entry forms for ICPs to update or make changes to the patient data, and document compliance with our standardized treatment protocol (Figure 2). We included a section for ICPs to write free text comments for delivery on subsequent abstracts.

We have standardized the infection control data and assembled implementation teams of frontline staff at three out of the six major healthcare systems in Indianapolis. We achieved over 90% adherence with these three measures in 2 ICUs at one participating institution, with a resulting elimination of MRSA transmission over the first 60 days of the program.

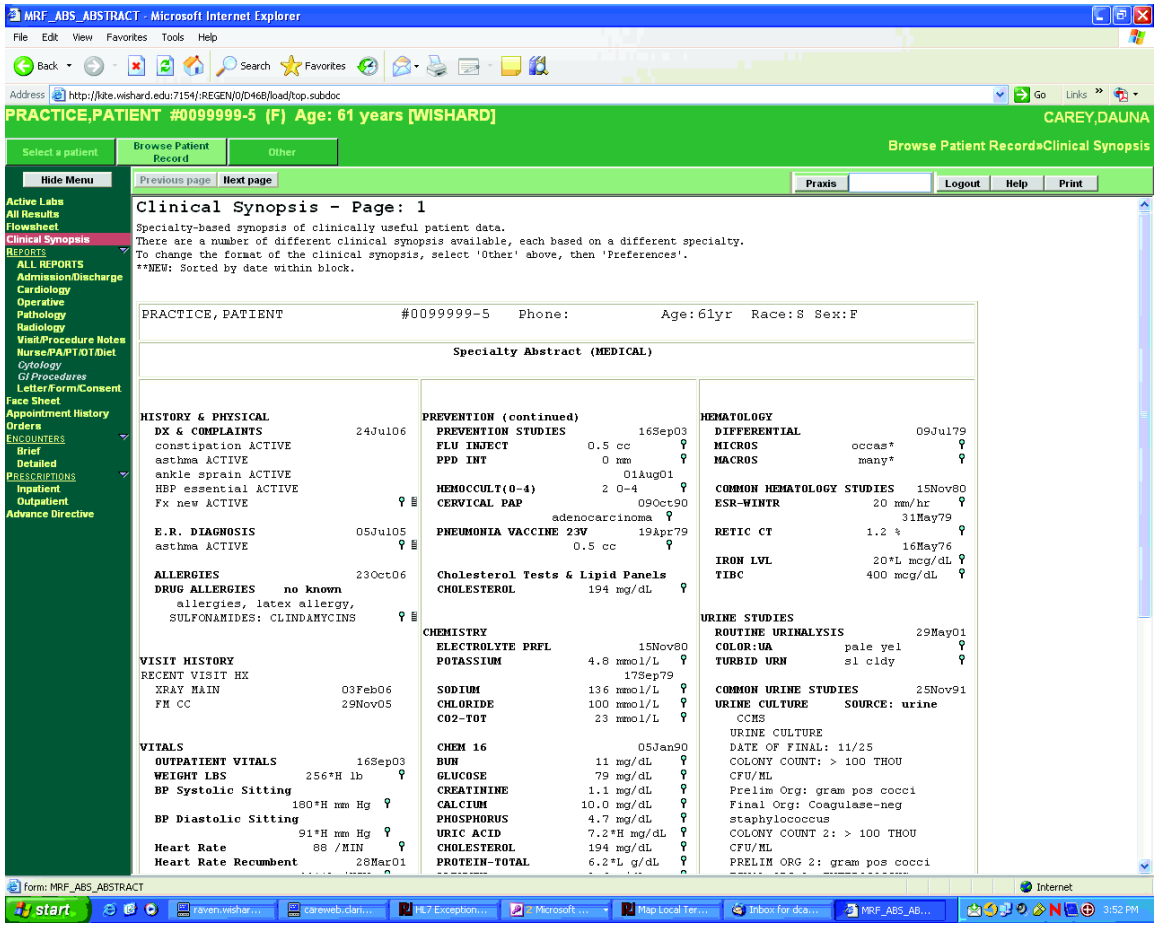

Figure 1 - Screenshot of sample abstract delivered to ICP when a patient admission

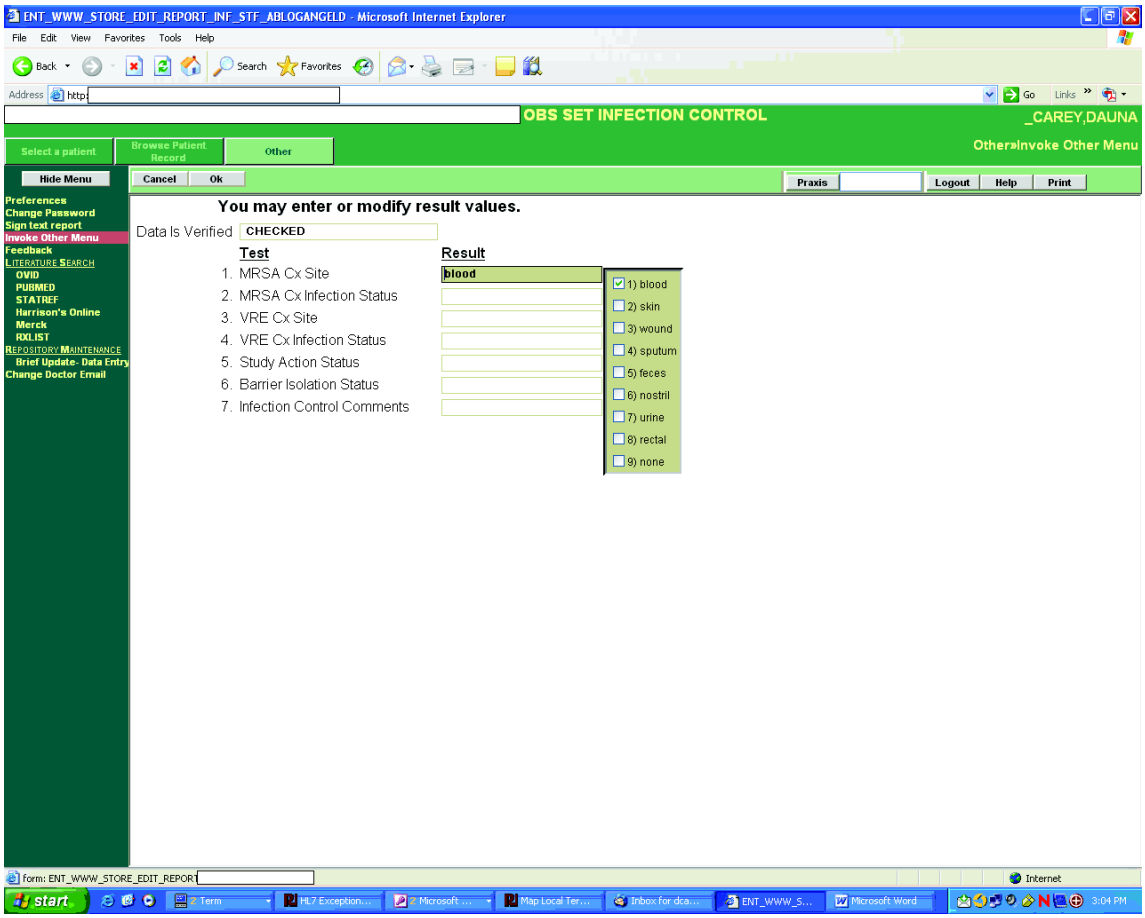

Figure 2 - Screenshot of sample webform for ICP to update patient data and document

Discussion

Common sense and the supporting literature demonstrate that the spread of bacterial resistance is a regional problem [7,12,13]. Patients colonized or infected with drug resistant bacteria travel without restriction and may arrive at another treating institution without warning labels. Our work focuses on delivering the latest available data from the whole community to guide the actions of the front line infection control staff and support implementation of evidence-based measures to control spread.

Our electronic network depends on years of "pipe laying" and builds on prior studies at our institution and others [6,7,8,9,10,11,14]. We successfully used our information sharing network to quantify the problem of crossover of MRSA patients between institutions within our network. We subsequently created a "closed" electronic network to track basic infection control information on any patients with a known history of MRSA upon admission to participating institutions. Coupled with coordination of best practices and standardization of infection control methods, we can both identify, and act to prevent the spread of infection. By combining the efficiency of electronic information exchange with continuous quality improvement methodology we hope to achieve and sustain the effort required to reduce drug resistant infections. Our aim is not 100% success at each opportunity, but rather, to reduce the rate of subsequent infections from each case to less than one. We believe that this approach will follow the model laid forth elsewhere and achieve similar reductions in resistance rates.

Our study is a work in progress, and we continue to incorporate feedback from the frontline ICPs. Our system does not currently integrate with the pre-existing institutional MRSA/VRE tracking systems, and this limitation may create additional work for ICPs and prevent ICPs from generating their own reports. We do not currently have the means to consistently deliver antibiotic susceptibility patterns from all institutions. Our current development work relies on grant support, although we believe that successful reduction in infection rates will more than justify costs.

Future work will focus on quantifying the frequency which our system correctly identifies patients with a prior history of MRSA/VRE, and the effect on ICP compliance with three quality improvement processes (barrier isolation, hand hygiene, and active surveillance). We will ultimately

measure our success by a citywide reduction in infection rates and their related adverse outcomes.

Dealing with Ecological Fallacy in Preparations for Influenza Pandemics: Use of a Flexible Environment for Adaptation of Simulations to Household Structures in Local Contexts

Abstract

Development of strategies for mitigating the severity of a new influenza pandemic is a global public health priority. The aim of this study is to examine effects on simulation outcomes caused by variations in local socio-demographic data. We used a spatially explicit geo-physical model of a virtual city as a baseline and employed an ontology-modeling tool to construct alternative population distributions and household structures. We found that adjustment for the case when single parents in practice were cohabiting led to a higher reproduction rate than that observed for a population with the highest formally recorded share of households with >2 children. When antivirals sufficient to protect 10 percent of the population were administered to schoolchildren, a preliminary effect on the reproduction rate was observed. This effect was eliminated when the household structure was adjusted for cohabiting single parents. Nations have been encouraged to develop estimates of morbidity and mortality during a possible pandemic outbreak. In order to deal with ecological fallacy, the present results suggest that this recommendation can be extended also to local communities.

Keywords:

public health informatics, influenza, epidemiological simulations, basic reproduction rate, health policy

Introduction

Recent human deaths due to infection by highly pathogenic (H5N1) avian influenza A virus have highlighted the possibility of a devastating pandemic similar to that of 1917-1918, [1]. The development of strategies for mitigating the severity of a new influenza pandemic is therefore a global public health priority. Even the concern that a global influenza pandemic may cause millions of fatalities is a public health issue on its own. In planning how communities should react to a potential pandemic, a reasonable balance must be struck between the rights and obligations of the individual and the protection of the population at large. To support such plans, national-scale epidemic simulations to examine intervention have been undertaken, e.g. using Great Britain and the United States as examples [2,3]. In practice, however, much of the planning of interventions and implementation of response actions have to be carried out at local and regional levels in order to deal with ecological fallacy. Moreover, the validity of policy effectiveness estimates will change if the characteristics of the pandemic strain differ substantially from those seen in past pandemics [4]. It is therefore necessary to allow a high level of flexibility in simulation models to be used at the local level during a factual pandemic outbreak.

We have previously reported general system requirements [5] and from the management of social geographic issues [6] during the planning of pandemic simulations in a local public health context. Based on these experiences and preliminary comparative simulations of influenza outbreaks in local communities in Europe [7], the aim of this study is to examine effects on simulation outcomes caused by variations in local socio-demographic data. Specifically, the geo-physical structure of a virtual city constructed on the basis of data from Linköping (population 135.800), Sweden, is used to study alternative household distributions and their influences on intervention planning. Studies of the morbidity patterns during the pandemic outbreak 1917-1918 have shown that the household structure is an important determinant of the strength of the epidemic [8]. One issue associated with modern census records is that they report households to which individuals formally are associated. In some cases, however, people factually stay at other locations than their formal residence, e.g. students and unmarried couples. The problem for pandemic simulations is thus that people are factually living together even though they are recorded as staying separately in the official registries. There is, thus, a need to study the impact from these variations on estimates used a basis for local policy development.

The basic reproductive rate, R_0, is defined as the expected number of secondary infections arising from a single individual during his or her entire infectious period, in a population of susceptible persons. R_0 is often used as a threshold parameter that predicts whether an infection will spread [9]. If $R_0 > 1$, the infectious agent is theoretically

able to invade the susceptible population. Accordingly, this rate was used as the main outcome measure in the present study.

Methods

We used a spatially explicit geo-physical model of a virtual city based on Linköping, Sweden (Table 1) as a baseline and employed an ontology-modeling tool [10] to construct alternative population distributions and structures. A mixing group design was used for the simulations. The model includes mixing groups for households, neighborhoods, schools, daycare centers, and playgroups. Children are assumed to attend local elementary and middle schools (n=45), whereas adolescents are randomly assigned to city high schools (n=5). One way of understanding this explorative experiment is to view it as moving populations with different household and family compositions to the geophysical structure of a specific city. R_0 was estimated by randomly selecting and infecting persons (n=1,000) from a fully susceptible population (n=135,800) and counting the number of secondary cases. The average number of secondary cases represents R_0. Our estimate of R_0 is the mean over 100 populations. Influenza transmission is represented by the number of infected individuals that are expected to pass through two phases. The first phase is an incubation period when they are not infectious and the second phase is the infectious period. The lengths of the incubation and infectious periods follow empirical probability distributions, with mean lengths of 1.9 and 4.1 days, respectively [3,11]. During the infectious period, the infected person may or may not develop influenza symptoms. The probability that a person will be symptomatic given that person has been infected is 0.67. An asymptomatic infection is assumed to be 50 percent as infectious as a symptomatic infection. In the model, the probability that persons with symptoms withdraw to the household is 0.67, exposing only the other members of their household. People who do not withdraw continue circulating in their mixing groups.

Children, 7–18	28.000
Adults, 19–65	85.000
Elderly, 66–	14.0 00

In the first test case, we compared the effects of different household distributions on the disease spread during an influenza outbreak. The distribution of household size (number of persons) was varied according to data from Statistics Sweden, USA standard data used for mixing group simulations, and local U.S. Census data on general demographic characteristics (DP-1) and households and families (QT-10) from the Census 2000 Summary File 2 (SF 2) 100-Percent Data for Utah and the District of Columbia (D.C.). The Utah and D.C. locations were selected because they represent U.S. extreme cases. For example, D.C. has the highest rate of single-person households (n=1; 43.8%). It can also be noted that more than 8% of the households in Utah contained more than three children, and >12% of the households in both D.C. and Utah contained more than two adults aged 19-65 years. These census data were the basis for the household model in the ontology-modeling tool. We also developed two alternative household structures for the Swedish reference populations. First, we moved in single adults to live with all single parents. For the second alternative structure, we pared all single adults to 2-person households.

Table 2 shows the distribution (in percent) of household types for the populations used to populate the virtual city in the study. The reference distribution is based on the Swedish national average, while the US standard (U.S. Std.) has previously been used for mixing group simulations [12].

Table 2 – Distribution (percent) of household types for study populations

Household type	Population			
	Refer -ence	U.S. Std.	D.C.	Utah
1 person	41	33	44	18
Adult	*32*	*24*	*34*	*12*
Elderly	*9*	*9*	*10*	*6*
2 persons	32	34	23	16
Adults	*17*	*17*	*12*	*11*
Elderly	*1*	*3*	*1*	*1*
Adult, elderly	*10*	*14*	*2*	*1*
Adult, child	*4*	*0*	*8*	*3*
3 persons	10	13	16	20
Adults, child	*8*	*12*	*3*	*9*
Adult, 2 children	*2*	*0*	*4*	*2*
3 adults	*0*	*0*	*6*	*6*
Other	*0*	*0*	*3*	*3*
4 persons	12	10	10	20
Adults, 2 children	*11*	*10*	*2*	*9*
Adult, 3 children	*1*	*0*	*2*	*2*
4 adults	*0*	*0*	*4*	*6*

5 adults	*0*	*0*	*2*	*4*
Other	*0*	*0*	*1*	*3*
Other	1	3	3	13

In the second test case, we investigated the influence from different household structures on estimates of intervention outcomes. In a first analysis, we simulated a policy intervention restricting interactions in the community. Closing the five high schools in the virtual city was used as an example. In the second analysis, we examined three different strategies to distribute antiviral medication in preventive doses to groups being candidates for prioritization on social or medical grounds. Preliminary studies in household contexts have suggested a satisfactory effect (80%) on reducing infectiousness from Oseltamivir [13]. Because these studies have not been randomized, we assumed a 60% antiviral efficacy from the preventive medication. In addition, the length of the infectious period was assumed to be one day shorter. The first strategy was to treat adults working at vital societal positions, e.g. in the police force, health care, and rescue services. The second strategy was to treat school children. The cost of influenza-related hospitalizations in children has recently been reported to be considerably higher than previously estimated. [14]. The third strategy was to treat the elderly. Excess hospitalization estimates among adults aged 65 years and high-risk 50-64 year olds during non-pandemic influenza seasons suggest that these groups should have priority for medical preventive interventions [15]. The latter strategies were studied with regard to R_0 in two resources contexts, having either 5.000 or 15.000 individual treatment packages available.

Results

Household structures

Computations of R_0 based on crude registry data displayed as expected the highest rate for the population with the highest number of large households with children (Utah; R_0 3.05) and the lowest for the population most single adult households (D.C.; R_0 1.49). The reference population (R_0 2.23) and the USA standard (R_0 2.45) showed similar rates. Table 3 displays the mean R_0 and standard deviation (*S.D.*) for the virtual city by the alternative populations. The Swedish census data are used as reference.

Table 3 – Mean R_0 for the virtual city by alternative populations

Population	***R₀***	***S.D.***
Reference	2.23	0.24
U.S. Std.	2.45	0.26
D.C.	1.49	0.16
Utah	3.05	0.26

However, when the reference population was adjusted for the instance when single parents formally recorded as staying alone but factually stayed together with another single adult, the R_0 reached a level (3.10) higher than that observed for the Utah population.

Table 4 – Effects on R_0 from differences in reported and possible factual household structures

Population	***R₀***	***S.D.***
Reference	2.23	0.24
Single parents cohabiting	3.10	0.31
Singles cohabiting	2.25	0.20

Table 4 shows the effects on R_0 from differences in reported and possible factual household structures, where the Swedish census data are used as reference. Adjustments are displayed both for the case when all single parents are cohabiting with another single adult, and when all single adults are cohabiting with another single adult. In contrast to the case of single parents, moving all single individuals without children together into 2-person households did thus not significantly influence R_0.

Interventions

Table 5 displays the mean R_0 for the virtual city, with high schools closed, by alternative populations and change in R_0 (R_0). In this scenario the Swedish household structure used as reference. The reference structure is also displayed adjusted for the hypothetical case when all single parents are cohabiting with a single adult. The most significant effect from closing high schools in the virtual city was observed when it was populated with the reference population adjusted for single parents cohabiting with single adults (Ro –1.64). In fact, in the city with closed high schools, the differences in R_0 between the reference population and the adjusted reference population were almost eliminated.

Table 5 – Mean R_0 for the virtual city, with high schools closed, by alternative household structures.

Population	***R₀***	***S.D.***	***R₀***
Reference	1.32	0.094	-0.91
Reference adjusted	1.46	0.099	-1.64
U.S. Std.	1.49	0.11	-0.96
D.C.	0.99	0.067	-0.50

Table 6 shows the mean R_0 for the virtual city with the reference household structure displayed by the three preventive strategies (covering adults in vital societal positions, school children, and high-risk elderly, respectively) and two resource conditions (5.000 or 15.000 longitudinal doses) for providing antiviral protection. The R_0 for the strategy targeting school children is displayed also with the household structure adjusted for cohabiting single parents.

The effect on R_0 was low for all strategies in the resource situation when 5.000 longitudinal dosages of antiviral

medication were administered. When 15.000 dosages were available, the only significant effect on the reproduction rate (R_0 reduction -0.49, 22%) was observed when the antiviral protection was administered to schoolchildren. However, when the adjusted household structure was used, the reduction in R_0 was similar in magnitude (R_0 -0.56; 18%) and did not alone lead to a satisfactory level of R_0 (2.54 compared to a desired level <1.80).

Table 6 – Mean R_0 for the virtual city by three strategies and two resource conditions for supply of antiviral protection.

Target group	*n*	R_0	S.D.	R_0
Adults	5.000	2.15	0.25	-0.08
Children	5.000	2.05	0.19	-0.18
Children adjusted	5.000	2.91	0.13	-0.19
Elderly	5.000	2.21	0.22	-0.02
Adults	15.000	2.18	0.21	-0.05
Children	15.000	1.74	0.16	-0.49
Children adjusted	15.000	2.54	0.22	-0.56
Elderly	5.000	2.20	0.21	-0.03
Reference		2.23	0.24	

Discussion

The aim of this study was to examine deviations in estimates of local morbidity during an influenza pandemic caused by variations in socio-demographic data. In specific, the geo-physical structure of a virtual city was used to study alternative household distributions and their possible influences on estimated reproduction rates. In the first test case, we compared the effects of different household distributions on the disease spread at the initial stages of an outbreak. We found that adjustment for the case when single parents were cohabiting led to a higher reproduction rate than that observed for a population with the highest formally recorded share of households with >2 children. The impact of possible differences between formal and factual household structures has relevance for local planning, when the intention is to suppress a pandemic before it is established in the local community, i.e. to fight the infection at the sites where it is most likely to disseminate at a large scale. If the R_0 is assumed to be relatively low in a community, it may be considered sufficient to protect high-risk groups and suggest general measures for reduction of person-to-person virus transmission, e.g. by increased personal hygiene. However, if this assumption is wrong, public policy interventions, such as closing schools, may be erroneously delayed with possibly fatal consequences.

In the second test case, we investigated the influence from household structures on estimates of intervention outcomes. The most significant effect from the policy intervention 'closing high schools' in the virtual city was observed when it was populated with the reference population adjusted for cohabiting single parents. In this setting, the differences in R_0 between the reference population and the adjusted reference population were almost eliminated. Regarding interventions involving antiviral medication, the effect on general disease transmission was low for all strategies in the resource context when 5000 longitudinal dosages were distributed to the virtual population of 135.800. When 15000 dosages were available, the only satisfactory effect on the reproduction rate was observed when the antivirals were administered to protect schoolchildren, but this effect was reduced when the household structure was adjusted for cohabiting single parents. These results suggest that it is important clarify the purpose of the intervention; containment of the epidemic or protection of high-risk groups. Also, these results highlight the fact that there are three broad areas in which the ethical issues associated with handling public health emergencies must be addressed,, i.e. rationing, restrictions and responsibilities [16]. In light of a pandemic influenza threat, some experiences from seasonal influenza may apply to the pandemic setting, but many preparatory decisions must be based on estimates. In 2006, two out of three nations prioritize health care workers at the highest level for antiviral distribution [1]. The justification for this prioritization is that health care workers are at increased risk of exposure and, therefore, for acquiring infection and/or transmitting it to patients. Additionally, health care workers perform vital services to the community. What ethical principles should guide rationing-based decisions in local communities, what data should inform these decisions, and how should rationing be implemented based on these data are all important questions.

Geo-physically explicit models of local communities seldom have been used for comparative experiments in the area of influenza response planning. However, detailed computational models of smallpox transmission and control based on agent representations or social networks have been reported [17,18]. The agent-based models explicitly represent an "artificial society" of individual human beings and physical structures, each implemented as a distinct object in the software. The agents interact locally with one another in code-represented physical places, e.g. homes, workplaces, schools, and hospitals. Although being more intuitive than the mixing-group method used for the present simulations, a limitation of agent-based model is the trade-off between inclusion of a large level of detail and the complexity of the resultant model. A secondary, and more important, consequence of the complexity is that the use of the results in policy development should be made with great caution.

The starting point for this study was the necessity for dealing with ecological fallacy in the planning of local responses to pandemic influenza: It must be acknowledged that what may be observed at global or national levels may

not always be applicable in the local setting. Nations have been encouraged to develop estimates of morbidity and mortality during a possible pandemic outbreak. These results suggest that this recommendation can also be extended to local communities.

Abstract

Information Technology (IT) enables health care providers to manage patients with chronic conditions through identification, follow up and administration of specific interventions. In our setting, we developed a surveillance system for chronic diseases. The aim of this study was to show its efficacy on monitoring blood pressure throughout a cluster randomized controlled trial. Patients without blood pressure registries (condition 1) or with high blood pressure measurements (condition 2) were randomized to be detected by the surveillance system or to receive usual care. The proportion of patients with at least one blood pressure measurement within three months of follow up was 49.9% (207 patients) in the intervention group and 37% (195) in the control group ($p<0.001$) for condition 1. And 61% (224) vs. 50% (239) respectively ($p=0.002$) for condition 2. Patients under the surveillance system have higher proportion of blood pressure measurements, showing this study an improvement on the process of care with this IT tool.

Keywords:

hospital information systems; chronic disease; hypertension; disease management; medical records systems, computerized; population surveillance; randomized controlled trials

Introduction

Chronic conditions are the major cause of illness, disability and death in Argentina like in other countries [1, 2]. Attempts to accomplish an effective control of chronic prevalent diseases are nowadays mandatory. In Argentina, studies performed in different socio-economic levels, showed that hypertension control is heterogeneous and not always done [3, 4].

Information systems generally offer a number of benefits in health care. Chronic Disease Management Systems (CDMS) are an effective information technology tool to improve the management of chronic diseases. CDMS enable health care providers to manage patient with chronic conditions such as hypertension, diabetes or asthma [5]

From an epidemiological point of view a CDMS might help to perform epidemiological surveillance. This means the ongoing, systematic collection, analysis, interpretation, and dissemination of data, being the ultimate aim of all surveillance systems, support disease control [6].

Similar to the surveillance of infectious and other acute disease, surveillance for chronic diseases has been largely implemented [7, 8]. Until now chronic diseases surveillance systems did not allow the quick identification and intervention of detected uncontrolled cases, as has been achieved in acute diseases.

Our setting, a Health Maintenance Organization (HMO) (Plan de Salud del Hospital Italiano de Buenos Aires), is an University Hospital based prepaid health care system. The Hospital is a 650 beds tertiary center with high standards in quality of health care and information systems [9-12]. To achieve control of chronic conditions we started in August 2000 a Disease Management Program (DMP) which its efficacy for hypertension control has already been demonstrated [13]. To improve DMP performance we developed in the year 2005 a surveillance system to detect and rapidly intervene patients with chronic disease [14].

The aim of this study is to show the efficacy of our surveillance system as a strategy for improving the performance of the hypertension care process.

Materials and methods

Study design

We performed a cluster randomized pragmatic controlled trial

Setting

In our HMO around 140.000 middle class residents of Buenos Aires are attended. Most of the HMO health care system is based on primary care physicians (PCP). Primary care is capitated and delivered at the Hospital and/or at any

Selected for best paper award.

of the twenty four HMO's peripheral outpatient care centers.

The total number of PCPs working in our HMO is 182, taking care of 50.110 patients with chronic conditions (average capita 735 patients ranging from 80 to 1415 patients).

Randomization

PCPs with more than 100 capitated patients were included in randomization.

Patients without blood pressure registries (see rules below) seeking for an appointment with their PCP on the following 15 days were prospectively randomized.

In order to achieve a balanced randomization, physicians were stratified in three categories according to the number of appointments scheduled: >5 to <10, > 10 to < 15 and > 15.

Within each strata, physicians were categorized in a random way to be 0 (not included in the surveillance system=control group) or 1 (enrolled in the surveillance system=intervention group).

Finally, according to their physician allocation number (0 or 1) patients were (or were not) enrolled in the surveillance system.

Patients allocated to the intervention group were detected by 2 conditions, patients in condition 1 were those without blood pressure registries, and patients in condition 2 were those with high blood pressure measurements, and listed for the DMP by the system every time they ask for physician's appointments. Patients in the control group were not listed during the 3 months of the study period. (Figure 1)

Sample size

Required sample size was 2200 patients, calculated to detect a difference of 10% in the proportion of patients with their blood pressure measured, considering an alpha error of 1%, a power of 80%, and a desire precision of 2%. We multiply by a design effect of 1.3 to adjust for the additional variability of the cluster design. 88 clusters were needed.

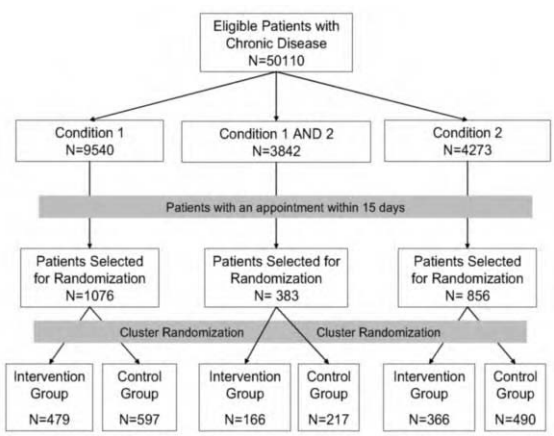

Figure 1- Flow chart of study subjects

Study outcomes

According to the standard outcome metrics for disease management programs published by the Disease Management Association of America [15], patients with chronic conditions must have their blood pressure measured at least once every 6 months, and uncontrolled hypertension patients must have this measurement done in every physician encounter.

The main outcome measure was the proportion of patients with at least one blood pressure measurement during the three months period, among those patients identified by the system according to the above criteria.

The main outcome was expressed separately for patients without registries during the last 6 months (condition 1) and for patients with uncontrolled hypertension (condition 2).

Secondary outcomes were mean systolic and diastolic blood pressures.

Statistical analysis

Means and proportions are shown with their respective standard deviations (SD) and 95% confidence intervals (95% CI) respectively. Comparability of baseline and pre-post intervention characteristics was ascertained by T test (either for single or paired samples) for continuous variables and Chi square test for proportions. The significance was considered at 1% level.

Intention-to-treat analysis was performed maintaining patients in their original groups. We used STATA 8 to perform the statistical analysis.

Intervention group

These patients were identified by the surveillance system and were followed by their PCP (usual care) and by the disease management program.

Surveillance System:

Patient Identification: the Master Patient Index (MPI) is the cornerstone of our health Information system [16]. Since 1999 our HMO has an Electronic Health Record (EHR) that is used by all physicians [12, 17]. Every entry in the record system, including pharmacological prescriptions and studies ordered (physician order entry), have to be attached to a medical problem. Each medical problem, diagnoses, risk factors and past history are automatically codified using terminological service based on SNOMED CT as referent vocabulary [18, 19].

The surveillance system uses information from two different sources:

1- EHR (medical problems, laboratory results, vital signs, pharmacological prescriptions)

2- Appointment Scheduling Software

Follow up: With data provided by this sources the surveillance system generates different surveillance lists(Figure 2), with the patients being classified as:

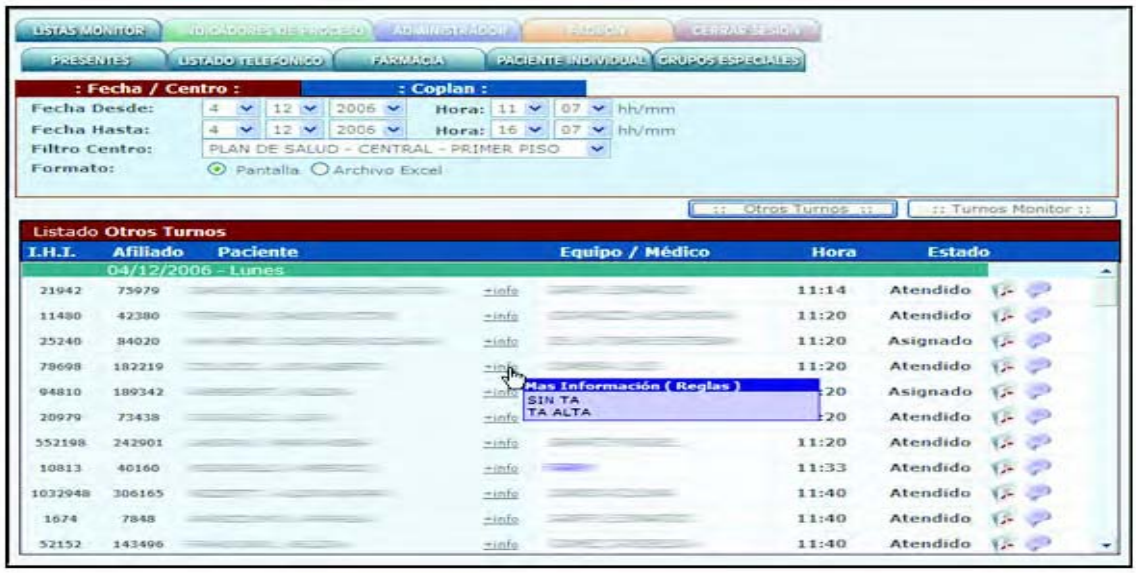

Figure 2 - Surveillance system lists

Not needing active intervention: hypertensive patient with blood pressure measurements recorded in EHR over the last six months with values under 140/90, or 130/80 in case of known diabetes.

- Patients to be enrolled: uncontrolled hypertensive patient (>140/90) or smokers or incident stroke not yet included.
- Patients already enrolled with interventions pending: hypertension patient without blood pressure measured in the last 6 months.

There are more than 10 rules running on our system to identify different medical conditions. In this study we tested the below two rules:

- Patients without blood pressure measurement in the last 6 months (condition 1)
- Patients with a high blood pressure measurement in the last appointment (condition 2)

Surveillance lists were daily matched with the Appointment Scheduling Software.

Appointments from the identified patients were marked generating a remainder for the receptionists so that they sent patients to program's office before physicians' visits.

Disease management program

Once in the program office, assistants measured and recorded risk factors, blood pressure, weight and height.

They reminded patients, verbally and with specially designed leaflets, to record their blood pressure weekly, to keep lifestyle changes and to comply with pharmacological treatment. They also invited patients to attend educational sessions that were previously demonstrated to be efficacious[20]

All the data was systematically recorded on the EHR before physician appointments so that the PCPs could make use of this information during consultations.

Control group

Patients in this group received usual care. This included health care administered by their PCP and by Disease Management Program only under PCPs request.

Results

A total of 2315 patients were included, 1011 were randomized to the intervention, and 1304 to usual care. 67 % attended to the scheduled appointment in both groups. Among them the median number of visits to primary care physicians was 1.93 (1.35) for the intervened group and 1.71 (SD 0.88) in the control group ($p < 0.01$) over the follow up period.

There were no statistical significant differences in basal characteristics between groups as is shown in table 1.

20% of patients control group were referred to the disease management program by their PCP.

Among those who fulfilled criteria for condition 1, there were 207 (49.9% with 95% IC from 45 to 55%) patients that had their blood pressure measured in the intervention group and 195 (37% with 95% IC from 33 to 41%) in the control group ($p<0.001$).

Among those who fulfilled criteria for condition 2, there were 224 (61%) patients that had their blood pressure measured in the intervention group and 239 (50%) in the control group ($p=0.002$).

Table 1 - Basal characteristics

Variables	Intervention Group (N=1011)	Control Group (N=1304)	P value
Mean age in years (SD)	73 (10.54)	73.77 (9.58)	0.73
Women, n (%)	661 (65.4)	846 (64.9)	0.801
Patients with hypertension, n (%)	919 (90.9)	1181 (90.6)	0.784
Patients with diabetes, n (%)	168 (16.6)	224 (17.02)	0.721
Patients with cardiovascular disease, n (%)	74 (7.3)	70 (5.4)	0.054
Patients with lipid disorders, n (%)	536 (53.0)	713 (54.7)	0.426
Patients with Stroke, n (%)	57 (5.6)	59 (4.5)	0.223
Smoker Patients, n (%)	214 (21.6)	260 (19.9)	0.468
Ex smoker Patients, n (%)	30 (3.0)	31 (2.4)	0.379
Mean Basal Systolic Blood Pressure, condition 2 (SD)	152.78 (14.06)	153.80 (13.32)	0.193
Mean Basal Diastolic Blood Presure, condition 2 (SD)	82.15 (11.15)	83.17 (10.58)	0.103

The groups did not differ significantly either initially (table 1) or at final assessment with regard to blood pressure (140/78 mm Hg vs. 138/78 mm Hg; p =0.162 and 0.914 respectively for systolic and diastolic). However both groups statistically reduced systolic blood pressure with a mean difference of 13 mm Hg ($p < 0.001$)

Discussion

The main outcome of our study is that patients in the intervention group had higher proportion of blood pressure measurements during follow-up, showing a statistically significant improvement with the intervention in the process of care of these patients.

Surveillance of chronic diseases has been based on population surveys or administrative data. Although this classic strategy is useful to plan future changes in clinical care process, it does not allow an active action on patients under the surveillance system.

Our program aims to monitor, detect and intervene as soon as possible those patients not fulfilling good quality of care outcomes. In this sense this program is more alike to active surveillance systems implemented for acute diseases than to those implemented for chronic diseases.

Although we were able to show improvement in process outcomes we could not find differences in clinical outcomes between groups. Several reasons could explain this discrepancy: this was a short term study (3 months), usually not enough to obtain clinical outcomes results. As PCPs` usual care in our Hospital includes sending patients to DMP, and there was a significant proportion of patients in the control group that actually received the intervention (20 % contamination). Also it has already been shown that there is more variability in outcome process than in clinical outcomes.

In previous reports, chronic disease management systems are shown as IT tools that could replace EHR [5], we think that this kind of surveillance systems must be integrated into a health information system, and the basic requirements that these IT applications should have are:.

- Identify, trace and continuously monitor chronic ill-patients to obtain a well cared population. Alert those patients reluctant to receive health care.
- Rank possible treatments, pharmacological and educational interventions, in terms or their greatest potential impact on outcomes.
- Keep adherence along the time in these chronic and asymptomatic conditions. Include IT solutions to schedule and remind preventive and needed interventions intelligently tailored to each patient profile

Further issues concerning the identification of barriers to comply with this chronic care model either from patients or physicians points of view should be studied and addressed.

Nurses and Computers. An International Perspective on Nurses' Requirements

Carol S. Bond

Institute of Health and Community Studies, Bournemouth University, England

Abstract

This paper reports the findings from a Florence Nightingale Foundation Travel Scholarship undertaken by the author in the spring of 2006.

The aim of the visit was to explore nurses' attitudes towards, and experiences of, using computers in their practice, and the requirements that they have to encourage, promote and support them in using ICT.

Nurses were found to be using computers mainly for carrying out administrative tasks, such as updating records, rather than as information tools to support evidence based practice, or patient information needs. Nurses discussed the systems they used, the equipment provided, and their skills, or more often their lack of skills. The need for support was a frequent comment, most nurses feeling that it was essential that help was available at the point of need, and that it was provided by someone, preferably a nurse, who understood the work context.

Three groups of nurses were identified. Engagers; Worried Willing and Resisters. The report concludes that pre-registration education has a responsibility to seek to ensure that newly qualified nurses enter practice as engagers.

Keywords

Nursing Informatics, ICT, Attitudes towards computers. Education.

Introduction

In the UK the government made Information and Communication Technologies (ICT) a priority area when the National Health Service (NHS) published Information for Health in 1998[1] The strategy identified the need for computerisation of many support systems, including the introduction of nationally available electronic health records, networked services to support appointment systems, electronic handling of a wide range of diagnostic tests and results and a networked prescription service. Information for patients as well as professionals was a key element of the programme, the strategy stated:

> *'People need information about health and healthcare in many different circumstances. Patients want to know more about what is wrong with them and how they can best look after themselves. Carers or relatives or friends seek information on behalf of others'*

Providing information to patients was seen as 'an integral part of the local clinical care process', it was however recognised that a culture change was necessary to achieve this aim.

The need for these developments to be managed nationally was identified, and they are currently being implemented through the National Programme for IT (NPfIT) and the Connecting for Health programme. This ambitious programme will see all patient administration, patient records (including nursing care records) and communication between professionals being computerised.

Nurses need to be engaged with these developments. At the very least they need to have the skills and knowledge to use the systems efficiently and safely. They need more than just the skills to use systems provided by the NHS. They also need to have the skills to support patients and their family/carers in meeting their information needs, and to have an understanding of the systems that will enable them to transfer their skills to new systems as they are developed.

Nurses however generally have poor ICT skills [2, 3, 4,] and are resistant to the introduction of ICT [5]. Heather Tierney-Moore, the nursing clinical lead for Connecting for Health has stated that

> *'The problem is that IT is a big turn-off for most nurses…. If things are branded as IT it's unlikely nurses will bother to pick them up, let alone engage with them,'*

A National Audit Office report into the implementation of the National Programme [6] stressed that the lack of IT skills within the NHS were a risk to the timely implementation of the programme.

Just what skills are needed is not universally agreed. The NHS[7] has published competencies required of nurses, which includes a range of knowledge and skills, e.g. clinical informatics and information security, as well as basic IT skills. In spite of this the perception found in some studies[8, 9] is that all nurses need are basic IT skills.

One of the aims of Information for Health[1] was to establish, amongst other things, a culture to ensure that NHS clinicians would be able to access the information that they need to provide effective patient care. In the case of nurses the evidence suggests that this culture is not yet established.

Background to the study

With the support of a Florence Nightingale Foundation Travel Scholarship a five week visit to New Zealand was undertaken to talk to nurses about their requirements both in what a computer system should provide, and what support they considered essential.

The study was undertaken in New Zealand for a variety of reasons. The New Zealand health system and culture is similar to that in the UK. The challenges faced, identified in the Health Information Strategy for New Zealand [10] are very similar challenges to the UK:

- an ageing population, which will increase the pressure on our health sector
- rising incidences of chronic diseases such as diabetes and cardiovascular disease
- the re-emergence of some diseases
- the emergence of new infectious diseases such as Severe Acute Respiratory Syndrome (SARS)
- new technologies that are making more effective treatments available, often at higher prices.

The IT systems underpinning the health care systems are also under review. The New Zealand strategy contains many of the same aims and initiatives as the UK. There are however subtle but important differences in focus. Whilst the UK is currently focusing on NPfIT commissioning and purchasing national computer and records system, New Zealand considers the need for local customisation of the systems to be an important feature of their strategy.

New Zealand is also putting information for clinicians and patients higher in the priorities than the NPfIT is. The initial launch of the New Zealand strategy was the 2001 WAVE - Working to add value through e-information, project which emphasised the information needs of clinicians. The 2005 Health Information Strategy for New Zealand[10] also makes the need for Consumers and their advocates to have access to information to make informed choices about health and independence a top priority.

New Zealand has the benefit of a lower profile of developments than the UK has. This meant that there was not the high level of critical news stories to influence nurses' reactions to IT developments and therefore there was clearly the potential for UK nursing to benefit from the experience of New Zealand nurses.

The visit

Visits were made to specialist informatics groups, educational institutions and Health Board managed hospitals. These were on both New Zealands's North and South islands. In the time available for the visit it was not possible, nor was it the aim of the travel scholarship, to construct a rigorous structured research project. Several organisations hosted me for periods varying from a day to a week, and each visit reflected the local expertise and circumstances and therefore each was a unique experience. I am grateful to each for the programme that they put together for me. Because of the variety of locations visited the study tour was approached as 'conversations with nurses', rather than as a structured research project, although the underpinning ethical considerations were based on normal research ethics. The aim was to explore nurses' experiences and listen to their views and suggestions.

All participants were given a brief overview of the nature and purpose of the study tour, and permission was sought to take notes of conversations and in meetings. Anonymity was promised unless specific exceptions were agreed, therefore generally neither the location of the information gathered nor the name of participants has been identified.

The people who participated in the conversations fell into two main groups.

- Academics & specialists in health and nursing informatics
- General Nurses in practice.

Information from nurses in practice

I talked with approximately 50 qualified nurses about their computer use and wishes. Most qualified nurses were spoken to on a one to one basis, although small groups were used e.g. when speaking to staff in shared offices. Nurses came from a wide rage of disciplines including community care, intensive care, day care, mental health, children's, acute medical and surgical areas. Nurses spoken to split into 2 distinct groups. Senior & specialist nurses (clinical specialists, nurse educators and clinical nurse leaders) and general nurses. I also met several larger groups of nurses in the invited lectures that I gave.

Initial questions were similar for each group, and conversations started with my asking about the nurse's experience of using computers, and the support they had received or felt that they needed. The conversations then developed according to the experiences of the nurses. Nurses generally mentioned using a combination of patient record systems and care planning systems. Fewer staff mentioned using computers to access evidence based information, or information for their patients.

One group of staff spoken to were educators in practice. These were employed by hospitals and did not have formalised links with higher education. This group were quite anti-computer. One thought that they belonged only in high dependency areas, but not in general wards. Several had the view that computers took nurses away from patients. On behalf of the staff they supported they also made the point that many nurses had poor IT skills, found online learning difficult, and that they had neither the computer access, nor the protected time, to use it.

The comments from nurses covered three main areas.

Systems in use

Often nurses did not feel that the systems in use meet their needs. One very heavily criticised problem was that there were often duplicate systems in use (especially paper and computerised systems) as systems did not have the ability to talk to each other. This was felt to be especially true for systems in different organisations (e.g. hospital and com-

munity) which made transferring patients time consuming. The need to enter the same data into different systems, or more than once, was also criticised.

In one location nurses had the choice of using a computerised patient care planning system, or a hard copy one. Most nurses, especially those who liked the computerised system, complained that they never knew where to look for information as not all the computerised records were printed out and put in the patient's file.

Some nurses, especially those who were uncertain about using computers or who found them complicated, felt that a familiar 'look and feel' would help them, the example given was if the navigation was similar to that in Microsoft programmes, as the nurse was familiar with them, but found the interface of professional systems to be cumbersome and difficult to learn.

Email was sometimes seen as a poor way of communicating; some general nurses felt that senior nurses expected them to use it too much. Many nurses suffered from a common problem for users of email systems, that of receiving too many irrelevant emails which had been copied unnecessarily to large numbers of people.

Nurses wanted systems that would save them time, eg send orders to pharmacy when a prescription is written, or identify equipment necessary for a care pathway and place the order automatically. Some nurses, especially those who were uncertain about using computers or who found them complicated, felt that a familiar 'look and feel' would help them.

Having to remember several passwords, all with a different length and expiry date was seen as a big problem, and as leading to writing them down or sharing other peoples logins rather than people logging out after use.

Equipment

In order to use computerised systems nurses wanted greater availability of equipment. Senior nurses generally had access to their own computers, however ward staff had to share, and in some locations nurses did not consider that they could access computers when they needed to. Nurses did not generally want more desk based systems. Computers that could be used at the bedside, or wherever else patients were, were in demand.

Skills

Some nurses felt that they did not have the skills, or the confidence, to use systems. This did not generally apply to senior nurses, or to nurses who had completed their training in the past couple of years.

Most nurses felt that more support needed to be provided. Training was available, and most nurses who mentioned skills did appear to know how to access training or the helpdesk in their organisation. The support available however did not meet the nurses' requirements, as it was not available at the point of need, or delivered by other nurses.

Nurses who considered themselves to have poor skills did not generally feel comfortable with worksheets or other written guidance. Computer based training materials, especially if nurses had to use them in their own time, were also unpopular.

Most nurses who mentioned the need for support wanted something available that fitted with their work patterns (e.g. on the ward) and that addressed immediate problems when they arose.

Information from health/nursing informatics experts

Nursing Informatics experts agreed that within New Zealand, as with England, nurses had a wide range of IT skills and informatics knowledge, but that many nurses lacked the skills and knowledge to fully engage with the informatics agenda.

Unsurprisingly the majority of experts saw the use of computerised systems as being beneficial to nursing. They were more aware of the potential for quality improvement, for example systems being used to provide reports on tests that were ordered but not carried out so nurses can check if anything is outstanding and what action is needed (although this was also seen as being a new nursing task that took nursing time). There was a strong view that new systems should promote change (quality enhancement) not just computerise the current way of doing things.

This group could see also scope for a range of improvements to the available computer systems. Practicality was high on the list. Equipment was seen as needing to be small but lightweight to make it portable around a ward. Wireless networking was considered a good way of enabling portability. Speed of the equipment and programmes was also important, the systems needing to be able to work at the same speed as the nurse.

The need for systems to support communication across the health sector was considered essential for sharing information about patients and to ensure that notes etc. would always be available when and where needed.

Nursing informatics experts felt strongly that managers also needed to be knowledgeable about IT. Support from the top was considered to be particularly important for the work culture to be one where computer use is seen as being a part of care giving.

Decision support systems were wanted, but with the proviso that they must be linked to up-to-date evidence, and have the ability to be updated rapidly.

What nurses want

Generally nurses wanted computer systems that would make their lives easier. This included saving them time by automating tasks such as stock ordering. One essential element to meet this need was that systems need to talk to each other so that information from all points of care were included, and that data entry was minimised.

Offering good quality decision support and access to evidence based information was not as high a priority for many practice based nurses, although it was considered a higher priority by the nursing informatics experts. Those who did want it, wanted it to be available when and where they needed it, and for it to regularly updated.

A very important requirement was that computers needed to be available wherever the nurse and patient were. Wireless networks and portable computers were suggested as the best way of meeting this need. Computers at workstations were not popular for several reasons, including the pressures to find a free computer at the end of shift to update records. Point of care data entry not only meets nurses' requirements but will also contribute to improved patient care by allowing records to be updated contemporaneously when memories are fresh, a great improvement on handwritten notes being scribbled and kept until the nurse can get back to a free computer.

Passwords were a big problem for many nurses. Each individual system often requires its own login information, each renewable on a different cycle. Nurses were almost unanimous in wanted this simplified. The ideal solution was seen as each nurse having just one password that would give entry to all systems.

Support was a frequently mentioned need. Nurses wanted help available that fitted with their work patterns (e.g. on the ward) and that addressed immediate problems when they arose. Although training on systems was seen as important the need for ongoing support was also identified. Most nurses did not want this through manuals or computer aided learning programmes that they had to use in their own time. Nor was the ability to contact a helpdesk that would get back to them, often a couple of days after their enquiry, seen as meeting their needs. The most popular support method mentioned was for a specialist nurse to be available to come and give one to one help when and where problems were encountered. A nurse was requested rather than an IT person because there was a feeling that a nurse would understand the context of the situation, and what the nurse was trying to do and how they needed to do it. Nurses, especially those who lacked confidence, did not feel that IT specialists 'talked their language' or saw their problems in the same way that they did. This supports a study carried out in 2003 with rural New Zealand health professionals, including practice nurses, by Janes at al [11]. This study found that many respondents reported having poor IT skills. These professionals reported that learning methods that included some social interaction were more popular than computer based learning.

The four biggest barriers to the use of computers that were identified were:

- The co-existence of paper based systems, meaning that nurses didn't have to engage with the computerised systems. This was seen as leading to computerised systems being incomplete and therefore promoting the use of paper-based systems.
- Systems being slow and not user friendly so that using the computer took longer than doing the same task did (or had done) in a paper-based system. Linked with this was a distrust of computers with the fear that they would increase workload by making tasks that were previously done by administrative staff part of the nurse's workload.
- Lack of support when and where it was needed. Nurses did not see waiting for help as being acceptable when a problem was stopping them doing work that they needed to do.
- Computers not being available where and when they were needed. A culture of using computers not being seen as being as important as giving patient case was often mentioned. Nurses keen to engage would like to have computers available at the bedside (or consultation) so that they become part of care giving rather than part of a separate administrative workload.

Nurses tended to focus more on using systems than they did on accessing information to support care. Part of this may just be a lack of awareness of what is available, but part is also likely to be attributable to a culture where spending time on a computer is not seen as being as valuable an activity as spending time with a patient, irrespective of what is actually being done in either case.

A thematic analysis of comments about attitudes to computers produced three distinct groups:

The engagers

Nurses who used computers quite extensively. As well as using the systems that they were required to use they also mentioned using computers to access research and library resources to support evidenced based care. One nurse from the UK who fell into this group felt that New Zealand systems offered more flexibility than the systems experienced in the UK. Another commented that she wouldn't want to see nursing without good computer systems to support it. This group were more willing to tolerate imperfect systems and to see ways that they could be improved.

The worried willing.

Nurses who were willing, but felt that they lacked the skills to use systems confidently. One nurse, who was finding that patients and families were using the Internet for information felt that they expected her to be competent as well. She considered that education programmes should be including this so that newly qualified nurses had these skills from the outset, and that programmes should be available for qualified staff to catch up. This group struggled with imperfect systems and wanted access to help and support that met their needs.

The resisters

Nurses who did not want to use computers. The comments from nurses in this group included; that paperwork was easier before computers, and that with new computerised systems nurses were having to do work that ward clerks did previously. These nurses also tended to see computers as taking nurses away from patient care. This group felt that poor systems justified their not using them.

Before my visit to New Zealand a project was undertaken with an English hospital looking at nurses use of the hospital intranet. Nurses who participated in that study expressed very similar comments to the New Zealand nurses.

Conclusions

Many of the essential elements of systems identified by New Zealand nurses are already key elements of the UK National Programme for IT. These include the 'do once and share' concept, and having one integrated health record, available to all healthcare providers. The National Library for Health is also part of the National Programme, giving nurses access to reliable up to date information to support research and evidence based care.

There are however aspects of implementation that may not currently be present. Computing at the point of care was an important requirement. Achieving this may contribute to nurses seeing computers as being part of nursing care rather than being seen as a task that takes them away from patients.

Nurses who are comfortable working with computers appear to be much more tolerant of failures in the systems and most importantly want to develop systems that meet their needs. The 'willing worried' nurses who feel that they lack skills but are willing to engage want support that meets their needs. If this is met there is clearly the potential to shift these nurses into 'engagers'. There is also a risk that if their needs are not addressed they will join the resisters.

Whatever the resisters may wish, computers are not going to disappear from healthcare, rather their use is going to increase. Changing the views of these nurses is a challenge for staff development. Including informatics targets in appraisal will be important to achieve this. The aim however must be to stop nurses starting their careers as resisters and seek to ensure, through effective pre-registration education programmes, that newly qualified nurses enter practice as engagers.

Acknowledgments

This work was supported by a Florence Nightingale Foundation Travel Scholarship, sponsored by the English Department of Health.

The Need for Global Certification in the Field of Health Informatics: Some Ethical Issues

Eike-Henner W. Kluge[a]

[a] *Department of Philosophy, University of Victoria, Canada*

Abstract

In the past, the training of health information professionals (HIPs) has focussed almost exclusively on technical matters, the concerns of software developers and purveyors have essentially centred on security and functionality, and health care providers have mainly worried about costs and efficiency. This paper outlines some ethical threats that are ignored by such a purely technical focus and argues that because of the increasing globalization of health care delivery through e-Health, and because of the international threats to confidentiality posed by legislation such as the US Patriot Act, the health informatics community should pursue a project of global certification for HIPs that includes information ethics as an integral component. It also argues that a corresponding certification process for health care institutions and software developers should be initiated.

Keywords:

certification, informatics, ethics

Introduction

Health care is in the process of evolving from a paper-based to an electronically-based technology. While the speed and penetration of this evolution varies from country to country [1] it has already begun to assume international dimensions with the advent of e-Health, and it is merely a matter of time before it becomes a global reality. As in all cases when a new technology is applied to an established modality, this change has not been without concerns and challenges. In the beginning, most concerns had been technical in nature and had focussed on electronic techniques of data collection, storage, manipulation and communication as well as on reliability, quality control, accessibility and usability [2]. More recently, the portability and integration of electronic health records (EHRs) have become of issues of major concern [3], and the standardization of their architectures and the interoperability of networks have become the focus of careful consideration [4]. Similarly, the standardization of nomenclatures has begun to receive considerable attention, and syntax and semantics have been the subjects of extensive investigations [5-7].

Nor has the debate focussed solely on technical issues. From the very beginning it was clear that, given the extremely personal and sensitive nature of patient health data, ethical and legal issues would figure prominently in these developments and that issues such as consent to data collection, control and secondary use of the collected data, as well as privacy, security etc. would have to be treated not merely as add-ons to technical development but as integral factors in the development and deployment of the technology itself. It was also realized that technological security and privacy measures are only as good as the conduct of the professionals who are involved in their application. Consequently there was a move to develop ethical guidelines for health information professionals, and in October of 2002, the General Assembly of the International Medical Informatics Association approved a Code of Ethics for Health Information Professionals [8] that was intended to function as a template for its member organizations.

Ethics and the professions

Health information professionals

It would therefore seem reasonable to expect that the education of a conscientious, well-trained and literate health information professional (HIP) should include not merely mention of, but also training in, the relevant ethical issues, and should instil a familiarity with the fundamental ethical principles that should govern the collection, communication and handling of EHRs. It is therefore surprising that with the exception of one statement by the Council of Ministers of the European Union [9], neither the professional literature nor the premier discussion of the subject - the Recommendations of WG1 of IMIA on Education in Health and Medical Informatics [10] - stresses that ethics education and certification should form a standard part of the training of HIPs. A literate person is someone who is well educated and familiar with the relevant topics and the literature [11]. One would therefore have thought that a properly educated and literate HIP could be expected to demonstrate competence in information ethics.

However, what is at issue is more than merely a matter of literacy. What is at issue is the very status of health informatics as a profession. Professions are characterized by the fact that their members usually have undergone an intense period of post-secondary education in a specialized subject, provide a socially important service and belong to an activity-related organization that has a code of ethics. Formal or statutory recognition of a profession usually confers

the right to set licensing and/or certification requirements, the right of self-government and the duty to enforce appropriate standards [12-14]. In practical terms, the formal or statutory recognition of a profession may be delayed but the profession may have *de facto* recognition as a profession simply because of the nature of what it does and because of the fiduciary or quasi-fiduciary nature of its relationship towards clients and towards society. Nursing is here a good example. Nursing was not formally recognized as a profession until fairly recently and yet, for all that, nurses were considered professionals because of the fiduciary nature of the nurse-patient relationship and the dependence of patients on nursing care. Health informatics meets the above criteria and therefore, *de facto,* is a profession [15]. Therefore HIPs may be held to professional standards, the lack of formal recognition of health informatics as a profession notwithstanding.

This is especially important at the present time because EHRs and e-Health present challenges of privacy, security, communication, handling, manipulation and inter-jurisdictional operability that did not exist with purely paper-based records. Moreover, given the increasingly global mobility of HIPs as well as the diversity of legal data-handling provisions and regulations that they encounter as they move from jurisdiction to jurisdiction, the only constant that defines appropriate professional behaviour remains the IMIA Code of Ethics.

In more specific terms, the appropriate functioning of contemporary health care systems depends not merely only smooth and efficient technological operation but also on appropriate behaviour on part of the professionals who make these systems technically possible. The successful deployment of e-Health, therefore, assumes not merely a secure and interoperable technical infrastructure but also an integrated and comparable set of professional standards for the informatics professionals who are responsible for its development and operation, where this set of standards is not confined to considerations of technological competence but also includes an ethical component that measures the competence of the professionals in identifying and dealing with ethical issues that arise in the handling and communication of EHRs. This, in turn, necessitates some means not merely for assessing and certifying these qualifications but also for enforcing the relevant standards and, if necessary, for administering disciplinary measures in a transparent and globally consistent manner.

As yet, only limited steps have been taken in this direction even in the domain of technology [9]. There is no international set of technological proficiency standards and no internationally recognized certification process for HIPs. Matters stand even worse with respect to ethics. Thus, not all national informatics associations have formally adopted the IMIA Code of Ethics as a template for their own statement of ethics. This holds true even of some organizations who are members of IMIA. However, unless and until globally integrated professional codes of ethics have been adopted and are included in a standardized education that leads to formal certification, the actual delivery of health care in the electronic age will remain threatened by this lacuna in the education of the professionals on whom the delivery of that care depends. The inability to identify and deal with ethical issues sets the stage for technologically competent but ethically inappropriate behaviour that easily leads to legal confrontation and to litigation on the national as well as on the global level. Explicit and standardized training and certification would minimize such a risk. In an ideal world, such standards and certification would ultimately be referable to an independent body that would function in association with the WHO, and that would rely on the expertise of professional organizations such as IMIA. It remains to be seen, whether the profession will adopt such a stratagem.

Health care professionals

As an addendum, it should be noted that this plea for the inclusion of ethics in training and certification extends beyond HIPs. e-Health and telemedicine cannot function without the participation of health care professionals (HCPs). Consequently it would seem not merely appropriate but also prudent to have informatic qualification and certification standards for HCPs who engage in e-Health and telemedicine, and to include an information-ethics component in their training. Given that currently there is no mechanism for ensuring internationally comparable standards in medical qualification, this may pose an even greater challenge than the medical certification of HIPs. However, absent international standards for health care professionals in informatics, e-Health will never be as good - or as secure - as it could be. IMIA and its affiliate national organizations may therefore wish to explore the issue with the corresponding organizations in the field of health care.

EHR system purveyors, institutions and the ethics of certification

The discussion so far has concentrated on professionals; however, the concept of certification includes more than proficiency: It also applies to the systems that are certified and to the protocols that are involved in their operation. Consequently, EHR system certification is also relevant for purveyors of EHR systems and for the institutions that operate them. In each case, there arise serious ethical issues, and in each case the relevant certification should reference these matters.

Purveyors

The ethical issues that arise for purveyors centre not merely in functional efficiency and reliability - issues that traditionally have been dealt with under the legal rubric of product liability - but also in security from unauthorised intrusions into the system. Most EHRs run on existing operating systems, and these have millions of lines of code. It is therefore a virtual certainty that they include backdoors that potentially allow a compromise of system security. However, purchasers such as health care institutions (as well as individual providers) who run such systems when using EHRs owe an obligation of confidentiality to the subjects of these EHRs. The health care providers, therefore, purchase the relevant operating systems not merely with the expectation that the systems will

function as efficiently as advertised but also that they will meet relevant and applicable privacy and security requirements. Consequently, from an ethical perspective, purveyors of operating systems have two choices: *either* develop entire operating systems from the ground up under strict quality control that allows them to certify that every element of their new systems is not only fit-for-the-purpose but also secure; *or* develop a standardized way of evaluating the vulnerability of their systems and establish an independent body that will be able to certify the vulnerability level of the existing systems. Unless at least one of these alternatives is adopted, purveyors of operating systems will continue to rely on the expertise of their lawyers to deal with the issues that arise, and will leave to the legal process what is essentially a matter of business ethics. With due alteration of detail, similar comments apply to developers of EHRs.

In this connection, one further issue needs mention. Some countries - notably the United States - have passed legislation that allows their security and intelligence agencies to demand that companies that are incorporated in their jurisdictions, and that the subsidiaries under the control of these corporations, provide the agencies with any and all items – the phrase used is "any tangible things (including books, records, papers, documents, and other items) ..." - if, in the estimation of the agencies, access to such items will assist them in evaluating and pursuing what the agencies believe to be are security threats [16].

The source codes for EHR software and for the operating systems on which they run are clearly included under the rubric of "other items." It is therefore ethically incumbent on any certification system that might be developed to include information as to whether the developers have complied with a request that has been made under such legislation.

However, this presents a serious ethical dilemma if the enabling security legislation follows the example of the *USA Patriot Act.* That *Act*, under §215 (2)(d), stipulates that "No person shall disclose to any other person (other than those persons necessary to produce the tangible things under this section) that the Federal Bureau of Investigation has sought or obtained tangible things under this section." The dilemma for developers and purveyors, then, is the following: If they do what is required by such a law, they will *de facto* mislead their purchasers about the security of their systems by withholding the fact that their systems are potentially penetrable by the security agencies of the country in which the purveyors or developers of the system are incorporated. On the other hand, if they do what is ethically appropriate and reveal that the codes have been made available to these security agencies, they will be breaking the law [17]. Under the circumstances, it may be appropriate for system developers and purveyors to consider whether ethical business practice allows them to be incorporated in a locality such as the United States, which could legally require them to falsify any such certification. Moreover, it may be appropriate for IMIA to examine whether it should develop an appropriate policy in this regard. Neither the IMIA Code of Ethics nor any other IMIA policies or declarations currently address this issue, whether that be in a direct or even an indirect fashion.

Institutions

In a world that is haunted by the spectres of efficiency and financial bottom lines, buying a service from the cheapest possible provider is considered good institutional practice. Information service outsourcing is therefore proceeding apace, even in the field of health care [18]. However, health care institutions owe an obligation of confidentiality to their patients, which means that they have a duty to ensure that their operating systems and the EHRs that are under their control or in their possession are secure. Consequently they have an ethical obligation to purchase only from purveyors who can provide appropriate security-certified software. More specifically, it means that they have an obligation not to purchase operating systems, EHR software or related programmes that are security-uncertifiable because the purveyors are subject to provisions such as those that are found in the *US Patriot Act*. In the event that they cannot purchase such software, they have an obligation to inform their patients that they cannot guarantee the confidentiality that is normally expected in the field of health care.

Moreover, institutions themselves are subject to a certification process that determines whether they meet appropriate institutional operating standards. This means that institutional certification processes should include a rubric that identifies whether an institution meets the informatics privacy and security standards that have been traditional in health care. It may be that such a certification process would have to examine whether the institutions should purchase their systems from purveyors who are subject to legislation such as the *USA Patriot Act,* and to rank the relevant institutions accordingly. As for those health care providers who are themselves subject to provisions such as he *USA Patriot Act* - and this would include institutions that are currently certified under JCAHO (Joint Commission on Accreditation of Healthcare Organizations) guidelines - these clearly have a legally mandated duty to provide EHRs when requested to do so by a duly empowered authority. However, that does not mean that they must abandon their traditional ethical duty of confidentiality towards their patients or that they must violate the duty of openness as stipulated in the IMIA Code of Ethics [8]. They can both fulfil their ethical duties and meet the requirements of the law by making it known to all incoming and/or prospective patients that they cannot guarantee confidentiality because the records in their possession will be subject to the provisions such as those contained in the *USA Patriot Act*.

Conclusion

The delivery of health care has become a multi-billion dollar global industry, and the rationalisation of health care delivery through the use of EHRs and e-Health systems is proceeding apace. It has generally been recognized that the quality of health care is best served through the certification of health care institutions. To date, this certification

has proceeded independently of informatic considerations. The time has come for this to change and for informatic parameters to be integral to any such certification. The time has also come for the concept of certification to be extended to include HIPs, since these are instrumental to the functioning of EHR-based health care systems and of e-Health. The preceding has identified some ethical and legal issues in this regard, and has argued that an independent and global certification process should be developed. It may be time for organizations such as IMIA to exert every effort in this direction, and to make strategic alliances with other bodies in order to achieve this end.

Using Fieldwork in Analyzing Ethical Issues Related to IT in Health Care

Ellen Balka[a], Christine Reidl, Ina Wagner[b]

[a] Simon Fraser University and Vancouver Coastal Health, Canada [b] Institute of Technology Assessment and Design, Vienna University of Technology, Austria

Abstract

This paper describes how an understanding of everyday conflicts that have ethical implications – what we call 'situated ethics'— can be explored through ethnographic field techniques in healthcare settings. Our approach to ethics is followed by findings from two ethnographic case studies focussing on issues arising as information technologies such as electronic patient records and automatic drug dispensing machines are introduced into varied health sector workplaces. By close and careful observation of these technologies in use and by incorporating narrative accounts from different perspectives the complexity and entangledness of real life occurrences are revealed. Our data suggest that several types of ethical issues (e.g., issues related to intellectual property, literacy, standardization, transparency, work ethics, and equitable allocation of resources) can be identified through fieldwork, and can have an impact on identification of everyday ethics in healthcare.

Keywords:

ethics; ethics, institutional; principle-based ethics, ethics, professional; narration; work; ethnography

Introduction

Our interest in this paper is in understanding the situated, everyday conflicts that have ethical implications – what we call 'situated ethics'. We developed an approach to studying 'situated ethics' as part of the Canadian Action for Health project which investigates the role of the internet, electronic patient records, computerized information systems and other forms of information technology in the health sector.

Our aim of studying 'situated ethics' is to bring everyday conflicts about IT in health care and their moral dimension to the fore. Ethical issues reveal themselves in the complex dynamics which unfold in everyday situations between actors, such as doctor and patient, nurse and management, clinical personnel and technical support/vendor. Their situated character lends itself to the narrative form – storytelling. The situated, everyday conflicts are connected to larger ethical issues – they are instantiations of such larger issues. They are often also connected to legal issues. We argue that understanding the context and the mundane details of situations in which ethical issues arise, and grounding them in people's everyday experiences may make it easier to address, and deal with ethical issues.

'Situated ethics' is about ethics as an integral part of everyday action. It treats ethical problems as researchable through social science methods. It claims neither to offer 'solutions' to the identified issues nor to be a substitute for a professional case deliberation but it can prepare the grounds for such a case deliberation. Hence one of our aims is also to explain the difference between the work of professional ethicists who analyze ethical issues, eventually helping people to come to a moral judgment of a situation and plan appropriate action; and the work of social scientists, who through qualitative research methods -observation and interviews -unravel ethically problematic aspects of everyday life/work situations.

Here we describe how to study the ethics of everyday practices, using (ethnographic) fieldwork. We make a case for 'narrative ethics'. We use vignettes based on fieldwork in two research projects on IT in health care to explain our approach to studying ethical issues and we reflect on how our approach may enrich the discourse about ethics and IT in health care.

How to study ethical issues

Researchers have for some time criticized the principled philosophical approach to ethics-in-practice. One major point of objection is that the principled approach assumes common moral intuitions, failing to recognize the existence of multiple cultural and religious traditions. For example, in her study of ethical decision making in cases of terminal diagnosis Turner [1] introduces the concept of 'local moral worlds' as meaningful for understanding different modes of moral reasoning. Another point of criticism is that clinical/medical ethics has been couched in general and abstract terms and focuses on dilemma-type issues. Guillemin and Gillam [2] argue that when it comes to looking at day-to-day ethical issues, these can rarely be phrased in the form of a dilemma. Using an example of a woman informant disclosing that her husband has been sexually abusing her daughter, [2] argue this can be interpreted as a classical ethical dilemma of whether to breach confidentiality or prevent harm. However, there are also more immediate ethical concerns, like whether or not to take up what the woman disclosed, in which words, what tone, whether to switch off the tape recorder, abandon the

interview, and offer help. These practical but highly relevant ethical concerns cannot be framed as dilemmas. Guillemin and Gillam [2] talk about 'ethically important moments', moments of response where wrong can be done. They focus on sensitizing people to ethical tensions, and through this enable ethical action, rather than prescribe specific types of responses.

In her study of different types of medical decision-making, Hall [3] proposed an approach, based on the work of Johnson, who sees the basis for moral sensitivity in the 'moral imagination'. Her notion of narrative ethics puts imagination and interpretation at the centre of ethical decision-making. Narrative ethics includes constructing and telling one's own story and comprehending the story of the other. This may include decisions such as: What is my story? What is important to relate? What is the best way to express what I consider to be the ethically most relevant material? Narratively crafting our understanding allows us to enter a decision-making process which includes contextual elements. The imaginative capacity is revealed in the images, metaphors, and symbolism the narrator uses, and in the small details s/he fills in. Hall [3] stresses that narrative ethics and arguing on the basis of rules and principles are not mutually exclusive but can complement each other.

The notion of 'narrative ethics' resonates well with methods of ethical case deliberation that see moral intuitions embedded in narratives. Participants are encouraged to bring forward/argue through stories and organizers of a deliberation process are required to provide suitable case descriptions. Throughout the literature we find the term 'vignette' for such descriptions. Vignettes are short, narrative accounts of a 'case' from the field that illustrates one or more ethical-legal issues. They are constructed on the basis of extensive practical experience in the field or of fieldwork material produced through research. They may be real cases or hypothetical cases based on experience. When simulated, a vignette can be constructed to look at the same situation from different perspectives or contain one manipulated variable (e.g. the gender or ethnicity of one of the people in the scenario). When based on field work, a vignette can describe a real-life dilemma as it occurred. Advantages include that all contextual information required to understand and analyze the issues are at hand; and that the situation described is sufficiently complex and enriched with detail.

Ideally, vignettes should be written so that readers understand the context (of people, tasks, IT support, organization, cultured practices, history, etc.) in which ethical issues arise. Vignettes should have a clear focus on describing the issues. Video material, cartoons and other techniques have been used for producing lively accounts. A 'good' vignette is defined as an account that has "great hermeneutic power in its capacity to enhance our understanding of behaviour" [4, p. 83]. One characteristic is ambiguity, which leaves space for participants to define the situation in their own terms. Another important feature is narrativity, which introduces specificity and detail, helping to understand the context in which an ethical issue arises. Both encourage and enable reflexivity and discourse. Our interest is in using vignettes as part of qualitative research and in vignette writing based in fieldwork. This ensures that vignettes genuinely represent phenomena that occur in real world settings and that they reflect the complexity of an area being studied. Moreover, "the ethical decision-making in such a situation has a narrative context, in which competing moral stories containing strongly rhetorical elements present themselves" [4, p. 84].

The cases

We have worked with ethnographic fieldwork material for constructing vignettes, and we elicited vignettes from other project partners. The material we collected – 34 vignettes from 16 different projects – differs vastly. Vignettes can be rather short and 'typifying', (putting forward a case that may be encountered in other places) or they can be very specific and rich in social detail.

The two cases we selected for this paper are very different. The Canadian case is about an automatic drug dispensing machine (ADS) that had just been introduced in a hospital; hence, it is about a system in use, the problems users encountered and how these were handled. The Austrian case is about the introduction of an electronic patient record (EPR) in five clinics and deals with the introduction process, the problems that came up and how these were addressed.

Case 1: New automatic drug dispensing machines

In 2003, several units of a large hospital moved into a new building, and several new technologies were introduced, including ADS. The vignette contained here emerged from extensive observationally based fieldwork (see [5, 6] for more detail). These machines consist of cabinets with a keyboard and screen. A nurse logs on by keyboard, enters information about her patient, and selects the medications she administers to her patient from a computerized list. Once the medications are selected the drawer containing the medication opens, and the bin containing the desired medications is automatically unlocked.

When the ADS was introduced, nursing staff had difficulty locating the name of drugs they had to administer in the machine's pre-programmed drug inventory. Nurses using the ADS shortly after its introduction reported that the names of drugs included in the ADS' inventory list differed from the naming conventions in use prior to the introduction of the ADS. We observed several instances of nurses searching through pre-programmed drug names in the cabinet before finding the correct name of the drug they wished to administer. Another problem appeared to be that the nomenclature programmed into the ADS (generic drug names) differed significantly from the nomenclature that was in use previously on the hospital units (both generic and trade names).

Although the ADS accommodates naming conventions different from those programmed into it, the planned integration of systems both within one hospital and across hospitals necessitated use of a common drug nomenclature across multiple computing platforms. As a result of this

standardization, the convention which had been in use to include common brand names after the generic drug name on medication orders ended, leaving nursing staff to translate between doctor's orders (that typically use brand names such as lasix) and generic names (such as furosemide) used by the central pharmacy, and now programmed into several computer systems. The location of drugs within the ADS were also standardized.

Another issue related to the ADS concerns the processes put in place for inventory control and ADS discrepancy reporting. One of the main justifications used for the implementation of ADS has been inventory control. Drug inventories are controlled through the ADS in part through count back procedures, where staff count back, or verify that the locked storage drawer compartments that house the drugs contain the quantity of drugs indicated on the ADS screen. Each time medication is removed from the ADS, the user is prompted to verify that the quantity of the listed drug is stored in the machine. In instances where the quantity of medication in a drawer varies from the quantity listed, staff are prompted to address the discrepancy, by either choosing a pre-defined reason from a menu of options (e.g., discrepancy already documented in report; error in previous count back quantity; error in previous remaining quantity; medication not removed; or unexplainable loss–see report), or entering a user supplied reason for the discrepancy. Dealing with a discrepancy in the manner dictated by the ADS required staff to count the quantity of medications on hand – a time consuming process when a frequently used, well stocked medication (e.g., 200 tablets) is involved.

Case 2: Introducing an EPR into 5 oncology clinics

The 5 clinics participating in the EPR project form part of the Community Hospital Organization (CHO), the association of hospitals, nursing homes and geriatric centers run by the city of Vienna. The CHO is one of the biggest health service institutions in Europe with an average of 400.000 admissions per year and a staff of 32.000. Our description is based on interviews with different stakeholders, an in-depth study of paper-based and computer-supported documentation practices in three clinics (ONC1, ONC2 and ONC4), and participation in several user group meetings.

The decision to introduce such a system was a central-political one, initiated by one of the five clinics (ONC4) which has been successfully running an EPR for 12 years and had hoped to convince the CHO that their system should be implemented in the other clinics. The CHO in turn was interested in the project since it was in line with their strategy to replace the old hospital information system (HIS) and to generally look for unified solutions/products, since these seem easier to maintain, and hence more economical. The project had the support of 4 of the 5 clinic heads, who delegated the work of formulating a requirements document to interested physicians in their clinic, with the experienced ONC4 in a dominant role. It was decided that ONC1 and ONC2 should start implementing the system. Several user group meetings were conducted at ONC2 who seemed ready to work with the system.

Confronted with the system which was demonstrated by the vendor, physicians at ONC2 started an intense discussion about a variety of issues, none of which seemed as easy to resolve as the CHO had imagined. A major concern was the interface to ordering lab exams and viewing the results, which is currently done within HIS. This was immediately declared as technically very difficult, hence too costly, by both the vendor and the CHO. The next point was the ordering of chemotherapies, for which each of the hospitals has a different system run by their pharmacy. The question of who should be responsible for the process and who should be responsible for the maintenance of the drug catalogue – clinicians or the pharmacy – arose. There was also the question of interfacing here. Without interfaces, a nurse or physician, after having documented in XX (the new system) what should happen with the patient, a blood test, an X-ray, a nuclear-medical exam, etc., would have to log into another program, identify the patient a second time, and again type in the order. There was also concern about how to integrate orders issued by external consultants. Questions arose about protocols, which in chemotherapy seem to change quite often – how many should be supported? Who should do the work of updating them?

There were heated discussions about the different templates physicians need, from the anamnesis sheet (a long and a short version) and the discharge letter to different kinds of overview sheets (patient status, overview of activities). How should they be designed? Which data can/should be automatically inserted from the system? How much standardization should be designed into a template? What kind of overviews should be enabled? etc. It became clear that at what seemed the start of implementation a time-consuming process had started, which uncovered contextual richness and highly relevant detail that would require much more attention than both the CHO and the vendor were prepared to give.

Discussion

The vignettes presented here in a shortened version are fieldwork accounts, rich with social detail. They do not just address one particular ethical issue but tell a story that needs to be analyzed to identify areas of ambiguity and complexity. Our analysis follows what Steinkamp and Gordijn [7] describe as 'clinical pragmatism'. This protocol is based on a structural analogy between clinical judgment and the structure of ethical reflection. It requires 'contextual factors' to be taken into account in "concentric circles. Implying first and foremost the perspectives of the other professional groups as well as their contributions to care giving" [7, p. 237]. Narrative elements, representing moral intuitions and stories are to be included. Institutional policies have to be examined. In this mode, we use the case descriptions to identify conflicts that can be related to ethical issues such as transparency, standardization, work ethics, privacy and confidentiality, intellectual property, equitable allocation of resources, literacy, etc. Different stakeholders' perspectives on issues are considered and we describe how organizational as well as inter-organizational relations mediate these issues.

Identifying the ethical issues

For identifying ethical issues we use a framework which draws on several sources. Biomedical ethics [8] introduces a four-principles approach – autonomy, justice, beneficence, and non-maleficence. Related to virtue ethics, the ethics of care originally emerged as a feminist critique to traditional theorizing (see the pioneering work of Gilligan [9]). It focuses especially on personal relationships and character traits that are valued in them. It has been reformulated as an ethics of responsibility, which with respect to science and modern technology stresses issues of accountability and liability. Furthermore, given the many opportunities information and communication technologies offer, it is vital to take account of the need for privacy, respecting people's right to maintain boundaries, but also to preserve privacy, autonomy, confidentiality, and solitude. Other ethical issues connected to ICT are transparency – awareness of and the ability to understand IT systems and their implications – and literacy. This widening catalogue of principles or issues reflects the plurality of perspectives and the complexity and specificity of areas such as modern technology and health [10]. Here we discuss only a few of the categories of ethical issues identified. In the Canadian case these are:

Issues regarding intellectual property – The use of ADS will result in the collection of more sophisticated data about drug use by patients during hospital stays than has previously been available. Drug companies have been trying for years to gain access to British Columbia health data, as BC has one of the most comprehensive data sets in North America. Who owns the data that the ADS collects and consolidates? Should patients have to consent to having anonymized data collected during their hospital stay used at some future point for health research? Which health researchers should have data access?

Issues of literacy – Gaps in computer literacy among nursing staff became evident with the introduction of the ADS. Also, issues of literacy emerged again in relation to the nomenclature issue -pharmacy staff felt everyone (nurses, doctors and pharmacy staff) should use the generic names for drugs, because this constitutes better practice. However, as staff struggled when the brand names disappeared, differences in the drug literacy of pharmacy staff and other staff become evident, along with physicians' non-compliance with a policy to use only generic names when prescribing.

Issues of standardization – The problem of drug naming conventions raises issues of standardization. Standardization was adopted for good reasons, but has had unintended consequences. The generic nomenclature is not in common use among floor staff who must now translate doctor's orders (which are often written in trade names) into generic names. Staff may spend more time looking up drug names than they did in the past. Standardizing the location of drugs within the ADS was intended to make it easier for staff who move between floors to use the ADS. However, staff on some floors were frustrated by having to retrieve commonly used drugs from the bottom drawer. In both cases it is not clear if the benefits gained from standardization out weighed the costs.

The issues in the Austrian case were somewhat different:

Issues of transparency – As local IT experts where not involved from the project's start, misunderstandings arose among physicians concerning system requirements and interfaces. For example, it was not clear that the new system would not support easy retrieval of lab results. Also, local system experts were not aware of hardware requirements of the new system, with the consequence that these were not included in local budgets. Nurses had been invited to attend the user meetings but it remained unclear how they might be affected by the implementation of the new system. At the same time the roll out of another IT project in support of care documentation was taking place and its status was far more advanced. How should nurses decide which system will meet their requirements best?

Issues of literacy – Vendor and project management asked physicians to provide specifications of working routines and work flow to be supported by the new system, although they lacked the experience and skills required for writing a useful requirements document. It turned out that the way physicians specified their requirements lacked relevant social detail so that something they had thought was a key requirement – easy retrieval of lab results – was formulated in a rather general and vague way, for example not defining when and in which form lab results should be communicated. This led to misunderstandings when translated into technological solutions by IT experts. The 'medium' of participation – a traditional requirements document – turned out to be inadequate.

Issues of work ethics – The system has been designed exclusively from the physician's perspective although nurses will presumably have to work with it too – how can their perspective be included? There is also the issues of time physicians don't have the time to participate in the set up of the project. For reasons of cost control physicians' possibility to work overtime has been limited to 20 hours a month. Whether physicians get compensatory time off for their collaboration in the implementation process is up to the head of their department. Also, the new system requires attention to issues, such as complicated login procedures or regular maintenance and updating of drug catalogues and protocols for chemotherapies inside and across clinics that have not been accounted for.

Issue dealing with equitable allocation of resources – As soon as it was decided that the oncology departments would get a new documentation system all further investment into the completion or updating of any old systems in place was stopped. This has led to a continuous slow down in data processing in some of the involved clinics.

Stakeholder perspectives

In the simplest sense, the stakeholders in the Canadian case are the central hospital pharmacy (pharmacy management, those who re-stock the ADS), the information management department of the hospital (responsible for the units' connection to the hospital information infrastructure), nurses on the units, their managers, and the patients. Other stakeholders are people who might use ADS data – one compelling reason for introduction of sys-

tems such as ADS is to improve data availability for research. The ADS implementation also provides insights about ethical issues related to assumed actors and assumed use contexts, both of which become stakeholders in system implementation processes. The ADS was designed with a U.S. market in mind, replete with all the record keeping required to bill for 100% of all services rendered or medication dispensed. This was reflected in the machine interface. Although in Canada the reasons for introducing the system did not include the ability to track costs associated with each patient, the financial need to do so within the US market influenced software design and subsequently work practice in a Canadian hospital.

The Austrian case reveals a complex network of actors, with the CHO as central hospital organization, the vendor, the five clinics with their own interests, and future users of the system – physicians and nurses. The perspective of ONC4, one of the main players, is of special interest here. In the 1990s they developed their own documentation system. When attempts to get funding for necessary improvements failed, the idea to promote purchasing of a standardized documentation system for all oncology departments arose. Responding to the call for tender was seen as a way to get a complete system update and at the same time standardize the systems of the other big oncology departments, thereby improving the possibilities to exchange data and promote research. But their system did not win – it was too expensive. Although it had been continuously improved over the years and adapted to changing work practices, these efforts and advantages were not included in the rating of the system. A lack of attention to the effort and expertise of one actor contributed to jeopardizing the whole project.

Mediating (inter) organizational relations

In a previous paper [11] we discussed the fragmented character of complex organizations and interorganizational relationships as a source of problems in systems development. Looking at the ethical issues in the oncology case we can identify fragmentation of (inter) organizational relationships as one of the reasons for the problems encountered. Systems development takes place in several loosely coupled social arenas between heterogeneous actors -CHO, vendor, the different clinics with differing interests, different occupational groups in the clinics, and within different hospitals, vendor, and varied occupational groups in the ADS case. We can also see action in other arenas shaping the process: the CHO using its power position, curtailing the needs for updating old systems by stopping financing.

Looking at the ethical issues in the ADS case, we see that a lack of attention to work design contributed to some of the problems, particularly related to the timely process of counting back commonly used drugs. Problems associated with which drug nomenclature were programmed into the ADS (generic or generic and trade names) were heightened by (inter) organizational relationships, which on the one hand did not adequately take into account current work practices (e.g., of doctors who use trade names in writing prescriptions), and on the other hand were not clearly visible to staff who had to cope with the consequences of the use of only generic names were programmed into the new machines – a decision that was taken because of inter-organizational relationships, but was not visible to staff. This lack of transparency, combined with a lack of transparency associated with how the communication of drug count discrepancies were reported to the pharmacy with the ADS undermined medication safety and inventory control.

Conclusions

The 'politics of systems design' is not a new agenda (see e.g. [12]). Our notion of 'situated ethics' proposes to use descriptions of (work) situations involving technology, to look into the moral dimension of technologies at work – how they are introduced, how they affect people and the quality of their work. The cases we have presented are based on extensive fieldwork. They are by no means simple; they reflect the complexity and entangledness of real life occurrences. As we have tried to show, the problems emerge in the social detail which can only be uncovered through close and careful observation of the technologies in use and/or the process of introducing the technologies in complex settings.

Abstract

The right to use patient data in treatment is based on the conditions of a need to know and patient consent. In electronic health records, these two conditions can be applied in various ways. We study the handling of consent in two Norwegian hospitals, with a view to how access control and consent handling can be integrated across electronic systems that process patient data. A workshop was held, where two consent handling scenarios were simulated, one in-hospital, the other external. Activities were identified and tied to roles and to the documents and systems used. Electronic systems were found to support the execution of the scenarios to some extent. The electronic functions used in-hospital were consent storage and logging of access; access control was not sufficient. When sharing information externally, the typical approach is a declaration signed by the patient or a referral; such external information sharing should be supported by specific functionality. A first step towards integrated access control is integrated consent handling.

Keywords:

confidentiality, informed consent,
computerized patient records

Introduction

Health care workers, such as physicians, nurses and managers have a need to access sensitive patient data in order to treat and manage patients. Patients have a right to be given good treatment as well as a right to privacy. Confidentiality of patient data is both a requirement for privacy, and an argument for openness between a health care worker and a patient. Confidentiality may thus enable the worker to get more important information of a potentially embarrassing nature from the patient; confidentiality may, however, also keep previously recorded data out of the worker's reach. Depending on the circumstance, confidentiality is thus both a hindrance and support in the work of healing illness. A health care worker's right to access patient information is typically based on two conditions: A need to know, and patient consent.

Need to know and patient consent

Norwegian health legislation contains a diversity of rules governing the legal basis for when and on what conditions a health care worker may or may not have access to patient information. The principle of "need to know" could be interpreted as an abstraction to those rules governing access, they include an obligation of secrecy, several conditions where consent may be needed, some degree of a right for the patient to participate in decisions concerning himself, and even a few situations where patient information may be revealed to third parties on the health care worker's discretion.

There is a complex body of legal acts influencing the rights to access patient information. For simplification, we mention the three most important acts regulating consent as a legal basis for access rights.

The Health Register Act is a Norwegian implementation of the EU Directive 95/46/EC. The term "consent" is explicitly defined in the Health Register Act; a valid consent must be informed, explicit, and given freely. The function of the consent in the Health Register Act is to serve as a legal basis on which responsible enterprises process the information.

The Health Personnel Act contains obligations and rules of conduct for the health care workers as professionals, regardless of whether they are self-employed or employed by a hospital, or have any other kind of assignment as a health care worker. The term "consent" is not explicitly defined in the Health Personnel Act, and for some important situations (e.g. sharing information with another health care worker involved in the same treatment episode) implicit patient consent will be sufficient. In these cases the patient consent is presumed, but the patient may object to the sharing of information.

The Patients' Rights Act also contains rules on patient consent. While the Health Register Act and the Health Personnel Act are mainly focused on the obligations to obtain the consent when it is needed, the Patients' Rights Act views consent as a means to ensure that the patient has a proper understanding of his own situation and can take part in important decisions concerning the treatment.

In the case of a patient not being able to make valid decisions on his own behalf, consent may be given by a duly empowered proxy.

Access control supporting consent management

Patient data are increasingly held and processed in electronic health record (EHR) systems, with potential for integration between systems. The access control mechanisms of existing EHR systems contain, to some degree, representations of the users' rights to access information. The access rights represented in the systems are in part authorisations based on organisational properties (i.e. roles and/or organizational units) and in part an interpretation of the legal basis for accessing information. Support for consent in access control imposes restrictions at a very fine level of granularity, in some cases as detailed as the relation between one specific health care worker and one specific patient.

Objectives

The objectives of this study are: Finding whether consent can be successfully managed with existing EHR systems; identifying challenges in consent management and access control for patient information inside a hospital and between health care providers; identifying implications, if any, that our findings have for integration of access control.

In the rest of this article we first present academic work that is related to consent management and security; we then present the methodology and results of our survey; discuss the results and conclude the paper.

Related work

A questionnaire survey in New Zealand [1] studied patients' attitudes towards sharing their health information. One of the major findings of this survey was that 90 % of the respondents had incomplete or no knowledge of how their information was shared, and that they would prefer to be consulted about the distribution of their information. Based on this study it is suggested that future systems should incorporate sophisticated and flexible access control policies that can be adapted to meet the preferences of individual patients.

Adams and Blandford highlight the importance of understanding the users' work practices and their relevance [2]. The paper claims that to effectively implement systems to protect organizational and personal security, one needs to understand the organization, and its social structure, norms and work practices.

Kluge [3] discusses some limitations to the suitability of consent as a means to protect the patients' right to privacy. For instance, denying consent may not harm the rights of other persons. The use of consent is also limited by the principle of impossibility: If the patient expects treatment he may not refuse necessary access to relevant data.

Coiera and Clarke [4] categorize electronic consent (e-Consent) along two axes: Form of consent that the patient can express (model), and function of consent in the system. The three functions of consent identified were as follows: Patient consent captured as a legal record only; the system requires the health care worker to verify that the patient's consent has been read and understood; the system automatically executes the consent and uses it as access control rules, i.e. as a "gate-keeper".

Methods

This survey was performed in one of the health regions of Norway in the fall of 2006. The aim of the survey was to get qualitative information on how patient consent is handled, and how it is related to access control. We chose to direct our survey towards the following types of participants:

- IT department representatives: These have knowledge of the IT systems in use, their possibilities and limitations. The representatives range from technical staff to project leaders and decision makers, including those responsible for information security.
- Representatives from decision makers in two of the hospitals of the health region. These have knowledge of the legal requirements, the overall decisions that have been made, and the overall problems experienced with today's solution.

Some important groups were left out in this initial qualitative study: Types of care givers involved in patient treatment, and administrative personnel like secretaries. We plan to include these groups in future more quantitative surveys.

Since our aim in this phase was to collect qualitative information, we chose to gather representatives from the above types of participant groups in a workshop. The workshop was organized as a process workshop [5]. This type of workshop had already been used successfully in other qualitative studies on access control in hospitals [6]. The focus of such a workshop is on finding out how important processes are handled today, identify those responsible and documentation and tools that are relevant. Based on the identified current processes one can discuss challenges and future solutions. We were interested in both how the processes are implemented in the organization, and how the IT systems support the processes.

The workshop was centred on the following scenarios:

- A patient A does not want one specific physician to have access to A's health information. What happens?
- A patient that earlier has given consent to share health information with another health care enterprise now wants to withdraw this consent. What happens?

Based on the scenarios, the participants identified activities, roles and documentation/tools, wrote them down on sticky notes and organized them on a process sheet. After doing this in small groups, a plenary session synthesised the results and associated each activity with roles and documentation/tools, as illustrated in Figure 1. We recorded audio and video to capture all details discussed.

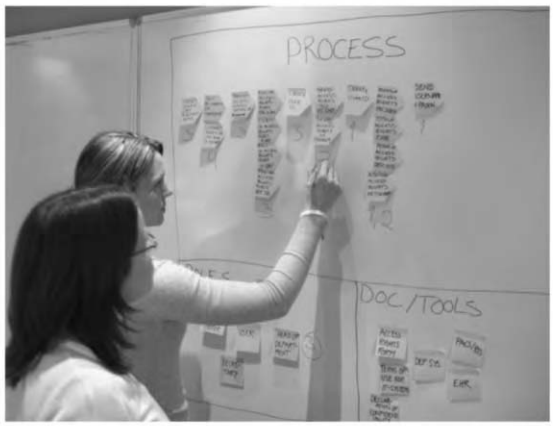

Figure 1 - Demonstration of process workshop plenary

Results

Scenario 1: denying access to a specific physician

The workshop participants considered the scenario to be realistic and to be something that occurs from time to time. In some instances of this scenario, the patient can not be adequately treated if the patient's request is to be carried out. This can occur if the physician and patient are at the same hospital department, but also if they are at different departments. In the former situation, even if there would be several other physicians present during the day, the physician in question would have to withdraw from certain parts of meetings. During the night and weekends, the physician in question might have been scheduled to be the only physician on call, meaning that the most available physician can not treat the patient. This can also happen in the latter situation, when the physician is at a different department, because the physician might be on call for several departments. In such cases, the patient would be better served by being treated at a second hospital; the first hospital might thus refuse planned non-emergency treatment on the grounds of its obligation to provide safe treatment.

The health care worker that speaks to the patient would first discuss the matter with the patient and colleagues to establish that the patient can be safely treated. Provided that the patient can be safely treated, the groups agreed that the patient's request would be carried out in the following manner.

The patient's request would be recorded in the EHR by the person responsible for the record or a secretary. Each medical record has a person responsible for it, as required by law. In some departments this person is registered in the record, while in other departments this role is taken by the department head or by the person in charge of medical systems.

The physician that should not access the patient's record would then need to be informed about the patient's request, warned about consequences and confirm that the warning has been understood. Subsequently, the patient would be informed about how his or her request was carried out.

After the patient has been discharged, the record responsible person must audit the access logs to confirm that the physician in question has not accessed the record of the patient in question. This would include access logs from both the dedicated medical record system and associated systems like medical image retrieval systems. If the patient wishes to confirm who has accessed the record, and requests the access logs, then the record responsible would also need to give these logs to the patient.

Even with these measures in place, the physician in question is able to access the records of the patient. The solution can still be considered adequate, if the patient is satisfied that the warning and subsequent log auditing reduces the risk of un-authorized access to an acceptable level. To completely remove access for the physician would, with today's access control solutions, involve keeping the record in a separate system, such as on paper, or transferring the physician to another hospital department for the duration of the patient's stay.

Scenario 2: withdrawal of consent to share information with other health care enterprise

When the workshop participants discussed this scenario, they first questioned the scenario. The common Norwegian definition of "health care enterprise" only includes those owned by the state, i.e. hospitals. General practitioners in private enterprises, as well as private clinics, are thus not included in this definition. There are more referrals and discharges between a hospital and a general practitioner than there are between hospitals, and the scenario might have been more relevant with a party called something else than "health care enterprise". The groups thus chose to expand the scope of the discussion to also include general practitioners, after first discussing inter-hospital information sharing.

Another point discussed was that in the hospitals represented, there is no mechanism for periodic handover of patient information, and as such few ongoing automatic handovers to break off.

There are mainly two types of handovers that are not based on an explicit consent given by the patient: Providing access to medical images in the region wide image system, and the routine sending of a discharge note to the referring health care worker when their patients are discharged from the hospital.

In other cases some form of instance by instance consent from the patient or other legal documentation is always needed. When giving information to the Norwegian patient compensation agency (Norsk pasientskadeerstatning), the patient consent is considered expressed by the patient filing a complaint with that agency, while it in other handovers, such as to the police or an insurance agency, is based on a signed declaration of consent from the patient.

In the plenary discussion, three different sub-scenarios of this scenario were identified and discussed. The first involved access to the imaging system, where it was stated

that once read access was given to a set of images the access could not be easily revoked.

The second and third sub-processes involved the referrals and discharge notes (the latter called "epicrises" in Norway). If the patient in these scenarios wants to withhold information from the referring health worker, the hospital staff needs to make a note of this in the referral and discharge module of the medical record saying that referrals and discharges should not be sent to the health care enterprise in question; this is only a note and would need to be discovered by the discharging personnel and be acted upon accordingly every time. There is thus no automatic method for stopping the sending of a discharge note to the referring health care enterprise.

Discussion

We discuss what the results tell us about the potential for consent management and for integration of policies and access control across systems.

Fulfilling denial of consent in present situation

As shown by the results, the current systems in use at the studied hospitals do not support the technical exclusion of one health care worker from accessing the records of one patient while still keeping access to the records of the other patients at the hospital department, or indeed at the same hospital. Even if the health care worker in question is temporarily re-assigned to another department within the hospital, emergency access would still be available.

Carrying out the procedure in Scenario 1 will only fail to deter the physician in question if this physician is willing to risk a near 100% chance of disciplinary action. For accessing the data after being told not to, and knowing that logs will be reviewed.

The procedure is suited to hospitals where default access is given to the records of patients at the same department as the health worker, but it would need to be adjusted for hospitals where the default rules are different. Some hospitals, for example, allow access to the records of discharged patients for several months after discharge, for the purpose of follow-up and avoiding using emergency or other non-standard access for answering questions from discharged patients and their referring health workers (e.g., General practitioner). In such cases, access logs audit may have to wait until this access expires, or to be repeated at intervals.

When auditing access logs, the record responsible person must also remember to audit access logs for departmental clinical systems.

Viewing consent in all hospital systems

In the hospitals studied, consent is documented in the primary medical record system, as required by Norwegian regulations. This system is simply called "the Electronic Patient Record (EPR)" within the hospital, although other systems such as laboratory and imaging systems also store patient data. These systems do not support the registering of consent, and some of them can be accessed without going through the primary record system. Thus, ensuring that a possible special consent or denial from the patient is acted upon would require that the health care worker checks the consent information in the record before accessing such systems; this would cause a deviation of the work flow.

One solution for better consent handling within the hospital would be accessing imaging, laboratory and department specific clinical systems through the primary EPR system; another is to add a common consent module to those systems. In this way, consent can function without substantially deviating work flow, and without risking that the health care worker forgets the consent (accidentally or deliberately). Some parts of the system could require the health worker to verify having read and understood patient consent and consent denials.

Fulfilling denial of consent with executable rules

Converting existing systems to using consent as access control "gatekeeper" [4] is a more involved process than that of displaying consent and consent denial in all systems with patient data. Integrating access control between systems inside a hospital and between hospitals would involve having a common definition model and language for representing the access rules, integrating role definitions and work descriptions and standardising information classes across systems. Today, the hospitals have established procedures for giving access to the individual systems, but this access is provided on the basis of each system being an "object" of information. Since patients may have much more detailed consent requests, e.g., concerning a diagnosis rather than concerning the type of system where the data exists, integration would need a much higher granularity of information objects.

Subject granularity

The issue of subject granularity has consequences for consent management. In access control, the subject is the person or system that is denied or granted access; subject granularity is thus a measure of how precisely we can define subjects. In other words, are we able to give access to individuals, or only to departments or entire hospitals? Work inside a hospital department is collaborative [7] and information flows through other channels. One physician may also have patients at several departments, or having tasks to do at other departments, necessitating some kind of access across departments [6].

It entails that denying access to a specific person in some cases means denying access to an entire department. This is because this specific person would be unable to function normally within such a highly collaborative department. As found in our study, by denying access to a single individual, it might also effectively make treatment at the hospital impossible without infringing on the patient's consent. Even weekday treatment of outpatients may become difficult; an outpatient might develop medical complications resulting in hospitalization, or the department might simply be a small one, meaning that the patient can not be treated without potentially infringing on denial of consent.

Withdrawing consent for other external actor

As shown by the results, the current systems in use at the studied hospitals support referrals and discharge notes that are sent as the patient is transferred. If the patient has a specific consent denial, denying that the referring health worker should get results on discharge, then this can be registered in the relevant part of the EHR system, but this is not a standard location of consent. This kind of consent denial may be improbable, but a consent function related to external exchange of information will become necessary.

As of today, information exchange not related to discharge and referral is based on a signed declaration by the patient. There will still be a need to consider what to do when such a signed declaration conflicts with a patient's prior expressed consent and finding out whether the consent is informed. With the arrival of new types of external information sharing, consent and consent denials should be shown at places in the system where a health care worker evaluates external requests for information.

Informing the patient

As in other cases of handling patient consent, the consent, or the denial, for access to data must be an informed one. As emphasized in the results, the patient must be aware of how patient data will be used, and that a denial of consent could lead to treatment becoming unavailable at that particular hospital.

If the patient is to directly control access with a computer interface [8], the patient also needs to be informed about consequences of such control. If the patient gives less or more access to patient data than what was intended, then the interface should make this evident to the patient.

Conclusion

Current EHRs that record consent claims can support the manual execution of patient consent denial, but with some caveats. If patient information is kept both in the application called “EHR” and in other systems like imaging systems and departmental systems, then the consent should also be used by both. Points in the system where information is transmitted to outside parties may need specific consent functionality that is stricter than that which applies to general access.

Although a wider integration of access control in the hospital and between health care providers is a goal, there is a beneficial step that can be taken first: Making sure that the consent is viewed by the health care workers at relevant points in the process of using the EHRs. Whether a consent viewer or gatekeeper is the best solution will depend on the setting and on the implementation of consent.

Acknowledgments

We would like to thank the workshop participants for their valuable contributions and their employers for letting us use some of their time. We also thank Per H. Meland and Lillian Røstad for assisting with the preparations for the workshop. We thank Øystein Nytrø for assistance and for supervising the project Integrated Access Control for Health Care Information Systems. The project is funded by the Research Council of Norway's IKTSOS programme.

Abstract

One of the goals of the NIH Roadmap Initiative is to re-engineer the national clinical research enterprise, with an emphasis on information technology solutions. Understanding end-users' workflow is critical to developing technology systems that are grounded in the context of the users' environment and are designed to fulfill their needs. Community practices are becoming the prevailing setting for conducting clinical research. Few studies have assessed clinical research workflow in such settings. We have conducted a series of investigations to model the workflow and have previously reported on some basic aspects of it, like the lack of information systems to support the workflow. In this paper we describe finer details of the workflow, using results of observational studies. These findings highlight the needs and inefficiencies that suggest the kind of information system that must be developed to enhance collaboration, communication and improve efficiency. This preliminary investigation also opens ground for more extensive studies to further elucidate the workflow.

***Keywords*:**

clinical research, workflow, community practices, direct observations

Introduction

The National Institutes of Health (NIH) has embarked on the Roadmap Initiative, to achieve, among other goals, an increase in the clinical and translational research capacity of the United States [1]. This increase in capacity will require a substantial effort to develop and deploy information technology (IT) to improve efficiency, communication and collaboration among the diverse and distributed research networks and patient communities [1]. However, successful adoption of IT systems has always been a challenge, as evidenced by the slow adoption rates for Electronic Health Records (EHRs) and Computerized Physician Order Entry (CPOE) Systems in the United States and elsewhere [2]. Besides financial hurdles, numerous social and individual factors (such as understanding end user needs and workflow) have impacted the adoption of health care IT systems [2,3]. These factors must be considered even more carefully when considering a fundamental re-engineering of a national multi-stakeholder enterprise like clinical research. Such an onerous task requires one to address such fundamental questions as which stakeholder does the re-engineering target, what processes need to be addressed and how does one achieve the desired changes.

Columbia University's InterTrial project, which is funded as part of the Roadmap, has focused its re-engineering on community practices, which are becoming the prevailing setting for clinical research. Several factors, including lower administrative overhead and access to more representative subject populations, are motivating this shift [4]. To inform our re-engineering effort, we have undertaken a series of empirical studies (using qualitative and quantitative methods) to investigate stakeholder roles, organizational structures, workflow, information needs and communication patterns. Our multi-phase inquiry began with a focus group of clinical research coordinators (CRCs) from several member community practices of the Clinical Trials Network (CTN), Columbia University. This was followed by surveys, key informant interviews and preliminary field observations to develop an initial CRC workflow model [5]. This model (Figure 1) was used in a time-motion (TM) study to determine the workflow of a CRC in terms of what tasks (e.g., documentation, recruitment) and activities (e.g., scheduling a patient visit) were performed as part of research, what tools (e.g., phone, paper) were used to accomplish these activities and, ultimately, what outcomes were achieved (e.g., completed, incomplete).

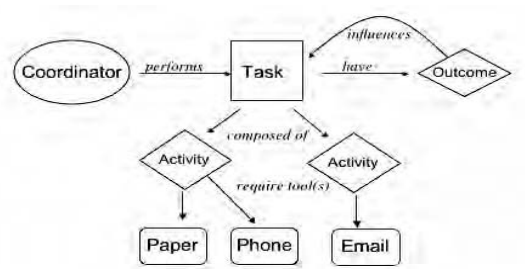

Figure 1 - Basic CRC Workflow Model

The TM study provided useful insights into the research workflow, highlighting such aspects as, the paper-driven

nature of work, the occurrence of several interruptions and the identification of often repeated and time-consuming activities [5]. However, it only provided snapshots of workflow and was insufficient to articulate the richness of the several interactions, conditions and circumstances influencing the workflow. For example, the TM study was unable to demonstrate who communicated with whom or to identify the reasons behind excess documentation. The observations described in this paper were done to elucidate this richness of the workflow.

Methods

In this study, we have used the method of direct observation to shadow CRCs in community practices and to record their work activities, interactions with other stakeholders, communication patterns, information needs and other aspects of workflow. Direct observation (and other qualitative methods) can provide a *deeper* understanding of a phenomenon, especially in the context of questions such as *why* and *how* [6]. This technique is also helpful in validating interview results and discovering unstated findings, since most respondents cannot precisely recall their work habits in an interview or survey [7]. Such studies are being increasingly undertaken in the biomedical domain to assess workflow [7].

We built on the findings from our initial time-motion study of three community practices by doing direct observations at three additional sites. For the purposes of this study, a community practice is defined as a physician office providing outpatient clinical care. Each of these sites also has a small research division with, typically, a single CRC managing some 8-10 trials. Those sites managing more clinical trials had a correspondingly larger team. Each of the three community practices was visited for three days, during which we conducted interviews with the CRC at the site, performed direct observations of the workflow and discussed certain work processes. The observations were recorded in field notes, which were later transcribed and analyzed for important workflow findings. In this paper we report on some aspects of workflow learned from these observations and supplement them with findings from the interviews, process descriptions and our earlier studies. What we describe is a *representative* day in the life of the CRC, though not all findings can be observed in the course of one particular day. We will not discuss workflow processes (e.g., scheduling a patient visit) in step-by-step detail (which were captured in our process discussions) but instead will highlight general crosscutting workflow themes. Example excerpts from our field notes are used to support the description of the findings. To make the paper readable and personable, we will allude to a fictitious CRC named Sarah, who epitomizes a composite of all the observed CRCs.

Findings

General aspects of sarah's workflow

Sarah is busy throughout the course of work. She is the *hub* of all work and information related to clinical research (if she is the main research staff) or all the trials under her supervision (if part of a research team). Sarah performs several tasks/activities in the course of her day, which can begin at 7.30 in the morning (particularly on days when patients are scheduled for a fasting blood glucose test) and go late in the evening. One of the characteristics of her workflow, also discovered in our earlier time-motion study, is the occurrence of regular interruptions (Figure 2).

> *As Sarah is completing a patient case report form (CRF), the Principal Investigator (PI) comes to ask about the protocol-related spirometry values. She points him to the protocol binder and he picks it and leaves. She returns to completing the form. After a minute the PI returns and says the binder doesn't have the value he is looking for. Sarah leaves the form and begins to search for another reference manual, which could have the value.*

Figure 2 - Excerpt showing an interruption

These interruptions usually happen because of incoming phone calls, or if some staff member (e.g., the Principal Investigator [PI] walks up to request some information). The occurrence of interruptions to workflow in clinical research parallel the interruptions noticed in other health care settings [8]. It is also common to see Sarah carrying out many activities in parallel, i.e., different activities being executed concurrently, but not necessarily requiring attention at the same time point. Sarah also engages in multi-tasking, i.e., actively doing two things at the same time (for example, speaking on the phone while flipping through the patient chart). Sarah usually does all types of activities related to research herself, i.e. at one point she could be taking calls, filling patient CRFs or examining a patient. There is some *division of labor*, i.e., different types of work being done by different people (e.g., phone calls being screened at the front desk or blood samples being drawn by a nurse other than the CRC) but this is usually limited to phone calls being received at the reception. During the course of her work, Sarah frequently moves in between shelves stacked with study binders, the examination room or the reception area equipped with the common fax and photo copy machines. This back and forth movement necessitates that she have at hand the information required to do a particular location specific activity. For example, having the right documents and the fax number before she walks to the fax machine. This movement may also require her to strategically economize her *travels* by grouping location specific activities (faxing and photocopy work). In a similar way, Sarah also makes simple strategies to group her work temporally, i.e., she may decide to do time-consuming paperwork in the afternoon when there are fewer interruptions.

Aspects of communication

Being the hub of information and work, Sarah must communicate with various stakeholders involved with research. These include the PI, other research and clinic staff, the sponsor, the monitor (some trials are managed by sponsor-appointed external monitors), patients and clinical laboratories. There are two noteworthy aspects about Sarah's communication channels. One is the apparent lack of access to other CRCs in nearby practices. This inability to reach out to other CRCs and create a peer-to-peer support network is a barrier to leveraging peer knowledge for self-help. Second is the authoritative *top-down* hierarchical directionality of the communication between Sarah and her communication partners (like the PI, sponsor and the

monitor), the nature of which usually results in Sarah's compliance with others' decisions.

Sarah communicates several times during the day, about wide-ranging topics including trial updates, obtaining documents, scheduling patient appointments or dispatching patient samples for blood work. Back-and forth communication (as can be discerned from the excerpt in figure 2, in which the PI returns twice to obtain the same information) is frequent and can stretch for hours or days, when, for example, a patient fails to show up for an appointment and repeated calls must be made to reschedule it. Communication occurs through various channels of which the most prevalent is verbal communication, followed by phone, fax and others. In fact, verbal communication happens in interesting ways (Figure 3), with Sarah at times, calling out to the entire office requesting a patient's medical chart ("chasing the chart" happens frequently) or to find out if a patient has called to cancel a visit.

Sarah comes out of the examination room and asks the office, "Does any one have this patient's chart?" Later that day, she realizes that a patient hasn't shown up yet. She asks, "Did John Doe come in today?" From her office space, both the receptionist and the medical record assistant are within earshot, affording her this small luxury.

Figure 3 - Excerpt of intra-office verbal communication

Multiple communications of the same information were observed in several instances. For example, during a patient visit, Sarah is required to dial an Interactive Voice Response System (IVRS) to obtain a code that confirms the occurrence of the visit. The code in some trials also serves to function as the code for the specific medication packet that must be dispensed to the patient. This information is communicated by the IVRS to Sarah during the call, is then later faxed and may also be sent by regular mail. Hence, three copies of the same information are communicated, in three different modalities, and each has to be maintained in the corresponding patient's study binder for later verification by the monitor. In contrast to multiplicity, there were instances of lost, delayed or unnecessary communication. Each of these sources of inefficiencies is particularly worrisome for Sarah. On occasions, she has completed and faxed documents only to be told (much later) that it was no longer required to fax that document. There have also been instances where the sponsor returned an entire batch of completed CRFs because an old version of the form was used. She once received two document packets for a study that ended months before. In most instances, the communication is dropped from the "other" side but Sarah has to face the consequences and has little influence to correct such mistakes (usually due to the top-down directionality of communication). She accepts it as "the nature of her job".

The burden of documentation

Documentation can indeed be a burden for Sarah. She spends considerable time doing it [5]. Most of the documentation deals with completing source documents (the main record of a patient visit, which she usually tries to complete during the patient visit) and then transcribing pertinent information into the corresponding CRFs for the study. The paper-based forms make the process of documentation tedious because they necessitate redundant data entry. For example, she needs to enter a patient's trial identifiers, trial name and other such information on every page of the CRF. Similarly, there is considerable overlap between reporting forms addressed to different stakeholders. A serious adverse event (SAE) report form used to notify the IRB maybe organized differently than that for the sponsor, even though both contain almost the same information, requiring duplicate data entry. Duplicate documentation effort is also necessitated when an entire batch of CRFs has to be redone because of version change (as explained earlier). Another particularly troublesome aspect of documentation is answering queries (a list of questions pertaining to the data in a CRF) sent by the trial monitor. To resolve the queries, Sarah has to look up old source documents or the patient's medical chart to revise the queried data element's value. This process can be laborious, especially when the queries refer to CRFs completed months or even years before. Besides completing CRFs, Sarah also has to write letters to the IRB or to a patient's primary care physician to apprise them of the patient's enrollment and progress in the trial. Most of the CRF and other forms are paper-based, though some trials provide software (some even provide exclusive trial laptops) for electronic data capture (EDC). Sarah finds EDC easier and more convenient because it offers automatically populated patient identifiers and immediate data integrity prompts. But such supporting systems have their own problems.

Information management and information needs

During her day's work, Sarah is actively managing several information exchanges in various formats and from diverse stakeholders. Her primary tools in managing the bulk of the information are the protocol and the individual patient binders. The protocol binders contain all the documents pertaining to the study. It is not uncommon to see protocol binders that are several inches thick and contain hundreds, if not thousands, of pages. Every notification of an amendment must be attached to the appropriate section in the binder and the monitors verify these during audits. Similarly, all patient-specific information (like new laboratory results, newly filled CRFs) must be filed in patient binders. The binders can quickly occupy much of the prime office space; half of Sarah's office is just shelves upon shelves of binders. It is necessary to store older binders until the sponsor permits destroying them or sending them offsite. Other information management tools commonly used by Sarah are a to-do list and a calendar. She uses a to-do list to remind her of the immediate or impending tasks. She usually maintains this list on a simple piece of paper and uses several highlighters to mark different activities in different colors (for example, highlighting blood work in red). She frequently uses her calendar to mark dates corresponding to her to-do list. She maintains her personal work calendar separately from the calendar that is maintained for the entire office (it can be in paper or electronic format), which she consults when scheduling visits.

Sarah has different information needs. She routinely seeks trial-related information (an important finding of the time-motion study [5]), which includes ascertaining the next visit for a study patient or determining a study's inclusion/exclusion criteria. Sarah also refers to her address-book or

the numerous artifacts (like small sticky notes littered all about her computer and office space containing phone numbers or other snippets of information) while making phone calls to sponsors, monitors, patients or the postal service for scheduling pickups. She typically needs to have several pieces of information to complete any activity. For example, while scheduling a radiology test for one of her patients, she needs to know, among other things, the trial inclusion/exclusion criteria, the patient's name, date of birth, contact information, preferred test dates, and the sponsor's name. Artifacts are routinely used by Sarah to take quick notes or post reminders around her. These notes provide easy reference to oft-needed information. The use of visual and spatial cues is a significant information retrieval strategy employed by Sarah. She has learned the spatial location of the protocol binders or other objects used in her work and can often find information at a glance. Similarly, the different color codes on her to-do list or of the objects in her surrounding, act as strong cues to narrow down her vast search space in a few milliseconds. As shown in the excerpt in Figure 2, she was quickly able to determine, by the spatial organization of her protocol binders, the location of the binder sought by the PI.

Use of information technology

Sarah does utilize a variety of computer-based tools to accomplish her work. She is adept at checking her email, accessing a website (she usually tracks updates in trials that maintain a website). She often uses word-processing programs and also knows how to use spreadsheets. Despite no formal computer training, Sarah can type quickly (25-30 words per minute), understand the concept of files or folders (which come in handy when managing her documents) and is aware of the security threats posed by viruses. She does EDC in two trials, one of which requires her to send data using a dial-up modem with which she has become familiar. As mentioned earlier, Sarah does note that computer systems improve efficiency but she highlights their quirks too. For example, a troubling aspect of using one of the EDC systems is the enforced password expiration. The software accepts her current password for only 60 days, after which she is required to change it. However, she uses the system *only once* in 90 days, to complete the CRF of the only patient in the trial who visits once in 3 months, by which time her password has expired. She then has to go through a laborious process of getting a new one from the sponsor's customer service hotline. The other vexing issue with computer software for Sarah is the lack of almost any control over the organization of the software or its features.

Discussion

The above findings illustrate interesting aspects (summarized in Table 1) of Sarah's workflow including some of the inefficiencies. These inefficiencies become more pronounced when examined in light of information management principles. First, the inefficiencies identified can be partially attributed to the *paper-based* workflow processes, which are limited by the nature of paper as a medium for information management. Paper forms are difficult to copy and disseminate, provide no error checking and are limited to one point in space or time (causing "chasing the chart" phenomenon).

Table 1 – Summary of workflow findings

Workflow themes	Important aspects
General	Frequent interruptions, multi-tasking, minimal division of labor
Communication	CRC is hub, several channels, multiple, dropped or lost communication
Documentation	Paper-based, redundant, some EDC
Information Mgmt./needs	Binders, to-do lists, calendars, artifacts, trial information sought, visual cues used
IT tools	Email, productivity software, EDC issues

Second, there is evidence to suggest considerable *redundant data entry*. For example, patient visits are first recorded in source documents and then transcribed to CRFs. Next, the CRFs require filling the same fields many times over or filling the same information for different purposes or audiences (the SAE example discussed earlier). Such a process can directly result in both transcription and omission errors. A consequence of redundant data entry is redundant update/delete efforts when data changes over time. Third, our examples indicate, that the processes have minimum provision for *reuse of data*. This is particularly troublesome, as in the case of managing medication logs. As mentioned earlier, Sarah obtains a medication code through an IVRS system while dispensing medications. She is required to log this information in a drug-dispensing log and also tally this with a drug inventory list, which she uses to order new supplies. Both the lists could be automatically generated through the sponsor's IVRS because the system has a record of all the drugs dispensed (and also of drug supplies received). In fact, the system could easily be programmed to send out new drug supplies automatically, based on the dispensing and previous order history. Going further along the lines of reuse of data, a system that allows the research team to share information on frequently sought information or repeated tasks, could drastically reduce time spent in repeatedly seeking the same information from other colleagues or slower mechanisms. As was mentioned earlier, trial inclusion/exclusion criteria, patient study visit schema, contact information and commonly used forms are frequently sought by all members of the research team and these could be obtained faster if provided in a collaborative, accessible and easily maintainable space like a FAQ web page. Fourth, there appears to be a lack of standards to specify the workflow processes pertaining to clinical trials. It was commonly noted that same tasks/activities (like *draw patient blood samples*) or other semantic concepts, were being represented using different syntactic phrases. Similarly, there are no standards for designing the various forms used in trials. Using standards would greatly allow reuse of data. Recently reported works on clinical research task vocabularies [9] and the initiatives led by the National Cancer Institute to create clinical research interoperability stan-

dards, would greatly aid information exchange among research information systems.

Several other shortcomings in the workflow merit discussion. The communication mechanisms frequently fail to provide up-to-date information or result in several duplications (that add up to cost in dollars and time). These can be corrected by adopting a paradigm of a central information repository that always stays up-to-date. For example, a trial-specific website (some sponsors provide this now) that hosts the latest versions of all required documents and forms, news updates and allows for the provision of such updates to be broadcast as emails or via really simple syndication (RSS) feeds, can greatly cut down the delays in communicating such updates via faxes or mail. In some cases, there is simply a lack of appropriate tools to carry out tasks. For example, some trials don't provide a handy one-page reference for the inclusion/exclusion criteria or the protocol visit schema (which are so frequently sought), leaving Sarah to devise her own reference sheets. Similarly, she needs to prepare her own checklists to remind her of the steps needed to complete a long sequence of activities correctly or create templates for letters. When tools exist, they may not have been designed keeping the workflow of the coordinator in mind. The example of the EDC system's password expiring every 60 days when Sarah only uses the system every 90 days is a good illustration of this disconnect. Similarly, getting a site's address printed in the "from" field of a shipping label (that is affixed on the boxes used to dispatch blood samples) can save Sarah some time. The IVRS system referred to above can also be better designed. It was not uncommon to see Sarah lose enthusiasm when navigating the depths of a complex IVRS system. The impersonal tone of the automated voice asking her to "press 1 if your entry is correct, press 2 if its wrong or 3 to go back to the previous menu" at every selection step, adds monotony and can be made more pleasant. Another important observation was that the information needed to complete a task or activity resides in multiple places including patient study binders, patient's medical charts, emails, protocol binders, or with the PI or some other person. The unavailability of any one of them can delay the completion of an activity.

It is important to emphasize that we don't intend to suggest that the clinical research workflow is *totally broken* or that the inefficiencies should be attributed to the CRCs. In fact, the resourcefulness (as demonstrated by Sarah in designing her own checklists), persistence and the *just get it done* attitude of the CRCs is very commendable. We briefly highlight a few strengths. One, an interruption in workflow is not always undesirable as it may support work through dissemination of unknown information through social exchanges. Two, audits by trial monitors do serve as useful checks to identify documentation errors. Third, the use of visual and spatial cues is a very rapid and effective mechanism for information retrieval as they narrow down the search space very acutely.

These observations have significantly informed our re-engineering efforts which are now focused on developing a web-based resource named the WorkWeb. The WorkWeb is intended to bring together, the currently distributed information resources (documents, phone numbers, etc), tools (a shared calendar and other applications designed to support specific tasks) and stakeholders (PIs, CRCs). It aims to enhance collaboration by supporting the creation of peer-to-peer support groups (via forums and blogs). The WorkWeb will also provide mechanisms for delivery of educational resources (like Good Clinical Practices training) through online multi-media delivery. As desired by the CRCs, almost the entire system will be under the control of the end-user who can add/modify content as they see fit and use features as needed, representing a paradigm shift of empowering our CRCs.

We acknowledge the limited nature of our observations because of which we may have overlooked (or incompletely understood) some aspects of the studied workflow. However, given the paucity of research in this field, we believe this is an important first step and contend, "One doesn't have to know everything in order to understand something [10]."

Conclusion

Clinical research is at the cusp of a fundamental re-engineering that involves substantial adoption of IT. Understanding workflow is critical to the design of the right IT solutions and their ultimate adoption. The InterTrial project is advancing efforts to elucidate the nature of workflow associated with clinical research in community practices in a bottom-up and empirical manner. These studies only represent preliminary work that needs to be further enriched by other (qualitative) inquiries before a detailed workflow model can be elicited. The initial results have informed our re-engineering efforts and we believe, illustrate the types of knowledge necessary to ensure the successful deployment of IT in community-based clinical research.

Acknowledgement

We thank our funding agency, the NHLBI and the community practices and CRCs for contributing their time to this study.

Abstract

We developed and fielded a survey to help clinical information system designers, developers, and implementers better understand the infusion level, or the extent and sophistication of CPOE feature availability and use by clinicians within acute care hospitals across the United States of America. In the 176 responding hospitals, we found that CPOE had been in place a median of 5 years and that the median percentage of orders entered electronically was 90.5%. Greater than 96% of the sites used CPOE to enter pharmacy, laboratory and imaging orders; 82% were able to access all aspects of the clinical information system with a single sign-on; 86% of the respondents had order sets, drug-drug interaction warnings, and pop-up alerts even though nearly all hospitals were community hospitals with commercial systems; and 90% had a CPOE committee with a clinician representative in place. While CPOE has not been widely adopted after over 30 years of experimentation, there is still much that can be learned from this relatively small number of highly infused (with CPOE and clinical decision support) organizations.

Keywords:

Computer-based Provider Order Entry,
health services research

Introduction

Several recent surveys of U.S. hospitals have estimated that less than 10 percent of all U.S. hospitals currently have Computer-based Provider Order Entry (CPOE) available, and of those that do, it is not known what percent of all orders are entered by clinicians [1, 2]. An earlier assessment of clinical information systems' capabilities (incl. CPOE) at five, early Davies Award winning institutions [3], was completed by Doolan et al. near the end of 2001 [4]. They found that the percentage of orders entered by clinicians at these leading institutions varied from less than 5% to well over 95% and that many different types of CDS were available. In 2004, Ash et al. found that CPOE "saturation", or "the percent of orders entered by physicians using a computer vs. other mechanisms" had a bimodal distribution (i.e., in hospitals with CPOE, 28.2% had less than 10% of their orders entered via CPOE, while 35.2% reported over 90% of their orders were entered using CPOE)[1]. In addition, of those hospitals that are using CPOE, no one knows the full extent to which real-time clinical decision support (CDS) has been incorporated into the clinicians' new CPOE-centered workflow [9].

The goal of this study was to further our understanding of CPOE and CDS infusion levels, both through improved definitions of CPOE and CDS infusion, as well as to actually measure these levels nationwide. Therefore, we developed and fielded a survey to help clinical information system designers, developers, and implementers better understand the infusion level, or the extent and sophistication of CPOE and CDS feature availability and use by clinicians within acute care hospitals across the United States of America.

Background

Infusion

Infusion of technology is described as the degree to which one uses an innovation in a more complete and sophisticated manner [5], and it occurs as information technology applications become more deeply embedded within the organizations' work systems [6].

Measuring the infusion level of any type of information system is difficult [7]. To compound the difficulty, separating the CPOE system functionality from the remainder of the clinical information system (CIS) can be even more difficult. We used the following definition for Computer-based Provider Order Entry (CPOE) - Entry of orders directly into the computer by the person responsible for making decisions about the patient's care. This person could be a physician, advanced practice nurse practitioner, or physicians' assistant with ordering privileges [8].

Methods

Initial survey development

We based our initial survey on that of Doolan et al. and added several additional questions about CPOE and deci-

sion support features after an extensive review of the literature [9,10,11,12] [see Appendix A for a copy of this initial 42-item survey]. Following IRB approval, we identified institutions who had successfully implemented CPOE by reviewing the literature, consulting with experts in the field, and talking with representatives from several of the major CPOE vendors. We included two sites (Wishard Memorial Hospital, Indianapolis, IN & Brigham & Womens' Hospital, Boston MA) from the original Doolan article for comparison. From each institution, we identified a key individual to answer our survey and contacted them directly via telephone or email. We sent a copy of the survey to each of our key informants and asked them to fill out as much of it as they could as of January 1, 2005. We followed up each returned survey via email or telephone to clarify and verify their responses.

Final survey development

We used the responses from these 16 organizations, discussions with several outside clinical informatics' experts, and our experience in the field of clinical information systems to create our final, shorter and more focused 6 question survey [see Table 1.] along with a weighted scoring system. Briefly, we created this 6-item survey by eliminating questions in which nearly all the organizations provided similar or highly correlated responses (e.g., 4 questions regarding order entry system attributes were replaced by one question that asked whether they had implemented CPOE for medications, clinical laboratory tests, or radiology examinations), those questions that upon further reflection did not add meaningful information to our survey (e.g., descriptive information about the hospital such as number of annual admissions or make of the CPOE system), those questions that were difficult for interviewees to understand and/or answer (e.g., the type of order communication interfaces in existence), nearly all of the detailed questions regarding specific types of clinical decision support (e.g., drug-drug interaction checking or preventive care reminders), questions about additional CPOE-related applications such as an electronic medication administration record or use of barcode medication administration, and we combined all of the organizationally-related questions (e.g., presence of a Chief Medical Informatics/Information Officer – CMIO, or type and extent of information technology support in clinical areas) into one question (i.e., Do you have a CPOE-related oversight committee with physicians on it?). All of the questions were scored on a scale from 0-1, except for "number of years the CPOE system has been active". For this question we gave organizations that had been using their CPOE system for greater than 10 years an extra point.

Development of final survey scoring categories

To allow us to combine the answers from the six survey questions, we created an ad hoc scoring system that ranged from 0 – 1 for each of the individual questions. We created the individual scoring ranges for each question based on an extensive review of the literature [13] and discussions with various experts in the field clinical information systems. Table 1 shows the actual scoring categories along with each question.

Table 1 - Questions from the final version of the survey.

Questions	Scoring categories
What percentage of all orders throughout the hospital is written by physicians using CPOE?	<50% = 0; ≥ 50% = 1
Which of the following types of orders do the physicians enter – medications, labs, radiology?	≤ 1 type=0; 2 types =0.5; 3 types =1
Can you sign in once to get to all aspects of your clinical information system?	no = 0; yes = 1
Do you have any decision support (e.g., order sets; drug-drug interactions; pop-up alerts) at the time of order entry?	≤ 1 type=0; 2 types =0.5; 3 types =1
Do you have a CPOE system-related committee (with physicians on it)?	no = 0; yes = 1
How many years has the CPOE system been active?	< 1yr = 0; <3 yrs = 0.25; <5 yrs = 0.5; <10 yrs = 1; ≥ 10 yrs = 2

Final survey site selection

We used the HIMSS Analytics database to identify 448 hospitals that identified themselves as "having implemented CPOE" (i.e., all sites reporting to have CPOE (the presence of a CPOE application that was "live and operational") from over 4500 hospitals. We then added all 113 Veterans' Affairs (VA) hospitals to this list. Using this combined list of 561 hospitals we systematically began to contact them. We sent email messages to all organizations for whom we could find email addresses. In addition, we telephoned all organizations for which we had a telephone number. For each of the remaining organizations we searched on the Internet in an attempt to find a contact number for each organization. In the end, we were able to find either a telephone number or an email address for all 561 organizations, although we were not able to verify their accuracy. We attempted to contact all of these organizations. Following completion of the survey, we carefully compared respondents to non-respondents using number of licensed beds and ownership as proxies for "other important organizational characteristics"[14], as well as geographic location and teaching status.

Results

Final survey administration

We were able to conduct telephone interviews with staff at 299 of the 561 acute care hospitals targeted, discovering that a large number (89) listed as having CPOE did not,

and finding that a number of hospitals (34) have policies against doing surveys. Consequently, using the Institute for Social and Economic Research (ISER) calculation for response rate [15], which takes into consideration the ineligibility of some sites (e.g., listed as having CPOE when they actually do not), our response rate (based on 176 valid interviews) was 47%.

Using logistic regression (forward, stepwise, likelihood ratio), we compared respondents and non-respondents. There was no difference in response rate with respect to number of licensed beds or teaching hospital status. Ownership type differed between respondents and non-respondents. The VA hospitals were most likely to respond, followed by other governmental hospitals, private institutions and non-profits (compared to VA, governmental LR = .63, private not for-profit LR = .38 and private for-profit LR = .35; $p<0.001$). There was also a small difference in response rate by geographic location with a site in the Northeast region most likely to be a responder, followed by the West, South and the Midwest, in that order (compared to South, Northeast LR = 2.11, West LR= 1.65 and Midwest LR = .93; $p=0.007$).

The length of time that CPOE had been in place ranged from 6 months to 25 years (median = 5 years). The percentage of orders entered electronically ranged from 1-100% (median = 90.5%). Greater than 96% of the sites used CPOE to enter pharmacy, laboratory and imaging orders; 82% were able to access all aspects of the clinical information system with a single sign-on; 86% of the respondents had at least 3 types of clinical decision support (order sets, drug-drug interaction warnings, and pop-up alerts) even though nearly all hospitals were community hospitals with commercial systems; and 90% had a CPOE committee in place.

Using our ad hoc scoring system (Table 1 Scoring Categories), we calculated a numeric infusion score (on a scale from 0 – 7) for each hospital (e.g., CPOE installed for 6 years receives score of 1). Fifty percent of the hospitals had an infusion score greater than or equal to 5.25 (7 max.). Figure 1 shows a graph of the cumulative percentage of all organizations surveyed in terms of total infusion score attained from the survey. From this one can identify the infusion level scores that place an organization in the 10^{th} (3.8) through the 90^{th} (5.9) percentiles.

Discussion

The most striking finding from our survey was the high degree of infusion at the vast majority of institutions we surveyed. We interpret this to mean that if organizations decide to, and are actually able to implement a CPOE system, they do it quite thoroughly as evidenced by a 50^{th} percentile survey score of 5.25 (7 max.). In addition, it was reassuring to find that most of the organizations surveyed (86%) had implemented at least some form of clinical decision support in three different areas. This is critical from our view since the vast

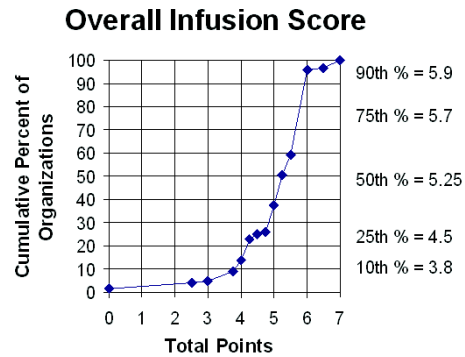

Figure 1 - Graph of cumulative percent of organizations vs. overall infusion score.

majority of the benefits accrued from CPOE result from the clinical decision support that can be simultaneously provided [16].

Also of interest was the fact that over half of the hospitals surveyed had been using CPOE for more than 5 years. This goes to reinforce our belief that complete implementation and incorporation of CPOE into the normal clinical workflow takes a significant (at least 5 years) period of time. In addition, the relatively high percentage of all orders entered via CPOE (median 90.5%) highlights the fact that once CPOE is in place, having both paper-based, manual order entry along with CPOE is not a good work practice and potentially increases the complexity of clinical workflow processes and can lead to additional unintended consequences [17].

Study limitations

The major limitation of this survey was the relatively low response rate of 47%. On the other hand, there were no differences between respondents and non-respondents with respect to hospital size or teaching status and only small differences with respect to ownership type and geographic location.

Conclusion

We have developed and tested a new CPOE infusion measure that demonstrates a very high level of infusion at those hospitals that have successfully implemented CPOE. Using this measure we have identified several key components of CPOE that nearly all successful sites have installed. While CPOE has not been widely adopted after over 30 years of experimentation [18], there is still much that can be learned from the sites that have successfully implemented these systems and incorporated various real-time clinical decision support system features into the clinicians' workflow.

Acknowledgements

This work was supported in part by grant LM06942-02 from the National Library of Medicine. We like to acknowledge the tremendous efforts on the parts of our telephone survey team including: Caroline Wetherton, Ashley Jones. We would like to

give a special thanks to those individuals who helped with our first survey: Abel Kho, Eric Poon, Jason A. Lyman, Karen L. Hughart, Brian R. Jacobs, Terri Andrews.

Appendix A. Initial Survey sent to 16 organizations with known successful Computer-based Provider Order Entry implementations.

Hospital characteristics
Number licensed acute care beds
Annual admissions
Annual Emergency Department visits
Hospital Type
Clinical service profile
CPOE Availability [Measured or (est.)]
Maker of CPOE system
Years since first in-patient go-live
Hospital Locations with CPOE (% of units)
ICU's
General Nursing units
Emergency Department

Order Entry System Attributes
Medications/Therapeutics i.e., IV medications, Blood products, Chemotherapy, Parental nutrition
Diagnostic tests(i.e., Pathology laboratory, Radiology)
Clinical consults / referrals (i.e., Specialty in-pat. consultations, out-patient, community nursing)
Patient Care or Ancillary Therapies (i.e., Nursing, Dietary, PT, OT, RT)
Order Communication Interfaces (e.g., Paper, fax, electronic 1-way, electronic 2-way, etc.)
Pharmacy
Clinical Pathology laboratory
Radiology

Clinical Decision Support Types Available Medication ordering
Subsequent or Corollary orders (e.g., order ACE inhibitors prompts for serum creatinine level [19]
Context-sensitive information retrieval (e.g., Info based on patient or drug-specific information [20]
Patient-specific relevant data displays (e.g., potassium levels when ordering digoxin)
Dose adjustments based on Renal impairment [21], Age (either pediatrics or elderly), Weight
Automatic Formulary checking
Order by indication (e.g., enter hypertension, get suggested medications)
Drug-drug interaction checking [22]
Drug-allergy interaction checking [23] by specific drug or by drug family?
Display of medication cost
Alternative/substitute Medication suggestions
Order sets [24]
Hospital-wide
Departmental
Personal
Diagnostic test ordering
Duplicate order checking
Display past results before ordering new test [25]
Charge display [26]
Preventive care reminders [27]

CPOE-related applications
Medication Administration Record [28]
Barcode Medication Administration [29]

CPOE-related Organizational support
Chief Medical Informatics/Information Officer
Multi-disciplinary CPOE design review/oversight committee
Multi-disciplinary Clinical Decision Support review/ oversight committee
By-laws modified to account for CPOE
IT support in clinical areas, how available
Multi-disciplinary Clinical Decision Support review/ oversight committee
By-laws modified to account for CPOE
IT support in clinical areas, how available

E-Healthcare in India: Critical Success Factors for Sustainable Health Systems

Udita Taneja[a], Sushil[b]

[a] *University School of Management Studies, GGS Indraprastha University, Delhi, India*
[b] *Department of Management Studies, IIT Delhi, India*

Abstract

As healthcare enterprises seek to move towards an integrated, sustainable healthcare delivery model an IT-enabled or e-Healthcare strategy is being increasingly adopted. In this study we identified the critical success factors influencing the effectiveness of an e-Healthcare strategy in India. The performance assessment criteria used to measure effectiveness were increasing reach and reducing cost of healthcare delivery. A survey of healthcare providers was conducted. Analytic Hierarchy Process (AHP) and Interpretive Structural Modeling (ISM) were the analytical tools used to determine the relative importance of the critical success factors in influencing effectiveness of e-Healthcare and their interplay with each other. To succeed in e-Healthcare initiatives the critical success factors that need to be in place are appropriate government policies, literacy levels, and telecommunications and power infrastructure in the country. The focus should not be on the IT tools and biomedical engineering technologies as is most often the case. Instead the non-technology factors such as healthcare provider and consumer mindsets should be addressed to increase acceptance of, and enhance the effectiveness of, sustainable e-Healthcare services.

Keywords:

e-Healthcare, critical success factors

Introduction

Proponents of adopting increasingly high levels of technology in the healthcare field justify this by stating that technology helps to improve the quality of healthcare provided while reducing overall costs. Qualitatively it is easy to see the level of healthcare being improved but as to how costs are cut is not so obvious. In this increasingly cost-conscious era, however, rigorous studies must be undertaken to measure the effectiveness of adopting newer ways of delivering healthcare. In the developing world e-Healthcare is often proposed as a solution to certain healthcare problems – accessing the rural population and trying to bridge the huge gap between the demand and supply of healthcare services [1, 2]. As resources are limited, especially in a developing country, it is important to ensure success of new and sustainable ways of healthcare delivery [3, 4]. Based on a literature survey we identified ten critical success factors that influence effectiveness of e-Healthcare in terms of their impact on increasing reach and reducing cost of healthcare delivery. We then attempted to determine the relative importance of these factors as well as understand the interplay among them in the Indian context.

Critical success factors for e-healthcare

Data warehousing and data mining

Appropriate data warehousing and data mining techniques are important as online patient record storage and retrieval of relevant data for medical decision making is an indispensable component of any e-Healthcare paradigm [5, 6].

Expert systems

Decision support systems for diagnoses and for demographic analysis for public health programs are extensively applied in the delivery of e-Healthcare [7].

Data access control

The healthcare sector in the West has stringent requirements for data security and controlling access to confidential patient data. In the United States the Health Insurance Portability and Accountability Act (HIPAA) was passed for improved patient privacy and data security [8]. In India, however, laws and standards for protecting a patient's electronic healthcare record are still in their infancy.

Biomedical engineering technology

Appropriate biomedical engineering technology is necessary to support telemedicine applications [9].

Telecommunications and power infrastructure

Reliable networks will be of prime importance as e-Healthcare activities increase [10]. Nowhere is this more important than in India where an uninterrupted power supply is yet to be realized in most parts of the country. This will need to be coupled with a high-bandwidth, zero-downtime telecommunications network to support e-Healthcare delivery.

Government policies

Government policies concerning healthcare, education, infrastructure, technology, insurance, and legal issues all have a bearing on the success of e-Healthcare in India. A radical change in the healthcare delivery process is necessary to achieve success in the e-Healthcare arena [11]. It is,

therefore, important for the government to be actively involved in this paradigm shift in healthcare delivery.

Healthcare insurance

Health insurance is another sector where the entry of third party administrators and private players is set to change the way healthcare coverage is provided in India. Providing insurance cover for illness as well as maintaining wellness is another factor to be taken into account.

Literacy levels

A literate population with a minimum level of computer awareness is essential for the success of e-Healthcare. Technology is useless when faced with ignorance and an inability to use it appropriately and effectively.

Consumer mindset

A literature review on the effect of telemedicine on doctor-patient communication showed that telemedicine was favored in approximately 80% of the studies [12]. In India, however, there exists a face-to-face culture that will have to be overcome and the use of technology actively encouraged to ensure the success of e-Healthcare.

Healthcare provider mindset

To be able to fully utilize the potential of e-Healthcare, healthcare providers will have to be responsive and committed to telemedicine [13]. Effective change management will be necessary to overcome resistance to adapting to new ways of delivering healthcare.

In light of the above, we assessed the critical success factors that influence effectiveness of e-Healthcare in terms of their impact on increasing reach and reducing cost of healthcare delivery.

Methods

Analytic Hierarchy Process (AHP) [14] was used to determine the relative importance of the success factors that influence the effectiveness of e-Healthcare. Interpretive Structural Modeling (ISM) [15] was used to determine the interplay between the success factors that influence effectiveness of e-Healthcare and establish the strategic drivers necessary for success. The independent variables correspond to the ten success factors influencing the effectiveness of e-Healthcare. The dependent variable is effectiveness of e-Healthcare. Increasing reach of healthcare services and reducing cost associated with healthcare delivery drives the effectiveness of e-Healthcare. These are used as the performance assessment criteria for measuring effectiveness of e-Healthcare. In light of the above, reach and cost were treated as the mediating variables connecting the independent variables and the dependent variable. This is shown in Table 1.

Table 1 – Analytical tools and associated variables

Analytical Tool	Variables
AHP	Objective: Select critical success factors influencing the effectiveness of e-Healthcare initiatives Criteria: Increasing reach, Reducing costs Alternatives: Data warehousing and data mining, Expert systems, Data access control, Biomedical engineering technology, Telecom and power infrastructure, Government policies, Healthcare insurance, Literacy levels, Consumer mindset, Healthcare provider mindset
ISM	Issues: Data warehousing and data mining, Expert systems, Data access control, Biomedical engineering technology, Telecom and power infrastructure, Government policies, Healthcare insurance, Literacy levels, Consumer mindset, Healthcare provider mindset Contextual relationship: Has an impact on

AHP

Based on the above objective, two criteria and ten alternatives, a vector ranking the ten alternatives was obtained from a group AHP performed on the inputs provided by individual healthcare providers. A Microsoft Excel spreadsheet was programmed to compute the group AHP rank vector. The ranking in this vector denotes the perceived importance of the alternatives.

ISM

The ten critical success factors were treated as issues to be assessed within the framework of a contextual relationship. The contextual relationship refers to each issue having an impact on another issue. These success factors were used to develop a group ISM based on the inputs provided by the same individual respondents. To develop a group ISM, the majority answer was taken for each question from the individual answers provided by the respondents. GMU ISM software, a Microsoft DOS based software, was used to perform the ISM calculations. The ISM shows, in a graphical form, the contextual relationship between the issues in terms of whether an issue has an impact on another issue. This helped determine the strategic driver issues that have an impact on the other issues.

Data collection

An exploratory study was carried out with data gathered using a survey instrument tailored for AHP and ISM and consisting of two sets of questionnaires. The questionnaires were personally given and explained to thirty-one healthcare providers out of which eighteen responded. Eleven of these respondents were doctors from a large

government teaching hospital, four were doctors in private practice, one was an e-healthcare manager for a large private chain of hospitals, and two responses were obtained from academics specializing in information technology and healthcare management.

Results

The results obtained from the analytical tools used on the questionnaire responses from the healthcare providers surveyed are given below.

AHP results

A group AHP computation was performed on the collective set of inputs obtained from all the respondents. The group AHP results, in terms of the ranking of the criteria and alternatives with their relative weights, are as given in Table 2. Healthcare providers, as a group, perceive increasing reach to be more important than reducing cost in increasing the effectiveness of e-Healthcare. Keeping in mind the large population of India that is currently underserved in terms of basic healthcare services, any initiative that attempts to provide healthcare services should increase the reach of services.

Healthcare providers rank literacy levels as the most important factor influencing reach. Consumer and healthcare provider mindsets along with telecom and power infrastructure follow in close succession as to their importance in increasing reach. Without a literate population it is not possible to fully utilize e-Healthcare services. The mindsets of people as well as the basic infrastructure issues are important for reaching a larger number of people.

With respect to reducing cost, literacy levels are once again considered the most important factor, with telecom and power infrastructure a close second, and government policies in third place. For e-Healthcare to service the country a literate population is desirable. When dealing with an illiterate population greater costs are incurred and this is reflected in ranking literacy levels as the number one factor affecting the cost of e-Healthcare. The infrastructure costs also have a bearing on e-Healthcare costs and hence they are in second place. Government policies, in third place, also have an impact on the cost of e-Healthcare.

Table 2 – Group AHP ranks

Criteria

Increasing reach	0.5778
Reducing cost	0.4222

Alternatives with respect to increasing reach

Literacy levels	0.1951
Consumer mindset	0.1298
Healthcare provider mindset	0.1274
Telecom / power infrastructure	0.1262
Government policies	0.1042
Expert systems	0.0703
Data access control	0.0665
Healthcare insurance	0.0644
Data warehousing / data mining	0.0632
Biomedical engineering technology	0.0531

Alternatives with respect to reducing cost

Literacy levels	0.1644
Telecom / power infrastructure	0.1537
Government policies	0.1337
Consumer mindset	0.1070
Healthcare provider mindset	0.1055
Healthcare insurance	0.0887
Data warehousing / data mining	0.0877
Expert systems	0.0679
Biomedical engineering technology	0.0536
Data access control	0.0378

Overall ranking

Literacy levels	0.1821
Telecom / power infrastructure	0.1378
Consumer mindset	0.1201
Healthcare provider mindset	0.1181
Government policies	0.1167
Healthcare insurance	0.0747
Data warehousing / data mining	0.0736
Expert systems	0.0693
Data access control	0.0544
Biomedical engineering technology	0.0533

In the overall ranking, literacy levels are considered the most important factor influencing the effectiveness of e-Healthcare. The telecom and power infrastructure is ranked second with consumer and healthcare provider mindsets a close third and fourth. As mentioned earlier a literate population is a prerequisite for effective e-Healthcare delivery both in terms of increasing reach and reducing cost. Without telecom and power any e-Healthcare initiative will not function properly. The mindsets of both the healthcare providers and consumers are also important for e-Healthcare to gain acceptance as a means of giving and receiving healthcare services. The technology aspects of the business such as appropriate IT and biomedical engineering technologies are ranked the lowest in their impact on e-Healthcare.

ISM results

A group ISM was developed from the complete set of inputs obtained from all the respondents and the digraph is shown in Figure 1. Government policies are the most important strategic driver having an impact on the other factors. Relevant government policies need to be in place to accelerate the pace of infrastructure development in the country without which e-Healthcare cannot hope to achieve any measure of success. Government policies also have a direct impact on the literacy levels in the country that will, in turn, drive changing consumer mindsets.

The telecom and power infrastructure in the country is the second most important strategic driver for e-Healthcare initiatives. With an adequate infrastructure in place the healthcare provider mindset will be influenced positively in favor of e-Healthcare as a successfully delivery mechanism. The information and biomedical engineering technologies are not as critical in e-Healthcare delivery as can be see from the digraph.

Discussion

Healthcare providers, as a group, perceived increasing reach to be more important than reducing cost in increasing the effectiveness of e-Healthcare. In the overall AHP ranking, literacy levels were considered the most important factor influencing the effectiveness of e-Healthcare. The telecom and power infrastructure was ranked second, with consumer and healthcare provider mindsets a close third and fourth. A literate population is a prerequisite for effective e-Healthcare delivery and without telecom and power e-Healthcare will not work. The mindsets of both the healthcare providers and consumers are also important for e-Healthcare to gain acceptance. The technology aspects of the business such as appropriate IT and biomedical engineering technologies were ranked the lowest in their impact on e-Healthcare. The ISM digraph identified government policies as the most important strategic driver. Government policies need to be in place to accelerate the pace of telecom and power infrastructure development in the country. Government policies also have an impact on the literacy levels in the country, also an important driver for e-Healthcare effectiveness. The information and biomedical engineering technologies are not as critical in e-Healthcare delivery as can be see from the digraph. The results from both tools show that non-technology issues such as government policies, telecom and power infrastructure, and literacy levels in the country are more important than technology issues.

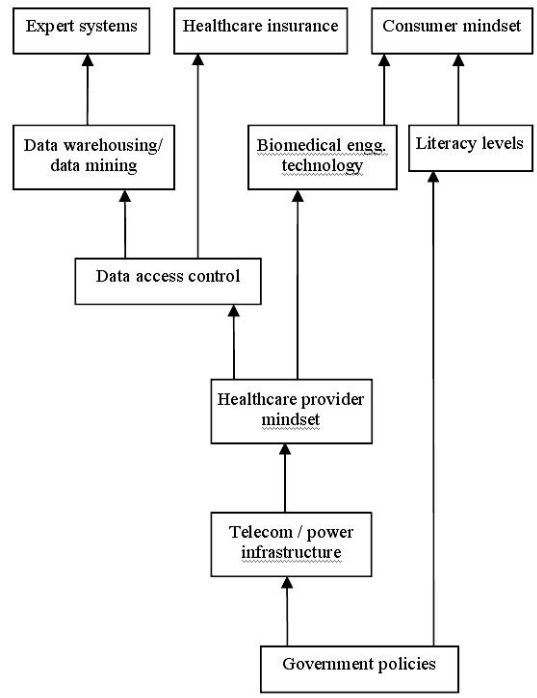

Figure 1 – Group ISM digraph

Conclusion

We have sought to evaluate the ten critical success factors that influence the effectiveness of e-Healthcare in India. We have attempted to determine the relative importance of these factors as well as understand the interplay between them. Increasing reach and reducing cost were the performance assessment criteria that were used. AHP was used to rank the factors. ISM was used to establish a causal relationship diagram between the critical success factors and identify the strategic drivers. To succeed in e-Healthcare initiatives the critical success factors that need to be in place are appropriate government policies, literacy levels, and telecommunications and power infrastructure in the country. The focus should not be on the IT tools and biomedical engineering technologies as is most often the case. Instead the non-technology factors such as healthcare provider and consumer mindsets should be addressed to increase acceptance of, and enhance the effectiveness of, sustainable e-Healthcare services.

Health Information Systems Adoption: Findings from a Systematic Review

Maryati Mohd. Yusof[a], Lampros Stergioulas[b], Jasmina Zugic[b]

[a] *Dept. of System Mgmt. & Science, Faculty of Info. Tech. & Science, National University of Malaysia, Malaysia*
[b] *School of Information Systems, Computing & Mathematics, Brunel University, UK*

Abstract

Earlier evaluation studies on Health Information Systems (HIS) adoption have highlighted a large number of adoption problems that were attributed to the lack of fit between technology, human and organisation factors. Lessons can be learned from these evaluation studies by identifying the most important factors of HIS adoption. In order to study the adoption issue, a qualitative systematic review has been performed using a recently introduced framework, known as HOT-fit (Human, Organisation and Technology fit). The paper identifies and highlights the following critical adoption factors: technology (ease of use, system usefulness, system flexibility, time efficiency, information accessibility and relevancy); human (user training, user perception, user roles, user skills, clarity of system purpose, user involvement); organisation (leadership and support, clinical process, user involvement, internal communication, inter organisational system, as well as the fit between them. The findings can be used to guide future system development and inform relevant decision making.

Keywords:

Medical informatics, informatics, information systems, evaluation studies, framework.

Introduction

Although we are currently witnessing a rapid growth in the development and use of Health Information Systems (HIS), HIS stakeholders (purchasers, patients and physicians) experience familiar levels of disappointment associated with more general system development. Such disappointing systems are mainly caused by the inability of HIS to match the work patterns and settings of healthcare, which results in barriers to the use of HIS. In general IS development, past experience shows that overemphasizing technical issues while overlooking social issues can result in system failure [1]. For HIS, the lack of fit among the main organisational elements such as organisational strategy, structure, management process, the skills of people and their roles, and technology contributes to a large number of system failures in public health [2]. The most significant socio-technical issues therefore need to be identified in order to enable HIS to improve, drawing upon the past experiences, and to assist the health care process. The aim of this paper is to present the main findings of a systematic review of selected case studies on HIS adoption in clinical practices.

Theoretical framework

The proposed Human, Organisation and Technology-fit (HOT-fit) evaluation framework was developed after a critical appraisal of previous HIS and IS evaluation studies [3]. It makes use of the IS Success Model [4,5] in categorizing its evaluation factors, dimensions and measures. The IS Success Model is adopted on the basis of its comprehensive, specific evaluation categories, extensive validation and its applicability to HIS evaluation. In addition, the IT-Organisation Fit Model [6] is used to complement the IS Success Model by integrating its featured organisation factors and the concept of fit between the human, organisation and technology factors (See Figure 1).

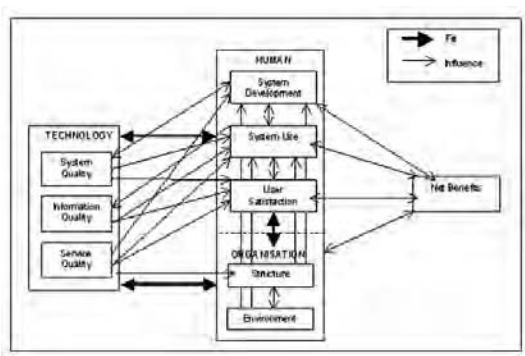

Figure 1 – Human-Organsation-Technology Fit (HOT-fit) framework

Methods

The research approach employs a subjectivist, systematic review strategy with a combination of both qualitative and quantitative methods. A subjectivist approach was chosen in order to gain an extensive understanding of the healthcare context surrounding the HIS through detailed, insightful explanation of the study [7]. A systematic review was adopted to synthesise both qualitative and quantitative research in a comprehensive manner.

This systematic review consists of a number of discrete activities [8,9,10]: 1) identification of the need for a review, 2) formulation of a research question, 3) development of a review protocol 4) location of studies, 5) selection of primary studies, 6) quality assessment of included studies, 7) data extraction, 8) data analysis, 9) interpretation of results, 10) report writing.

The search for articles that addressed issues pertinent to HIS evaluation was conducted using a number of databases ranging from medical, informatics and engineering field. The search terms were individualized for each database and included terms for: (health or medical) informatics, system, computer based, evaluation and assessment. In this systematic review, evaluation study is defined as a methodical, empirical assessment of health information system in clinical settings. The type of study design selected is *case study* as it provides understanding and insight into the research question. Thus, other study designs, such as experiment and survey are not included in this systematic review. HIS stands for any computer based information systems that involves human interaction used in healthcare settings. All computer or knowledge based training and education systems for healthcare professional are excluded in the review, as they are not directly related to clinical care (or clinical use of technology). Searches were limited to human subjects and articles published in English, between 1985 and 2005, and were completed from January to February 2006. The studies were searched both electronically and manually in order to cover a comprehensive range of literature. The selection of studies involves a multi-stage process [8] (See Figure 2).

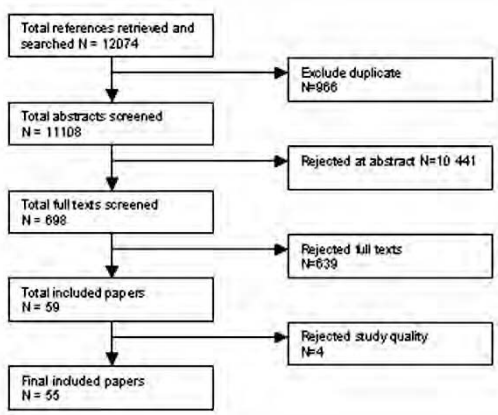

Figure 2 – Methods of study selection

Results

Study description

Fifty five studies from various resources listed in Appendix A and at www.ftsm.ukm/mmy/sr1985-2005list were selected to be analysed. The participants in the selected studies range from top managers to clerical staff, with doctors and nurses being the main informants. Their numbers vary from 3 to 1500. Most studies employ a combination of these data collection methods: documentation, archival records, interview, questionnaire, observations and physical artifacts. About half of the studies used a mix of qualitative and quantitative methods. The review has found that, nearly 40% of the studies focused on a combination of technology, human and organisation factors of the HIS adoption; the rest of the studies focused on either single or combination of two of those factors. In terms of the evaluation time, 44 out of 55 (80%) studies took a summative approach, while only 9 studies chose both formative and summative approaches and 2 studies used a formative approach. The type of HIS evaluated and their occurrences are as follows: Electronic Medical Record (EMR) (13); Telemedicine (10); Computerised Provider Order Entry System (CPOE), Clinical IS (CIS) (8), Picture Archiving and Communication System (PACS) (7); Clinical Reminder System (CRS) (4); Patient Care IS, Radiology IS (RIS), Hospital IS (2) and Laboratory IS (1).

We used the following qualitative research appraisal criteria for assessing all empirical papers to be included in our review by judging seriously flawed papers [11]: clarity of 1) aims and objectives, 2) research design and process by which their findings were produced; appropriateness of analysis method; results credibility and importance; and conclusions drawn. All 55 studies were assessed to be of sound quality. Qualitative quality assessment showed that nearly half of the studies have excellent study quality and the other half have acceptable study quality.

Principal findings

Adoption factors were identified according to technology, human and organisation category outlined in the HOT-fit framework, as well as new evaluation dimension (system development) and measures identified from the themes emerging from the extracted data. Table 1 shows the occurrences of critical adoption factors according to their category and dimension.

Overall, data analysis shows that successful HIS adoptions tend to have many occurrences of human and organisation factors relevant to strong human support and collaboration namely user involvement, relationship with IT people, teamwork, leadership, top management support, system champion and medical sponsorship. Highly positive cases of HIS adoption also had a clear purpose and benefits of system and employed effective installation strategy. On the contrary, unsuccessful HIS adoptions showed a high number of conflict among stakeholders, negative user perception and user resistance. Interestingly, the occurrences of technology factors are almost equally the same within the positive and negative adoption. In the system quality dimension, the following measures are cited more in negative adoption compared to positive ones: system flexibility, system sophistication and turnaround time. Meanwhile, most studies of positive HIS adoption reported a high number of information quality measures in system net benefits, particularly information accessibility, relevancy, legibility and format. In the negative adoption studies, apart from information relevancy, other information quality measures were not cited.

Table 1 – Dominant factors of HIS adoption

Technology	Human	Organisation
System Quality	**System Development**	**Organisational Structure**
Ease of use N=28 Usefulness N=24 Time (response & turnaround) N=23 Flexibility N=18 Reliability N=13 Technical support N=13	User involvement N=13 System purpose N=12 Installation strategy N=11	Leadership & support N=34 Clinical process N=20 Internal communication N=11 Resources N=10
Information Quality	**System Use**	**Organisational Environment**
Accessibility N=26 Relevancy N=20 Completeness N=13 Legibility N=12 Format N=10	User training N=24 User perception N=18 User skills N=17 User attitude N=10 User roles N=14	Inter organisational systems N= 10

Technology

Ease of use was identified as one of the highest adoption factors cited in this review. In many studies, positive HIS adoption has been linked to the ease of system use in a number of ways including friendly user interface, 'point-and-click' features and free-text entry [12,13]. Ease of use is a major incentive to system use. According to a physician, "… it needs to be convivial, easy to use, and functional. If you don't have that, physicians get fed up and don't want to use it anymore" [14]. Unfavourable comments on ease of use include 'cumbersome', 'unintuitive' and 'restrictive' [15,16]. Poor usability results in many problems, such as error in the use of patient record as the record was not visible enough and excessive complexity of screens [17,18].

Within the system quality dimension, system usefulness was the second most quoted factor. Various systems functions including query, messaging, data storage and access, reporting, image manipulation, and educational tool were described as beneficial to users. Examples of useful system features include prescription writer, templates, document imaging, minimal free text format, graphical display and order sets.

Time efficiency in terms of response time and turnaround time of HIS was highly regarded by user, as reported in many studies. Users viewed this as the most important aspect of CPOE to be considered; perceptions of time vary according to role [19,20] An organisation where a CIS was implemented had to make trade-offs between adding new functionality and keeping the system response speed to a level that was acceptable to clinicians on a constant basis [21]. Meanwhile, many studies reported long turnaround time that affected healthcare delivery. Examples include accumulated time for entering orders for a whole group of patients at a time that can add up to hours [20]. Data entry and capture was time consuming, seldom error-free and distanced the user and patient, thus resulting in patient dissatisfaction [22].

System flexibility has been frequently described as one of the most important factors of HIS adoption. Flexibility of a system was viewed as the degree to which it personalized departmental or individual requirement and the ability to integrate to other HIS. For example, the Southeast Health Center staff felt that the EMR was easy to adopt and flexible enough to accommodate different provider requirements. Moreover, the EMR was found to promote increased efficiency and effectiveness in the billing process, attributed largely to the system ability to automatically link clinical diagnoses with the disease and health related problem codes [12].

Positive effects of HIS adoption were commonly associated with information accessibility and relevancy. Information accessibility benefits users and organisation in many ways. Increased access and availability of EMRs patient information to multiple users has resulted in increased efficiency (e.g., less staff time searching for charts; time saver; speedy and improvement of physicians decision making) [12,23,24]. Information relevancy was highly regarded by clinicians. For instance, an Imaging System was found to provide real patient experience; it helped students associated a visual image to a patient history and eased the linked of verbal reports to visual symptoms [24]. In a telemedicine project, visual information provided an essential dimension for healthcare provision (e.g. they enable detailed assessment of patients, including for example emotional states and skills) [25].

Human

Most successful HIS implementations were attributed to the provision of extensive, continuous user training and support [19,20]. Some users had some basic computing skills before participating in system training. In a practice, for example, staff who were pleased with their training had the chance to familiarize themselves with computers and play computer games, months before the system operation [23]. A common problem identified with training was that time needed for training constantly conflicted with clinicians' busy schedule [18,26,27]. User perception was highly cited as a contributing adoption factor of HIS. Low adoption studies reported the use of HIS that was perceived as "add-on" rather than integral task; cumbersome and clerical functions [28,29].

Many studies cited the influence of user roles and skills on system use. Effective system use in many organisations was impeded by the hierarchical structure of the organisation, which affected the way users perceived the system and unable to respond to its deployment [30]. Residents were reluctant to enter patient data, regarding it to be a traditional task for support staff [28]. A RIS project team acknowledged the importance of having the right combination of personalities and talents to achieve the outcome [31]. In contrast, the dramatic pattern of decline in the frequency of telehealth consultations was attributed to the

lack of physician familiarity with equipments, particularly in emergency situations [25].

Clarity of purpose and expected benefits has been very influential in both highly positive and negative HIS adoption. During the early stage of a successful RIS adoption, the project team set an objective that was very visible to the staff; their completion helped provide a jump-start as well future progress to the whole project [31]. A problematic telehealth installation was partially caused by improper needs assessment [25]. User involvement was also identified as an important HIS factors. At the service level of a telemedicine project, "the optimal approach appears to be one that is highly inclusive in the full involvement of stakeholders…" [25]. Over time, continuous improvements suggested by users yielded to a simpler, user friendly and comprehensive version of the system [22].

Organisation

More than half of the studies cited stalwart individuals in both leadership and support positions as one of the most important factors for implementing HIS. Ash et al., [19] categorized essential people to the successful implementation of CPOE. These people were also very influential on the adoption of other types of HIS. Their roles are classified into three major levels: the leadership level, including the Chief Executive Officer (CEO); the clinician level, including champions, opinion leaders, curmudgeons, and the clinical advisory committees and the bridger level, which includes those who do training and support and interact directly with users (bridgers translate user needs to the higher level and vice versa). In addition, top management support can also be included in this special people category. These special people have been very instrumental and influential in gaining users buy-in through strong support, commitment, persistence and assistance in overcoming fear and even providing technical support.

The adoption of HIS was also commonly linked with the ability of system to fit with the clinical practices. Other relevant issues of clinical process are heavy workloads that leave clinicians with limited time availability to undergo training and use HIS [18,26,27].

Discussion of the findings

Many human factors were identified as barriers and enablers to HIS adoption. User training and user perception were particularly common, followed by user skills/ knowledge, user roles, user involvement, system purpose and installation strategy. The aforementioned critical technology factors such as ease of use, system flexibility, and information usefulness are related to its ability to align with human and organisational needs. Organisation also plays a major role in supporting the uptake of HIS through leadership, resources and moral. Many instances of fit were identified in the included studies. In particular, the fit between system and clinical practices was quite common. Cases with misfit between the system and clinical practices were more common compared to the cases with good fit. In one US hospital, the design of the CPOE was clinician-oriented and the physicians' current workflow was preserved to a great extent [26]. An exemplar of internal fit was identified in a large scale CPOE implemention where both workflow and system requirements were accordingly changed to fit with each other [32]. In contrast, an EMR was disintegrated into current clinical practices and its documentation was interspersed among other more important physician's tasks [27]. Lehoux et al. [30] concluded that problems in the EMR implementation indicated a design that interfered with the clinical practices it was supposed to support.

Conclusions

Many adoption factors of HIS have been identified from this systematic review. Different types of systems have certain unique adoption factors, but they nevertheless share a lot of common adoption factors. The variables that seem to have a major determinant effect on adoption of Health Information Systems are ease of use, system usefulness, system flexibility, technical support, response time/ turnaround time, information accessibility, information relevancy, clarity of system purpose, user involvement, user training, user perception, user skills/ knowledge, user roles, clinical process, champion/ medical sponsorship, leadership, internal communication, and resources. All three technology, human, and organisation factors are equally important, in addition to the fit between them. Findings from this systematic review can be used to inform decision making in the investment and development of HIS and IS in general.

The presented review of HIS adoption factors has also demonstrated the capability of the HOT-fit evaluation framework to address the essential components of IS, namely human, organisation and technology, and the fit between them. This evaluation framework is potentially useful to researchers and practitioners for conducting rigorous evaluation studies of other IS or IT applications in healthcare settings or any other domain. The systematic review can be extended further by including hand searched, high quality conference papers. From this study's findings, recommendations for improving HIS adoption can be identified to guide future development of HIS.

Acknowledgments

We gratefully acknowledge the funding received from both the Public Serv. Dept. of Malaysia and from Univ. Kebangsaan Malaysia (National Univ. of Malaysia) that helped sponsor this study. We would also like to thank Prof. E. Ammenwerth and Prof. J. Wyatt for their valuable suggestions on this review.

Telemedicine Portal and Standardized Clinical Documents

Ivan V. Emelin[a], Radik A. Eltchiyan[a]

[a] *General Research Computer Center of the Russian President's Management Department, Russian Federation*

Abstract

The paper describes the experience of creating a flexible telemedicine portal intended to improve a business process of information exchanges needed to manage real-time telemedicine events. The portal structure allows use of digitally-signed standardized clinical documents based on the HL7 Clinical Document Architecture.

Keywords:

telemedicine, telehealth, web portal, CDA,
digital signature

Introduction

Telemedicine is spreading over the Russian Federation mostly by efforts of the enthusiastic healthcare authorities, physicians and engineers using different kinds of telecommunication channels, communication and terminal equipment for real-time teleconsultations and telelearning [1]. Usually these real-time telemedicine events are rendered by the well-equipped Russian medical centers specialized in cardiovascular surgery, neurosurgery, oncology and other medical disciplines. Their clients are mostly the tertiary hospitals located in many Russian regions. There are also the mobile telemedicine units intended for field use – the telemedicine trucks and even the telemedicine trains. There is no common administration for all the participants of this telehealth network.

There is a lot of preliminary information exchanges needed to manage real-time telemedicine events. Typically these exchanges are made using phones, electronic mail and file transfer protocols. It is a time- and labor consuming error-prone task. Nevertheless it has one substantial advantage – it is quite affordable to the medical staff having limited knowledge of information and communication technologies.

This paper describes the telemedicine portal that may considerably lighten the burden of this preparatory work.

Use case

The real-time telemedicine consultation is to be negotiated by many people including a patient, an attending physician, the administrators of the participating telemedicine units (TU), the consultants and the accountants. The attending physician sends a referral to a local TU administrator. The administrator looks for the appropriate consulting medical center and forwards the referral to the TU administrator of this center (host TU administrator). This administrator checks validity and completeness of the referral, asks for additional patient data if needed, finds the consultants that may fulfill the referral, schedules the videoconference, sends reminders to the participants of the teleconsultation and does a lot of other related duty. This process may iterate before the videoconference.

The consultants write the referral notes after the videoconference and sign them. The host TU administrator sends notes and a bill to his vis-à-vis who in turn forwards the notes to the attending physician and the bill to his accountant.

The similar use cases may be written also for telelecture and for other types of telemedicine events.

Telemedicine portal solution

There are many possible solutions that may help to optimize the business process described above. We had set the following base principles helping to choose the better solution:

1. The solution shall be flexible: the TU administrators shall be able to customize it using non-custom tools.
2. It shall be secure: only the direct participants of the telemedicine event may have access to information related to this event. Clinical documents and their attachments are to be signed electronically. The crypto providers used shall conform to the national requirements.
3. It shall be affordable: the end users may get access to information having no more than office applications and web browser on their computers. They are to be able to use this solution having only base knowledge of these applications.
4. It shall be scalable: it shall support thousands telemedicine events simultaneously.
5. It shall supply the possibility to enter and use the standardized clinical documents based on HL7 CDA Release 2 standard.

The web portal may offer the collaboration environment conforming to these principles. There are a lot of telemedicine portals worldwide intended for similar use, for example TempoBy in Germany [2], Apollo's telemedicine portal in India [3], U.S. Military Health System portal [4].

But they are not flexible enough and not as affordable as we need.

Telemedicine portal structure

Each TU has its own web site on our telemedicine portal. A TU administrator has privileges to customize this site using non-custom authoring tools.

Each real-time telemedicine event is moderated by one TU (host). An administrator of this TU creates a separate site (workspace) for the telemedicine event and gives full access to this site to the administrators of other TUs (clients) participating in this event.

The telemedicine portal contains a central gallery of site templates. There is a separate template for each type of telemedicine event and also for TU site. Each site may have its own gallery of site templates. A TU administrator may construct his own gallery of site templates and may use them instead of templates stored in the central gallery.

This structure is shown on figure 1 as a UML class diagram. It ensures *portal flexibility.*

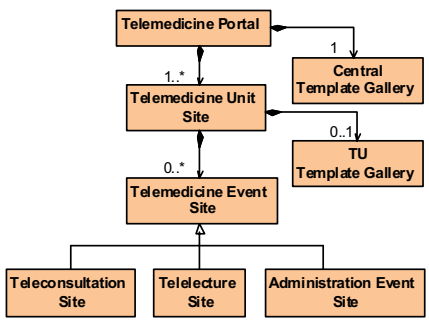

Figure 1- Telemedicine portal structure

A TU administrator grants the proper access rights to a telemedicine event site only to direct participants of this event. All the clinical documents needed for the event will be stored only on event site. There is no central electronic medical records (EMR) database. The telemedicine event site is accessed using the Secure Socket Layer (SSL) and the national crypto providers. All this ensures *security* and *privacy* of the telemedicine portal.

The sample of TU home page is shown on figure 2. It contains general information needed to communicate with this TU, a form library of the current referrals, a list of the scheduled telemedicine events, a list of the consultants and a list of the consulting TUs.

The TU administrator may reject or adopt a referral. If the referral is adopted the TU administrator creates a new entry in the list of the telemedicine events. A new workspace is created for this entry using a teleconsultation site template. The sample of a teleconsultation workspace home page is shown on figure 3.

Figure 2- Sample of a TU home page

Figure 3- Sample of a teleconsultation home page

This page contains the form libraries for the referrals, the discharge notes and the referral notes, a document library for the attachments to the referral (for example medical images) and other lists. It is intended to improve collaboration of TU administrators, the referring physician and the consultants and may be customized by TU administrator to optimize this collaboration.

Standardized clinical documents

There is a special form template for each form library. This template contains XML-schema, allows to create XML-document conforming to this schema and to store the created document in the library. As many documents as needed may be stored in each form library.

The first our idea was to construct the form templates using XML-schemas defined in CDA Release 2 [5] because CDA has good chances to be adopted as ISO standard. But we faced two main problems:

- CDA schemas per se are to complicated for template designer used
- They do not allow digital signatures

To resolve these problems we have constructed an “envelope” containing the following namespaces:

- Slightly modified CDA namespace
- Local namespace
- Digital signature namespace

The local namespace is used to construct XML-forms intended for entering referrals, discharge notes and referral notes. The local namespace is mapped to the CDA namespace immediately before submitting the form to a form library so this form will contain a CDA-compliant part. Digital signatures may secure the CDA namespace, the local namespace or both.

TU administrators may change the appearance of XML-forms using a standard office application. They may add, remove or change form fields and so on. But they cannot change internal XML-schemas using simple tools so the changed forms will still produce standardized XML-documents.

It is also possible to upload XML-documents immediately from the EMR system. In this case the local namespace may be not used at all and the uploaded documents may be viewed using web browser and XSL-transformation.

Conclusions

Our experience of deploying and using the portal described above shows that telemedicine portals may improve the business process of information exchanges needed before and after real-time telemedicine events. The structure of these portals will depend on the business process used. The hospital chain may use the portal together with centralized EMR. Our solution assumes that the participants of the telemedicine portal consider the portal as customizable collaboration environment. Different business processes may require another solution.

The experience of using CDA with digital signatures shows that it may be necessary to standardize the structure of an envelope containing CDA-compliant part and stored on the telemedicine portal. In principle CDA-documents may be sent as the binary enclosures in HL7 V3 messages. But the telemedicine portal stores documents, not messages and there still remains the problem of using XML-digital signatures.

IHE proposes to send XML-digital signatures as separate documents linked to the clinical documents to be signed [6]. This approach is not very convenient if we want to store the signed clinical documents on a portal, view them and modify document appearance using simple tools affordable to many medical users. So our proposal to standardize the envelope structure may help to involve more users in exchange of standardized clinical documents.

Currently our telemedicine portal is used by TU of the Russian President's Management Department. We promote it to several other Russian TUs. The process of portal adoption is rather slowly mostly due to the requirements to buy and install the national crypto providers. But electronic mail as a popular transport for the referrals and other clinical documents becomes less convenient because spam filters used by the biggest e-mail providers reject the messages from time to time and may blacklist other providers. We suppose that this unpleasant situation will fasten the portal adoption.

The method described above of using a web portal for real-time telemedicine events is patent pending in the Russian Federation.

The Development of an Information System and Installation of an Internet Web Database for the Purposes of the Occupational Health and Safety Management System

I. Mavrikakis[a,1], J. Mantas[a,1] , M. Diomidous[a,1]

[a]*Department of Public Health, Faculty of Nursing, University of Athens, Greece*

Abstract

This paper is based on the research on the possible structure of an information system for the purposes of occupational health and safety management. We initiated a questionnaire in order to find the possible interest on the part of potential users in the subject of occupational health and safety. The depiction of the potential interest is vital both for the software analysis cycle and development according to previous models. The evaluation of the results tends to create pilot applications among different enterprises. Documentation and process improvements ascertained quality of services, operational support, occupational health and safety advice are the basics of the above applications. Communication and codified information among intersted parts is the other target of the survey regarding health issues. Computer networks can offer such services. The network will consist of certain nodes responsible to inform executives on Occupational Health and Safety. A web database has been installed for inserting and searching documents. The submission of files to a server and the answers to questionnaires through the web help the experts to perform their activities. Based on the requirements of enterprises we have constructed a web file server. We submit files so that users can retrieve the files which they need. The access is limited to authorized users. Digital watermarks authenticate and protect digital objects.

Keywords:

occupational health and safety, workflow management, computer networks, World Wide Web, file submission, questonnaries

Introduction

The management of occupational health and safety constitutes a field which concentrates the interest of enterprises. Particularly the enterprises with a modern concept of management, not only care to comply with the legal obligations as far as it concerns occupational health and safety, but also implement a health and safety management system, in order to improve the work conditions. Quality management systems are developed and implemented into enterprises following standards. For health and safety management, ISO 18001 is widely applied. For the development of such systems the workflow and information management between experts and enterprises is very important and interesting. The use of computer networks and the whole infrastructure is significant for this purpose. Such a system can be administered via the WWW. An external expert can handle the information in a way to correct and to intervene to improve the quality of occupational health and safety services. We have developed such a system in order to allow authorized users of each enterprise, mainly those responsible for occupational health and safety, to communicate and submit files. On the other hand, we can use comments for each submission to explain the files in a more executive way and retrieve them. For the purpose of managing and detecting some very important workflows we use questionnaires; the processing of which are very useful for management and decision making in this field. The depiction of interest is important because we adopt new technologies and methods in order to accommodate the procedures for the occupational health and management system.

The interest of the potential users responsible for occupational health and safety is included on the analysis cycle of the software. At the second phase we are searching for the requirements of the enterprises analyzing the answers of the questionnaires. The evaluation of the results by the experts will lead us to create pilot based applications for communication between enterprises and selected branches.

At the second phase of the implementation work we are developing a system which will be responsible to inform the interested parties about the subjects of occupational health and safety management system. On the other hand this system is going to store information about educational

1 Health Informatics Laboratory, Faculty of Nursing, University of Athens, 123 Papadiamantopoulou street, 11527 Athens, Greece, email imavrik@nurs.uoa.gr, jmantas @cc.uoa.gr

issues. A relational database is a scientific tool for the purposes of storing and retrieving useful information.

We insert new technologies to depict the daily situations on the working conditions and in order to support the work of the administration and the work of the employees. We initialize a measuring system based on ISO 18001 in order to evaluate and shape new working conditions. The instability at the working conditions forces us to initiate some rules to protect and promote health and safety of the employees. We are trying to develop a system which will be useful to the users. Such a system after the frequent use must be improved in order to keep the practical features and be more operational. The improvements of such a system is not an easy task. We must find the principle components which support our system and follow some equations to intervene to improve the state of the system. We should pose some limits for the states of the system. In case we exceed them we must enable some actions to correct and to prevent the unsafe conditions. We should restore to the initial regular state the system in case we find that we have exceeded the initial parameters.

In order to achieve the above ideas we should install some means of communication between enterprises. The Internet supports this communication. The protocol on which the Internet is based is TCP/IP [9]. The IP address is a 32-bit number fundamental to Internet addressing and routing. It is also used for addressing the servers and clients. TCP/IP provides a realiable transport service which is used by most Internet Applications. Examples of applications are electronic mail (e-mail), File Transfer Protocol (FTP) and Web Page access through the World Wide Web via HTTP. The evolution of the e-mail was the incorporation into the web.

Another issue that we are going to analyze is videoconferencing. Based on some protocols we are going to insert some categories of research subjects. The compression based on H.263 protocol. The difference in quality of video between the protocols H.263 and H.261. We are searching for the limitations of teleteaching environment which are included on web enviroments. We depict a system of applications and services.

Some issues on computer networks

Interconnection networks play a major role in the performance of modern enterprise management. There are a lot of factors which can differentiate the design of each network.

- Performance requirements (on time and reliable decisions from the informations we collect): All operations are usually performed by explicit message passing or by accessing shared variables. To reduce the message latency, we reduce the idle time of processes and memory access time to remote memory locations [6]. The delay of information trasmission between two points is a very important aspect in case we take some useful decisions. The validity of information is also important, if we can collect information from all the enterprises we have reliable data, otherwise the latency of communication between the enterprises and the experts may cause an unreliable source of information.
- Scalability: As we add more enterprises in the network, we should proportionaly increase the network bandwidth, the I/O bandwidth and the memory bandwidth. If we are not able to use a scale factor for all the above requirements, at the network, it may become a bottleneck for the rest of the system decreasing the overall efficiency accordingly [6].
- Incremental expandability (example of ISPs): Customers are unlikely to purchase a computer network with a full set of computers and other electronic devices. More enterprises may be involved in the network until a system's maximum configuration is reached. We should find a way that the new nodes we add, do not decrease the performance. For example if we have 10 enterprises and we want to install an internet service provider we may not use a provider exactly for 10 enterprises, we should predict that after a long time we may provide our services to 15 enterprises, so we must use a provider with incremental expandability in order to reach the new requirements.
- Partition ability: It depends on the work we want to do. We devide the work in several partitions and then we dedicate certain tasks to computers of network [7]. This partition is very efficient for the performance of the network. We can use it also for the design of the network, we configure a network for the requirements of our work and we do not configure the work to the requirements of the network. For example we can use one node of the network as file server, another as database server, another as network server etc. Partition ability may also be required for security reasons [6].
- Simplicity: It is useful for the customers who understand the design and can easily exploit their performance. Otherwise the network may not be so efficient [6].
- Distance span, Locality: There are appropriate mechanisms which can reduce the noise during the transmission of the data, but there are a lot of constraints mainly on the distance between nodes on this domain. The use of optical links solve these problems equalizing the bandwidth of short and long links up to a much greater distance than when copper wire is used [6]. The locality is a very importat parameter, we must know where the enterprises are placed in a map in order to design a network.
- Physical Constraints: The operating temperature control, the wiring length limitation and the space limitation are constraints for the network design. We must be careful in case we put together a lot of wires, the overheating may cause damages to the wires [6].
- Reliability and Repairability: It should be able to transmit information reliably. In addition interconnection networks should have a modular design allowing upgrades and repairs [6].

- Expected Workloads: The network design should be robust. The performance should be efficient independently of the wide range of traffic conditions [6].

Cost Constraints: We should find an optimal solution between the cost of the implementation and the performance of the network. A solution which is probably expensive it is not necessery and efficient [6].

Interconnection networks

At the design of a network we should predict its connectivity with other networks, such as wide area networks [18]. We may need to connect our network with a network of an enterprise and to communicate with an establishment of the enterprise, in order to find useful informations for our work. We can connect our network with leased lines of the telephone network, in order to use services such as voice over ip, teleconference, video conference etc. Interconnection networks exist between parallel and distributed systems [4], [7]. In general purpose the usage of the above systems is the efficient solution of a problem. The network design helps us to divide our work into small tasks and try each computer to solve these small tasks. Then we combine the solution of each node to the final [7]. For those systems the network should reduce the message latency in order to be efficient. A decomposition technique based on interconnection network should care for the load balancing of the work between computers. A central unit can recursively divide the work, sending partition of work to nodes and control the overall work.

Meanwhile an application can not use general rules, the services we want the network offer to their users and the quality of services determine the parameters of a network. There are a lot of issues in network design [6], [27], [28]. First issue is how many routers we are going to use. Having a topological map of the whole network where shall we put them? The connections are going to be wireless (data links), which routing algorithm we are going to use, Dijkstra or smth else. There are also some challenging issues such as the network bandwidth and the time delay of packets. Computer networks individual for enterprises are crucial for their speeds in transfering data and for the internal communication.

Programming and configuring an internet web database

For the purpose of installing a web database we used the Apache Server Program and a Database Management System. The apache server enables some files of the host computer to be accessible from the Internet via the HTTP. For the communication of the database we use some script programs written in PHP language. The accessible files via HTTP are HTML forms which communicate with PHP programs [29]. For safety reasons we used some global variables (sessions) on php scripts in order only experts and executive persons from enterprises could administer the internet web database. The information on the Internet Site is accessible to everyone. On the site we can find which enterprises are interested on the domain of Occupational Health and Safety. We can find the executive persons of each enterprise which are responsible to communicate with us. We install a communication between the database and one program in java [8] in order to compute some interesting statistical values from the dataset. The internet web site which host a part of our work is located at the address http://healthandsafety.nurs.uoa.gr/sdyaergasia.php .

In order to construct an Internet Web Site, we find the system requirements and the users requirements. Then we design the web site in order every user to find easily whatever he wants on the domain of occupational health and safety. Then we configure the web site in order to achieve a communication between the site and the database. The updates for news on research in occupational health and safety are appropriate. The updates on the software are also important. The file management we present [29], uses the classic way of FTP. We insert documents, files, data and multimedia [21] in a directory which is structured in such a way for displaying into the www. Using some additional attributes to the above attributes we can cluster the data into groups [20]. The development of an Internet Web Site for efficient storing and indexing documents is a pioneering research work on the domain of Occupational Health and Safety. These attributes help the users to retrieve the data easily. They are inserted by the system administrator or by the composer of digital data. The metadata are all the appropriate elements which describe the uploading documents. Some operations that a system administrator can do are the uploading of a document and the updating of metadata using a simple web interface.

We develop this internet web site in order the executive person of an enterprise be informed about the issues of Occupational Health and Safety.

We are heading the Semantic Web [17]. Through the Semantic Web the Internet can support workflow models. Workflow models are abstractions revealing the most important properties of the entities participating in a workflow management system. The workflows are of three types: (1) Human-oriented (a person is responsible to execute a workflow), (2) System-oriented (we use databases and decision support systems [16, 22] in order to find answers to our queries) and (3) Transactional workflows (consisting of a mix of tasks, some performed by humans, others by computers and support selective use of the transactional properties for individual activities or for the entire workflow). The workflow models consist of entities that interact with others in an Interconnection Network, and they participate in a management system [1, 17].

Administration by authorized users

The administration of an Internet web site could be performed via the web. The web interface is quite familiar to everyone who wants to use it. We use HTML forms to upload documents. We insert metadata and documents in a database using php scripts. Experts on the domain of Occupationl Health and Safety are responsible to update the site with news and with the latest scientific research. The web interface which supports the administration can be seen in Figure 1.

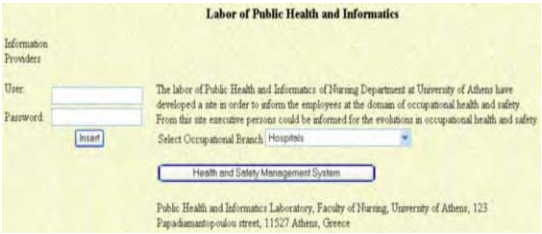

Figure 1 - Web interface for administrating and presenting information on occupational health and safety

There are some constraints at the insertion of data. We can insert only text documents, Microsoft Word Documents, and documents which can be read by the Adobe Acrobat Reader. Meanwhile we may need to insert files for educational reasons, such as power point files, video and images. On multimedia files we can insert a digital watermark in order to authenticate the constructor of the object [15]. We can insert a list of notes for each document in order to have a dialogue about certain ideas [27, 28]. This dialogue is important for improvements in work.

The data we insert at the internet site are peer reviewed in order to be reliable. We also protect the authenticity of the digital objects inserting to them digital watermarks resistant to attacks such as compression, smoothing and geometric transforms [15] (mainly for multimedia data).

In the web site http://healthandsafety.nurs.uoa.gr/sdyaergasia.php, figure 1, developed in the Department of Public Health in the Nursing Department, University of Athens, we have configured the server to be able to find all the relevant information useful to this task. We can search the documents [20] placing keywords. There is also the possibility of browsing in all data lists.

Services provided by the system and applications on distant learning

The transmission of video in real time is critical for designing this system. We make a lot of experiments broadcasting the enviroment and scenes and we are going to transmit through the Internet some lectures. The main program we used for the experiments is a product of Microsoft which is named Windows Media Encoder. We are encoding audio and video using certain sampling rates and analyzing the video on certain number of frames per second. All these experiments made in order to adapt the rate of transmission data with the channel capacity avoiding delays. We also search the number of clients a video server can serve with certain criteria of quality of services. The video on demand has as target to inform enterprises about the subjects of common interest. The subjects will be registered electronically among all the speakers and finally the revised lectures will be inserted in the information system in a corrected form. Meanwhile there are some difficulties on the transmission of multimedia data: firstly, the subject about the quality of service; second, the decompression of the data; and, finally, the removal of the jitter.

Another issue is that the system can provide training packages for the protection and promotion of health at the workplace and the implementation of safety procedures [26]. These packages are disseminated through the network or applied by e-learning techniques [2]. The function and the effectiveness of those packages will be evaluated at the ability of installing integrated solutions and applications to support experts on Occupational Health and Safety.

Conclusion

In this paper we have described a web application, which is administrated by authorized persons only. We intend to inform executive persons of each enterprise for the evolutions in Occupational Health and Safety. This site will inform and allow communication among enterprises. Documents and data based on ISO 18001 will be submitted, processed and presented in appropriate format in order to be useful to the interested executive persons. The corrections and the control of the whole infrastructure is significant to our work. Our target is to improve occupational health and safety, to find new policies, to design new systems, to control new procedures and, finally, to review the whole structure in order to be comprehensible to the users. An application has already been installed at hospital. The application will be evaluated continuously in order to achieve the standards of ISO 18001.

Reliability Assessment of Home Health Care Services

Stergiani Spyrou, Panagiotis Bamidis, Vassilis Kilintzis, Irini Lekka, Nicos Maglaveras, Costas Pappas

Lab of Medical Informatics, The Medical School, University of Thessaloniki, Central Macedonia, Greece

Abstract

In this paper, a model of reliability assessment of services in Home Health Care Delivery is presented. Reliability is an important quality dimension for services and is included in non-functional requirements of a system. A stochastic Markov model for reliability assessment is applied to patient communication services, in the field of home health care delivery. The methodology includes the specification of scenarios, the definition of failures in scenarios as well as the application of the analytical model. The results of the methodology reveal the critical states of the Home Health Care System and recommendations for improvement of the services are proposed. The model gives valuable results in predicting service reliability and, independently of the error types, it can be applied to all fields of Regional Health Network (RHN).

Keywords:

home health care delivery, reliability, quality in health

Introduction

Patient communication services in the health delivery domain are supported by information and communication technology (ICT) systems [1],[2],[3]. Contact centers in home health care delivery are a modern way to provide services to patients efficiently and are mostly implemented as call centers or portals on the Web. The purpose of this work is to present the application of an innovative model to assess quality indicators of the provided services in home health care delivery domain. The innovation is in the direction of reliability assessment on the analysis, the specification and the verification phase of developing such systems, with the ultimate scope to lead to a concrete system at the implementation phase. The analysis and the results are based on scenarios of the services of a contact center for chronic disease patients.

Reliability analysis for information systems supporting health care delivery services or even hospital information systems is not met on the literature. This work has been based on the technical report [1], where a model based on stochastic reliability model (Markov model) is applied to health care delivery services.

The analysis has been applied to a project under the title 'Quality Healthcare Management and Well-being through INTERLIFE services (INTERLIFE[1])' [4] implemented in the Lab of Medical Informatics[2], The Medical School, Aristotelean University of Thessaloniki. INTERLIFE is a generic and modular contact center platform for the communication, management, processing and assessment of multimedia medical information, and the provision of high-quality pervasive tele-health services to the citizens. It aims at reaching a high number of patients in a simple way and with low-cost budgets through telephone and WEB communication. The aim is to perform a clinical, technical and economic evaluation of the INTERLIFE system when applied in real environments for the management of two chronic conditions: chronic heart failure (CHF) and obesity/diabetes. The INTERLIFE platform at AUTH is based on the CHS system developed in the context of the CHS program [5], IST-1999-13352 that had been evaluated mainly for its technical features.

The model can be applied to any field of systems supporting health care delivery and it gives valuable results in the area of quality assessment of services and, specifically, reliability assessment in health care.

Materials and methods

INTERLIFE Contact Center

The methodology has been applied to INTERLIFE Contact Center [4]. It is described below with emphasis on the scenarios used in our model. The INTERLIFE core system offers the infrastructure that allows home-monitored patients to easily communicate with the INTERLIFE Contact Center by exchanging their data. During the LAB pilots, patients are offered three interfaces to choose from: simple telephone, mobile phones and WEB. The cheapest technology with the widest penetration is the use of regular telephone with call-center automation. At the Contact Center of INTERLIFE, patient data are stored so they can be securely accessed by the clinicians for reviewing either through a client/server application or through a WEB application. Technical infrastructure and support is provided by the INTERLIFE technical team at the LAB and the Department of Cardiology of Aristotelean University

1 INTERLIFE: stands for the project 'Quality Healthcare Management and Well-being through INTERLIFE services (INTERLIFE)'

2 LAB: stands for the Lab of Medical Informatics, The Medical School, Aristotelean University of Thessaloniki

Selected for best paper award.

of Thessaloniki hosted at the AHEPA Hospital of Thessaloniki, Greece which participated in the study. Patients on this trial are chronic disease patients.

The main contact center services are:

- Transmission of patient data
- Educational sessions in the form of voice messages
- Patient and physician communication via voicemail for problem reporting, advice, etc.

The session describing the patient contact with the contact center is shown in Figure 1. The two scenarios implemented and included in the trial setting are described in Tables 1 & 2.

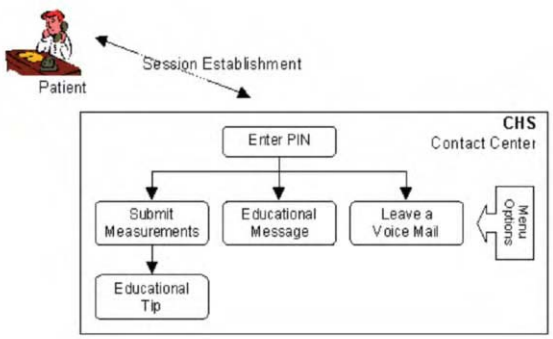

Figure 1 - The patient session using the automatic call center

First, patient authorization takes place. The user can dial 1 on the phone to enter the measurement session (menu choice 1 of contact center) or 2 to enter the educational session (menu choice 2 of contact center) at the main menu of the contact center. The voice mail menu option was excluded for the trial.

Each patient session is recorded in a (text) log file with the interaction details. Log files have been used for the assessment of technical failures, performance and system usage. Moreover, analysis of those log files gave the transition probabilities and other information, such as error reports, that constitute the necessary parameters for our model. A patient calls in the center to report the measurements three times per week (three sessions per patient per week). In this trial, **2.887** patient sessions are included.

The model's focus is to assess how reliable patient contact is with the center, based on the following dimensions:

1. The patient data input errors regarding the usage of the system
2. The technical infrastructure problems that obstruct the successful termination of a scenario.

Applied to our model, those factors can determine the reliability of the system in view of assessment of technical failures and patient data input errors.

Table 1 - Scenario for measurement session

Purpose of Measurement Session: Patients transmit parameter patient data.
1. Patient calls the call center to report the measurements frequently.
2. Patient enters their PIN by dialing it into the phone to be authorized by the center.
3. The patient dials measurements such as body weight, temperature, heart rate, blood pressure and answers (yes or no) to five simple questions; for example: 'Were you breathless during the night?', 'Are your legs swollen?' etc. The selected questions target two objective symptoms (paroxysmal nocturnal dyspnea and peripheral edema), two subjective symptoms (fatigue and dyspnea) and a gentle reminder to take their medicine.
4. Voice verification of each measurement value is provided immediately after it is keyed in. There is the option to correct the keyed-in value after entry and verification.
5. In case of no entry, the patient is repeatedly prompted to enter a value.
6. The patient is informed when the measurement values have been saved.
7. Goodbye tip of the day contains advice according on patient's situation.
*[The following actions are not recorded in log file:]*Daily review of patient data will be performed by a clinician at the contact center; the cardiologist will be in contact with the patient for advice in special cases during the week.

Table 2 - Scenario for educational session

Purpose of Educational Session: Patients Listen to Educational Voice Messages
1. Steps 1 & 2 are the same as the measurement session.
2. Patient dials the 2-digit code of the category of educational message they are interested in
or
3. Patient can interrupt educational session by exit (0) key.
4. The repetition (*) and the interruption keys (#) can be initiated at any point even while listening to a message.
5. The system always keeps track of what the user has heard.
6. A goodbye tip ends the session.

Scenarios and failure behavior

Reliability is the probability that a system will operate without failure for a specified number of natural units or a specified time – known as the mission time [8]. Reliability, R(t), is related to failure probability, F(t), by $R(t) = 1 F(t)$ where, $F(t)$, is the probability that the time of failure is less than or equal to t. To model software reliability, one must mostly consider the fault introduction that depends mainly on the characteristics of the software system and the development process [1]. The steps to describe fault introduction to systems are mainly (1) describe the scenarios that the system implements and (2) identify the failures of the scenarios' activities.

In this work, we are going to predict and assess reliability for processes based on a scenarios analysis of contact center of home care delivery. The idea is based on [1]. The methodology is based on scenarios as the main focus is to predict the quality dimension of reliability for processes at the early stage of building a home care system.

The methodology as presented in [1] and customized for the needs of the presented work is:

1. Describe behaviour of the contact center using scenarios.
2. Draw state transition diagrams based on the analysis on previous step and annotate them with transition probabilities to also describe the failure behaviour of the system.
3. Use Markov modelling to calculate the reliability of the system described by the scenarios.
4. Experiment with transition probabilities of states. or reliability factors of states, to find the most critical phases of the system which are the outcome of the Markov modelling.

A state transition diagram, as needed in step 2 of the methodology for INTERLIFE Contact Center, is presented in the results part of this paper.

The transfer of control of such a diagram has a Markov property and [1] we model software execution behavior with an absorbing Discrete Time Markov Chain (DTMC) with a transition probability matrix $P = [p_{ij}]$, where p_{ij} is the probability to transfer the control from module (state) i to module (state) j [6]. We assign multiple absorbing states (F0, F1, F2, F3 etc) according to the failure behavior denoting failures, and state T denoting correct output and successful termination. Then the transition probability matrix can be calculated based also on the reliabilities of each state R_{si} which denotes the Reliability of component-state of State S_i, $P_{Si\text{-}Sj}$ denotes the probability to transfer control from state S_i to state S_j. Based on a transition probability matrix and the DTMC model with absorbing states, we can calculate [1],[8] table $A= [a_{ik}]$, where a_{ik} is the probability of reaching an absorbing state k starting from a transient state I and the probability to reach a terminating state is calculated.

Results

This section presents the results of applying the model to INTERLIFE project. As described previously in the methodology, the following scenario specification is the identification of failures of the scenarios' activities. The failures of the system include the patient data input errors and technical infrastructure failures. However, it is important to note that the methodology does not depend on the type of errors that are specific to each project according to its functionality. The INTERLIFE system has to check for possible failures due to:

- Patient errors (mistyping, bad measurement technique)
- Instrument errors
- Transmission errors.

The types of patient data input to the system are: (1) parameter data (e.g. weight, blood glucose), (2) signal data (e.g. heart rhythm, ECG) and (3) image data (e.g. wound image from digital camera).

Figure 2 shows state transition diagram for INTERLIFE scenarios that includes the failure behaviour as described above. Abbreviated names for the states are included in parenthesis in capital letters following each state in the diagram. Abbreviations are used in the state transition tables and the rest of the figures.

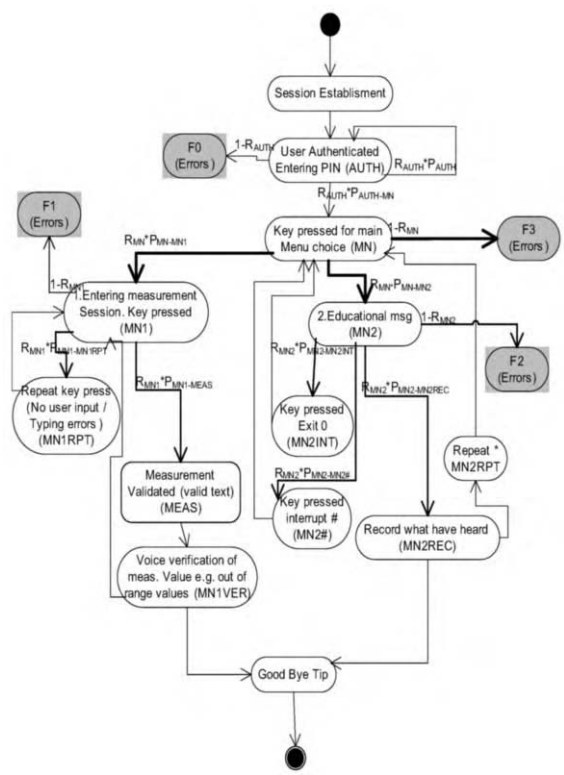

Figure 2 - State transition diagram for INTERLIFE scenarios

The diagram has been annotated with transition probabilities (P_i) and reliability factors of states (R_i). For example,

Transition probability from state MN to MN2, considering that reliability of state MN is R_{MN}, is given by $R_{MN}*P_{MN\text{-}MN2}$ in the state transition diagram. When no probability is assigned it is assumed to be equal to 1.

Analysis of the log files of the trial the probabilities for the case of **2.887** total patient sessions are shown in Table 2.

Table 2 - Probability reaching a terminating state starting from any state in the scenario

Probability	*Value*	*Probability*	*Value*
P_{AUTH}	0.051	P_{F1}	0.077
$P_{AUTH\text{-}MN}$	0.754	$P_{MN1VER\text{-}MN1}$	0.241
P_{F0}	0.195	$P_{MN1VER\text{-}T}$	0.759
$P_{MN\text{-}MN1}$	0.923	$P_{MN2\text{-}MN2INT}$	0
$P_{MN\text{-}MN2}$	0.053	$P_{MN2\text{-}MN2\#}$	0
P_{F3}	0.024	$P_{MN2\text{-}MN2REC}$	0.837
$P_{MN1\text{-}MEAS}$	0.668	P_{F2}	0.163
$P_{MN1\text{-}RPT}$	0.255	$P_{MN2REC\text{-}T}$	1.0

The following results are obtained from analysis of the log files: of a total of 552 errors in the measurement session, there are **165** patient errors and **387** instrument and transmission errors.

Applying the model, the transition probability matrix is created and then matrix A, describing the probability to reach a terminating state is shown in Table 3. Title T in second column denotes successful termination of the scenarios. Title F1, F2, F3 in the following columns denotes failure at measurement session, at educational session and at initiating menu choice respectively.

Table 3 - Probability reaching a terminating state starting from any state in the state transition diagram

MN2REC	1.0000	0.0000	0.0000	0.0000	0.0000

From the matrix the following results can be excluded: implementing the scenarios and starting form initial state, AUTH the probability to have:

(1) Successful termination (T) is equal to 0.6719

(2) Termination with error F0 is equal to 0.2058

(3) Termination with error F1 is equal to 0.0966

(4) Termination with error F2 is equal to 0.0

(5) Termination with error F3 is equal to 0.0256.

It is important to note that, excluding patient errors from measurement session (165 errors), the total number of errors at this session would be 387 (instrument and transmission errors) and the total reliability of the system becomes **0.5512**. If patients could perfectly use the system (at measurement session only), the reliability of the system is significantly improved.

Conversely, if there are only patient errors in the measurement errors (excluding instrument and transmission errors), the reliability of the system would be **0.6719**.

Experimenting with transition probabilities, such as the probability of reaching the absorbing state F1, the total reliability of the system increases dramatically (shown in Figure 3). In addition, by varying the reliability of states, one can see how the total reliability of the system is affected. More complicated and descriptive behavior of the system can be the outcome of applying the model, as shown in Figures 3 and 4.

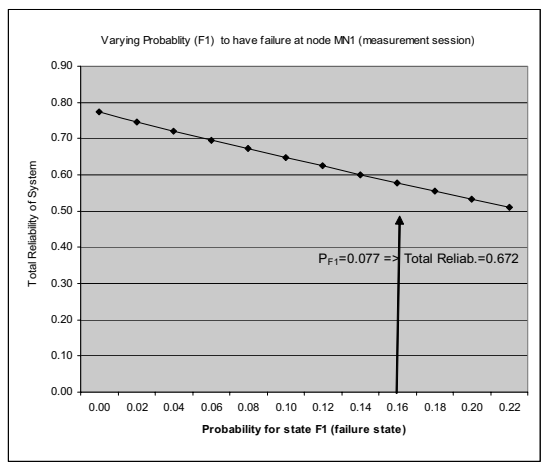

Figure 3 - Varying probability to have failure at measurement session and reach failure state F1

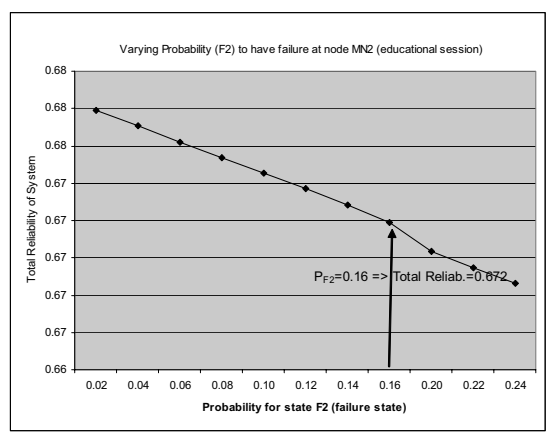

Figure 4 - Varying probability of failures at educational session and reach failure state F2

Discussion and conclusion

Analysis of quality issues of home health care systems and reliability modelling techniques provides an innovative way to predict performance measure, even at the design phase of the system. The model presented can be applied at the design, verification and implementation phases of systems supporting health information systems and give valuable results predicting the reliability of services.

The approach focuses on defining the sources of errors and failures, and the impact those errors can have at services. It does not depend on the type of errors. The more elaborated the failure analysis is, the more accurate the results of the model can be. It becomes feasible then to identify the critical states of the system in the scenarios [1] and propose interventions for improving the provided services.

Even when prototyping or implementation data are not provided, this model provides a way to estimate or predict reliability. However, the more data that are available, the more accurate the results the model will produce. The depth of analysis to describe the states depends on the analyst, where elaborated states would reveal analysis in detail. It is valuable to analyze failures and errors in the design phase of the system to have records of the failures.

The methodology's limitations are linked with the need to have an elaborate requirement analysis of the system to define the state diagrams in detail. In the methodology presented, no severity analysis was included.

Future focus will be directed towards enhancing this analytical calculation, with the combination of software tools for simulation and evaluation.

The presented analysis could be the preliminary analysis to calculate factors of the systems like Mean Time To Failure (MTTF) or Mean Time To Repair (MTTR) [7], [9], [10], [11], which define crucial factors for the service-level agreement contracts for the organizations.

The model and the analysis can be applied to any type of health information system. The results in the area of home health care systems are important for improving the provided services to patients.

Abstract

Management of clinical processes and hospital activities takes advantage of business process reengineering methodology. It is now recognized that care process modeling must integrate the definition of goals and the assessment of risk. Two kinds of issues have been outlined: 1) the lack of an integrated model to identify and describe processes and their components according to a functional point of view; and 2) an increasing amount of documents that hospital staff members have to create, collect, index and maintain. As initial models focused only on a structural view of activities, we reviewed different sources of standards and norms to extract and classify a set of metadata aimed at describing any activity and its outcomes. The model includes links to structured terminologies to name attributes or value them. An object-oriented information model has been created and implemented to test the relevance and the feasibility of the modeling approach. Conceptually speaking, this model gives opportunity to bridge tacit and explicit knowledge. Practically speaking, limits to generalization remain partly due to the lack of a template processes database.

Keywords:

process assessment (health care), risk management, systems analysis, systems integration, hospital information systems.

Introduction

During the last twenty years or so, French hospital management has been impacted by successive policies which led on to: 1) the end of "limitless" budgets and the setup of a national and external process of evaluation, certification and regulation; 2) the emerging of integrated information systems, shifting individual centered practices to collaborative working methods; 3) the increasing desire for transparency, whether coming from the state or the patient; and 4) the end of the dumb patient, captive and submissive recipient, becoming an enlightened client aware of his(her) power and duty. Therefore, hospital staff, from caregivers to managers, have had to join and collaborate for a new way of hospital management, consisted of *saying*, *doing* and *justifying*. If the "doctor manager" is going to be the emergent logic of hospital management, a big issue is to put everyone on a collaborative track, to create synergy and be able to justify the survival or the continued existence of the establishment.

Context

From now on, to comply with the national and mandatory process of certification, it has been recognized that business process reengineering (BPR) methodology suited fairly well to represent hospital activities [1]. Its application to health care facilities is related: 1) to the optimization of patient flows [2] and of care deliveries [3], especially in emergency and acute care wards [4,5]; 2) to the evaluation of the performance of clinical pathways [6] or clinical training scenarios [7]; and 3) to the design of information systems for identifying and sorting out activities to simulate the potential performance of target systems, and, further, to organize and synchronize users views [8,9]. Whatever the objectives are, the initial work of staff members always starts with the description of activities performed towards the patient. Requirements for the quality and the security of care delivery make them to pay attention to several normative specifications such as the national guide for certification published on behalf of the French Health Higher Authority [10] as well as quality management standards framing the production of services (ISO 9000:2000) [11], the environmental requirements (ISO 14001:2004) [11] and the occupational health and safety (OHSAS 18001:1999) [12].

Documenting activities and identifying related risks, as precisely and as relevant as possible, necessitate usually to involve a lot of people in order to produce lots of documents. From a hospital level point of view, such a publishing action needs to be structured, planned and monitored. Relevant indexation and accuracy maintenance of the content is crucial, in order to make material be rapidly retrieved and easily used by professionals. Solutions can be found out with implementing project and digital libraries management tools. From a clinical staff member point of view, the initial work of describing care activities, writing procedures, and pointing out their potential risks can be suitably framed using "continuous quality improvement" tools [13]. But, critical issues remain, such as: 1) making authoring staff member be aware of other similar activities described previously and/or elsewhere in the hospital; providing him(her) with the ability: 2) to "re-use" pieces of data (and so preserve the overall coherence of the system), 3) to interconnect new pieces of data with existing ones (in order to enrich or expand processes or sub-processes); and 4) to be informed of updates according to his(her) profile.

As an example of issues, regarding the methodology suggested at a national level [14] to create and structure a hospital-based medication process, steps can only be described from a clinical point of view (ordering, dispensing and administrating). A multi-level analysis is not clearly identified. Thus, trade actors (pharmacist, nurse, and physician) are solely motivated to build their own view of the system without embracing the whole process, starting with the referencing of medication, following with the monitoring of patient and ending with the report of adverse events. For each process component, only one level of specification is available, making difficult the identification of risk characteristics. Such a methodology gives an opportunity to make staff be aware of the necessity of activity modeling. But is lacks methodological and collaborative tools to share the generated material between actors or processes. Applying such a guide results in a poor quality process model, potential misunderstandings and mistakes, as well as difficulties to review, organize and browse documentation.

Basically, solutions addressing such issues deal with knowledge representation and ontology, merging health related concepts and enterprise modeling concepts, such as: 1) structured sources of explicit knowledge (e.g. diagnoses and procedures) ; 2) emergent enterprise manufacturing research approaches [15] (attempting to create a globally shared conceptualization of organizational domains as reservoir of concepts and re-usable components for organizational modeling); 3) non standardized representations (types and meta-description of processes, activities, roles and risks).

Objectives

Our proposal is centered on the "clinical content management" part of the overall hospital information system. It aims at identifying and describing any care process, its components and its outcomes, according to a single view merging three aspects of clinical management: structure/resources, strategy and safety. To achieve this integrated view, three sets of metadata have to be defined: 1) the activity/process metadata set; 2) the indicator metadata set; 3) the risk metadata set. This paper aims at proposing a pragmatic approach in order to identify metadata sets, to describe a process component, and to structure a minimal information model to be implemented in a cross-referencing documentation system. Discussion will highlight the benefits and the limits of this bottom-up approach, as well as the derivate potential usage of the tool.

Materials and methods

A process is a structured collection of activities, a set of partially ordered steps or scenarios according to which a user interacts with its environment (other users, patients, context of practice), has a set of responsibilities and reaches goals [16]. The basic process model identifies: 1) agent: an actor (human or machine) who performs a process element; 2) role: a coherent set of process elements to be assigned to an agent as a unit of functional responsibility; 3) artifact: a product created or modified by the enactment of a process element. This "macro" definition does not offer enough meaningful details to frame a generic set of attributes. The "process element", the activity, must be categorized and refined.

Primary work has been published, reporting a methodology for applying enterprise modeling tools to explicit health care practices, especially in the field of transfusion medicine [17]. Concepts and views of care process modeling have been extracted from a structured design and analysis technique, called IDEF0/SADT [18]. The atomic element of this modeling technique is called "ICOM box" (I for Input, O for Output, C for Control, M for Mechanism). It is intended to express the notion of any form of activity or task. Semantics of this box is: "under Control an Input is transformed into Output by Mechanism". Using this representation, a clinical agent can easily tell what is going to be done, who is going to do it, and how it will be done. But he cannot tell why it will be done and who is dependent on its being done. These questions are related to the purpose, the strategy and the regulation controls which initiate or not an activity. Due to the lack of "functional" attributes to qualify components, goals and outcomes of any activity, sub-process or process, we analyzed normative reference frames as listed above.

First, action verbs were listed by merging analysis of clinical documents and verbs describing learning objectives [19]. Then, description of an activity was refined with a grammar extracted and rearranged from the conceptual domain of Enterprise Ontology [20]. Goals of clinical activities were described according to a grid aimed at creating guidelines ontology [21]. Terms to qualify an indicator came from the FD X 50-171 norm [22] and from categories of healthcare quality measures defined by the Agency for Healthcare Research and Quality [23]. Regarding the metadata set for risk identification, we studied the Failure Mode, Effects and Criticality Analysis (FMECA). This method is used in industry to prevent process or product failures. It has been applied in health care to investigate risk issues [24]. We picked up attributes to define actions related to risk control. Finally, concepts of the "Risk paradigm" were taken from the environment metadata record, promoted and maintained by the Environmental Protection Agency [25]. Terms used to name or qualify information elements, as well as terms to value attributes, were put into a global dictionary with their respective source. The resulting information model was built according to UML notation. Material produced in our hospital was used to test the relevance of the model and the feasibility of this approach. It consists of clinical processes descriptions (transfusion medicine, organ transplant, clinical pathways in cancerology, medication delivery process, etc.), procedures and other quality documents published by our hospital staff members.

Results

Various kinds of processes can be identified within an enterprise: individual human work processes, organizationally-defined processes, operational processes, production processes, management and change processes, etc. [16]. In the context of clinical activities, the main processes encountered are individual human-based processes (e.g. care delivery processes with diagnosis screening, therapeutic ordering processes, etc.), organizationally-defined processes (e.g. patient registration, patient discharge, medication delivery, appointment records, etc.), and operational processes (e.g. surgical act performing, monitoring of medication administration, etc.).

Table 1 - Terminology extracted from organizational, management and modeling sources

Core terms	Refined terms	Components / Attributes terms [Values]	Source
Activity		Action verb (see table 2)	ISO/Ha
Input			ISO/IDEF0
	Object	Data; Material; Product; Service; Men	ISO/IDEF0/EO
	Environment	(see below)	ISO
Control			IDEF0
	Methods	Scenarios; Strategy (see below)	ISO/EO/Ha
	Environment	Context; Triggers; Conditions	ISO/Ha
	Constraints	Temporal [periodicity, delay]; Scheduling [priority, ranking]; Cost; Requirement	OC
Mechanism			IDEF0
	Men	Person; Role [doer; owner; partner]; Function; Skill; Capability;	ISO/EO
	Machines		ISO
	Material		ISO
Output			ISO/IDEF0
	Object	Data; Material; Product; Service; Men	ISO/IDEF0/EO
	Risk	(see below)	EO
	Indicator	Category [resource, process, outcome, satisfaction, conformity; safety; patient centeredness; behavior; access; effectiveness; timeless; environmental condition; environmental performance]; Field; Parameters; Computation; Periodicity	ISO/AHRQ
Strategy			EO
	Goal	Type [action, knowledge]; Action verb (see table 2); Object (see above)	EO/Ha
	Objective	Criterion	EO
	Assumption	[critical; non-critical]	EO
	Influence Factor	[critical; non-critical]	EO
	Success factor	[critical; non-critical]	EO
Risk			EO/FMECA
	Exposure		EPA
	Cause	Methods; Environment; Mechanisms *(see above)*	FMECA/ISO
	Effect		FMECA/EPA
	Priority	Severity, Probability, Detection	FMECA
	Corrective action		ISO/FMECA
	Preventive action		ISO/FMECA

AHRQ: Agency for Healthcare Research and Quality [23]; EPA: Environmental Protection Agency [25];
EO: Enterprise Ontology [20]; FMECA: Failure Modes and Effects Analysis [24]; IDEF0/SADT: [18]; ISO: International Organization for Standardization [11]; Ha: Hashmia et al. [21]

The resulting terminology for naming activity, sub-process and process components is listed in Table 1. Sources are mentioned for each term. The core terms refer to the starting schema based on IDEF0/SADT notation. For each action, a strategy details goal(s) and objective(s). Strategy is also part of the methods used to achieve an action because it mentions influence factor(s). Indicator has been considered as an output of action. Risk information model combines description items (exposure, effect) and assessment items (priority). Risk (or failure) has been considered as an output of the activity. Some components are used to describe cause of failure such as: methods, men, machines, materials and medium (environment), which are the "5M" categories of the Root Cause Analysis methodology [13]. Priority, corrective and preventive actions are three elements extracted from the FMECA methodology. They are part of the "risk paradigm" state by EPA: exposure, effects, assessment (identify, prioritize), and management (correct,

prevent). Action verbs are classified according to four domains as listed in table 2. They are used to name the action underlying an activity or a goal. An object-oriented information model has been built (figure 1), based on this metadata repository.

Table 2 - Action verbs to name actions and goals (from [19])

Creative behaviors	Problem solving behaviors
ask, create, document, group, inform, modify, predict, prescribe, question, review, revise, search, simplify, synthesize, validate, write	analyze, appraise, assess, classify, combine, compare, decide, deduce, diagnose, evaluate, explain, formulate, generate, induce, infer, interpret, interpolate, plan, rank, rate, schedule, substitute, translate
General discerning behaviors	**Practical behaviors**
associate, choose, collect, define, describe, detect, differentiate, estimate, identify, indicate, list, locate, match, omit, order, pick, place, point, recognize, select, separate	apply, calibrate, compute, calculate, convert, demonstrate, diagram, insert, keep, lengthen, limit, manipulate, operate, practice, prepare, remove, replace, report, reset, score, set, specify, straighten, time, transfer, transport, use, weigh

This information model has been implemented with an object-oriented framework called Zope. This web service is based on libraries containing elementary information objects which can be associated to describe activities and compose sub-processes and processes. Each element is described by means of an identity form and belongs to a category. In order to populate libraries, users start from structured documents (templates are available to guide them to write procedures and draw schemas). They sort these electronic documents according to their purpose and content. They extract relevant information to create data objects in the libraries. Doing this, they easily index each document according to the business process it belongs. As a final result, the browsing of the database makes user able to cross-navigate from activities to documents and backwards.

Discussion

Documentation of care processes is from now on a founding part of care management in order to comply with the quality and certification rules. One must pay attention to it. Creating, collecting, indexing, and publishing electronic documents are becoming big issues for hospital staff members. Scientific and evidence-based information is not enough to answer daily questions raising throughout care delivery processes. Beyond the narrative of diseases, diagnosis procedures, therapeutics algorithms and recommendations, staff member must be aware of internal policies and external legal constraints, as well as evaluation methods to review the relevance of care and the risk occurrence throughout clinical pathways.

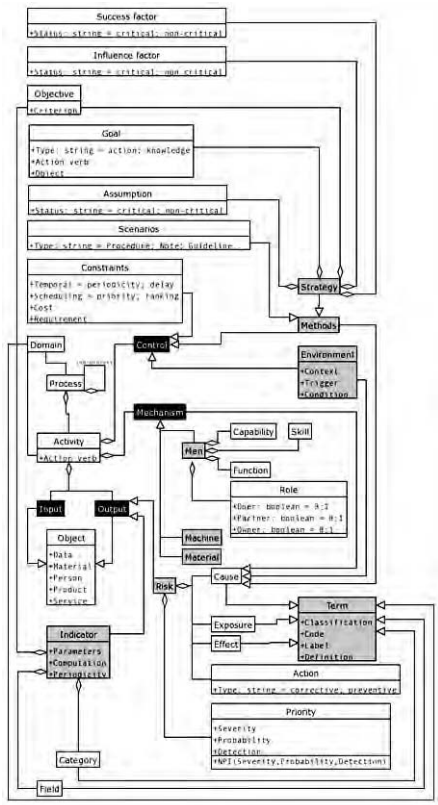

Figure 1 - Object information model for describing an activity (IDEF0/SADT core elements are black colored; new elements deduced from quality and safety tools are grey colored; terms to name indicator and risk elements belong to classifications.)

Basically, the information model we built is activity-based and follows common design conventions. But, it also integrates the definitions of strategy and risk/failure as elements of a functional view of processes [26]. Combined into a unified metadata repository, this set provides staff members with an integrated framework to create documents while indexing them at the same time. Links to standardized terminologies enrich the model providing users with material to query external knowledge databases. The resulting "business process" content management system can be browsed according to a given role (a physician, a nurse…), a category (a procedure, a technical note, a form, a legal rule…), a type of activity (prescribe, validate, synthesize…), and a goal or an output (all tasks with potential adverse events). A hierarchy of information elements is automatically generated and provides users with an overall map of the processes and components managed in the hospital.

In terms of knowledge, the elements of care delivery express the knowledge of collaborative practice (who, when, where), the knowledge of the content of each care process (what, how to) and the knowledge of the indication and the outcomes of the care process (why). In terms of information systems, providing clinical actors with sharable knowledge is a key feature to create collaborative

practice. Our model helps users to value data elements with medical concepts: domain of a process/activity, field of an indicator, exposure, effect and cause of a risk/failure. Doing this, a link is set up between knowledge of practice and explicit knowledge (Figure 2).

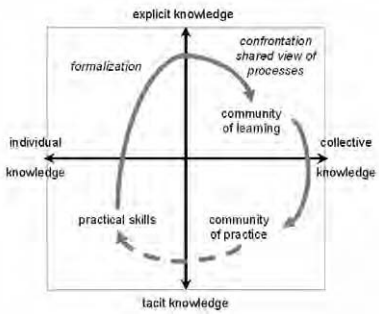

Figure 2 - Linking explicit and tacit knowledge by means of structuring and sharing views of processes

Testing the relevance and the feasibility of the model has been carried on in different domains of care delivery while focusing on risk assessment (transfusion medicine and medication delivery process). Nevertheless, applying limits raised, more likely related to the level of granularity choosen to define activities and to generate documents than related to the understanding of the information model itself. The lack of documents at the beginning of the project makes people uncomfortable, but the review of already published materials is also a burden that cannot be easily avoided. As a conclusion, the purpose of our work was to demonstrate the feasibility and the utility of a rich information set to describe care processes and their outcomes, focusing on risk management. Issues remain related to the compliance of staff members. They can be solved with the building of a "startup" knowledge database describing a "virtual" hospital enterprise.

Near-Miss and Hazard Reporting: Promoting Mindfulness in Patient Safety Education

Leanne M. Currie[a,b,c], Karen S. Desjardins[a], Patricia W. Stone[a], Tsai-ya Lai[a], Eric Schwartz[a], Rebecca Schnall[a], Suzanne Bakken[a,c]

Abstract

Patient safety efforts advocate for transforming healthcare from a culture of blame to a non-punitive "culture of safety." One of the most challenging hurdles is to encourage healthcare practitioners to be mindful about their activities. To promote mindfulness during clinical education for entry-level nurses, we developed a web-based dangerous situation and near miss reporting system for a cohort of baccalaureate nursing students (N=156). For this curricular innovation project, we provided wireless handheld devices to students who were required to submit one report for each of their clinical days in the medical-surgical, pediatric, psychiatric, obstetrics and community settings. During a ten-week period, students submitted 1487 reports. Of these, 63% were dangerous situations and 37% were near misses. The most frequently occurring dangerous situations were poor infection control practices. The most commonly reported near misses were medication errors. Free text comments from students identified inadequate patient identification and poor documentation as commonly occurring dangerous situations observed.

Medical Errors, voluntary reporting, patient safety education

Introduction

Despite efforts to improve safety of healthcare environments [1, 2], many patient safety concepts are not fully integrated into educational curricula and are instead acquired when clinicians begin clinical orientation for their job [3]. Although there is a growing interest in integration of these concepts into healthcare education [4], formal patient safety training is minimally represented in medical, nursing and pharmacy schools. Internationally, academic programs for patient safety are beginning to be formalized. In the United States the Institute for Healthcare Improvement is partnering with medical, nursing and pharmacy schools to formalize patient safety education [5], however, patient safety curricula have yet to reach the main stream.

Background

Safety culture dimensions

Promotion of a safe culture in the healthcare environment is increasingly being seen as a critical factor in reducing medical errors [6]. A safe culture is one in which identification of errors is seen as an opportunity to improve the system. Historically, an error was viewed as *an incident*, which was committed by an individual who was then reprimanded. Unfortunately, this stimulated individuals to cover up errors for fear of being punished. Moving from a culture of blame and shame to a culture of safety is an actionable goal in healthcare. However, the perception that error reporting will lead to reprimand persists as a barrier to voluntary reporting [7].

Towards the goal of enhancing patient safety, several dimensions of safety culture have been identified [8]. These dimensions include, i) leadership commitment, ii) professional salience, iii) presence of a non-punitive environment, iv) systems for error reporting, and v) communication. Leadership commitment is defined as the degree to which a leader perpetuates a culture of safety (e.g., fixes problems identified by staff; promoting a blame free environment). Professional salience is the degree to which healthcare professionals perceives that they can perform their work safely. A non-punitive environment is one in which error reporting does not result in punishment and in which systems for error reporting are in place to capture all errors (including near misses). Lastly, communication methods must be in place and communication must be encouraged to promote a culture of safety [8].

Two elements that, if identified early, can ostensibly lead to system improvement include staff identification of dangerous situations (or hazards) and near misses [9]. Dangerous situations include those situations that make the environment or care process hazardous or unsafe. Near misses are those situations in which an event nearly happens, but in which an *interception* prevents the event from reaching the patient. Two types of interceptions have been identified in relation to near misses: 1) a planned interception which occurs when a system is in place to prevent an event from happening (e.g., two nurses checking transfusion); and 2) an unplanned interception which occurs when an event is prevented serendipitously. Double-checking blood products is a systematic barrier to prevent error that is widely used to promote patient safety. Encouraging vol-

untary reporting of dangerous situations and near misses is a method to identify risks so that institutions might be able to develop other barriers to prevent errors from occurring as well as promote the clinicians' mindfulness regarding patient safety.

Electronic error reporting

Electronic error reporting is increasingly common [10]. Nurses perform approximately 50% of voluntary reporting in electronic systems [10, 11], likely because incident reporting was historically considered a nursing activity. Milch and colleagues examined more than 92,000 reports and found that 13% of the reports were near misses and 14% were environmental problems. However they also found that reporting rates were variable between institutions and that physicians reported less than two percent of the events [11]. Low physician reporting rates were also noted by Tuttle [10]. The implications of who performs reporting is unclear.

The purpose of this report is to describe a curricular innovation project in which mindfulness of patient safety was promoted by providing baccalaureate nursing students with a Web-based reporting system to document dangerous situations and near misses observed during their clinical experiences in multiple sites in a large metropolitan area.

Methods

Website development

We developed a Web Portal, which was modeled after the electronic Medical Event Reporting System for Hospitals (MERS-TH), a system in use at Columbia University Medical Center (CUMC) and elsewhere [12]. Table 1 shows the event type categories used in this project. The categories *infection* and *food/nutrition* were not in the MERS-TH system, but were added because they were considered important based on the clinical expertise of the team.

The website was accessed by students from the student page at the school of nursing. Figure 1 shows the interface from which the student would login. Once logged into the website, the student was asked two questions:

> **Q1:** On your shift today, were there any "dangerous situations" that could cause a future event?
>
> **Q2:** On your shift today, were there any near misses (i.e., events that almost happened)?

For each of these questions there were 13 and 26 associated questions, respectively. The student was able to select as many elements as he or she wanted to document. In addition to the questions and sub-categories, a free text comment section was provided at the end of each question.

Student training and reporting

Use of the Hazard and Near Miss reporting system was part of an overall Patient Safety education series, which was integrated into the students' curriculum. The students received training to use the web-based system via a demonstration and one-on-one support if necessary. Academic leadership decided that students would be required to submit one report for each of their two clinical days every week during their clinical time.

Data Analysis

Data were analyzed for frequencies and proportions of each reported question and sub-category. In addition, comments were analyzed for themes using content analysis techniques.

Table 1 - Dangerous situation and near miss event-type categories with examples

Event Categories	Examples
Accident (non-fall)	Needle stick, electrical shock, burn, poisoning
Environmental Hazard/Safety	Body fluid exposure, chemical exposure, chemotherapy spill, hazardous material spill
Equipment/ Device	Equipment malfunction, poor maintenance, inappropriate use, non-availability
Fall	Factors related to the individual or the environment
Food/Nutrition*	Diet and NPO orders
Infection*	Sterile precautions, hand washing
Laboratory	Laboratory orders or results
Medication	Prescribing, ordering/ documenting, administering, monitoring
Patient Disappearance	Increase risk of patient disappearance
Procedure/ Treatment	Consents, delays, wrong procedure/treatment, failure to perform
Restraint	Improper bedrail use and other types of restraint use
Transfusion	Sample collection or product administration
Other	Another type of risk

* Items added to extend MERS-TH categories

Results

Student reporting

Data for this project were collected over two five-week clinical rotations. During the ten-week period, 156 students submitted a total of 3086 reports with responses to the two questions (dangerous situations and near misses), for a total of 6172 responses. Of these, 1487 (24%) responded 'Yes' and 4685 (76%) responded 'No'. Of the 'Yes' responses, 933 (63%) reported Dangerous Situations and 554 (37%) reported Near Misses. Tables 2 and 3 display the rates and percentages for each of the subcategories for each report. There were almost twice as many reported dangerous situations as near misses.

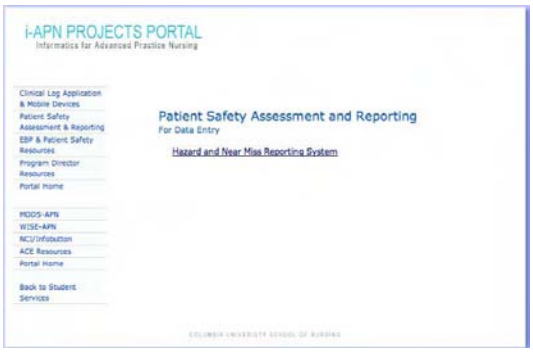

Figure 1. Hazard and Near Miss Reporting Website

Near miss reports

Of the near misses, 208 (38%) were noted to have a planned interception in place and 346 (62%) were intercepted by an unplanned act. The most frequently reported near miss was medication-related and was rescued by an unplanned interception. Transfusion-related near misses were relatively infrequent as were laboratory-related near misses (see Table 2).

Table 2 - Reported Near Misses (N = 554)

Category	Interception Type	n (% of all near misses)
Accident (non-fall)	Planned	23 (4.2)
	Unplanned	25 (4.5)
Environmental Hazard / Safety	Planned	16 (2.9)
	Unplanned	17 (3.1)
Equipment / Device	Planned	25 (4.5)
	Unplanned	39 (7)
Fall	Planned	13 (2.3)
	Unplanned	35 (6.3)
Food/ Nutrition	Planned	10 (5.5)
	Unplanned	22 (3.8)
Infection	Planned	33 (6.0)
	Unplanned	29 (5.2)
Laboratory	Planned	2 (3.7)
	Unplanned	11 (1.9)
Medication	Planned	43 (7.8)
	Unplanned	69 (12.5)
Patient Disappearance	Planned	15 (2.7)
	Unplanned	11 (1.9)
Procedure/ Treatment	Planned	15 (2.7)
	Unplanned	29 (5.2)
Restraint	Planned	2 (3.7)
	Unplanned	8 (1.4)
Transfusion	Planned	2 (3.7)
	Unplanned	3 (0.5)
Other	Planned	9 (1.6)
	Unplanned	48 (8.7)

Note: Percentages do not total 100% due to rounding

Dangerous situation reports

The most commonly occurring dangerous situations were environmental hazards, equipment or device failures, infection control processes, and medication-related situations. Only five transfusion-related situations were reported and only seventeen laboratory-related situations (see Table 3).

Table 3 - Reported Dangerous Situations (N = 933)

Category	n (% dangerous situations)
Accident (non-fall)	49 (5.25)
Environmental Hazard/ Safety	134 (14.4)
Equipment/Device	135 (14.5)
Fall	51 (5.5)
Food/Nutrition	74 (7.9)
Infection	138 (14.8)
Laboratory	17 (1.8)
Medication	128 (13.7)
Patient Disappearance	33 (3.5)
Procedure/Treatment	64 (6.9)
Restraint	18 (1.9)
Transfusion	5 (0.5)
Other	87 (9.3)

Note: Percentages do not total 100% due to rounding

Free text comments

Seven hundred and forty-four free text comments were submitted; 495 were associated with the dangerous situation questions and 249 were associated with the near miss questions. Table 4 provides examples of comments for reported dangerous situations.

Table 4 - Examples of comments for dangerous situations

Response Categories	Example
Accident (non-fall)	Needle left on patient's bed
Environmental Hazard/ Safety	Wet floor
Equipment/Device	Broken BP cuff
Fall	No rails in bathroom
Food/Nutrition	Milk left on counter

Response Categories	Example
Infection	No alcohol hand cleanser
Laboratory	Urine specimens without labels in bathroom
Medication	Medication cart drawer left open
Patient Disappearance	Doors open on psychiatric unit
Procedure/Treatment	Delay with post op patient getting medication
Restraint	Patient restrained using pins and gauze post operatively
Transfusion	No comments reported for transfusion events
Other	Illegible documentation

The major themes that were noted were as follows: 1) poor infection precautions related to poor hand washing, lack of soap or alcohol-based hand cleansing solution; 2) environmental hazards such as construction, wet floors; and 3) medication-related issues such as a medication cart being left open and expired medication on a code blue cart. Of particular interest were the comments related to the 'Other' category for both questions. Of 87 reported dangerous situations in the 'Other' category, 79 had comments. The common themes across the dangerous situation comments for the 'Other' category included: 1) privacy issues with patient information being communicated in public spaces, patient charts being left in public location or a computer screen with patient information being on display; 2) patient identification bands either not being on patients' wrists (or ankles); 3) patient data concerns such as the wrong labels in a patient's chart, documenting on an incorrect patient and finding the wrong note in a patient's chart; and 4) three comments noted physician and nurse handwriting as being illegible.

Of the 57 'Other' reports for the near miss question, 45 comments were submitted. Two comments related to near misses with planned interception reported a missing wristband and documentation on the wrong chart. Of the 48 near miss reports with unplanned interceptions, 43 had comments. These comments addressed a wide variety of near miss events including inaccurate allergy documentation, nearly placing baby in the wrong bassinette, and near patient disappearance in the psychiatric setting. Tables 4 and 5 provide examples of comments in each of the categories.

Table 5 - Examples of comments for each reported near miss

Question 2: On your shift today, were there any events that almost occurred ("near misses" or "good catches")?		
A planned interception occurs when a system is in place to prevent an event from happening (e.g., two nurses checking transfusion). Unplanned interception occurs when an event is prevented serendipitously.		
Response Categories	**Interception Type**	**Examples**
Accident (non-fall)	Planned	Needle on counter, placed in sharps container
	Unplanned	Baby bathed in baby warmer, which got very hot, baby could have been burned
Environmental Hazard/Safety	Planned	Construction taking place. Negative air flow vent working
	Unplanned	Noticed that soap was out in all the bathrooms had maintenance come and refill them
Equipment / Device	Planned	Electronic thermometer broken, new thermometer obtained
	Unplanned	Glucose monitor reading incorrectly, second device used
Fall	Planned	Nurses' aide found patient trying to walk by self
	Unplanned	Patient's roommate prevented patient from getting out of bed
Food/ Nutrition	Planned	Diabetic diet not given to patient; nurse checked when handing out tray
	Unplanned	Wrong food tray given to patient, patient's family notified staff
Infection	Planned	Family members not gowning up before visiting patient with contact precautions
	Unplanned	Staff not informed about TB positive patient, Unit Clerk found out when talking to Lab
Laboratory	Planned	Labels hastily placed on samples, but double checked with nurse
	Unplanned	A patient's birthday was recorded incorrectly on a lab form, and was noticed by the administrator of the clinic, and fixed

Medication	Planned	Wrong medication drawn into syringe, nurse noticed when double checked vial
	Unplanned	Pharmacist refilled medication that had been discontinued. RN caught mistake
Patient Disappearance	Planned	Patient with psych issues had tried to escape from her room several times and had wandered out of the unit during the night before
	Unplanned	Patient left floor to smoke, found when nurses' aide went for lunch
Procedure/ Treatment	Planned	NPO patient who's surgery was cancelled waited very long time for food
	Unplanned	Isolation patient unable to reach call bell
Restraint	Planned	Patient had all 4 bed rails raised. Two rails lowered because 4 side rails is a restraint
	Unplanned	Restraints inappropriately applied by previous shift, reapplied by nurse
Transfusion	Planned	Two units to be given, but five units sent by blood bank, caught when double checking
	Unplanned	Nurse entered patient information into wrong chart then realized her mistake
Other	Planned	Illegible charting, second nurse asked for clarification
	Unplanned	Wrong chart was put with the wrong patient, quickly corrected once doctor looked at it

Discussion

We developed a Web-based patient safety education curricular innovation project in which we asked baccalaureate nursing students to report dangerous situations and near misses during their clinical experiences. We provided students with web-enabled handheld devices to enter these reports. Dangerous situations accounted for more than twice as many reports as near misses, which may indicate that dangerous situations are more visible and therefore easier to report for entry-level students. Alternatively, near misses may occur less frequently because systems are typically in place to catch these types of events, or perhaps, the difference resulted from the fact that students at this stage of learning might not notice the nuances of near miss type events.

Infection control practices were one of the most common reports from this student group. Infections are not typically reported in a patient safety reporting system, instead, they re collected by the infection control nurse in a separate system. However, the ability to examine near miss and hazardous situations related to infections may improve infection control practices. Three reports indicated that patients on isolation precautions were not frequently monitored by staff. In one instance, the student reported that the patient had not been seen 'all night'. This may help to elucidate the report by Stelfox, Bates and Redlemeier who identified higher rates of falls in patients on isolation precautions [13]. We intentionally did not track actual incident reports in this project, because the students were taught to report actual events via the appropriate methods at their sites. Therefore, such outcomes cannot be identified.

The second and third most commonly reported dangerous situations were environmental and equipment problems. The list of problems included ongoing institutional construction and water on floors with a large time delay before clean up. These hazards could be easily remedied by improving the safety system. Medication mishaps were the most commonly occurring near miss with unplanned interceptions being more common than planned interceptions. Although the proportion was small, it would be important to identify the root causes of these problems. A very small number of reports identified problems with blood product processes. The two comments related to blood products indicated that the near misses were caught by processes in place in the organization. Double checking blood immediately prior to blood administration is an example of a barrier that is in place very *near* to the patient. Although not a specific category in our reporting system, lack of patient identification bracelets, documentation in the wrong chart and other patient identification methods was a common report. This item could have been documented in the procedure/treatment section, but this was not intuitive to students, thus creation of a communication problems item might be suggested. Some comments were not categorized correctly which is likely due to the novice status of students in this phase of nursing education, however, most comments were relevant and represented mindful thinking.

Conclusion

Encouraging students to participate in reporting during their studies may help to improved voluntary reporting in general. More importantly, it may help to improve students' mindfulness regarding the proximity of barriers in relation to the patient. The wide variety of comments demonstrated that the students were indeed mindful of the clinical environment despite being novices. It is hopeful that integrating patient safety concepts and voluntary reporting into the curriculum will instill safety culture concepts sufficiently early to ensure safe practice throughout one's career.

Acknowledgments

The Wireless Informatics for Safe and Evidence-based Advanced Practice Nurse Care (WISE-APN) project is sponsored by an educational grant from the Health Research Services Administration (HRSA). The authors thank the members of the Mobile Decision Support for Advanced Practice Nursing (MODS-APN) team for their advice and assistance.

Abstract

In Hong Kong, a pilot project is being undertaken to implement a web-based electronic patient record system to allow integrated, real time patient based information to be shared in clinics, private and public hospitals. Such sharing aims to ensure that complete and accurate healthcare information is available to citizens' multiple points of care through a stable IT system. A challenge is to share this electronic information whilst ensuring privacy and security. Hong Kong has achieved its initial goals and pioneered in building a territory-wide electronic health record (EHR). This paper will outline the tasks involved, approach, method used and initial review of the pilot project. Barriers to implementation are discussed and critical success factors are identified.

Keywords:

Medical records systems, computerized; implementation; evaluation; Hong Kong; electronic patient records; public-private interface.

Introduction

The Institute of Medicine's 2000 report *To Err Is Human* generated a flurry of publicity on the issue of medical errors [1]. The report concluded that as many as 98,000 deaths occur annually in U.S. hospitals as a direct result of medical errors. In his review of patient safety issues in the Canadian healthcare system, Dr. Matthew Morgan stated [2] that "coordinated national EHR initiatives will cost less, save lives and prevent harm when compared to the status quo." An interoperable EHR is seen as the one solution that solves most of the problems. According to one study in the US, universal adoption of a complete EHR will save US$77.8 Billion annually [3]. In Canada, the federally funded Infoway has estimated savings of CAD $3.4 billion [4].

The race is now on for electronic health record adoption. Denmark is leading the pack. As such, Denmark has a public healthcare system and developed a national system to electronically communicate messages between healthcare stakeholders since 1994.

In recent years many other governments have also set up e-Health programs to implement EHR. However, success in Denmark has not been replicated in many other OECD countries and barriers to adoption have been identified, such as interoperability, security, and financial considerations.

It is estimated that only about five percent of all U.S. primary care providers currently use EHR systems [5], and other studies describe rates at under 10% in all inpatient settings [6]. EHR adoption is hindered by a more fundamental failure of the HIT market in general in the United States [7]. The concept of an interoperable EHR is easy to embrace, but difficult to implement. This paper will outline the method used in Hong Kong to build a territory wide EHR.

Background

Hong Kong has a population of over 7 million people. There are 44 public hospitals and 12 private hospitals in Hong Kong. All 44 public hospitals are governed and managed by the Hospital Authority (HA). In the past, private hospital treatment was often the choice for those who could afford them. However, improvement in public hospital standard since the establishment of the HA has substantially narrowed the quality gap between the public and private sectors. Currently, private providers accounted for around 5% of all inpatient bed days in Hong Kong [8]. Nowadays, patients often seek care in both public and private sectors, and medical manpower is about equal in the two sectors

HA adopted a centralized approach in developing its IT system for clinical care, the clinical management system (CMS). This has reduced IT cost per hospital, whilst ensuring compatibility. High mobility of both patients and doctors characterizes practices in Hong Kong. Therefore, inter-operability between different hospitals was one of the key aims in developing the clinical management system. A familiar user interface is important in enhancing the efficiency in a busy clinic setting. The HA CMS has very high user acceptance and is in use in everyday care delivery [9].

From 2000 onwards, a web-based system of patient lifetime record in public hospital has been developed - the

electronic patient record (ePR). This system provides a comprehensive and easy to use view of all patient encounters within the Hospital Authority in the lifetime of the patient. Tremendous responses have been received from both the patient and doctor perspectives. This can reduce cost by minimizing repetition of investigations and administrative cost and delay in obtaining patient's information for continuation of care from another hospital. It can reduce risk by having a complete, up-to-date medical history at the point of care. Now the benefits of this longitudinal electronic record are being piloted to the private sector and wider community.

Methods

The Public Private Interface – Electronic Patient Record (PPI-ePR) project commenced development in mid-2005 with the following objectives:

- to enhance collaboration between the public and private sectors;
- to allow continuity of care for the patients;
- to facilitate a free flow of patients between the two sectors; and
- to allow timely access of information.

A one-year pilot is currently being conducted to test the concept, the technical feasibility, including the protection of patient data privacy in the internet environment. During this phase, selected clinical records in the ePR are being shared (with the consent of patients) with participating practitioners through the internet, as depicted in Figure 1.

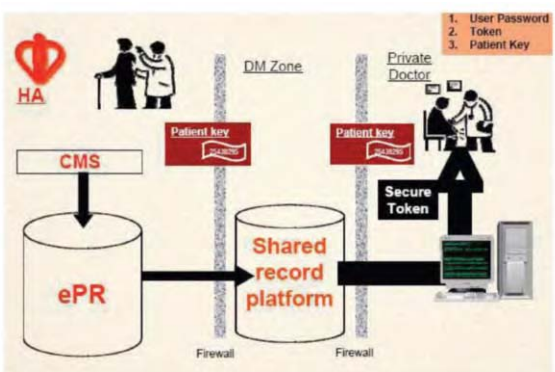

Figure 1 - Schematic diagram of Hong Kong ePR sharing mechanism

On the one hand, we want the free flow of information between the public and private sectors. On the other hand, we want the tightest security to protect patients' privacy and confidentiality.

When a patient consents to sharing his record from HA to the private sector, his record in HA will be extracted from the ePR in HA's internal network to a Public-private interface (PPI) database, where important data fields such as name, Hong Kong identity card number, date of birth and address are encrypted using triple DES encryption algorithm. The platform is protected by firewalls and intrusion detection systems. Patient will be given a PIN (personal identification number) when his record is put on the database.

Private doctors who wish to view patient's records need to register with the HA and agree to comply with the rules and regulations of the project. He will then be given a PIN and a security token. A 6-digit number will be refreshed once per minute on the token. These form the two-factor authentication for doctor's sign in.

Figure 2 - Two-factor authentication of doctors login via web browser

An enrolled doctor has to logon to the PPI-ePR system via web browser with his password and security code generated by the security token (figure 2). To access the patient's ePR record, the patient needs to provide his Hong Kong identity card number and his PIN for input at the web browser. Upon successfully authenticating the enquiry request, PPI-ePR will display the patient's record on the web browser, which is protected all the way through in an encrypted tunnel through the public internet. The contents shared will include: diagnosis, procedures done, discharge summaries, laboratory reports, radiological appointments and reports, medications, allergies and recent appointment schedules. This content covers much of ASTM Continuity of Care Record [10]. On the end-user workstation, we have been careful not to cache pages. As an additional security measure, an SMS message will be sent to the patient's mobile phone, alerting him of such access (figure 3).

Figure 3 - An SMS message showing ePR access

Results

From the start of the pilot in April 2006, enthusiastic responses have been received from many healthcare providers. They range from solo doctor clinics to private hospitals with more than 600 beds. Doctor-to-patient ratio ranges from 1:1 to 1:200 in elderly care homes. This creates different challenges to implementation of the project, but also trials implementations in different healthcare settings.

Doctor registration

We enlisted the help of the three largest doctors' association groups to recruit doctors, namely the Hong Kong Medical Association, Hong Kong Doctors Union and the Association of Licentiates of Medical Council of Hong Kong. A total of 117 doctors were registered this way.

Three group practices have been invited to join and signed a Memorandum of Understanding before their member doctors and nurses could join the project. 30 healthcare providers were registered via their groups. We also worked with five private hospitals in recruiting patients. In total, 131 healthcare providers (doctors and nurses) from private hospitals have joined the program.

We reached the quota of 500 doctors in one month and the waiting list has about 200 doctors, demonstrating the support and enthusiasm of the private sector for the program.

Patient registration

It has taken longer for patient registration to catch up with doctor registration. Since not all HK citizens will attend both private and public clinics, we hope to target our pilot patient population to those standing to benefit most from our pilot. Two target patient groups were those in elderly care homes, or in shared care program. Patients will be given drugs and special tests for chronic disease in the public whilst other problems are dealt with by their family doctors. The PPI-ePR acts as a bridge between the two sectors to provide real time, accurate information to enhance quality of care. As of March, 7800 patients have registered in the program and their private doctors are reviewing their medical record via the secure platform.

Future work will focus on expanding the program to cover more doctors and patients, and to make use of the Hong Kong SmartID card for registration and authentication. However, during this pilot, a few critical success factors and barriers to adoption have been identified, as discussed below.

Discussion

There are several critical success factors identified for community wide EHR. Protection of individual privacy is of paramount importance because it will take some time for citizens to have confidence in the system security and reliability. Having a pilot is a good way to pave for wider acceptance. Any information leak via the system will be a severe blow to the progress towards a Community wide EHR. Therefore, every precaution must be taken in the design of the system, while not affecting the ease of use.

Security and confidentiality

The PPI-ePR system houses a strong enterprise-wide encryption, two factor authentication, centralized database which allows audit trails, additional SMS and protected by surrounding firewalls and intrusion detection system. Since the start of the pilot, there is no report of security nor privacy issues.

An additional independent audit has been done in Aug 2006 to ensure that adequate security and control measures have been put in place to protect the privacy of patient information in accordance with the relevant requirements of the law.

Broad participation

Another important factor is broad participation, particularly from the private health sector, and building of community and stakeholder trust and confidence. In the pilot, over 500 doctors joined in the program and started to use the system. This accounts for about 10% of the private doctors in the market. A survey by the Hong Kong Medical Association showed that 87% of the private doctors are interested in using the PPI-ePR system. This supports our observation that response for doctor registration is very strong.

Nonetheless, there are certainly some barriers to adoption. The most obvious one is the lack of standards for community wide interoperability. In the US, electronic patient information resides on many isolated islands that have been very difficult to bridge. Hong Kong has taken a centralized approach in developing the ePR and thus solved most of the interoperability issues during its development, using the same data standard and vocabulary. The next phase will be to explore sharing of the HA system with the private sectors. However, a further development of the community-wide ePR is to encourage two-way sharing, so that private health records are also shared with the public sector, which leads to the need to delineate roles, responsibilities and ownership across sectors.

Another challenge is to identify who will make the initial investment in extending this pilot program to a community wide EHR. HA has taken the first steps in investing the manpower and infrastructure for the development of a pilot system. The subsequent maintenance and enhancement costs will need to be shared between the government and different stakeholders to make it financially sustainable.

Conclusion

Hong Kong has taken a centralized approach to develop the community wide EHR and sharing the contents with the private sectors. Ninety-five percent of inpatient records are electronic and shared to the remaining 5% of the healthcare sector. The implementation of EHR in the Hong Kong will ensure that complete and accurate healthcare information is available to Hong Kong citizens at the point of care. The primary goal of EHR is and will be to store and share this electronic information while guaranteeing privacy and security. We believe Hong Kong has demon-

strated a viable platform and pathway to a community wide EHR.

Acknowledgments

We would like to thank Dr Fung Hong, Ms Nancy Tse, Dr WL Cheung and Mr Andre Greyling and members of the PPI Working Group for their support and leadership. We appreciate the HA management team in cultivating this sharing culture and We would like to thank many of the stakeholders in making this pilot a success, thus paving our road to a community wide EHR.

Northern Territory Health*Connect*: Shared Electronic Health Record Service Implementation Experiences and Benefits Realised in Indigenous Health

Stephen Moo, John Fletcher

Northern Territory Department of Health & Community Services

Abstract

This presentation summarises the learnings from the HealthConnect Northern Territory (HCNT) Shared Electronic Health Record Service (SEHR) from Trial to Implementation and the emerging benefits realized as the project is implemented across the Northern Territory of Australia.

The presentation:

- *explores the challenges and experiences of implementing a SEHR service in urban and in some of the remotest regions on the Australian continent.*
- *demonstrates the emerging health benefits e-Health can provide in enabling the sharing of medical information between public and private health service providers in particular the service delivery and benefits provided to a highly mobile Indigenous population who currently experience the greatest health problems and experience difficulties accessing continuum of care created by factors which include remoteness, mobility and communication.*
- *explores the evolvement of the "opt in" consumer consent model adopted by the Territory for the implementation of the HCNT SEHR.*
- *advises of plans for future development, which inform other implementations, and NeHTA standards development for the implementation of the National SEHR Service.*
- *Informs project plans to incorporate NeHTA standards as they are developed and transition the HCNT SEHR to the National SEHR Service when implemented recognising the importance of developing strong partnerships with key stakeholders, in particular consumers, health care providers and system vendors who inform project development and implementation.*

Health*Connect,* e-Health, Health*Connect* NT Shared Electronic Health Record Service.

Introduction

Health*Connect* NT trial

Sponsored by the Australian and Northern Territory Governments, a Health*Connect* research and development trial commenced in Katherine in the Northern Territory in June 2002.

The Trial was established to help determine whether Health*Connect* could improve continuity of care in remote and rural areas of Australia by enabling health care providers timely access to vital health information.

The Trial centered on the development and utilisation of a secure Health*Connect* repository.

With a registered consumer's consent, health service providers participating in the Trial were able to send event summaries of health events including medical summaries and hospital discharge summaries via a secure network to the repository. Once in secure storage, other authorised health care providers involved in the Trial were able to access consumer medical summaries with consumer consent.

Consumers and providers embraced the concept of Health*Connect* in the Territory and 1,800 consumers, mostly from remote areas were registered to participate in the Trial by March 2005.

There were 49 registered Providers involved in the Trial. Users of Health*Connect* NT included Hospital medical officers and district medical officers, some accident & emergency nursing staff, remote clinic doctors, remote clinic nurses and Aboriginal Health Workers.

Consumer consent

During the early stages of the Trial Providers were required to obtain consumer consent at each occasion of care to retrieve and view consumer health information on Health*Connect* and to send a summary of that occasion of service to Health*Connect.* This created some issues in early 2004, where Providers became concerned that the model in their view could be medically dangerous and were also concerned that they could be legally exposed if they failed to obtain consent or forward information to Health*Connect.* Consumers also complained that it was humbug to be asked to consent each time they visited a health care provider. Many stated that the reason they had joined Health*Connect* was to enable providers to access their health information and expected their information to be sent to Health*Connect* after a consultation as a matter of course.

Provider and consumer concerns regarding the requirement to consent at each occasion of care culminated in a major consumer and provider workshop being held in Katherine. The outcome of this workshop resulted in a new consent model being introduced in the latter stages of the Trial with full consumer and provider support. The new consent model complied with national privacy legislation and required a Health*Connect* registered consumer to consent on registration to their health information being sent, retrieved and viewed from the repository on each occasion of service, unless at a particular occasion of service the consumer instructed the provider that he or she did not want the information viewed or sent. This model was adopted by the Territory and proposed by the Territory as the preferred model for national implementation.

Evaluation

The phase 2 evaluation conducted during 2004 found that the Health*Connect* concept was unanimously supported by providers, health care managers and consumers involved in the Trial and that providers and consumers strongly supported the implementation of Health*Connect* across the Katherine Region and the Northern Territory. There was a strong belief among providers and consumers that Health*Connect* would provide major benefits in the delivery of coordinated health care across the Territory. There were also a number of lessons learnt from the evaluation, which are included in the "Lessons Learned from the Medi*Connect* and Health*Connect* Field Test and Trials" Report.

Promotion

During the Trial and as a major promotional tool supporting implementation, promotional material was developed using MARVIN. The development of MARVIN is a result of a collaborative partnership between Industry, Community and Government in the NT and contributes part of its existence to the Australian Flexible Learning Framework's (Framework) LearnScope professional development project. MARVIN allows community members to develop the learning and training resources themselves, typing in their own messages and recording their own voices, in their own languages. What is then seen onscreen is walking, talking computer generated characters, most of them modeled on elders within the community or upon the learners themselves. Promotional material developed for the Health*Connect* NT Trial and more recently for implementation has received wide acclaim.

Health*Connect* NT shared electronic health records service - implementation

Following the success of the Trial and the enthusiastic support of consumers, providers and other major stakeholders, the Territory decided to implement the Health*Connect* NT (HCNT) Shared Electronic Health Record (SEHR) Service Territory wide and to investigate the possibility of expanding the SEHR to cross border regions in South Australia and Western Australia.

Planning for the phased implementation of the Health*Connect* NT SEHR commenced in the latter part of 2004/2005 and initial implementation commenced across the Katherine Region on July 1 2005.

Health*Connect* NT implementation aims to break down over time the Territory's distance barriers to health services delivery, particularly to highly mobile remote indigenous populations by enabling:

- participating providers to create and view shared electronic health records for consumers in participating remote communities; and
- participating hospitals to generate discharge summaries to participating providers automatically.

This will contribute to enhanced clinical services in participating remote communities, including greater ability to manage chronic disease and enhanced care for children in remote communities through greater capability to deliver primary care, childhood development, immunisation and nutrition services.

Consumer registration

Vast distances complicate the registration of consumers to participate in the Health*Connect* NT SEHR, remoteness of communities, climate (in particular wet season access) and cultural diversity. This provides significant challenges in terms of engaging with, and gaining the informed consent of, consumers particularly with Territorians for whom English is a second language and where there is a range of cultural considerations.

- New marketing and promotional materials were developed, tailored to communicate with, and educate consumers from diverse cultural backgrounds and language groups.
- A partnership with Medicare Australia was negotiated and new registration forms for implementation were developed to register consumers to participate in the SEHR service, to confirm Medicare registration details and facilitate new Medicare registrations. A detailed registration process was established with data compatibility checks undertaken to a strict criteria – data compatibility at time of registration is checked to ensure consumer demographic details are a complete match with home health centre CIS, Medicare and CMI (Hospital) data prior to information being entered into the SEHR.
- New pamphlets informing consumers of consent, privacy, provider access to records etc were prepared and issued to consumers at time of registration.
- Consumer Advisory Group (CAG) established. The Chair of the CAG and an Indigenous cultural representative of CAG are represented on the HCNT Implementation Steering Committee.
- A dedicated Consumer Services team was established to focus on consumer registration and provide secretarial support and information to the CAG.
- Consumer registration involved community and stakeholder promotion and the appointment of casual Local Project Officers to assist with registration and consumer identification. This created employment and skills

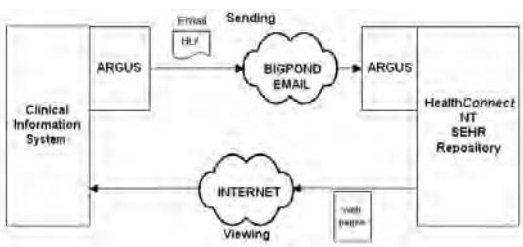
development opportunities in areas of high unemployment and community ownership in the program.

- Consumers across the region embraced the concept of Health*Connect* and readily committed to register to participate. A 90% uptake was realized in remote communities across the Katherine Region.
- Over 9,000 consumers registered to participate in the HCNT SEHR service by 30 November 2006, most from remote communities spread over a very large geographic area.

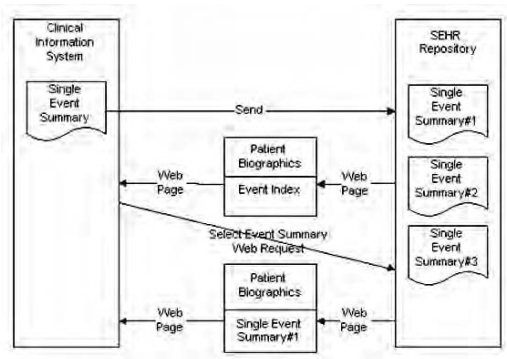
System capability

The HCNT SEHR system is designed around a central server sending and receiving medical information from numerous clinical information systems. The HCNT SEHR system receives secured medical summary messages (called event summaries) from feeder systems and stores them in the HCNT SEHR Repository database. Medical providers via the Internet can view these event summaries.

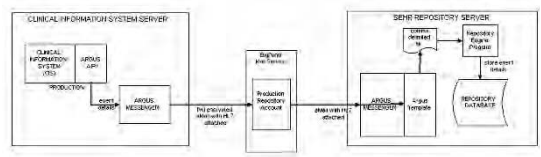
The HCNT SEHR system uses an Argus messaging tool to generate HL7 messages, containing the event summary, and attaches them to HeSA PKI encrypted message sent to the Repository Database via a Big Pond email account. Medical providers using their clinical information system can securely view, using SSL, via the Internet the medical information stored in the SEHR Repository for a specified consumer. The diagram below illustrates these concepts.



The event summaries generated by the feeder systems are usually single consultation events from health centres, or hospital emergency/inpatient discharge summaries, but may also be an initial health profile summary or a pathology test result. All these summaries are stored as discrete pieces and these events can be viewed specifically via the Internet directly or via a web window within a clinical information system. Accessing the medical data over Internet requires medical providers to enter a user id and password. An index listing all the event summaries for a patient is shown. Once selecting the appropriate event summary a web view of that event summary is sent to the viewer. The following diagram shows the basic overview of these concepts.

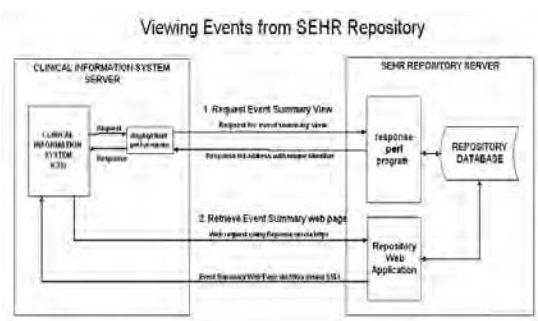


Sending and Viewing Technical Design in detail



The above diagram shows in detail the sending processes. The key to sending is the use of the Argus email tool, which has two key components; the first is the Argus API that allows the Feeder System to directly call functions that interact with Argus Messenger. The second Argus component is Argus Messenger, which can generate an email, attach files to them and encrypt the emails. These emails are sent to a single bigpond email account where it awaits retrieval.

At the HCNT SEHR Repository Argus Messenger is also running, automatically downloading emails from the bigpond email account about every 10 minutes. Argus Messenger has a set of predefined rules that require HL7 attachments on emails to be interpreted by Argus' Template tool, which convert the HL7 into a more readable comma delimited file. In turn a perl program called the Repository Engine reads the comma delimited file and stores the event summary against the appropriate patient in the Repository Database.



The diagram above describes the viewing processes required to allow a medical provider using their Clinical Information System to read the SEHR Repository event summaries.

The first step is a request to view made by the medical provider via their clinical information system, in which the provider must enter their HC NT SEHR user id and password. The HCNT SEHR Repository server through a response program returns a url address with a parameter of the selected patient's unique identifier, only if the provider's user id and password are accepted.

In the second step the clinical information system on receiving the returned url puts this url into its built-in web browser, which makes a web request for that url address. This url address uses https, which uses SSL encryption. The url address location is the SEHR Repository's web server, which returns the requested first web page containing the patient's demographics and an index of event summaries. The event summaries can be reached via links on the presented web pages.

System features via seamless integration into participating feeder systems include:

- automatic flagging notifying of consumer registration status.
- notification (prompt) to send event summaries including inpatient and emergency discharge summaries in hospital systems.
- viewing features of event summaries.
- sending of initial health profiles (IHPS).
- sending of pathology results.

Participating providers are able to create and view initial health profiles, medical event summaries and pathology results for consumers who have registered to participate.

Participating hospitals generate inpatient discharge and emergency event summaries to participating providers automatically for consumers who have registered to participate.

Daily notification to providers of inpatient and emergency discharge summaries for their clients is provided.

Medical summaries generated by the HCNT SEHR Service include:

Medical Summary of a consultation/encounter with Individual - includes Diagnosis, Medications, Immunisations, Observations, Risk Factors, and Allergies.

Hospital Discharge Summaries (ED and Inpatient) - includes Diagnosis, Procedures, Medications, Observations, Pathology Results.

Pathology Results.

Initial Health Profile - 2-year history of patient from their home Health Centre. Includes Diagnosis, Medications, Immunisations, Observations, Pathology Results, Risk Factors, and Allergies.

Current Health Profile – Will replace Initial Health Profile in 2007 and be generated at each occasion of service.

Provider engagement

- Providers enthusiastically supported the HCNT SEHR service, believing it would assist greatly in delivering health services to their clients across the continuum of care.
- 258 providers registered and participating in the HCNT SEHR service by 30 November 2006. These include Hospital medical officers and district medical officers, some accident & emergency nursing staff, remote clinic doctors, remote clinic nurses and Aboriginal Health Workers.
- Clinical Advisory Committee (CAC) established and meets monthly. Representation on the CAC includes Drs, Nurses, Aboriginal Health Workers and Allied Health Professionals. The CAC informs HCNT management and the Implementation Steering Committee on issues including: protocols, privacy, change management / provider engagement and training, QA and system requirements, capability, user friendliness and has a major influence in the system enhancement development program.
- Provider protocols were implemented and provider agreements at organizational level were agreed to. All providers apply to register, are trained in Health-*Connect* and are provided with user ID and Password access.
- HCNT hotlines were introduced to enable providers to obtain HCNT HCIDs for consumers visiting their health service from another location, to address user ID password / access issues and to report system faults.
- Quality Assurance procedures in conjunction with providers were established to monitor data quality and audit provider access.
- Considerable effort was undertaken in engaging providers and influencing change management to enable providers to incorporate utilization of the HCNT SEHR within normal work practice when utilizing feeder
system clinical information systems. A joint Communicare / HCNT SEHR user manual was developed by HCNT with input from participating providers and "how to" sheets were prepared for users of all participating CIS's.
- 17 sites actively participating in the SEHR service at November 2006 as well as the Royal Darwin, Katherine and Tenant Creek Hospitals.
- Provider participation increased markedly during 2005/2006 as a result of the increase in the number of registered consumers, efficient provider engagement practices, system reliability / major decrease in system failure and faults, system enhancements, data quality and the SEHR began delivering real service outcomes.

Governance

New Governance arrangements were implemented in 2006 to reflect Territory e-Health implementation and the HCNT Implementation Steering Committee (HCNTISC) was established.

The HCNTISC is responsible for providing advice on policy and business issues associated with the implementation of

HealthConnect NT in accordance with project objectives and the revised HealthConnect Implementation Strategy.

The following sub committees inform the HCNTISC

- Implementation Management Group
- Consumer Advisory Group
- Clinical Advisory Committee
- Information Technology Advisory Committee
- Indigenous e-Health Advisory Committee

Progressive implementation – major program outcomes:

The Northern Territory is progressively implementing the HCNT SEHR service across the whole of the Northern Territory targeting first all remote communities and urban-based Aboriginal Medical Services.

Implementation of the HCNT SEHR builds upon and complements the implementation of the HCNT Point to Point (P2P) Service and major e-Health initiatives being implemented by the Northern Territory Department of Health and Community Services in the Northern Territory public hospitals and Remote Health Services Program which include:

- Implementation of Advanced Medication Management and Point of Care Clinical Workstation in NT Hospitals.
- Implementation of Remote Communications Infrastructure and WAN connections into all departmental operated Remote Health Clinics.
- Progressive implementation of a standardised integrated Patient Recall and Chronic Disease Management System (Primary Care Information System) into all public Remote Health Clinics.

Results

The implementation of the HCNT SEHR service in the Northern Territory will achieve the following major outcomes:

- *Passing the Patient Safely Back to their Community* – the generation of electronic discharge summaries (including electronically generated discharge medications for patients of NT Hospitals) for inpatient and Emergency Department attendances by consumers registered for the expanded HCNT SEHR Service.
- *Caring for the Chronically Ill and Children* – critical health information about consumers registered for the HCNT SEHR service, including records of immunisations, medications, accessed by participating health providers across the NT, enabling those professionals to better manage chronic disease and high risk child health issues such as "failure to thrive".
- *Breaking Down the Distance Barriers by Improving the Co-ordination and Delivery of Health Services to Indigenous Populations* – engagement and maximisation of registration of residents in the Northern Territory receiving services from health providers participating in the expanded HCNT SEHR service, targeting first, remote indigenous communities, Aboriginal Medical Services operating in remote and major urban centres and small regional centres and towns across the Territory;
- *Greater involvement of consumers in their health care* – establish two (2) consumer resource centres in remote health centres to pilot strategies for consumer access to their SEHR, telehealth services and video-conferencing with relatives in hospital;
- *An informed community ready for participation in integrated health care* – the Northern Territory will make continued progress in the development of the communities' understanding of and willingness to participate in Health*Connect* through localHealth*Connect* marketing and promotions aligned to national e-Health Strategies.

Conclusion

The Northern Territory will build on the proven successful development and implementation of its HCNT SEHR Service. The Northern Territory's HCNT SEHR implementation is the most advanced Health*Connect* service implementation of its kind in Australia in terms of range of services, service coverage, provider and consumer participation. The HCNT SEHR is being expanded to target the most disadvantaged Indigenous populations with the greatest health needs, residing in rural and remote communities and major urban centres. There is clear evidence that Indigenous populations have embraced the concept of HealthConnect with 90 % voluntary consumer participation rate and 100% provider participation achieved. There is also clear evidence of benefits realisation for a highly mobile Indigenous population through improved coordination and quality of health service delivery spanning vast distances, in some of the remotest areas in Australia. These initiatives will provide significant learnings and opportunities to inform the development of emerging national and cross-jurisdictional e-Health implementation strategies and standards/infrastructure developments, that is, the NEHTA work program.

Abstract

This paper addresses through simulation experiments a number of technical issues which are raised during the development and operation of a National Electronic Health Record System (NEHRS). The simulation experiments represent the NEHRS performance for a variety of technological infrastructures, within the context of a realistic scenario. The scenario includes the estimation of the delays created in queues during the exchange of Electronic Patient Records (EPR) between different health service points. It is essential to clarify the delays derive from LAN and Internet technologies, the EPR encryption/ decryption, the HL7 message generation/parsing, and the databases. The results of this study identify how a number of technical aspects influence the NEHRS development and operation.

Keywords:

National Electronic Health Record System, simulations, performance

Introduction

Creation of national services for maintenance of and access to Electronic Health Records (EHR) has been a prominent issue in health information management and technology strategies in developed countries over the recent decade. In fact, EHR have been assigned a catalytic role within many national information management and technology strategies in healthcare. The UK, 'Information for Health: An Information Strategy for the modern NHS 1998-2005' [1] for example has presented a strategy based upon a vision of patient-centered data flowing freely across all areas of healthcare, to be accessed and utilised wherever needed. Similarly Canada [2], Australia [3], New Zealand [4], Denmark [5,6], Israel [7] have presented comparable plans for their countries. In the same manner, the European Union expects from all its member states to define, promote and achieve progress on e-Health by the end of 2009 [8].

However, National Electronic Health Record System (NEHRS) programmes, as for example the English, expand the NEHRS delivery date since the means to realize this vision remains problematic [9] [10]. A number of problematic aspects are the security and confidentiality issues that occur during data storage and transmission, the lack of standardisation (coding of medical conditions, vocabulary of medicine) and the need to support and reconcile different views on the structure and the content of the EHR due to the different users and their different needs (physicians, patients, nurses, administrative staff) [11]. Another critical issue which has been identified by the English National Health Service (NHS) is the physicians' unwillingness to use the EHR Systems of their Health Service Points (HSP) which in future will be connected building up a NEHRS. This problem is caused mainly by the lack of motivation and computer literacy of the physicians [12]. Particularly, 60% of physicians in England do not want to use available EHR systems in their HSPs, since they feel it overloads the amount of their work without adding any significant advantage [13]. On this problematic issue are also added the EHR Systems harms which are presented because of technical problems on these systems causing further delays on the work of the health care personnel. A representative example is the English case, where the NEHRS which is partly in operation broke down 110 times in four months during 2006 [14]. Our study focuses on these technical problems simulating the Electronic Patient Record (EPR) exchange process in an NEHRS environment and studying the factors which could cause these system harms. An EPR is a record of a healthcare episode, such as a course of treatment within a hospital, and therefore forms a component of an electronic health record (EHR), which is a birth to death healthcare history of an individual.

Although there are multiple studies on the factors which influence the NEHRS operation and development, only a few address the impact of technical design options. A similar study to the current investigation (by Huang and Liou [15]) has simulated the EPR exchange of text data measuring the number of users that can be served per hour in one of the health service points of Taiwan. However, their estimations were covering only two Internet link technologies and one EPR size. We extended the simulation experiments examining the NEHRS performance for 13 Internet link technologies, 3 sizes of text EPR, and adapting more precise estimation methods for the time spent for the

records' encryption/decryptions [16] and transfer over the Internet [17]. The expansion on the simulation experiments gave us the opportunity to elaborate extensively the results and retrieve better insights.

Methods

The general strategy employed in this study was to analyse the performance of a range of technical NEHRS configurations by simulating a realistic scenario. Performance was analysed in terms of response times and information capacity. The realistic scenario included the estimation of the service times for the generation/parsing of HL7 messages, the EPR query and EPR transfer over the Internet, the EPR encryption/decryption, the public key search, the EPR search in the database and the LAN transactions. The scenario also includes the use of smart cards which hold the unique identification keys for each EPR of the patient which owns the card.

Generation and parsing of text messages

Estimation of transmission speed is complicated by the overheads of employing HL7. The HL7 (2.3.1) standard presupposes the generation and parsing of RQC/RCI-I05 messages. In the simulations the estimated time for the generation and parsing of HL7 RQC/RCI – I05 messages takes the value calculated in a study by Huang and Liou [15]. Their estimation is based on averaging the time taken by 1000 actual HL7 encoding/decoding transactions using workstations comparable with those assumed in the current simulations. Accordingly, generation of RQC/RCI-I05 is estimated as 12 milliseconds (ms) and the parsing of RQC/RCI-I05 is 50ms. Note that these times are constant, since the HL7 overheads are independent of message size.

Encryption/decryption of text

Calculation of the delays due to text data encryption/decryption is more complex since it depends on three different aspects; (i) the size of the encrypted/decrypted file; (ii) the public key size and algorithm; and (iii) the specification of the computer performing the encryption/decryption. In the current simulations, the calculation is that of the Snyder and Weaver method [16]. Their estimations is based on averaging the performance measurement for a powerful PC (P4, 3GHz) performing encryption/decryption for a range of public key algorithms and key lengths. Specifically, their estimate is based on 400 different tests for each algorithm and key length in order to measure the average encryption/decryption times. We selected for our study the AES public key algorithm [16] with a 128 bits key length since this is a sufficient technology for EPR encryption/decryption, in order to maintain a sufficient level of security [18]. In the study by Snyder and Weaver, the results show that using the specific algorithm, the PC (P4, 3GHz) can encrypt 6.63 MB/seconds and decrypt 7.19 MB/seconds. Since we decided on the EPR sizes it was easy to calculate the encryption/decryption time (e.g. the encryption time for the 10KB EPR was: (10KBx1second)/6630KB = 0.0015 seconds).

EPR sizes

As in [9] [15] [16], record size is a parameter in our simulations. This is in order to investigate the relationships between information capacity and performance. In particular, this allows us to explore where certain thresholds, such as that of acceptability, are reached for given compromised ratios of information capacity and infrastructure performance. Accordingly, the record sizes that needed encryption/decryption in our study were varied as follows:

1. The RQC-I05 message is set to 5KB, a typical size characterising this HL7 part [15]. This size is determined by the HL7 protocol irrespective of the EHR size, and it therefore a constant within the simulation.
2. The RCI-I05 message, which includes the EPR, is set to 10KB, 100KB and 500KB, so as to range from minimal textual EPR content to the more comprehensive patient histories envisaged for NEHRS.

EPR and public key retrieval

In both use cases, EHRs are retrieved from HIS databases, the location of which is stored on the smart card. Estimation of the time associated with searching an HIS database to retrieve a requested piece of information is also based on the method developed by Huang and Liou [15]. Accordingly, it is assumed that the database is well indexed and the indexes are assumed to be memory resident. Consequently, query execution times can be estimated as that of a binary search, which has a service time of the order, $O(\log_2)$. The service time depends on the number of records that compose the database. Huang and Liou [15] calculated the query service time using the function $\log_2(N/760000)$, where 760000 is the number of records that can be searched in 1 second of query processing, and N is the total number of records in a database. Although the records' number in the database is a dynamic value, in order to carry out the simulations we defined to one million the records (in the database) since a static value is necessary for their accomplishment. Therefore, for 1 million records the calculation of database search time is as follows:

$$\log_2 (N/760000) = \log_2 (1000000/760000) = 0.396 \text{ seconds} \quad (1)$$

As regards the time associated with searching a public keys database to retrieve the public keys necessary for the encryption/decryption, we used the estimation by Huang and Liou [15]. Their estimation is considered to be appropriate for our study because it is based on real empirical data from a Taiwanese governmental organisation for the management of public keys (National Public Key Infrastructure Organisation (NPKIO)) and therefore the time demands for public key retrievals is considered to 0.4 seconds.

EPR and public key transfers

Another point to stress with respect to our simulation experiments is that the measurement of the network (Internet and LAN) service time has been estimated using the method of Menasce and Almeida [17]. Consequently, estimation of performance takes account of the next net-

work attributes: LAN Bandwidth - *(LAN Bandwidth in megabits per second)*; Max. LAN PDU - *(maximum Protocol Data Unit (PDU) size for the LAN's network layer protocol in bytes)*; LAN Frame Overhead - *(frame overhead of the LAN's link layer protocol, in bytes)*; Router Latency - *(router latency in microseconds per packet)*; Internet Link Bandwidth - *(bandwidth, in megabits per second, of the connection to the ISP)*; Internet Round Trip Time - *(Internet average Round Trip Time, in milliseconds)*; Internet Data Transfer Rate - *(Internet Data Transfer Rate, in Kbps)*; Browser Rate - *(rate, in HTTP operations/sec)*; Average Size of HTTP requests - *(Average size of the HTTP request sent by the browser to the server, in bytes)*; Maximum Segment Size - *(Maximum Transmission Control Protocol (TCP) segment size, in bytes)*; Record Size - *(EPR/Query size that is transferred in Kilobytes)*. We used the large combination of equations from [17] which involve the above network attributes and we estimated the EPR and public key transfer over the network.

The *Internet Link Bandwidths* and the *Record Size* had dynamic values that were changing during the simulations, so as to model the differences in infrastructure performance. In particular, the Internet Link Bandwidths varied from 56Kbps (PSTN) to 52Mbps (VDSL) and the EPR Size varied from 10KB to 500 KB. The rest of the simulated attribute values remained static [17].

The above static and dynamic values are the attributes which assisted in the estimation of the time demand (service time), M, for record and public key transfers, using a number of complex equations [17]. In particular, M or else the total service demand, was a summation of five different service demands which are shown in equation 2.

$$M = D_{LAN} + D_{router} + D_{OutL} + D_{Int} + D_{InL} \quad (2)$$

To understand the 5 different service (time) demands of equation 2 better, we will briefly explain all the steps of the EPR order process. The doctor sends the EPR order from her PC and this is received from the LAN station of her HSP (D_{LAN}). Then the HL7 standard is adapted on the order and the latter is encrypted. After that, the router receives the order (D_{router}) and forwards it though its outgoing link (D_{OutL}). Afterwards, the EPR order is transferred through the Internet (D_{Int}) and it is received from the LAN station (D_{LAN}) of the HSP which holds the record, having passed first through the incoming link (D_{InL}) and the router (D_{router}). Then the order is decrypted, the HL7 message is parsed and the search in the database is taking place in order to locate the record. Later on, the record is becoming an HL7 message, it is encrypted, and sent back though the outgoing link (D_{OutL}). The record is transferred through the Internet (D_{Int}) and it is received from the LAN station (D_{LAN}) which sent the EPR order originally, passing first through the incoming link (D_{InL}) and the router (D_{router}). The record is decrypted and parsed making the EPR available to the doctor.

Accordingly, we simulated NEHRS performance for different numbers of (user) requests. The number of simulated requests were 100, 500, 1000, 1500, 2000, 3000, 4000, 5000 per hour. The Queues which are presented during the EPR exchange process in the real order are the following: 1) Queue of the network service time for sending the query for public key, 2) Queue of the NPKIO, 3) Queue of the network service time for receiving the public key, 4) Queue of the RQC-I05 message generation, 5) Queue of the RQC-I05 message encryption, 6) Queue of the network service time for sending the RQC-I05, 7) Queue of the RQC-I05 message decryption, 8) Queue of the RQC-I05 parsing, 9) Queue of the search in the database, 10) Queue of the network service time for sending the query for public key, 11) Queue of the NPKIO, 12) Queue of the network service time for receiving the public key, 13) Queue of the RCI-I05 message generation, 14) Queue of the RCI-I05 message encryption, 15) Queue of the network service time for sending the RCI -I05, 16) Queue of the RCI-I05 message decryption, and 17) Queue of the RCI-I05 message parsing.

The equation which was used for the estimation of the response time of each queue is [17]:

$$R_q = 1/(\mu(q)-\lambda(q)) \quad (3)$$

where $\mu(q)=1/T$ (T is the time demand per request) and $\lambda(q) = n/t(q)$ (n is the number of requests and t(q), is the time taken to service n requests queued on q). The Internet technologies which were used for the simulation experiments: PSTN (56 Kbps), ISDN, IDSL (128 Kbps), ADSL (384 Kbps), Cable (1 Mbps), HDSL, ISDN PRI, T1 (1,544 Mbps), SDSL (2 Mbps), ADSL2 (12 Mbps), ADSL2+ (24 Mbps), T3 (45 Mbps), VDSL (52 Mbps).

Results

Applying the above calculation methods we estimated the NEHRS performance during the EPR exchange. Specifically, we experimented with the simulation variables to investigate the relationships between infrastructure performance and information capacity. Figure 1 presents the service times for the EPR exchange of 10KB which vary according to the different number of user requests and the kind of Internet technology. As it was expected the PSTN technology provides very slow responses even for 100 requests/hour (9.01 seconds). For 1000 requests the service time does not only overcome the 80 seconds but also the system is expected to stop the service. As it is mentioned in multiple studies [19] [20] the service time of a web system as in our case should not exceed 3 to 5 seconds. The simulation experiments also shown that even ISDN, IDSL, and ADSL are also slow providing service times larger than 5 seconds and the service stops on 2000 requests in an hour. The Cable, HDSL, T1, ISDN PRI and SDSL technologies offer faster service time lower than 5 seconds until the 2000 requests/per hour and stop the service on 4000 requests/hour. Finally, the ADSL2, ADSL2+, T3 and VDSL offer service times around 3 and 5 seconds until the 3000requests/hour and they can continue the service until the 5000 requests.

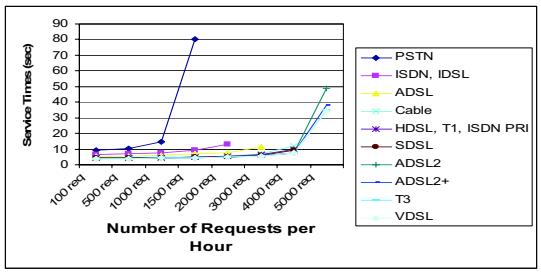

Figure 1 - Service Times for a variety of user requests and Internet technologies (EPR size 10KB was used)

Figures 2 and 3 intend to show which elements (queues) of the EPR exchange process cause delays. The results show that the lines (services times) for the EPR exchange of our scenario which includes everything and the EPR exchange without the HL7 standard are very close (almost tangents) which means that the HL7 overloads the above process with a very small amount of time which is approximately 0.125 seconds (Figure 2). On the other hand, the comparison between the lines (service times) of our scenario and the case of not having EPR encryption/decryption (PKI) shows that encryption /decryption process slows dramatically the process and it makes almost double the service time (Figure 3). Figures 2 and 3 also show how the service times are decreased while the Internet technologies are changed to faster ones.

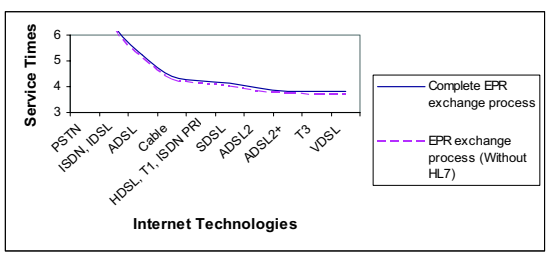

Figure 2 - Services Times for EPR exchange with and without HL7(10 KB EPR size was used, 100 requests/hour were taken into account)

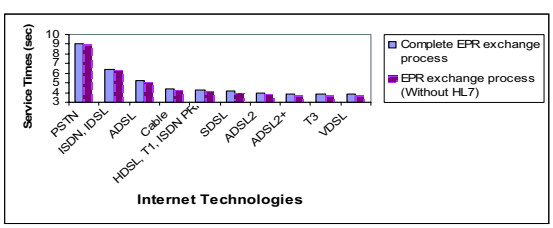

Figure 3 - Services Times for EPR exchange with and without PKI (10 KB EPR size was used, 100 requests/hour were taken into account)

The simulation experiments were accomplished by keeping the size of the database constant. It was interesting to be examined if and how much the database size can affect the EPR exchange process. We further expanded the simulation experiments and we estimated the service times for different database sizes (1, 10, 20, 50 and 100 millions records). We estimated the difference of service times (t) for 100KB EPR (t1) and 10KB EPR (t2) for 100 requests/hour while the database size was varied. The same estimation was repeated for 500 requests/hour. Figure 4 demonstrated that as the database size is increased, the service times are dramatically increased. In specific, service times exceed the 10 seconds for a 10 million record EPR database even for 100 requests.

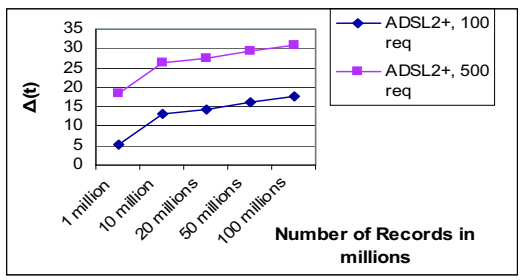

Figure 4 - Service Times increases with relation to database size, EPR size and number of requests. Top Curve: Difference of service times between 100KB and 10KB EPR size when a 500 requests/hour are taken into account. Bottom Curve: The same for 100 requests/hour

Discussion

The usefulness of the simulation experiments on the NEHRS research area is important. They assist the identification of the technical parameters considered to play a key role on the NEHRS operation and development. For example, in case of systems break downs as they exist in England, the simulations could indicate how to break the user requests (workload) by installing new workstations with autonomous Internet links. Moreover, even if the identification of the critical role of the kind of Internet link technologies was being expected, the database size seems that it has not been seriously considered until now. In addition, the simulation experiments demonstrate that the overhead of implementing HL7 is small, particularly when compared with the service time for PKI, which in effect doubles response time. It is envisaged that further elaboration of the simulation experiments will investigate the role of other factors such as different data structures and NEHRS architectures that can mitigate the slowdowns on the EPR exchange process.

Conclusions

The simulation experiments reached a number of interesting conclusions. Simulation of an NEHRS is a difficult process since there are parameters which have dynamic values and the absolute results' precision is not feasible. However, the simulations' precision was enough for examining the roles of the Internet link technologies, EPR sizes and user requests (per LAN station) on the NEHRS performance.

Moreover the experiments helped us to understand that the Internet link technologies cause long delays during EPR exchange and almost half of the NEHRS response time comes from the encryption/decryption process which is necessary for the data security. On the other hand, the HL7 standard, necessary for having data interoperability, loads negligible time on the total NEHRS response time. Finally, the database size increases dramatically the NEHRS service time and therefore solutions should be found to resolve this.

Principles-Based Medical Informatics for Success – How Hong Kong Built One of the World's Largest Integrated Longitudinal Electronic Patient Records

Abstract

Since 1994, the Hospital Authority has been developing and deploying clinical applications at its constituent 41 hospitals and 121 clinics. The Clinical Management System (CMS) is now used by over 4000 doctors and 20000 other clinicians on a daily basis to order, document and review care. The territory-wide Electronic Patient Record (ePR) has given clinicians an integrated, longitudinal, lifelong view of a patient's record.

Today the CMS and ePR form an essential clinical and management tool to the Hospital Authority. The CMS handles two million clinical transactions per day, and the ePR has over 6TB of data covering 57 million episodes for 7.9 million patients.

This paper describes how the HA has taken a principles-based approach to Medical Informatics to achieve its success in the enterprise-wide deployment and deep utilization of a comprehensive clinical information system.

Keywords:

electronic patient record, medical informatics

Introduction

The Hong Kong Hospital Authority (HA) was formed in 1990 to manage all public hospitals in Hong Kong. Today the Authority manages a Head Office, 41 public hospitals/ institutions, 47 specialist clinics and 74 general (primary care) outpatient clinics. Each year in the HA there are over one million inpatient episodes, 2 million emergency attendances and 13 million outpatient visits.

Clinical systems in the HA

In 1990 the HA was essentially a "greenfield" site, with very little computerization of any sort, let alone clinical computing. From 1991 onwards HA developed its basic information technology infrastructure, including financial, HR, patient administrative and departmental systems. In 1994 the HA began developing the Clinical Management System (CMS), an integrated clinical workstation giving clinicians access to all available electronic clinical information as well as providing direct entry of orders and care or patient documentation [1]. The Electronic Patient Record (ePR) was developed in 2000 to provide both a standardized repository of all the clinical data collected throughout the HA, as well as a clinician-friendly view into a comprehensive longitudinal lifelong record. The CMS and ePR are integrated across all settings – inpatient, outpatient and emergency, and have also been the platform for development of all subsequent clinical modules, including modules for different clinical specialties, the allied health disciplines and nursing.

By the turn of the century, the CMS had already been rolled out to all HA sites, and today the CMS and ePR are an essential clinical and management tool, handling over two million clinical transactions per day. The ePR contains the records from 57 million episodes for 7.9 million patients in a repository of over 6TB (not including radiology images) and receives 300,000 views per day. The total expenditure on system development and implementation of the entire clinical informatics portfolio has been under US$200million.

The wave that never breaks

Such a wide and deep penetration of computerized patient records is far from the norm. Despite promises of the "paperless" or "electronic" hospital for over 30 years, comprehensive adoption of such systems has not materialized in most countries – electronic medical records are "the wave that never breaks" [2]. The seminal Institute of Medicine report on the Computer-based Patient Record [3] released in 1991 shaped the thinking of a generation of systems, but implementation remained low. A decade later another pair of IOM reports on medical errors [4] and quality systems in medicine [5] has stimulated a fresh round of interest in the electronic medical record as a key enabler for quality improvement and error reduction. Other potential drivers include consumerism and the rise of personal health records [6] (PHRs), and estimates of positive returns from investments in electronic records, both at the institutional [7] and national levels [8].

Perhaps the age of ubiquitous clinical computing truly is imminent. However there are many indicators that a long

and hard road remains ahead. The Annual HIMSS Leadership Survey has shown an striking incongruence between intent and achievement in installing electronic medical record systems. In 2003 the survey showed that 19% of healthcare organizations in the US had fully operational electronic medical record (EMR) systems, and that 32% had begun installation. [9] In 2006 the same survey found that 24% now had fully operation EMR systems, and 42% had begun installation. [10] That is to say, in the last three years only a 5% increase in fully operational systems was seen.

Outside the US, some very well funded high profile national initiatives (such as the UK's £6billion Connecting For Health [11] and Canada's C$1.2billion Health Infoway [12]) are making headway, but are still years away from a nationwide EMR implementation at both hospital and outpatient settings.

So why is that in Hong Kong, with its comparatively modest expenditure on health IT, the wave has apparently broken? Success in clinical information systems is multifactorial [13], [14] and without doubt the nature of the healthcare system in Hong Kong and the leadership of the HA have played a major role. However this article will focus on one aspect that has been constant throughout the history of clinical systems development in Hong Kong – the integration of medical informatics into the leadership and execution of the clinical systems programme, and a consistent adherence to certain key principles and processes throughout this period.

Seven principles for medical informatics success

The customer is always right (well, almost)

This old adage from the retail industry is of course not to be taken literally, but points to the reality that meeting clinician needs is paramount [15] and that clinician resistance is often the critical factor leading to the failure of clinical system [16]. Focusing on the needs of the customer has always been of prime importance in clinical systems development in the HA. But to meet the needs of our customers, we must know who they are.

The clinicians using the system for care delivery are obviously the most direct customer. However, clinical and executive management, policy makers, payers, researchers and ultimately the patients are all customers of the clinical systems. To fully engage this large body of stakeholders in a manageable fashion, the HA has instituted formal Clinical IT Governance structures and processes. The key governance committee is the Clinical Informatics Program Steering Group (CIPSG), comprising nominated representatives from different hospitals, specialties, corporate areas and other constituencies. Each representative chairs a working group that looks at the detailed needs of that constituency, and reports back to CIPSG. The CIPSG in turns reports up to the board-level IT Governance Committee (ITGC).

The Health Informatics Team in close collaboration with the IT division runs the Clinical Informatics Program Office (CIPO), which is the executive arm of the CIPSG, and all developments, enhancements, collaborations and other activities are filtered through CIPO.

This constitutes the complete "top down / bottom up" approach to customer engagement in the HA, from detailed consideration of needs at the working groups and CIPO, to implementation decisions at CIPSG, to investment and strategic decisions at ITGC – with constant coordination and communication between the levels of governance (figure 1).

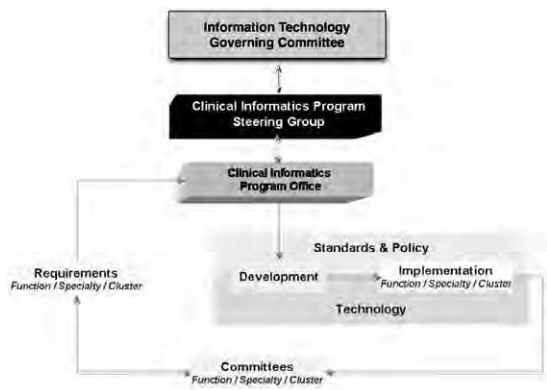

Figure 1 – Clinical Systems Governance Process

Win - win (and win - win)

It is often easy to create a IT-based program that provides benefits to patients or the organization, but at a cost to the clinicians asked to implement the program - often in the form of extra work, changes in process or simply loss of flexibility. Avoiding this problem by ensuring systems benefit, or at least are cost-neutral, to all stakeholders is vital to ongoing success. The four wins in this section heading refer to the four major stakeholder groups – 1) clinicians, 2) patients, 3) management and other secondary data users and 4) health informatics and ITD who need to ensure integrity of data and architecture.

Key considerations in enabling common benefits are: can the needs of individual clinicians be met with a standardized system? Can structured data be captured by clinicians at the point of care without using more time and impinging on clinical autonomy? Can the system adjust for different practices and workflows? Can the data gathered by the system flow onto management, quality assurance and other such uses?

The next two principles have been the key to answering these questions in the affirmative.

One step at a time (success breeds success)

In the complex domain of medical informatics it is extremely difficult, if not impossible to envisage a comprehensive solution to any problem de novo, and it is safe to assume that unexpected issues will arise [17]. In the HA "big bang" implementations are avoided wherever possi-

ble in favor of a rapid prototype design cycle, followed by one or two pilot sites with evaluation and redevelopment where necessary, followed by phased rollout to the rest of the organization.

Success stories are vital to the long-term health of clinical IT, and taking small steps allows continuous demonstration of success, developing a cadre of clinicians who have seen the benefits and understand the issues. A stepwise approach has also allowed us to make our mistakes earlier and on a smaller scale, providing continuous learning whilst minimizing the risk of catastrophic failure.

Medicine is an art and a science (and so is medical informatics)

Clinical systems sit at the uneasy interface between the vagaries of human biology/disease and the scientific requirements of quality management and evidence based medicine. There is a constant tension between the need for standardized, codified data and the clinical requirements for flexibility and expressivity. It has been shown that acceptance of structured entry is not uniform [18] and in the HA the optimum balance between the two is a key decision for any new module.

Although the degree of structure is negotiable, the way the data is codified is not – all systems must conform to the standards laid down in the HA's Information Architecture [19]. However the design of systems must always try to allow for flexibility whilst preserving structure.

Use it or lose it (data use begets data quality)

In the HA environment there are tens of thousands of users of varying levels of IT sophistication entering data from a variety of modules in different clinical settings. How do we ensure the quality of this data? The main strategy taken in the HA is to reuse the data wherever possible – "write once, use many".

One obvious reuse of data is secondary uses, such as quality management, planning and analysis. Where clinicians run their own quality or analysis programs they will soon see the need for good data, and we have developed sophisticated, clinician friendly data mining tools to allow clinicians to run their own ad hoc queries on the massive data warehouse that has accrued over the years.

However opportunities also abound for reuse of data in direct clinical care. The medications list on a discharge summary can be copied from the discharge prescription. The reason for doing a test can be drawn from the problem list. Key lab results can be automatically copied into a diabetic documentation template. Data reuse of this sort is a form of semantic interoperability – albeit *within* but not *between* complex clinical systems environments – and the Information Architecture provides the framework and standards to support this reuse.

Prioritize ruthlessly (first things first)

In the early days of clinical systems in the HA, overcoming clinician resistance and finding areas of benefit were of prime importance. However as a critical mass of "informatics aware" clinicians developed, there was fairly sudden switch from an informatics-driven "push" of clinical systems to a clinician-led "pull" of additional requirements. Today there are far more requirements than can be met by available resources, in terms of functionality, hardware or support for specific clinical initiatives.

Demand management is now crucial, and all requests must be evaluated, developed and either discarded or moved up the governance chain until the appropriate level is reached where a yea or nay decision can be made. At each level of governance evaluation criteria and processes have been put in place to enable an equitable approach which takes into account the needs of patients, clinicians and the organization as whole.

Embrace your Informaticians (and feed them well)

Implementing sophisticated clinical systems is a difficult endeavour, and there is no shortage of literature examining stumbling blocks [20], problems [21] and case studies of failure [22].

The principles listed in this paper all require constant attention, and a team that is able to navigate between clinical and organizational needs, technical limitations and possibilities, standards and architectures, policies and guidelines, change and demand management, and to do this over long time periods. In the complex HA environment, and in any large care delivery setting, this is not a task that can be done properly without dedicated, trained informaticians.

Conclusion

Healthcare operates in a sea of change – social, environmental, scientific and technological change. Electronic medical records are an increasingly important tool to enable healthcare delivery organizations stay afloat and perhaps prosper, but they can only do so with the necessary commitment, skill sets and a adherence to disciplines such as have been presented in this paper.

Acknowledgements

We would like to thank the members of Clinical Informatics Program Steering Group and all many others at the Hospital Authority who have contributed their time and efforts to shaping the CMS and ePR.

Knowledge-Level Querying of Temporal Patterns in Clinical Research Systems

Martin J. O'Connor[a], Ravi D. Shankar[a], David B. Parrish[b], Amar K. Das[a]

[a]*Stanford Medical Informatics, Stanford University, Stanford, CA, USA*

Abstract

Managing time-stamped data is essential to clinical research activities and often requires the use of considerable domain knowledge. Adequately representing this domain knowledge is difficult in relational database systems. As a result, there is a need for principled methods to overcome the disconnect between the database representation of time-oriented research data and corresponding knowledge of domain-relevant concepts. In this paper, we present a set of methodologies for undertaking knowledge-level querying of temporal patterns, and discuss its application to the verification of temporal constraints in clinical-trial applications. Our approach allows knowledge generated from query results to be tied to the data and, if necessary, used for further inference. We show how the Semantic Web ontology and rule languages, OWL and SWRL, respectively, can support the temporal knowledge model needed to integrate low-level representations of relational data with high-level domain concepts used in research data management. We present a scalable bridge-based software architecture that uses this knowledge model to enable dynamic querying of time-oriented research data.

Keywords:

clinical trials, temporal querying, knowledge-based systems, Semantic Web, ontology

Time in clinical research databases

Relational databases have become an essential part of biomedical research projects needing to maintain, integrate and share data. In biomedical research projects ranging from clinical studies to genomics research, relational databases are typically used to store data and custom queries are written to extract subsets of the data into specialized tools to support study management and focused analyses. A serious shortcoming of this approach is that the data-processing steps are often customized to a particular analysis and database and thus do not generalize to other research projects. By its nature, however, the standard relational model does not adequately support important biomedical domain concepts, such as hierarchies and time; thus, the link between domain knowledge and data representation used in database querying is often implicit. The lack of support for temporal information on research study design (such as longitudinal patient observations or time-course experiments) at the database level can limit the investigation of causal phenomena that are central to biomedical research.

As a result, there is a critical need to provide querying methods that can operate at the *domain knowledge* level rather than the *database schema* level. To address this problem, we have developed end-to-end methodologies and a software architecture that permit design-time encoding and execution of temporal patterns needed for clinical research management. Our approach consists of three knowledge-based components: a temporal ontology, a temporal pattern specification language, and a database mapping tool. The design of these components is driven by the needs of the Immune Tolerance Network [1], a collaborative clinical research organization focused on developing new therapeutics in immune-mediated disorders. Our methodology bridges the gap between clinical-trial specification and clinical-trial implementation, which enhances compliance monitoring and data analysis within this research environment.

Knowledge and database disconnect

Many clinical research systems have significant requirements for the querying and management of temporal data. Trial design and compliance monitoring tasks, for example, typically revolve around evaluating temporal patterns among data. Example patterns (found as free text in a study design document) include: "Visit 3 for a participant must occur with three weeks of visit 2," "clinical assessments are required twice a week until day 28 or discharge from hospital," and "test is scheduled on weeks 4, 6, and 8 during treatment." When encoding such patterns, developers may face two types of disconnect between the initial specification of these patterns and their execution.

First, there can be a knowledge specification disconnect. Constraints are typically expressed as unstructured free text throughout a study design document. Their interpretation is heavily dependent on the context of the research protocol being encoded. Even core terms—such as, for example, a definition of participant visit—can be poorly specified. Is a visit a single encounter between a participant and a provider, or can it span several encounters? If it can span several encounters, what is the exact definition of the visit end? Producing a precise definition for a constraint can thus be difficult. In addition, the unstructured

Selected for best paper award.

constraint specification process can also result in gaps in the final specifications.

Second, there can be a database specification disconnect. Constraints are usually encoded in terms of data that is collected during a study's execution. These data are often stored in relational databases. The schema design of the databases often reflects the operational requirements of the study managers whose activities were not defined within the research protocol document. Constraints can thus be encoded at a level that is at least one step removed from their initial specification, with a consequent loss of precision. This difficulty is compounded by the fact that developers may not have direct access to the protocol authors. A related problem is that constraints may only be checked after data has been entered into a database and not when the data is collected, allowing non-compliant data to enter the system. As a result of these disconnects, the encoding and implementation of protocol-specified constraints as temporal patterns may not reflect the intentions of the designers. The quality of the trial data can thus become seriously compromised, which may not be noticed until the final stage of analysis.

Methods

To overcome these types of disconnect, we apply existing knowledge representation and temporal relational methods.

Knowledge representation language

Our approach relies on using the standard knowledge specification methods for the Semantic Web. The Semantic Web is a shared research plan that aims to provide explicit semantic meaning to data and knowledge on the World Wide Web [2]. The Web Ontology Language (OWL) has been designed as the language of the Semantic Web. OWL can be used to build ontologies that provide high-level descriptions of Web content. These ontologies are created by building hierarchies of *classes* describing concepts in a domain and relating the classes to each other using *properties*. OWL can also represent data as instances of OWL classes—referred to as *individuals*—and it provides mechanisms for reasoning with the data and manipulating it.

OWL provides limited deductive reasoning capabilities, however, so recent work has concentrated on adding rules to it. The Semantic Web Rule Language (SWRL) allows users to write Horn-like rules that can be expressed in terms of OWL concepts and that can reason about OWL individuals. SWRL provides deductive reasoning capabilities that can infer new knowledge from an existing OWL ontology. We recently developed the first SWRL editor [4]. It was written as an extension to Protégé-OWL [3], an open source framework that provides a suite of tools for constructing OWL domain models and knowledge-based applications. Our editor permits interactive creation, editing, reading, and writing of SWRL rules. We have also developed one of the first systems supporting inference with SWRL rules using the Jess rule engine.

Temporal relational model

Most modern clinical research systems store data within relational databases, which provide a well-defined data model and query language. However the relational model provides poor support for storing complex temporal information. For example, if a database row contains some temporal information, there is no indication as to the relationship between the timestamp and the non-temporal data in the row. Does the timestamp refer to the point at which the information was recorded, or to the point at which it was known? Other shortcomings include no standard way to indicate a timestamp's granularity, no support for automatic coalescing or merging of temporally overlapping data, and no standard means of writing queries with relative times or that refer to the current time [5].

Several proposed extensions to the relational model address these shortcomings. Most have focused on *valid-time* model [5-7, 9]. In this model, all facts have temporal extent and are associated with instants or intervals denoting the times that they are held to be true. When this model is used in a relational database temporal information is attached to all rows in a temporal table. This approach effectively adds a third dimension to two-dimensional relational tables. In these tables, every tuple holds temporal information denoting the information's valid-time. Conceptually, this representation means that every tuple is held to be true or valid during the time or times associated with this tuple. This consistent representation of temporal information allows standard temporal operators top be applied consistently and greatly simplifies the temporal reasoning task. Several SQL extensions have been developed that support these operators [6, 7].

Results

We used OWL and SWRL to develop a valid-time temporal model to support methods for temporal constraint specification in a protocol tracking system. We also developed a set of mapping tools to allow the use of this model with existing relational data. A knowledge-driven architecture was then implemented to support the efficient deployment and execution of system components.

Temporal ontology

We have encoded a temporal model in OWL [8] based on the valid-time temporal model. The core class modeling this association in the OWL ontology is called `Extended-Proposition`. This class models information that extends over time. It has a property called `hasValidTimes` that holds the time(s) during which the associated information is held to be true. This property is modeled by an abstract class called `ValidTime`, which has subclasses `ValidInstant` and `ValidPeriod`. `ValidInstant` has the property `hasTime`, and `ValidPeriod`, has the properties `hasBeginning` and `hasFinish`. These classes represent instants and intervals, respectively. Valid times also have granularities associated with them. Named points in time—often called *anchor points*—can be modeled as subclasses of the `ValidInstant` class. Temporal durations are

modeled using a `ValidDuration` class that holds a count and a granularity.

There are two types of extended propositions in the model: (1) *extended primitive propositions*, which represent data derived directly from secondary storage; and (2) *extended abstract propositions*, which are abstracted from other propositions. They are represented by `ExtendedPrimitiveProposition` and `ExtendedAbstractProposition`, respectively, in the temporal ontology. The extended primitive and abstract proposition classes can also hold a value in addition to its valid times. This value is denoted by the `hasValue` property. The value is any XML Schema data types, such as strings or integers.

These extended propositions can be used to consistently represent temporal information in ontologies. For example, a set of visits in a protocol tracking application can be represented by defining a class called `Visit` that subclasses the extended proposition class. It inherits the `hasValidTime` property from that class, which holds its visit times. Similarly, an extended primitive proposition can be used to represent a drug regimen, with a value of type string to hold the drug name and a set of periods in the valid time property to hold drug delivery times. These extended propositions can then be associated with a class using OWL properties.

Once all temporal information is represented consistently using the temporal ontology, SWRL rules can be written in terms of this ontology. However, the core SWRL language has limited temporal reasoning capabilities. A few temporal predicates called *built-ins* are included in the set of standard predicates, but they have limited expressive power. Fortunately, SWRL provides an extension mechanism to add user-defined predicates. We used this mechanism to define a set of temporal predicates to operate on temporal values. These predicates support the standard Allen temporal operators [10].

Using these built-in operators in conjunction with the temporal ontology permits expression of complex temporal rules. For example, in modeling visits in a protocol as extended propositions and the start of treatment of a participant as an anchor point, a new SWRL rule can indicate that a second visit in a particular protocol must occur within two weeks of the start of treatment anchor, as follows:

```
Participant(?p) ^ hasVisit(?p, ?v) ^
V2(?v) ^ temporal:hasStart(?v, ?startV2) ^
hasAnchor(?p, ?a) ^ StartOfTreatment(?a) ^
temporal:hasTime(?a, ?sot) ^
durationGreaterThan(?sot, ?startV2, 2, weeks)
-> NonConformingPatient(?p)
```

Temporal pattern specification

Our efforts to model clinical trials is driven by the needs of the Immune Tolerance Network (ITN; [1]), which develops new therapeutics for immune-mediated disorders. In collaboration with ITN, we have created a knowledge-based architecture (called Epoch [11]) to support the management of multi-site clinical trial protocols and the discovery of common tolerance mechanisms across multiple trials. We have focused our efforts on developing participant and sample tracking models [11], both of which must specify complex temporal constraints at the knowledge level. To meet this need, we used the temporal ontology to model the temporal dimension of core components in the model and then analyzed a range of ITN's protocols to determine the types of temporal constraints required by protocols and if our model could represent them.

In principle, SWRL rules could be used to express all constraints within the protocol tracking application. However, while relatively concise, SWRL rules are not suitable for non-specialists. As a result, we decided to define a high-level user-friendly constraint language to allow ontology developers to encode constraints at the domain level. These constraints are then mapped automatically to SWRL rules at run time.

The constraint language allows times to be specified as absolute or relative times. For example, an indication that something must start within two weeks of a start of treatment anchor is `SOT + WEEKS(2)`, where SOT is the name of the start of treatment anchor, to which an offset of two weeks is added. Offsets can be positive or negative and can be combined at different granularities. Offsets correspond to durations in the temporal model may also be referred to as such. For example, an offset of one month and two days can be specified as `MONTH(1) + DAYS(2)`.

In addition to named anchors, the constraint specification language can work directly with temporal propositions. So, for example, if visit number two is modeled as an extended proposition subclass `V2`, a constraint can refer to its start time as `V2.hasBeginning`. This syntax could, for example, express the expect start time of a third visit as a two month offset from the end of visit two as `V2.finish + months(2)`.

Temporally constrained entities in the protocol model are modeled using a *plan* that can hold temporal constraints specified in the constraint language. This class is modeled using an OWL `Plan` class and has a number of properties that can specify the expected temporal behavior of the associated protocol entities:

expectedStart The time the protocol entity is expected to start. This is specified using the constraint language.

expectedStartVariance The temporal uncertainty of the start time. This is expressed using constraint language offset clauses, *e.g.*, `WEEKS(2)`.

expectedFinish, expectedFinishVariance End time specifications for an entity.

expectedDuration How long this entity is expected to last. Specified using duration clauses, *e.g.*, `DAYS(2)`.

expectedCycles Used for cyclical specifications to indicate the number of times the entity is expected to repeat and the intervals between repetitions.

A plan class also has two properties that hold run-time time values for the protocol entity. These properties—called actualStart and actualFinish—can be compared against expected values when validating an entity for compliance. Using plan specifications in conjunction with the constraint language allows us to express a large range of constraints for protocol entities, which can be mapped to SWRL rules for execution.

Database mapping

In principle, developers could take biomedical data in an existing relational database, develop an ontology to describe those data, and then convert the data into a knowledge-based form for all future processing. Apart from the significant development effort involved, this solution does not scale well. Current ontology-specification tools, such as Jena or Protégé-OWL, do not support high data throughput. For large data sets, an alternate mapping solution is needed. We have developed a customized mapping tool, called Synchronus [12, 13], that supports both a direct relational-to-OWL mapping and also a lightweight mapping mechanism for large data sets. This tool maps relation data described in terms of the temporal ontology to OWL individuals. Essentially, it creates extended propositions from time-stamped relational data. It also supports the reverse mapping of extended propositions to relational data.

Two OWL ontologies are used to drive Synchronus: (1) a *schema ontology*, which is a knowledge-level description of a relational schema; (2) a *mapping ontology*, which describes how relational data are mapped to extended propositions. The schema ontology describes the structure of one or more databases that will be mapped. It contains descriptions of the tables in the database, such as the names of types of columns in those tables. The mapping ontology uses this schema ontology to describe the relational or temporal-relational tables to be mapped. Every extended proposition in the temporal model has an optional input and output storage descriptor. The descriptor uses the schema ontology to point to data that is stored in a database. Synchronus uses this descriptor to perform run-time transformations of the data between rows in a relational database and OWL individuals.

The direct relational-to-OWL data-mapping method has two main modes of operation: batch mode, where an OWL knowledge base is fully populated with relevant data from a database, or a database is populated from an OWL knowledge base; and dynamic mode, where propositions are mapped on demand. The latter mapping mechanism reads and writes objects represented by extended propositions without creating OWL individuals.

Bridge architecture

We have developed a bridge architecture to support the integration of relational databases and reasoning methods into a knowledge-driven system. The Figure shows a schematic of the architecture and its five main components: (1) a knowledge base; (2) a relational database; (3) Synchronus; (4) a method; and (4) the bridge itself. A bridge is a customized method to provides a specific computational task through the integration of one or more existing knowledge sources (such as an OWL knowledge base); data sources (such as a relational database); and data-processing mechanisms (such as a rule engine). The bridge resolves low-level differences of how these software components interact with each other through the communication of data and knowledge. A deployed bridge may work with several databases, methods, and, potentially, knowledge bases.

Each bridge is driven from its associated knowledge base. The knowledge base contains a number of ontologies that are used in deploying the bridge: (1) a *method ontology*, which describes at a high level the analytic method or methods being used; (2) a *mapping ontology*, which is used by Synchronus to map relational data; and (3) a *domain ontology* that describes the underlying application domain.

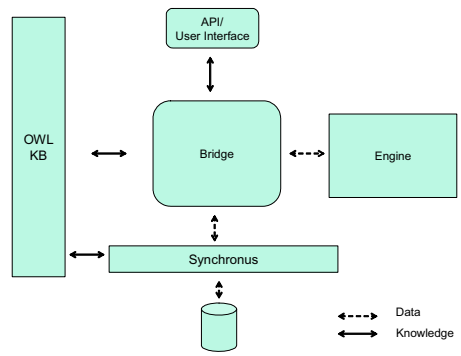

Figure 1 - Bridge architecture. Schematic showing how a bridge is deployed to isolate an existing analytic method (rule engine) from details of both an OWL knowledge base and an existing relational database, accessed through Synchronus

To support the validation of temporal constraints for clinical-trial management at ITN, we have developed a bridge architecture that provides the infrastructure necessary to incorporate rule engines into Protégé-OWL and execute SWRL rules specified in the knowledge base. The bridge provides a mapping layer that generates as input into the rule engine representations of all rules and relevant OWL classes, individuals and properties. A target rule engine implementation takes in these representations and implements them in the rule engine's native format.

Providing efficient data and knowledge access techniques is a central goal of our bridge design and implementation. For example, when translating OWL knowledge into an intermediate form, instead of transferring all knowledge in a knowledge base, only potentially relevant knowledge is represented. The bridge examines each SWRL rule and only represents OWL classes, properties and individuals that are referenced by those rules. Such references can be indirect, so the bridge must traverse the interrelationships between all OWL concepts mentioned in SWRL rules to ensure completeness. This step significantly reduces the amount of knowledge that needs to be reasoned with by a

rule engine and can ensure significant performance benefits.

Another optimization technique relates to data access. Extended propositions used in rules may be held in databases and accessed through Synchronus. SWRL rules can operate on these propositions using temporal built-ins. There is a fairly direct mapping from SWRL rules with temporal propositions to valid-time queries. This parallel structure can be exploited by the bridge to optimize its data access. The bridge examines each SWRL rule with temporal operators and looks for operators that temporally restrict the range of propositions. For example, if a temporal operator restricts the range of a proposition to dates after a particular time point, only data after than time will be requested from Synchronus. Because SWRL rules do not have disjunctions, this optimization process is not elaborate.

In our clinical trial management architecture for ITN, we currently use an implementation that invokes the Jess rule engine [3]. Our Jess implementation for a rule engine bridge employs the temporal built-in library for SWRL that we have presented and automatically undertakes the mapping of data and knowledge for knowledge-level querying of specified temporal patterns in a relational database.

Discussion

The gap between the specification of a study protocol and the management of resulting data can often be quite significant in clinical research systems, such as clinical trial management applications. To help close this gap, we have developed a set of end-to-end general methodologies for specifying and executing temporal patterns at the knowledge level rather than the database level. Our approach demonstrates that proposed Semantic Web standards for ontology and rule representation, OWL and SWRL, respectively, can support the knowledge model needed to integrate temporal representations of relational data with the domain-specific semantics needed to reason with them for biomedical and healthcare applications.

In contrast to previous work on constraint specification in clinical trials [14-15], our set of methodologies addresses the knowledge and database disconnect that exist in clinical research systems. Our approach requires that all relevant temporal knowledge on a study protocol and its corresponding data representation be encoded within an OWL ontology, which allows the uniform specification of temporal patterns in knowledge-level querying. Our bridge architecture supports robust optimization techniques to ensure that encoded constraints are automatically translated into an executable form at run time and are efficiently validated against study data held in an existing relational database.

Department of Health, Beijing 100050, P.R. China
[b]*School of Information Systems and Technology, Faculty of Informatics, University of Wollongong, Australia*

Abstract

This paper introduces the current status of data sharing in the People's Republic of China. It discusses barriers to data sharing and proposes three key solutions to overcome these barriers in China. The establishment of national laws and policies for data sharing is considered the key prerequisite to ensuring the successful implementation of resource sharing activities in public health. Driven by established laws and policies, the relevant operational models should be developed. It is also important to have strategies in place to ensure the established laws and policies are implemented by various organizations in different jurisdictions. These discussions are supported by relevant local and international evidence.

Keywords:

data, data sharing, public health, law, policy, implementation

Introduction

Scientific data is the original measurement or characteristic of a person or thing that is collected from various scientific activities, or extracted from databases or data warehouses by various data mining techniques. It may be 'a clinical measurement, a laboratory record, a medication dosage, or even a listing of treatment'.[1] Only after scientific treatment to comply with certain data standards of the relevant regulation bodies can data be used effectively for various public health purposes. 'Data are an expensive and valuable resource. Data have market value; they represent a revenue stream for many academic and governmental agencies'.[2]

The essence of sharing public health data involves the sharing and publication of information. Data sharing among organizations is important for (1) developing an essential information infrastructure that supports public health services and functions; (2) reducing duplication of effort in data collection and increasing the usability of the data that has already been collected; (3) providing information effectively and efficiently to inform public health policy and management decisions; (4) improving communication and standardization of core procedures and assessment to facilitate best practice in health care[3] and (5) realizing the scientific, economic and social value of scientific data. Therefore, to benefit society, the data stored in various databases owned by various departments and jurisdictions should be open to the public.

This paper will focus the current status, challenges and prospects of data sharing for public health. First, it will introduce the current practice of data sharing in China. It will then discuss the challenges to this data sharing in China. Finally, through a comparison of the practice of several countries, it proposes three essential strategies to overcome the barriers encountered.

The current practice of data sharing in the People's Republic of China

A significant amount of data has been collected in China. According to statistics, there are several billion bytes of scientific data collected by various levels of government departments and scientific research organizations sponsored by the government. The three major sources of these data include: (1) the administrative data collected by the health administrative organizations; (2) the scientific data generated from the scientific activities undertaken by staff in research, business and management organizations funded by government; and (3) the scientific data generated from scientific or productive activities undertaken by privately owned scientific, business, education or health organizations. These data are scattered in the databases of various organizations located in different jurisdictions. Although there is a critical need to compare these data to support public health research and policy making, the differences in data elements, the method of collection, the coding system and the structure of database tables that store these data etc. make comparison of these data impossible. As these heterogeneous, incompatible data are not readily usable for statistical analysis and reporting, they have rarely been published, despite the significant effort and resources spent in collecting them.

In recent years, the importance of data sharing has been emphasized by the Central Government in China. After a two-year, continuous, persistent effort, the Department of Health has gained considerable experience in the development and establishment of data-sharing policies. The Department of Science in China has implemented a scien-

tific data-sharing project to establish a platform to facilitate the sharing of scientific data. To date, more than 600 databases of varying size and quality have been established. Meanwhile, resources have been invested in digitizing the original paper-based data and establishing various databases to store these data. Some organizations that own these databases have initiated data-sharing services, which have resulted in some social benefits. However, the level and scope of scientific data sharing in China is still very limited.

There are many barriers to effective data sharing and the following section will discuss these barriers. Then, three essential strategies are proposed to overcome these barriers in China.

The barriers to sharing scientific data in China

Scientific data sharing in China is yet to break away from the custody of departments in various jurisdictions. The appropriate technology and model is yet to be developed for large-scope data sharing, the integration of heterogeneous data, and the distribution of collaborations to researchers and policy makers. To date, there is no network-based platform that is able to provide data services for clients in different regions that is underpinned by technology services, effective support mechanism and quality assurance.[3] The identified challenges fall into one of the following four categories: (1) a lack of laws and policies to guide the practice of data sharing; (2) a lack of coordination of effort, which leads to numerous isolated data sources that cannot communicate with each other; (3) a lack of an enabling structure and operational mechanism to sustain data-sharing services; and (4) a lack of a culture of sharing data. The following sections will provide a detailed explanation of each of these four categories.

A lack of laws and policies to guide the practice of data sharing

'Laws provide the mission, functions, and powers of public health agencies, set standards for their actions, and safeguard individual rights … They are an essential tool for improving public health infrastructure and outcomes.'[5] Therefore, the establishment of laws and policies are prerequisites for achieving data sharing for public health. However, the relevant data-sharing policies, the standards for data exchange, quality assurance and information services, and the relevant terminology and classification system have yet to be developed in China. Without the above regulatory protections, the owners of the relevant databases will not give end users access to databases to download data for the purposes of scientific research, disease prevention and control. If they are lucky, these end users can acquire a very limited amount of data, such as abstract of a publication. Conversely, the utilization rate is poor for databases established through public funding, which is a waste of public investment.

A lack of coordination of effort, which leads to numerous isolated data sources that cannot communicate with each other

Different levels of government and their departments have their own needs and targets for data collection and storage. Currently, there is no mechanism to achieve collaboration on data sharing among local, provincial and central governments. The reasons for this are similar to those identified in Canada: 'unclear constitutional roles and responsibilities for public health and the potential for disputes to arise over funding and data sharing'.[6] As in Australia,[7] there is a lack of national vision or a mechanism to implement data sharing. The consequences are duplicated effort and overlap in data collection, and the establishment of numerous heterogeneous databases at central, provincial, city and county levels of government departments and the private sector. Therefore, interoperability and data sharing among information systems is not possible.

A lack of an enabling structure and operational mechanism to sustain data sharing services

Data sharing is a process of social system engineering that needs the coordination of government departments in various jurisdictions. The limitations of the current government organizational structure in China mean there is a serious lack of communication between organizations in various industry sectors. This lack of coordination in information management has led to an inability to identify the availability, place of storage, ownership, accessibility, scale and scope of data stored in a database. Although a national identification system has been established for public servants, currently the system does not include the increasing number of employees in the private sector and farmers. In addition, there is no common data exchange standard that clearly defines how the organizations should share data with each other. [8] Therefore, it is difficult to link two information systems together. Even when two information systems are connected, it is challenge to integrate their data as these data are captured in different formats and semantics.

A lack of a culture of sharing data

As in Australia,[7] there is a lack of incentives for data sharing among the different levels of government without direct reporting relationships. To share data among organizations, an inter-organizational information network should be established to link data sources within organizations. This novel model of information networking challenges the traditional organizational structure and ownership of data in China. Therefore, its implementation will only be possible after significant organizational cultural change has been achieved.

In the following section, we will propose three essential strategies for overcoming the barriers discussed and facilitating scientific data sharing in China.

Our proposed solutions to overcome the barriers for scientific data sharing in China

We believe the following five key factors have to be satisfied before sharing of scientific data can be realized: data sources, data organization and management, regulations about data sharing, the development of technology to enable data sharing, and the interaction between these four factors. Therefore, to overcome the barriers for data sharing and optimize the benefits of these scientific data to the public, three key strategies are proposed: (1) the establishment of laws and policies for sharing data for the sake of public health (this action should take into consideration the culture and political structure in China); (2) the development of a comprehensive data-sharing mechanism that is guided by established laws and policies; and (3) the establishment of a mechanism to safeguard the implementation of the laws and policies. The following sections will discuss these three strategies in detail.

The establishment of laws and policies for data sharing in the context of China's culture and political structure

For the purpose of establishing an effective approach, the experiences of foreign countries should be examined if these countries have already taken action to achieve data sharing and interoperability in health care. For example, the Turning Point Model State Public Health Act in the USA has established clear definitions about the acquisition, use and disclosure of identifiable health information, security safeguards and fair information practices.[5] In Britain, the use and sharing of personal information in the public sector is governed by a number of laws including (1) the law that governs the actions of public bodies (administrative law); (2) the *Human Rights Act 1998* and the European Convention on Human Rights; (3) the common law tort of breach of confidence; (4) the *Data Protection Act 1998* and (5) the European Union law.[9] There are laws that define information management practice in either the public or private sectors in Australia. Canadians have also established their code of practice.[10, 11] However, as cautioned by Hodge *et al.,*[5] 'reforming public health laws is a delicate process that involves good timing, political will, and willingness to compromise'. Therefore, the Chinese political, social, cultural and organizational context has to be carefully considered, and the relevant stakeholders have to be thoroughly consulted when establishing laws and policies.

Data sharing can only be realized through negotiation between the organizations or stakeholders who own the data. Therefore, an adequate security protection mechanism has to be in place to ensure the scientific data owned by various entities will only be made available to the general public after the explicit consent of these entities. The legislation should clearly define the intellectual property of the owner(s) of the data. The interests of various stakeholders (such as individuals, organizations and society), should be appropriately balanced; whereas the information related to national security and commercial confidentiality should be adequately protected.

Before the establishment of such national laws and policies, different jurisdictions or industries could establish their own short-term policies or regulations for public health data sharing. Only through such practice could data sharing be achieved and scientific evidence acquired through analyzing these data. Such evidence will, again, support scientific research or management decision-making.

The development of a comprehensive public health data-sharing model that is guided by laws and policies

The fundamental requirement for public health data management is the proper configuration of these data to maximize their potential in serving the society. The federal governments in Australia, Britain and Canada have taken the lead in their efforts to establish a national health information network for sharing health care information across the continuum of care.[12, 13, 14] It is proposed that the Chinese Central Government should take the leadership and coordination role and provide incentives to encourage various organizations, such as various levels of health departments and public and private health care organizations, to collect and share data.[15]

An incremental update model[6] that uses a five-step implementation may be useful in achieving data sharing in the short term. Baker[6] defined the five steps as (1) the data authority is identified; (2) data are consolidated/redistributed: making sure the authority has the data; (3) the data authority allocates a persistent identifier for each feature within each theme; (4) data are redistributed: the data authority redistributes data with identifiers attached; and (5) incremental updating of the whole process. As mentioned previously, a national identification system has been established for public servants. This is in the process of being extended to the general public, including the rural population.

The best scenario is the complete publication of scientific data after acknowledging and protecting the intellectual property of its owners.[16] Of course, appropriate compensation should be given to the owners of these data to provide incentives for them to share data. The relevant regulations should also be established to define the rights and responsibilities of the providers of public health data, as well as the end users of these data. A possible definition might be: if a customer is an end user of the data, they have no right to redistribute the data; whereas the data provider should share authorship with the end user in the publications that result from the data sharing. Whether the data leads to a product for the end user or not, the data provider should always be given financial compensation to maintain the data-sharing system.

The establishment of structure and process to enforce the implementation of laws and policies for data sharing

Necessary mechanisms should be in place to enforce the implementation of laws and policies for data sharing. In fact, China has established a comprehensive primary health care network from village to town to county to province.[17] The system was established in the early 1950s based on the former Soviet Union model of epidemic pre-

vention and education, with focus on the hygiene and prevention.[17] This network has played an important role in controlling and preventing infectious diseases for the past 50 years. It will also be an effective structure to enforce the implementation of laws and policies for data sharing once these laws and policies are in place. The China CDC has established a four-tiered network of disease control (centrality, province, city and county) that is managed at different levels. In addition, the China CDC has close working partnerships with non-government organizations such as the Chinese Medical Association, the Chinese Preventive Medicine Association and the Chinese Epidemiological Association.[17] Therefore, the structure for public health data-sharing management and services already exists.

The experience of other countries in this area can also be valuable. For example, to enhance public servants' understanding of the country's complex legal framework, the Department for Constitutional Affairs (Justice, Rights and Democracy) published *Public sector data sharing: guidance on the law* in 2003 as a map to guide the practice of data sharing in Britain.[13] In the USA, the implementation of environmental justice at the federal level was matched by state programs.[18]

Conclusion

In summary, any complex social problem can only be solved by following certain laws and policies. In addition, any creative theory and strategy can only be implemented after following certain procedures. The established laws, policies and procedures can only be effectively implemented after an adequate assessment, reporting and feedback mechanism is in place. Therefore, the establishment of sound laws and policies is the first step towards achieving public health data sharing. Afterwards, the implementation of the clearly defined laws and policies and a strong monitoring mechanism for this implementation will lead to improving data sharing for public health in China.

Abstract

Failure to supply a care provider with timely access to a patient's medical record can lead to patient harm or death. As such, healthcare organizations often endow care providers with broad access privileges to electronic medical record (EMR) systems. In doing so, however, care providers may access a patient's record without legitimate purpose and violate patient privacy. Healthcare privacy officials use EMR access logs to investigate potential violations. The typical log is limited in its information, so that it is often necessary to merge access logs with other information systems. The problem with this practice is that sensitive information about patients and care providers may be disclosed in the process.

In this paper, we present a privacy preserving technique that enables linkage of disparate health information systems without revealing sensitive information. The technique permits any number of vested parties to contribute to audit investigations without learning information about those being investigated. We motivate the protocol in a real world medical center and then generalize the protocol for implementation in existing healthcare environments.

Keywords:

privacy, confidentiality, computer security,
electronic medical records systems, medical record linkage

Introduction

In the mid-1990's the National Research Council of the United States concluded that electronic medical record (EMR) systems increase the potential for the inappropriate disclosure of a patient's health information to parties both inside and outside of healthcare organizations [1]. The commission recommended that healthcare organizations design and adopt policies, as well as technologies, to prevent and address intrusions. Following recommendations from the NRC and other studies, such as [2], state and federal regulations were enacted in the United States to regulate the transmission, privacy, and security, of electronic personal health information [3, 4]. Regulations safeguarding medical information have been enacted by many other countries as well, including member states of the European Union [5], Japan [6], and Australia [7].

Technological protections for personal medical information have lagged behind policy ratification, which is due in part to the complexity of the healthcare environment. Many off-the-shelf EMR systems are equipped with role-based access control (RBAC) [8], a common policy requirement. However, RBAC is rarely enforced at point-of-care because a lack of medical record availability can cause patient harm or death. Rather, hospitals tend to use a "break the glass" model: they endow care providers with broad access privileges, but stress that harsh punishments will result for system misuse [9]. Nonetheless, unauthorized accesses occur. For instance, since 2002, the University of California, Davis has fired at least six employees, demoted one, suspended one without pay, and retrained eighty for inappropriate accesses [10].

System misuse is discovered through audits of medical records access logs. A recent survey found that 28 of 28 EMR systems incorporate audit capability [8]. Yet, only 10 of the systems alert healthcare administrators of potential violations. A principle challenge is that EMR systems do not always contain the necessary information to characterize violations. Oftentimes, it is necessary to gather information from other information systems. However, these systems can be controlled by different facets of the organization with diverse privileges and proprietary knowledge.

An EMR audit paradox

Consider the following example. The Vanderbilt University Medical Center (VUMC) is a large healthcare organization with a centralized EMR system. The EMR access log documents each medical record viewed, including a timestamp, the login of the care provider, and the medical record number (MRN) accessed. It is the role of the VUMC Privacy Office to audit the EMR access logs for inappropriate accesses.

A particular type of access privacy officials look for is pre-existing relationships between care providers and patients; e.g., "Are the care provider and patient coworkers at the university?" Such information is not in the EMR, but is in the university's human resources (HR) knowledgebase. Yet, no primary key exists between the EMR and HR databases. Thus, the common attributes are personal identifiers, such as personal names, demographics, or Social Security Number must be used to link the systems. However, the execution of a database join on patient's

identifiers, as shown in Figure 1, would reveal patient-specific information to human resources administrators, including information on patients that are not university employees. This investigation, though performed for surveillance purposes to detect wrongs committed against patients can violate patient privacy.

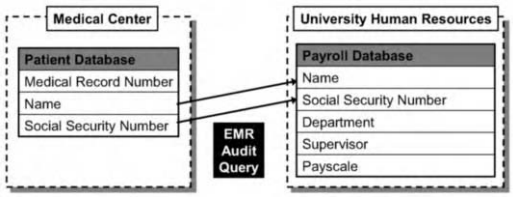

Figure 1- A query across organizational boundaries can violate patient privacy.

How can medical privacy officials determine if a patient is an employee without revealing patient identifiers?

Contributions of this research

In this paper, we propose a novel protocol called CAMRA (Confidential Audits of Medical Record Access) that allows an auditor to access information from non-EMR systems without revealing the identity of those being investigated. CAMRA leverages a secure protocol in which information is encrypted and stored at a third party. The EMR auditor sends queries of encrypted information to the third party to gather information from disparate systems for its investigation. The end result is that the identities of those being investigated are never provided beyond the EMR system. CAMRA simultaneously enhances confidentiality (i.e., no disclosure of person identifiers) and security (i.e., improved audit ability) in EMRs.

Methods

Record linkage and identity protection

Record linkage is an activity that is common to a range of biomedical environments. Record linkage within an organization is often performed via person-specific identifiers, such as name, address, or a unique identifying number (e.g., the Social Security Number is a feature frequently used in the United States). However, disclosing identifiers across organizational boundaries is often legally prohibited.

To satisfy legal constraints, biomedical researchers have applied various techniques to link records on entities without revealing identifiers. Secure one-way hash functions were developed and successfully applied for epidemiological follow-up studies [11]. Hash functions convert an individual's identifiers into a pseudonym; e.g., the name *John* becomes 0sad01a. To link information, each record is hashed and matching hashes are linked. A limitation of the one-way hash; however, is that all organizations linking data must share a hash key. The existence of a common key is a security risk because the hashed identifiers are susceptible to a "dictionary attack". For instance, an HR system administrator can hash identifiers until it matches a received hash from the medical center.

This is deemed acceptable risk in France, where the methods have been standardized for use at the Securite des Systemes d'information [12, 13], but in other countries this model has been contested.

To overcome the use of a common key, alternative methods have been proposed. For instance, Berman proposed a commutative random string technique [14]. In this method, each organization generates a string of random characters. The organizations exchange the strings and add them together to generate a set of common strings. Next, the organizations add identifiers (e.g., names, dates, etc.) to the random strings and compare the results.

One-way hashing renders it impossible to recover the original identities. Once records are linked, the organization must sacrifice the knowledge of the corresponding identities. This is adequate when identity is not needed. However, this model is not acceptable for EMR audits. To complete a privacy audit the EMR administrator must append knowledge to the identities of the individuals under investigation.

Commutative cryptography for record linkage

In this research, we adopt a commutative method. Specifically, we leverage a cryptographic technique called quasi-commutative encryption [15]. Each organization encrypts and decrypts identifiers to satisfy the following commutative property:

$$H(H(John\_Doe, \varepsilon_1), \varepsilon_2) = H(H(John\_Doe, \varepsilon_2), \varepsilon_1)$$

for any ordering of keys $\varepsilon_1, \ldots, \varepsilon_n$ and a function H.

A crucial distinction between the proposed method and prior models is that the function we apply can be converted into an asymmetric keyed cryptosystem. In other words, key ε_i can be paired with a key κ_i so that the original identifying value can be recovered using the same function, but different keys. So, organizations can encrypt and decrypt identifiers, such that

$$H\,(H\,(H\,(H\,(John\_Doe, \varepsilon_1), \varepsilon_2), \kappa_1), \kappa_2) = John\_Doe.$$

Fortunately, a variant of RSA cryptography satisfies these properties, such that $H(x, y) = x \bmod (n)^y$. RSA is an accepted standard for secure messaging in healthcare systems, so the CAMRA protocol can be built on top of existing healthcare information technology infrastructure. Unlike how RSA is used in practice; however, we define a private-key system, such that no organization discloses any keys. Note, the switch from a public to a private-key system does not require changing infrastructure.

CAMRA overview

The CAMRA protocol is designed so that disparate organizations can share encrypted versions of their identifiers with a "semi-trusted" third party. The third party is trusted to correctly execute a record linkage function, but the third party is not trusted to view the original identifiers for which it is performing the linkage. The third party analyzes queries of encrypted identifiers from the EMR auditor and responds with either encrypted identifiers

linked to relevant information for another organizations information system or "No Link Made". The feedback that is provided to the EMR auditor is encrypted information from which only the auditor, not even the third party, can learn the identifiers.

Let us walk through a basic, high-level, implementation of the CAMRA protocol. In this version, there are two organizations, such as the VUMC and the HR divisions in the example above. Figure 2 provides an illustration of the process.

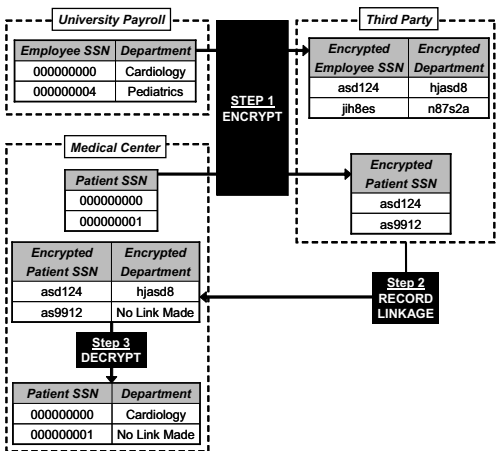

Figure 2 - Enrichment of access logs via the CAMRA protocol.

Step 1: Encrypt. The two organizations commutatively encrypt each other's datasets. Upon completion of this process, the organizations send their encrypted records to the third party. At no point throughout the encryption process can either participant achieve a dictionary attack because the records are not encrypted with the same key. After completion of the encryption phase, all records are comparable because they are encrypted with both of the participants' encryption keys [16].

Step 2: Link. Upon reception of the commutatively encrypted records, the semi-trusted third party performs record linkage on the encrypted identifiers. A list of matches, if any, is produced and sent back to the EMR auditor.

Step 3: Decrypt. The EMR auditor initiates a commutative decryption of the linked records. In the end, this provides the auditor with a list of decrypted identifiers that are linked to relevant information from outside of the EMR.

The above overview describes salient features of the proposed methodology. This example illustrates the architecture of the CAMRA protocol, but it obscures the exact ordering and manner by encryption and decryption process.

The CAMRA protocol

We now describe the CAMRA protocol in more detail, as well as showing how the protocol generalizes to settings with an arbitrary number of participating organizations.

To implement the commutative encryption and decryption required for CAMRA, each of the participating organizations must encrypt/decrypt each organization's sets of identifiers. To achieve this goal, two technical aspects must be in place. The first is a protocol for how to use maintain and use encryption/decryption keys at each organization. The second is a routing scheme is that specifies the order according to which organizations exchange sets of identifiers to eventually provide the semi-trusted third party with a set of encrypted, comparable records.

Protocol keys. Let D_V and D_R be the sets of patient and employee identifiers held by the VUMC and HR, respectively. Similarly, let $\langle \varepsilon_V, \kappa_V \rangle$ and $\langle \varepsilon_R, \kappa_R \rangle$ be the keys for the VUMC and HR, respectively. After commutative encryption the HR has $H(H(D_R, \varepsilon_R), \varepsilon_V)$. Notice, however, that HR is also in possession of $H(D_V, \varepsilon_V)$, which it received from the VUMC. Now, since HR can decrypt commutatively, it can generate $H(H(H(D_R, \varepsilon_R), \varepsilon_V), \kappa_R)$, which results in $H(D_R, \varepsilon_V)$. The consequence is that now the HR can compare its records and the VUMC records as if they were singly hashed by the VUMC: $H(D_R, \varepsilon_V)$ compared to $H(D_V, \varepsilon_V)$. This problem was recognized in [16] and so, to prevent such leaks, it is necessary to use "blinding".

More formally, let K be the set of organizations that share information with the third party. Each organization ($k=1,...,K$) will maintain two pairs of ⟨encryption, decryption⟩ keys,

$$\langle \varepsilon^b_k, \kappa^b_k \rangle \text{ and } \langle \varepsilon^m_k, \kappa^m_k \rangle,$$

for an agreed upon quasi-commutative hash function H as defined above. The function H is made public, however, all keys are kept private to each organization. The first key pair is used for "blinding" purposes (superscript b) by organization k with its own set of records, akin to the blind signature process defined in the original description of untraceable payment systems [17]. Blinding the records prevents leaks of information as illustrated above. The second key pair corresponds to "multi-party" keys, which each organization uses to encrypt/ decrypt each organization's set of records.

Record Routing. Alternative routing schemes share the property that each participating organization *starts* and *ends* each round of commutative encryption (initial and final) with its own set of records. In other words, each organization will blind its records before sending them according to a pre-specified routing scheme for commutative encryption. The organization will then remove the blinding from its records before sending them to the third party after all other organizations have encrypted it with their multi-party key.

Figure 3 depicts two possible routing schemes. The left panel shows a circular routing procedure based on commutative protocols. This procedure is efficient in terms of communication costs, but it requires that a peer-to-peer architecture be set in place. In contrast, the centralized routing model, shown in the right panel, are more computationally expensive, but can take advantage of existing network architectures that are designed for

high-speed environments with dedicated and trusted communication channels

The best routing option will depend on the features of the organizations involved in the audit. Regardless, the security of the CAMRA protocol does not depend on the specific routing scheme that is implemented.

The complete CAMRA protocol is executed as follows.

Step 1: Blinding to Encrypt. Each organization k creates a dataset of *dummy* records and adds them to their own set of EMRs, and encrypts the resulting set of records D_k using ε^b_k. After this initial encryption, a blinded dataset $H(D_k, \varepsilon^b_k)$ exists for, and is in the sole possession of, each organization.

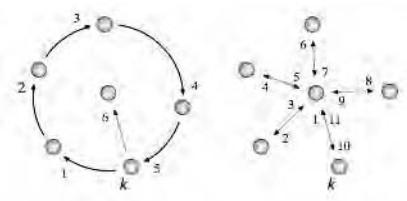

Figure 3 - Two alternative routing schemes from organization k to the third party (in the middle). Nodes are different organizations and numbered edges are routing steps.

Step 2: Commutative Encryption. Each organization encrypts its blinded records with its multi-party key and sends the result to organizations following the pre-specified routing scheme. Each organization encrypts the received sets of records its multi-party key, shuffles the order of the records, and continues to send the records around according to the routing scheme. At the end of this process, each organization k is in the possession of

$$H(H(H(\ldots H(H(D_k, \varepsilon^m_1), \varepsilon^m_2) \ldots \varepsilon^m_{K-1}), \varepsilon^m_K), \varepsilon^b_k).$$

Notice that the blinding key ε^b_K must be removed if the third party is to perform record linkage. This is where commutative decryption is handy. Organization k can remove the blinding simply by decrypting with κ^b_k.

Step 3: Encrypted Record Linkage. Each participating organization sends the resulting dataset to the semi-trusted third party, who performs record linkage over the set of encrypted EMRs. The resulting list is sent to the EMR auditor.

Step 4: Blinding for Decrypt. Upon reception, the auditor selects a new pair of blinding keys and blinds the list.

Step 5: Full Decryption. As in Step 2, the auditor, sends the encrypted list of matches to each organization according to the routing scheme. Now, each organization decrypts the list and sends it back to the auditor. Once every organization has decrypted the list, the auditor decrypts to remove the remove the blinding key.

Results

The CAMRA protocol is based upon our previous work on collusion resistant protocols [16] and inherits some of its desirable properties. We list them below.

Collusion-Resistant. It is possible to show that no set of organizations can successfully collude to learn the identifiers in the encryptions sent by the EMR auditor. Similarly, the EMR auditor can not collude with any set of organizations to learn the contents of another organization's set of records without proceeding through the commutative decryption process.

It is important to note that collusion resistance in CAMRA extends to prevent the third party from colluding with organizations against the EMR auditor. For instance, imagine the third party passes the VUMC records to HR. HR will learn which records the EMR and HR have in common, but will not know which records they correspond to. This is because 1) HR never decrypts records in CAMRA and 2) the VUMC shuffled the encrypted HR records. In doing so, HR cannot determine which of its encrypted records corresponds with any of its unencrypted records. The fact that HR cannot complete decryption without the assistance of the VUMC is the benefit of using a multi-party authentication mechanism with a single organization that is capable of decryption.

Detection of Malicious Actions. Collusion is a primary concern when organizations act according to the specified protocol. However, beyond collusion, there are actions that an organization can take to prevent record linkage from being correctly executed at the third party. For instance, an organization may use a faulty encryption key during the encryption process and the following comparison could be made by the third party:

$$H(H(John, \varepsilon^m_{\text{VUMC}}), \varepsilon^m_{\text{HR}}) \quad H(H(John, \varepsilon^{bad}_{\text{HR}}), \varepsilon^m_{\text{VUMC}})$$

In this case, HR correctly used $\varepsilon^m_{\text{HR}}$ with the name John from the first set of records (on the left), but inserted a "bad" key into the commutative encryption process to encrypt John in the second set of records (on the right). As a result, the names are not properly linked.

Fortunately, the CAMRA protocol can be extended to detect such malicious behaviors both during the encryption process and during the decryption process. These extensions are described in [16] and are important when trust between organizations is low.

Scalable. The CAMRA architecture is extendible in several ways. First, the security protocol is not limited by the number of organizations that are involved in the investigation. To increase the number of organizations that contribute to an audit, we only need an additional set of encryption/decryption keys. Second, CAMRA can be augmented so that each participating organization is provided with differential responses. To do so, the third party can send a response list to each organization. Each organization can use its own set of blinding keys to perform decryption. Yet, this extension must be performed with

caution as it violates collusion resistance property (i.e., the third party can collude with any organization).

Discussion

The CAMRA protocol illustrates that privacy does not have to be sacrificed in healthcare operations. The protocol prevents the disclosure of identifiers during the audit process. Nonetheless, the protocol has certain limitations that we now address.

Towards a fault tolerant model

Typographical errors and variation of personal information are a part of healthcare. For instance, an entity's name may be "Jon" in the EMR, but "Jonathon" at HR. Traditional record linkage methods account for such issues through string comparators and probabilistic matching algorithms [18]. Unfortunately, hashes and encrypted and encrypted versions of identifiers do not retain their similarities. As a consequence, linking encrypted identifiers can trigger false matches and non-matches.

Recently, methods have been proposed to measure the similarity between strings in an encrypted environment [19]. However, existing methods do not scale for use with CAMRA. This is because these methods are based on protocols that are designed for use between two organizations. Moreover, due to the cryptographic basis of these methods, they do not scale beyond two organizations. Yet, the CAMRA protocol is applicable to environments in which two or more organizations are involved. The development of scalable record linkage algorithms for encrypted data will limit the false non-linkage rate in CAMRA.

Third parties in healthcare

In the realm of healthcare, third parties are leveraged for a variety of purposes, including data warehousing, data aggregation, and brokering. Yet, from a data security perspective, the less number of organizations that handle data the better. As such, a more attractive possibility is to remove the third party from EMR auditing. Research in computational theory has shown that third parties can be removed from cryptographic protocols without sacrificing the level of security. However, the application of such theory in the real world is limited because resulting protocols are computationally burdensome and inefficient for daily practice. Nonetheless, minimal information sharing is the key to maintaining privacy in healthcare systems. We intend on developing confidential EMR audits models that limit the involvement of third parties.

Acknowledgments

Design of a Decentralized Reusable Research Database Architecture to Support Data Acquisition in Large Research Projects

Jimison Iavindrasana [a], Adrien Depeursinge [a], Patrick Ruch [a], Stéphane Spahni [a], Antoine Geissbuhler [a], Henning Müller [a]

[a] *Geneva University Hospitals, Geneva, Switzerland*

Abstract

The diagnostic and therapeutic processes, as well as the development of new treatments, are hindered by the fragmentation of information which underlies them. In a multi-institutional research study database, the clinical information system (CIS) contains the primary data input. An important part of the money of large scale clinical studies is often paid for data creation and maintenance. The objective of this work is to design a decentralized, scalable, reusable database architecture with lower maintenance costs for managing and integrating distributed heterogeneous data required as basis for a large-scale research project. Technical and legal aspects are taken into account based on various use case scenarios. The architecture contains 4 layers: data storage and access are decentralized at their production source, a connector as a proxy between the CIS and the external world, an information mediator as a data access point and the client side. The proposed design will be implemented inside six clinical centers participating in the @neurIST project as part of a larger system on data integration and reuse for aneurism treatment.

Integrated information management systems, hospital information system, multi-institutional research databases.

Introduction

The diagnostic and therapeutic processes, as well as the development of new treatments are hindered by the fragmentation of information which underlies them. Many developments have emerged in the genomics, proteomics and medical imaging domains during the last 10 years. Linking distributed, multi-format, and multi-scaled data from genetics, proteomics, the individual, and epidemiological data for diagnosis and treatment is a new challenge in the biomedical informatics domain [1]. Many research projects are working on the integration of genomics knowledge into clinical practice. The INFOBIOMED[1] project is studying the relationship between bioinformatics and medical informatics in provision of individualization of healthcare. Integrating multi-scale data also means a need to integrate expertise of various participants: clinicians, biologists, statisticians, etc.

To develop new diagnostic or therapeutic processes, prospective clinical research can be conducted across multiple institutions. The electronic patient record can be used as initial data input and the data can be used for more than the treatment of a single patient. A multi-institutional data collection permits to have a statistically significant number of cases in a shorter time period. On the other hand, sharing clinical data for external researchers creates many problems: 1) patient data privacy and confidentiality need to be ensured; 2) there is no standard secure communication protocol and format for data representation as HL7[2] and DICOM[3] are mainly used for communication inside a hospital and do not cover all aspects required, particularly concerning terminologies to be used.

In multi-institutional clinical research, most of the data are collected inside the clinical information system (CIS) or are exported to create databases for one particular task. Specialized data collections such as genetic sequencing are rarely incorporated into routine medical practice. These data need to be entered from the outside of the clinical centers. Moreover, connections with existing public knowledge bases such as SWISSPROT[4] are rarely done. Designing a research database infrastructure for managing heterogeneous data formats, heterogeneous distributed data sources, access by multiple experts to the entire data located in various geographical regions is a big challenge.

Two categories of architectures exist to conduct multi-institutional clinical research: centralized [2] and distributed [3, 4]. The main drawback of a centralized architecture is the maintenance and data security [5]. In a distributed architecture, data can be stored in a local system and all participating institutions use the same data model, query language and the same database management software (distributed database system - DDBS) [6]. In the DDBS architecture, the maintenance complexity of the centralized architecture is reported on the level of each clinical center. In the real world it is also difficult to have the same database management system installed on the

1 http://www.infobiomed.org/

2 http://www.hl7.org
3 http://medical.nema.org
4 http://www.expasy.org/sprot/

same operating system across various participating institutions, leading to a heterogeneous database system (HDBS) [6]. Mediators have been proposed to allow access to heterogeneous data sources [3].

For security reasons, a CIS is generally a closed system. However, more and more clinical research is conducted inside hospitals and an increasing number of research networks are set up to share clinical data among institutions. Generally, in DDBS or HDBS, data are stored in a secured zone outside the CIS for secondary use. Nevertheless, it is risky to leave clinical data outside of the CIS because it is difficult to achieve a complete anonymity of clinical data. Genetic sequences, for example, are unique for each individual. Clinical data are collected over time and a visit date can be linked to other databases and can permit to identify a patient. Moreover, in provision of a patient-centered healthcare, there is a need to go back to the patient to inform him about new discoveries that might arise in a research project and as a new treatment of a disease.

Data integration is defined as the problem of combining data residing at different sources, and providing the user with a unified view of these data [7]. Generally, clinical centers have their own security, access rights management and privacy protection policy according to the role the user [8], and have the know-how concerning data access and communication using standards such as HL7, DICOM, IHE, or business components such as web services [9]. In multi-institutional prospective clinical research, a decentralized HDBS architecture is most flexible. It is also often the safest for the management of multimedia, multi-source, and distributed user data. In this architecture, the data are stored at their source i.e. the CIS of the institution where the data were created. Across institutions this can be in multiple databases, managed by various database management system installed on distinct operating system.

Often, half of the money of large scale clinical studies is paid for data creation and maintenance.

The objective of this paper is to propose a design of a distributed re-usable research database architecture, which permits managing and retrieving heterogeneous data to have real-time and up-to-date integrated data. Interoperability issues, research database maintenance and access are also discussed. The work is being carried out in the context of the European Union research project @neurIST and is part of a larger infrastructure within this project. The architecture proposed concerns “open” CIS: accessible for change and having direct data access, in the context of a multi-institutional research project.

Methods

The article describes the design and first implementations of a reusable research database architecture for a large-scale European Union funded clinical research project. Clinical data acquisition is planned in four countries at the first phase and then in a larger number once all system components are in place.

To do so, many constraints were taken into account from these countries on the one hand side from a legal standpoint and also from a technical standpoint. The architecture is to be implemented between the clinical institutions that will produce the data and several research applications that are the potential users of the data.

A web-services HTTP/XML based approach was chosen for the communication. To model all possible scenarios a large number of use cases were defined among the participants of the research project. Based on these use cases, legal and technical aspects of the functionality were defined and an architecture planned that was proposed to all partners and that is currently under internal evaluation for possibly missing parts.

Results

Requirements

Critical tasks in a database project are: data collection and validation, data storage and communication. In a decentralized database architecture, most of the clinical data collection, data validation and storage are done inside the participating clinical centers.

Data categorization and storage

In a decentralized research database architecture, it is crucial to differentiate the treatment and the research cycle. The treatment cycle produces clinical data and the research cycle provides derived data.

Additional data such as genetic analyses and research results related to a specific patient are in our case collected outside of the clinical centers and have to be stored inside the participating clinical centers’ information systems. Other global research data such as epidemiological study results or other public knowledge useful for the users of the database cannot be stored in any participating clinical center’s information system.

Patient identification

In a patient-centered clinical context, a patient can have access to all data stored in the CIS related to his health. Derived data need to be separated from clinical data by the means of patient identifiers. An internal patient identifier is used to identify a patient in the treatment cycle and an external identifier is used to identify the patient for secondary use of its data. As other clinical data may be collected outside of the hospital, the internal identifier cannot be used to identify the patient during the upload. First, the internal identifier may be created from private information of the patient. Second, external clinical data need to be validated by a clinician before its insertion into the electronic health record. Other specific identifiers need to be set up to identify external clinical data. In prospective clinical research, a patient needs to be recruited and followed in a single center. At this stage, we do not consider mobile patients between centers. This problem could be resolved with a global identification solution but is discarded for now.

Data integration

One of the biggest issues in a multi-institutional research database is data integration. The decentralized research database architecture is implemented as a global-as-view [7] and is able to manage structural, naming, semantic and content differences of the data from different sources. Inside a participating clinical center, data are coded into the local terminological system. The normalization of the data into a common terminological system is done on-the-fly.

Communication and security

Interoperability is also a crucial point in the design of a research database. XML/HTTP is the de facto standard to achieve interoperability. The architecture will use XML for data encoding and HTTP as transport protocol.

Privacy of clinical data needs to be ensured by the architecture: all data leaving the CIS, for secondary use have to be anonymized and the process has to be done on-the-fly before the data leave the clinical center. However, the architecture needs to permit to re-identify the patient to store related research result in the CIS. The architecture also needs to allow identification of the end-user. All communication has to be encrypted.

Design

The architecture we present in this paper has 4 layers: 1) the *data source layer* inside the CIS or at a node of the research network; 2) the *connector* on each participating clinical center which is mainly responsible for the horizontal data integration; 3) the *information mediator,* which is mainly responsible for vertical data integration and 4) the *client* (Figure 1). For security reasons and re-usability, operations are decentralized at the appropriate layer.

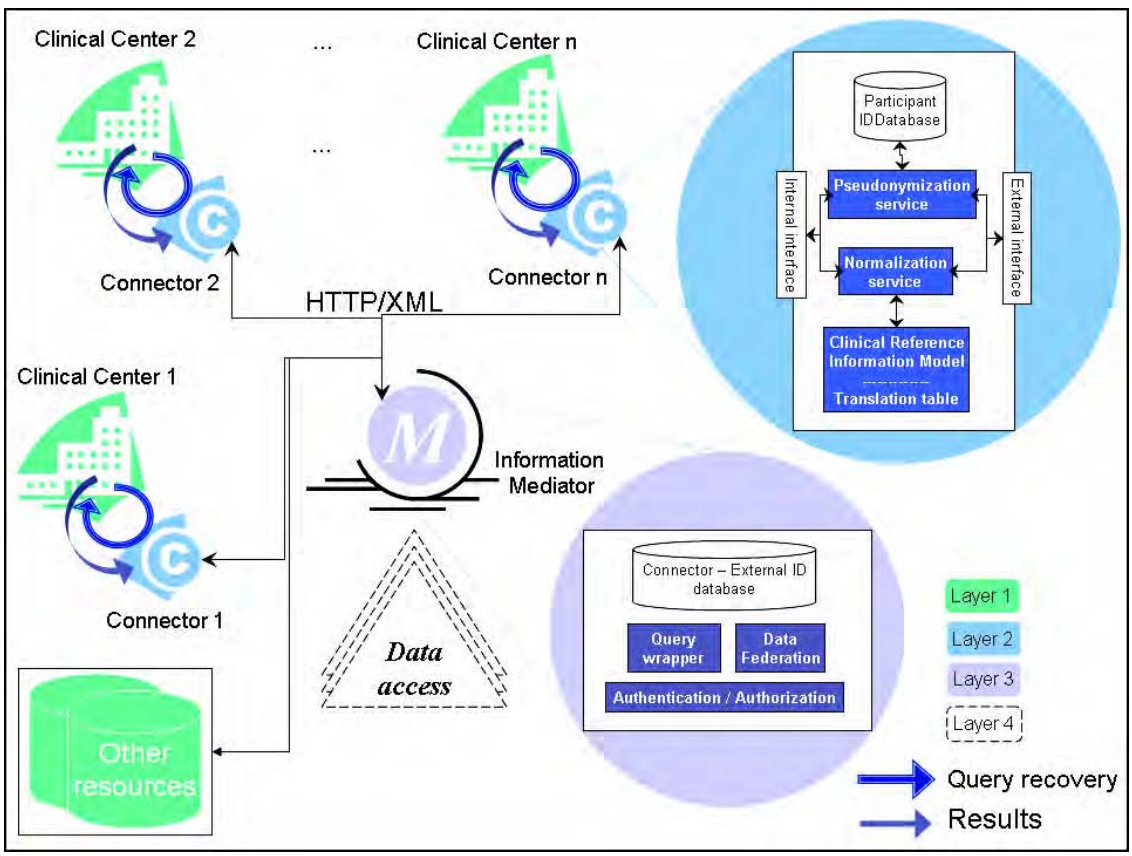

Figure 1 – A 4- layer architecture composed of: 1) the data source in the CIS or at a node of the research network; 2) the connector on each participating clinical center ensuring data normalization and pseudonymization; 3) the information mediator responsible for the query and user management and 4) the client

Data source

A large part of the data are stored inside the CIS and accessed using the existing data access components. Clinical data are stored in the electronic health record and derived data in a research database. The latter is integrated in the CIS because research results may contain private information such as gene sequences. There is no possibility to link clinical and derived data inside the clinical center: querying derived data using private information of the patient is prohibited. Even if derived data related to a patient are stored in the research database inside the CIS, it cannot be queried directly from the inside: it is only accessed through the information mediator. Other global or public derived data, not related to a specific patient are stored at their source.

The source can be queried using traditional communication protocols such as HL7 or DICOM or other components used inside the clinical center. The data access component inside the CIS communicates with the connector using XML/HTTP. For security reasons, the CIS always initiates the communication with the connector and pools the results. The CIS checks for new queries transmitted by the connector at fixed time intervals.

The connector

The connector is installed in the DMZ of each participating clinical center and uses the clinical reference information model (CRIM) for query and data translation. The CRIM contains the semantics of all existing data attributes: name, type and definition. These attributes are mapped to the local data attributes in the translation table. The normalization service is a bidirectional conversion of data format in the local or the global terminological system and it is invoked during the transition of the data inside the connector. The mapping has to be strong enough to ensure data integrity.

The pseudonymization service removes all private information from the local data before their delivery outside of the DMZ. It uses an ID database containing the mapping between various patient identifiers in the provision of re-identifying the patient for update tasks. The pseudonymization service can be extended as a patient identifier generator (external and other identifiers) but does not store any private information concerning the patient other than the internal ID.

The connector has two web service interfaces: the internal interface communicates with the CIS and the external one communicates with the information mediator. The connector does not identify the end-user: this task is centrally done at the information mediator level and the connector accepts only queries from the information model.

The information mediator

The information mediator is the data access point. It manages queries to various data sources: CISs and other public or private resources stored outside clinical centers. The user authentication and authorization are done at the information mediator level. The mediator also contains a database with the mappings between the external patient ID and all connector identifiers having information about the patient. This limits the network usage when a query is performed for a specific patient. It uses the clinical reference information model to formulate queries and it can be extended using an ontology to enable semantic mediation.

Discussion

We detailed in the preceding sections the design of a reusable research database for managing heterogeneous data sources to have real-time and up-to-date integrated data and address interoperability issues. The architecture permits to address data structure, naming, semantic and content differences across various clinical centers. Storing an internal identifier in the DMZ can raise legal issues. It has to be mentioned in the study protocol and the patient consent that the identifier will be stored in the DMZ and that it is never published beyond.

Limits of the approach

Using production databases for secondary use is badly perceived by IT decision makers in the health field because of: 1) technical constraints that the CIS is not open to change; 2) the sensibility of clinical data. However, with the increasing number of clinical and research networks managing and duplicating clinical data for secondary use will become increasingly expensive. For this reason most participating clinical centers prefer to export anonymized clinical data into a database in the DMZ instead of doing on-the-fly data extraction from the CIS. The research database will be hosted in a secured zone as shown in figure 2.

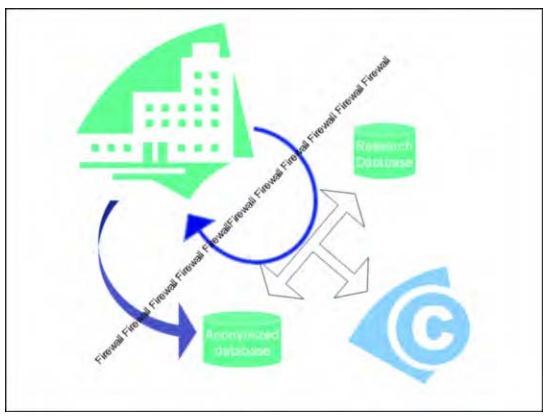

Figure 2 – Second storage architecture

In this second storage solution, the pseudonymization service of the connector is activated to pseudonymize data before their export into the DMZ. When there is a need to go back to the patient's data in the CIS, a message is sent by the CIS to collect queries from the connector. This process can be automated by setting up a service that will check for the existence of new queries at a fixed time interval.

In the proposed design, the communication between the CIS and the connector is unidirectional and intermittent. It can affect the query timing especially for *select* queries. Opening a permanent communication between the 2 layers of the architecture can raise security risks.

Contribution

The main advantage of the proposed architecture is its reusability, scalability and lower maintenance cost for research projects. Adding a new clinical center means installing a standard connector and providing a mapping between local and global data attributes. Defining a new research database project consists of defining the CRIM for this domain and adding clinical centers.

The emergence of GRID network technologies can empower the analysis and treatment of complex and manifold multimedia data: heavy computing tasks can be externalized onto a GRID-computing environment [10] and might allow new possibilities in the reuse of data. This

architecture can be interfaced with grid computing infrastructures that allow access to computational power that many institutions could not afford on their own [11]. In this case, the connector plays more than the role of a "data proxy". It receives computing requests from the CIS, pseudonymizes patient data if needed, and send the queries to a GRID-computing service provider. When the computation is finished, the connector receives the results, re-identifies the patient and sends them to the CIS.

Future developments

In the first part of the project, a patient is recruited and followed in a single clinical center. However, a patient may move between places after being recruited while continuing to take part in the study. There is a need to develop a unique external identifier to link information about this patient across clinical centers.

Conclusion

The design of a decentralized, scalable and re-usable, research database architecture with lower maintenance costs is described in this paper. The architecture has layers to manage heterogeneous data collection, storage and retrieval in a secured way and ensures the patient's information privacy. The architecture is suited for extensible clinical information systems. The structure is part of a larger @neurIST architecture.

The Cancer Biomedical Informatics Grid (caBIG™): Infrastructure and Applications for a Worldwide Research Community

The caBIG Strategic Planning Workspace[a]

[a] *Members and Affiliations Listed in the Acknowledgment*

Abstract

Information explosion and new advances in high throughput experiments have challenged biomedical research, and suggested a future in which inter-institutional and international collaborations will be the norm. The cancer Biomedical Informatics Grid is an ambitious initiative launched by the US National Cancer Institute to develop a network of tools, data, and researchers to support translational and clinical research in oncology, with an ultimate goal to improve cancer care for patients. The three year pilot phase of caBIG ends in 2007, and has engaged over 900 clinicians, scientists, and patient advocates as developers, adopters, and workspace participants. Progress has been demonstrated in creating tools and building prototype grid architecture for collaborative research. Accomplishments in the pilot phase set the stage for extension of the community into other biomedical domains and for federation of the caBIG enterprise with similar initiatives in other scientific areas and in other countries.

biomedical informatics; computer communication networks; diffusion of innovation; medical oncology

Introduction

In recent decades, the information infrastructure requirements of biomedical research have increased exponentially. Clinical trials now reach beyond the academic milieu to include the broader clinical community, while regulatory reporting requirements and concerns about patient confidentiality and data security have grown. Basic and translational sciences now employ high-throughput genomic and proteomic technologies that generate terabytes of data and require new analytical tools. Translational research demands that information from biological samples be merged with clinical and population data, yet rarely are data collected in ways that make this possible. These problems compound when considering research conducted in teams from several universities and research centers. In short, modern medical research requires integrating, evaluating, and searching large volumes of diverse data, generated at multiple institutions. While this integration is sometimes possible, it is often an inordinately time-consuming and difficult process. In this decade informaticians have identified grid computing as offering one set of solutions to enable inter-institutional biomedical research [1].

Grid computing in biomedicine takes several forms. Computational grids assemble processing power from multiple sites to tackle intensive algorithmic problems [2,3]. Data grids allow the assembly of information from multiple disparate sites [4]. Community grids link investigators who share common interests, and allow data from one site to be used in a computational tool resident at another [5,6].

Recognizing that integration is key to accelerating cancer research, the United States National Cancer Institute (NCI) in 2003 announced the Cancer Biomedical Informatics Grid (caBIG™, http://cabig.nci.nih.gov) whose goal is to develop the information infrastructure needed to share data, specimens, tools, and computing power within and across institutions involved in cancer research. caBIG is creating an infrastructure that individuals and institutions can use to connect, nationally and internationally, effectively forming a worldwide collaborative cancer research community. This paper describes the motivation for the caBIG community, the standards and tools used in developing its underlying architecture, some early applications and infrastructure generated in the initial three-year pilot phase, as well as the potential to link caBIG to other biomedical grid projects underway in the USA and worldwide.

The caBIG Pilot: 2004-2007

Development of the community

The NCI Director vested oversight for a new information technology infrastructure in the NCI Center for Bioinformatics (NCICB), and in late summer of 2003, over 30 NCI-designated cancer centers held on-site discussions with NCICB to identify informatics resources that they might be able to contribute to caBIG, as well as elements they would hope to acquire from their colleagues using this newly conceived network (Figure 1)[7]. These discussions led to the establishment of three domain-specific workspaces in which tools would be developed: Clinical Trials Management Systems (CTMS) would develop tools to facilitate the design, management, analysis, and reporting of clinical trials; Tissue Banks and Pathology Tools (TBPT) would develop tools for managing specimens from clinical trials and patient care and for

sharing those specimens and their data across institutions while protecting patient privacy; and the Integrative Cancer Research (ICR) Workspace would develop a set of bioinformatics tools to analyze and integrate data from across the spectrum of clinical and basic research. A fourth domain space to develop tools for in vivo imaging (IMAG) was added in the second year of the project. All domain areas would ultimately make data available to the cancer research community across a computational grid.

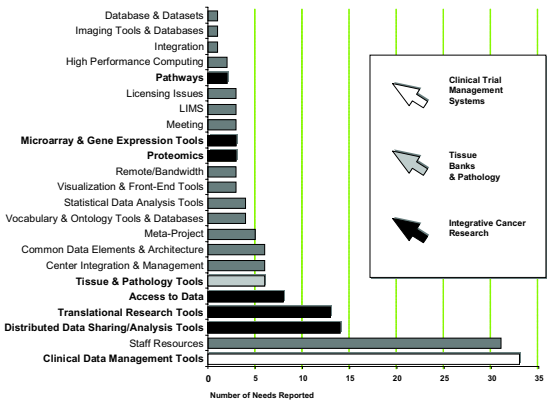

Figure 1 - Responses from Cancer Centers on needs in a biomedical informatics grid

Based on the feedback from the site discussions, NCICB and its general contractor developed a set of contracts to enable many institutions to take roles in caBIG [7]. Cancer Centers were contracted to participate in one or more of these workspaces as software developers, adopters, and/or working group members. In addition to the domain-specific workspaces, five others were formed to develop the standards for vocabulary (VCDE) and architecture (ARCH), to address issues of data sharing and intellectual capital (DSIC), to develop documentation and training (D&T), and to provide input on overall direction (Strategic Planning - SP). Patient advocates were recruited in each workspace to assure that patient issues and concerns were addressed.

The first year: Setting direction and expectations

caBIG was officially launched in February 2004 as a three-year pilot project. First year objectives focused on building the framework for workspace activities and engaging the cancer research community. Each workspace established its own timetable and set of strategic objectives. These were collated by the Strategic Planning Workspace into an overall Strategic Plan. The plan, presented at the first caBIG Annual Meeting in April 2005, set the stage with a scenario:

A motivating example: Scenario 2009[1]

> A researcher involved in a phase II clinical trial of a new molecularly targeted therapeutic for brain tumors observes that cancers derived from one specific tissue progenitor appear to be strongly affected. The trial has been generating proteomic and microarray data. She would like to identify potential biochemical and signaling pathways that might be different between this cell type and other potential progenitors in cancer, deduce whether anything similar has been observed in other clinical trials involving agents known to affect these specific pathways, and identify any studies in model organisms involving tissues with similar pathway activity.

This example includes a number of experimental systems and biological entities: small molecules, cell types, pathways, homologous proteins, animal models, clinical trials and therapeutics. In 2006 such a project would involve immense manual work getting information locally and from other sites. The fundamental idea behind caBIG is to develop the infrastructure and tools necessary to automate much of these steps so that by 2009 such multidisciplinary, multi-institutional research would be becoming routine.

Overall goals of the strategic plan

The caBIG Strategic Plan set three target dates for development: late 2005, 2008, and 2010. From the outset a dynamic tension has existed between delivering tools to satisfy the needs identified in Figure 1, while at the same time making progress on architecture and vocabulary projects that will enable the realization of the 2009 scenario. These were reflected in the 2005 short-term goals:

- Develop first generation caBIG compliant tools, data sets, and supporting data and architecture standards.
- Promulgate Gold, Silver, and Bronze development standards to the national cancer research community.
- Establish a mechanism for engaging the private sector, cancer research organizations not currently contracted under caBIG, and other Federal agencies and divisions into the caBIG community.

First generation tools naturally would arise from existing bioinformatics solutions, data sets would be those available, and standards were those already in adoption as of 2005. An important early goal was the development of three levels of standards that would guide caBIG participants and other interested parties in contributing projects to the grid (see below). Notably an interest in reaching out to other entities beyond the NCICB and the project itself appeared as a short-term strategic goal.

Goals for a year after the end of the pilot phase (2008) emphasized a functional community using the interoperable features of the grid, and a cancer research enterprise that was naturally adhering to caBIG standards:

- Develop sufficient research tools and standards to have a positive impact on the cancer research community, as measured by adoption of relevant caBIG principles in project proposals.
- Ensure widespread adoption of developer standards so that funded developer projects are operating under the Gold standard of compatibility.

1 Scenario courtesy of Michael Ochs, Johns Hopkins University, formerly of the ICR Workspace

- Adopt and use caBIG interoperable tools and data sets within the caBIG community.
- Develop mechanisms for engaging and promoting caBIG compliant technologies and established datasets within the oncology research community.

By the end of the decade the strategic plan envisioned caBIG principles and tools institutionalized within the cancer research community, and evidence of clinical impact:

Each workspace contributed specific goals for 2005, 2008 and 2010 to the strategic plan. The domain workspaces naturally focused on tools, whereas the cross-cutting ARCH and VCDE concentrated on construction of the grid itself, and the data elements that would link tools and datasets.[2]

The second and third years: Early results

In its second year, caBIG started to deliver products in its domain workspaces. More applications and the first working grid architectures appeared in year three. Table 1 shows a sample of these products, organized by maturity and workspace. As an example, the TBPT workspace has developed a comprehensive biospecimen management system to inventory, track, mine and visualize samples from geographically dispersed repositories, and link these specimens to clinical and molecular correlative descriptions. Modules within the biospecimen management environment include caTissue Core, caTIES (Text Information Extraction System), and CAE (Clinical Annotation Engine).

In addition to tools, the community has created critical components that, while not directly addressing researchers' needs, are required to ultimately make the caBIG tools work together. These include caGrid, caCORE, the BRIDG model, and the caBIG Compatibility Guidelines mentioned above in the strategic plan. caGrid, the heart of the entire project, sets the standards and protocols that allow researchers to use the Internet to access data, applications, processing power, and storage capacity at other institutions[8]. Built to international standards, employing the Globus Toolkit, with caGrid version 1.0 an institution can establish *data services*, allowing remote researchers to query the institution's data sources, and *analytical services*, allowing remote researchers to send data for processing by tools housed at the institution. The services already available on caGrid are noted in Table 1 with an asterisk, and a number of products from IMAG and ICR are planned in early 2007[6]. The ultimate success of caBIG in enfranchising multidisciplinary and cross-institutional research will depend largely on the continued evolution of caGrid.

Table 1 – caBIG Products, 12/2006

caBIG Product	**Workspace / Description**
C3D	CTMS: A web-based application for managing data across multiple cancer clinical trials. http://trials.nci.nih.gov/projects/trialmanagement/c3ds_project/c3d
C3PR 1.1	CTMS: A web-based application used to manage participants in cancer clinical trials. http://trials.nci.nih.gov/projects/trialmanagement/c3ds_project/c3pr
CRIX/ FIREBIRD	CTMS: A tool enabling investigators to file FDA Form 1572 online with NCI and other sponsors. http://ncicbsupport.nci.nih.gov/sw/content/crix.html
Lab Integration Hub	CTMS: An open source software tool that is used to collect, process and report laboratory data gathered during a clinical trial. https://cabig.nci.nih.gov/tools/LabIntegrationHub/
Patient Study Calendar	CTMS: A tool to assist in managing and documenting clinical trials protocols through the entire life cycle of the trial. http://cabig.nci.nih.gov/tools/PatientStudyCalendar
caArray*	ICR: A microarray data repository that is MIAME 1.1 compliant, supports MAGE-ML import and export, contains utilities for the submission and retrieval of Affymetrix and GenePix native file formats, and is accessed through a MicroArray and Gene Expression Object Model Application Programming Interface (MAGE-OM API) http://gforge.nci.nih.gov/projects/caarraydev/
geWorkbench 3.0	ICR: A suite of tools for loading, visualizing and analyzing gene expression data that will provide access to data from any repository with (MAGE-OM API), such as caArray. http://gforge.nci.nih.gov/projects/geworkbench/
caIntegrator	ICR: A platform that supports the retrieval, aggregation, analysis and sharing of data from heterogeneous operational repositories -- microarray, genomic, tissue array, imaging and clinical. http://caIntegrator.nci.nih.gov
TrAPSS	ICR: A system of several tools that aid scientists in searching for the genetic mutation(s) that cause a defect or disease. The system allows the researcher to create and prioritize a large list of candidate genes, select order, manage primer pairs, and predict secondary structure. http://gforge.nci.nih.gov/projects/trapss/
Reactome (GKB) Data	ICR: A curated database of fundamental biological pathways in humans that uses strict rules of assertion and evidence tracking to ensure a consistent high quality product. This database is compatible with the pathways exchanges standard identified by caBIG™. http://gforge.nci.nih.gov/projects/reactome/

2 The caBIG Strategic Plan can be viewed at https://cabig.nci.nih.gov/working_groups/SP_SLWG/Documents/index_html/document_view

caBIG Product	Workspace / Description
Rproteomics *	ICR: A system that aids cancer researchers in the processing of matrix-assisted laser desorption/ionization-time of flight (MALDI-TOF) data. These R (a software language for statistical computing and graphics) libraries are incorporated into a caBIG™-compliant system that will aid cancer researchers in post-processing of their mass spectrometry data. http://gforge.nci.nih.gov/docman/?group_id=52
National Cancer Imaging Archive (NCIA)	IMAG: An web portal to a repository of downloadable in vivo images obtained from patients who have or are being evaluated for cancer. http://ncia.nci.nih.gov/
Cancer Text Information Extraction System (caTIES) 2.0	TBPT: A general purpose Text Information Extraction System that automates the process of coding, storing and retrieving data from free-text Pathology Reports. http://gforge.nci.nih.gov/docman/?group_id=17
caTISSUE Clinical Annotation Engine 1.2	TBPT: A clinical data mapping module designed to retrieve data from tumor registries and clinical and anatomic pathology Laboratory Information Systems (LIS) to connect, query, and share data with the caTISSUE system. http://gforge.nci.nih.gov/docman/?group_id=20
caTISSUE CORE 1.0.1	TBPT: A tool for biospecimen inventory, tracking, and basic annotation,.which can be rapidly deployed by cancer centers that have no such system or need to replace an aging legacy system. http://gforge.nci.nih.gov/docman/?group_id=18

CaCORE and BRIDG address issues of vocabulary and modeling. caCORE (Figure 2) is a set of tools created by NCICB for vocabulary management and model-driven software engineering[9]. It is intended to ensure that data will be collected using common data elements (CDEs), so that the data can be shared. caCORE ensures that caGrid can serve as a production environment as the caBIG community matures. The Biomedical Research Integrated Domain Group (BRIDG)[3] protocol model is a domain analysis model representing protocol-driven biomedical/clinical research, developed to be understood by domain experts. BRIDG provides the basis for harmonization among standards within the clinical research domain and between biomedical/clinical research and healthcare. It is being developed in conjunction with other standards organizations, and once it is in place, software developers will be able to write code utilizing this model rather than going through the time-consuming process of developing their own models.

The caBIG Compatibility Guidelines[4] provide a set of definitions that measure the maturity level of caBIGapplications with respect to interoperability. The guidelines

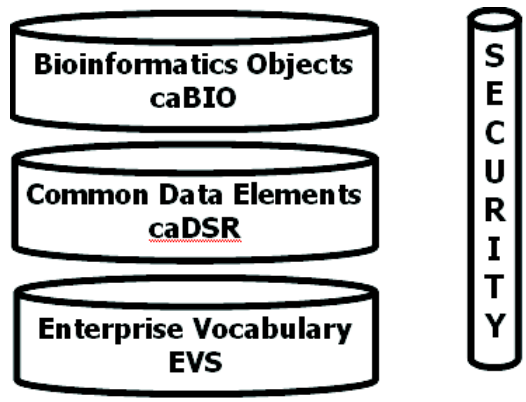

Figure 2 – caCORE Components: Cancer Bioinformatics Objects (caBIO), the Cancer Data Standards Respository (caDSR), and the Enterprise Vocabulary Server (EVS)

define requirements with respect to interfaces, vocabularies, data elements, and information models. The requirements reflect international standards, vocabularies that are firmly established across much of the scientific community, and IT industry "best practices" for technology development. Three levels of compatibility (Bronze, Silver, and Gold) are defined:

- Bronze: the application is built according to accepted standards and vocabularies, and can use external data
- Silver: the application contains caBIG validated application programming interfaces and vocabularies
- Gold: the application incorporates all Silver level requirements plus is fully operable on caGrid

The formal verification process for certifying the caBIG compatibility level of applications is still evolving, but when it is in place, users contemplating whether to adopt a caBIG or commercial product will be able to rely on compatibility level as an indication of how well the product will share data and analytic services with other caBIG™ products.

Workspaces also reached out to involve parties outside of NCI-designated Cancer Centers. Groups so approached include the Specialized Programs of Research Excellence (SPORE), cooperative clinical trials groups, the United States Food and Drug Administration, standards organizations, pharmaceutical companies, commercial software developers, and the United Kingdom's National Cancer Research Institute. caBIG now includes more than 900 participants across over 80 institutions and companies.

Moving beyond and reaching out

As these achievements demonstrate, caBIG is starting to deliver tools that will facilitate activities across the spectrum of cancer research, and connect these tools to caGrid. New projects extend interoperability. For example, the Cancer Translational Research Informatics Platform (caTRIP) will enable clinicians and translational researchers to query data resources in support of clinical decisions. caTRIP will integrate five tools, enabling queries across

3 http://www.bridgproject.org
4 https://cabig.nci.nih.gov/guidelines_documentation/

caTissue CORE, caTissue Clinical Annotation Engine, caTIES, Tumor Registry, and the Clinical Genomics Object Model of caIntegrator. Another integration project is LexBIG, which is strongly anchored in VCDE tools and resources, removes proprietary software dependencies in EVS (Figure 2), extends the API capabilities for vocabularies, affords interoperability with tools at the National Center for Biomedical Ontologies (http://ncbo.us), and addresses the broader use-cases needed in cancer research (relative to HL7).

From the outset, the Strategic Planning Workspace argued that staying within the cancer research domain would ultimately defeat the purposes of caBIG. caBIG is one of several promising projects that explore grid architectures to enfranchise multidisciplinary, multi-institutional research projects. In the United States, the Biomedical Informatics Research Network (BIRN) was initially established in 2001 to develop an inter-institutional collaboration in the area of neuroscience. BIRN's scope is smaller than caBIG, but it has been in existence longer and is significantly more developed. Although the recently launched NIH Roadmap Initiative to develop Clinical and Translational Science Awards (CTSA) does not directly address grids, the initiative does stress the role of biomedical informatics in translational research. The concepts embodied in caBIG are necessary to the collaborative success of the CTSAs. Internationally Biomedical Research Informatics Delivered by Grid Enabled Services (BRIDGES), a core research program within the United Kingdom, applies state-of-the-art concepts to cardiovascular functional genomics. Germany's MediGRID project, just getting underway, has a strong application focus. The main goal of MediGRID is the development of a Grid middleware integration platform enabling eScience services for biomedical life science. They have a bias toward early results, so caBIG's robust infrastructure tools could benefit MediGRID while their application use cases could stimulate caGrid applications.

For the vision of a worldwide web of translational and clinical research, where investigators can tap data and use tools that may "live" anywhere on the network, these and other projects must join forces. The European Healthgrid Initiative is a strong step in this direction-members of the caBIG community are collaborating with the association on "globalizing" the initiative. Extension of this collaboration to Asia/Pacific grid projects must follow [5].

caBIG was envisioned as a community of communities to support cancer research, and a solid contributor to the reduction of the burden of human cancer. It has succeeded in fostering collaboration among a diverse group of biomedical researchers and informaticians, to deliver a range of products and prototypes within its three year pilot phase. Focus on the infrastructure, adoption, training and outreach to other communities must characterize the next phase for the vision to be realized.

The Integration of Grid Resources into a Portal for Research Collaboratories

Yassene Mohammed, Sabine Rey, Fabian Rakebrandt, Ulrich Sax

Department of Medical Informatics (Professor Dr. Otto Rienhoff), Georg-August-University of Goettingen, Germany

Abstract

Information technology (IT) infrastructures for research collaboratories and virtual research businesses are essential elements of science in medicine. The sustainability of the infrastructure depends on how it becomes a normal element of the scientific process, including its financing as part of a scientist´s workbench that can be easily configured to their needs. The results should also be distributed through a suitable platform to other research networks. The development of such an infrastructure serves all parties – mostly the funding agencies. This objective could be achieved by the integration of several portals of different research networks and the interfacing between these portals to maximize the usability and minimize the cost.

Keywords:

grid-computing, portal, data protection, medical research networks, virtual organization

Introduction

International competition in optimizing collaborative scientific research in medicine has led to a general understanding that smaller research collaboratories [1] (term coined by the US National Science Foundation) have no chance to establish sustainable collaborative infrastructures at a higher level. Therefore, the US and the EU are pumping major funds into the development of appropriate generic infrastructures. Some results of such funding procedures offer software solutions for other users like the caBIG-project in the USA [2]. Others build a horizontal infrastructure for different user communities, including medicine, called national grids or e-Science infrastructures, e.g., D-Grid in Germany [3, 4].

In this context new policy objectives have to be considered in developing IT-infrastructure for medical research networks [5]. The new infrastructure should:

- Link all research modules, facilitate their research, and support translational activities between research, health professionals, patients and citizens
- Use national and international existing concepts and solutions to efficiently achieve maximum support
- Transfer experiences to, and import results from, the different medical research networks.

For new research consortia, the aim is the integration of support functions in a user-oriented portal, if possible with an integrated access function over all applications. The portal is designed as a solution for research networks and/or groups using a standardized and portable technical platform to enhance information exchange and cooperation. Usually, portals are linked to a public website where the users/researchers receive access to their role-oriented, customized portal working environment, and to the different functions of the collaborative working environment after appropriate authentication. The development of the collaborative portal for group research also leverages integration of data and applications.

However, with the different goals, technologies and requirements of the various research groups, and to stay competitive, it will be necessary to develop and implement interfaces among different services-portals from different research networks instead of integrating all services in one portal. This keeps costs low, maximizes the usability and saves implementation efforts.

A successful health care information technology (IT) solution offers the possibility of transferring data from research into the treatment process and vice versa. The conceptual design of the IT-infrastructure and IT-solution methodologies requires new concepts defined in cooperation with the different working groups [6, 7]. In medicine, this applies especially to the legal framework in data protection (e.g., conforming design of pseudonymization process) and standardization of services. Legal demands for quality assurance, such as monitoring and source data verification, also need to be handled with state-of-the-art technology that uses standardized interfaces to export clinical data into analysis systems.

Materials and methods

Since 2001, the University of Goettingen has been developing an IT-portal for research networks in collaboration with several medical competence networks. It is a specialized version of a more general solution provided to Goettingen University, the Max Planck Institute and the German Association of University Heads (Rektorenkonferenz) [8]. For many years, the Department of Medical Informatics in Goettingen has focused on the development of IT systems and IT solutions to support clinical research. This work is supported by major third-party funding in the field of competence networks. Comprehensive communication and infrastructure concepts for supporting eTrial processes were developed and imple-

mented. Particular relevance for the integrative application in the eTrial process is the integration of the content management system and the clinical electronic patient record (EPR) system iXserv. This portal system was acquired by current and earlier third party projects. Synergy effects resulting from the shared resources are invaluable. These projects are:

- Competence Network for Congenital Heart Diseases
- Competence Network for Dementia
- Research Network for Creutzfeldt-Jakob Disease.

The corresponding licenses were already available for these projects and only the maintenance (and additional resources related to the project) needed to be funded. Exemplified by these competence networks, a standardized and portable portal platform based on MS-SharePoint server was introduced to support work and communication processes. It offered role- and process-oriented access for a more efficient use of IT infrastructure.

The services in this infrastructure could be offered as operative infrastructure to new research networks that need these services, such as the Competence Network for Degenerative Dementias (KNDD), on a low-level budget that covers customizing activities to the changing needs of the research projects in the new network.

Thus, the Department of Medical Informatics has already built a research IT infrastructure: the mentioned collaboration research portal that supports clinical research and a variety of methodology procedures. Special requirements of new research networks can be realized by appropriate parameterizing of this system (see Figure 1).

Although this is an example of how new research networks can inherit and reuse services from established networks, difficulties could arise if the new network demands new services or resources that the current system cannot fulfill or integrate. While building a completely new IT solution is expensive, reengineering the existing solution could lead to unneeded complexity that may affect the old network's operation.

To face the challenges of new resource demanding research applications in medicine, the existing IT infrastructure shall be complemented by access to processing power, storage and special applications. These resources will not be available within new projects and it would not make sense to fund single powerful computing nodes for small research networks (such as the KNDD). Instead, access to such resources can be eased through implementation of a grid [9].

'Grid-computing' stands for making computer power, storage resources, data and algorithms easily available to the scientific end-user. It has become a key infrastructural component on the way to broadly applied computational medicine. In a project funded by the Federal Ministry of Education and Research in Germany since September 2005, the University of Goettingen and seven partners from the community medicine sector were asked to cooperate with four other communities (including engineering climate research, high-energy physics and astronomy) to build the national grid-computing infrastructure [3].

Representing the community medicine in D-GRID, the MediGRID project has the task of incrementally developing and providing a grid infrastructure to meet the needs of the biomedical users. The user communities are represented in three research modules for biomedical informatics, image processing and clinical research, and they cooperate closely with the four methodological modules: middleware, ontology, resource fusion and eScience, which have the task of implementing the MediGRID infrastructure and connecting it to D-Grid [3, 4].

Through MediGRID, there are various resources available that are shared with the biomedical community and other communities. Following the grid paradigm, the threshold

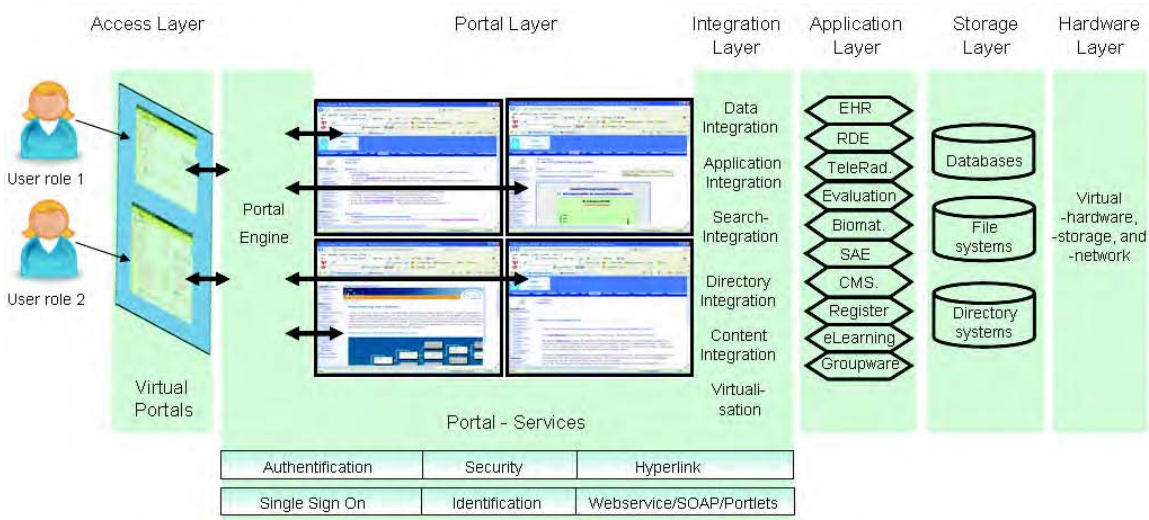

Figure 1 - Overview of the architecture of a portal for research networks. Beyond generic groupware, the services include study management, remote data entry (RDE), content management, clinical guideline management, eLearning module and other functions

to using these resources should be as low as possible for the academic user. Therefore, the grid resources are presented in one portal being set up in the MediGRID project (GridSphere and the specific portlets). Based on the experience in the MediGRID pilot applications current analysis methods as well as new methods and applications can be integrated as additional portlets in the online grid portal [10].

MediGRID is dealing specifically with the privacy and data protection challenges of the grid and distributed computing and storage. Sharing the MediGRID portal with new research networks (like KNDD), the latter could make full use of solutions for auditing, tracking, fine granular access control and privacy control in a distributed resources environment. Moreover, MediGRID policies would be used and applied to all new users/accounts; that is, all the administrative problems related to granting accounts and developing portlets in a distributed environment are solved [11, 12].

Depending mainly on open-source products and making all developments within one community available to other communities in D-Grid, MediGRID takes advantage of technologies developed within the overall D-Grid. Accounting, billing, monitoring, data provenance and long-term archiving are examples of such technologies [12] and will guarantee the sustainability of services.

The users of the MediGRID portal could access the different implemented portlets according to the MediGRID resource usage policies.[1] At the moment, portlets for image processing, bioinformatics and ontology are implemented.

Apart from the IT infrastructure itself, MediGRID also started a strategic cooperation with other grid projects hosted by the Goettingen State and University Library (SUB) and the Goettingen University Computer Center (GWDG). In March 2006, the three institutions set up the local grid-computing community in Goettingen, the so-called Goe-Grid. Goe-Grid is working closely with the kopal Project (Kooperativer Aufbau eines Langzeitarchivs digitaler Informationen – Cooperative Development of a Long-Term Digital Information Archive), also represented by SUB and GWDG, to import the kopal results into the grid environment and offer solutions for long-term archiving for grid users that could also be used by new research networks that have access to the MediGRID portal.

In this context, an approach to an operative infrastructure built on the collaboration portal could be massively extended by two elements that are of great benefit for collaborative research in medicine and need specific attention:

1. Integration of the grid portal for the life sciences into the portal for the research networks and harmonizing the two security infrastructures.
2. Solutions for long-term archiving by the corresponding kopal project.

Table 1 - Functions/services within the portals. While the collaboration portals focus on management, grid portals focus on sharing resources

(Medi)GRID portal [4, 10-12]	**Collaboration portal**
Enhanced security (audit, tracking, fine granular access control …)	Data protection and access control (PID-generator, pseudonymisation service…)
All applications are implemented as portlets in the portal. New application can also be implemented	Information services (accessed from www via browser, forums …)
Sharing resources, monitoring, billing, data and process provenance. Virtualization technology. Virtual organization management	Collaboration services (document management, project management, journal management, video conferencing …)
High-volume data storage and processing. Storage resource broker: data access on distributed platform	Data management (remote data entry system-KIS/KAS, national register-Ixmid/IXserv …)
Use of open-source standards and software	Quality management (evaluation systems-Evasys, transfer of knowledge …)

Results

The portal integration has to take place in the areas of security, the portal GUI and the applications.

Security

MediGRID is working under the umbrella of the German national D-Grid Project. D-Grid currently consists of 11 partners from different communities (engineering, astronomy, climate, libraries). This number will increase in February 2007 with new communities and projects from the second D-Grid Call. Dealing with patient data that is sensitive, MediGRID has the task of ensuring data security and data protection, and helping to develop/steer the technology for the D-Grid IT infrastructure regarding data protection laws and concepts [11].

Currently, MediGRID users need a DFN grid certificate that is harmonized in the EU Grid PMA. A security policy defines the process flow of granting MediGRID portal accounts. In addition, a three-step sign in the process using the DFN grid certificate and MyProxy upload tool enables

1 The MediGRID usage policies present guidance for the use of MediGRID resources. Current MediGRID policy is *Resource Usage Policy Phase One – Development Phase version 1.7.*

the use of grid resources for all authorized users without the need to install any middleware on local PCs (see Figure 2).

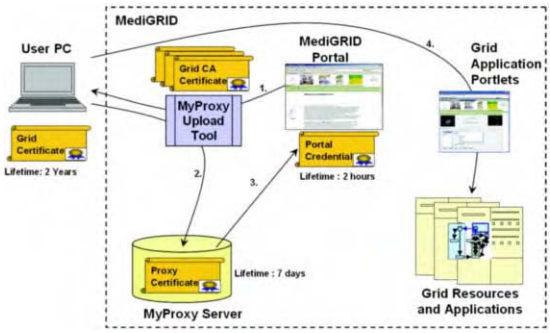

Figure 2 - Secure use of the resources and applications implemented in the MediGRID portal: (1) Signing into the MediGRID portal and downloading the MyProxy upload tool (2) Using the DFN certificate and the private key to create a MyProxy certificate and then uploading it in MyProxy Server (3) Creating own credential for the MediGRID portal (4) Using resources and applications

The kopal Project is a library-oriented solution for long-term archiving. It has its own security management using an SSL connection and users have, as in MediGRID, their own DFN certificate and portal account. However, unlike MediGRID, the access authorization in kopal is granted using an IP-white-lists that allow only certain PCs in certain institutes to access the resources.

The collaborative research portal uses the active directory system from Microsoft to administer user accounts. The security is managed using an SSL connection to the portal, and an access-control mapping process to the local resources using Meta-Directory from Novell and special connectors to these resources.

To be able to use the three infrastructures within one portal, the first step is to harmonize the security policies and the authentication/authorization methods between the MediGRID portal, kopal solutions and the collaborative research portal. Here, the MediGRID resources usage policies and user/developer agreements would be applicable, which means direct importing of solutions for administrative problems such as granting accounts, using the infrastructure for developing applications and so on. The security management for access to archived documents should be transferred from kopal, obtain legal acceptance for use with medical data (including patient data) and, if necessary, it can be redefined before implementation.

Harmonization of the portal GUI

MediGRID uses the open source GridSphere portal software that is implemented in Java according to java portal specifications JSR 168 that is expected to be in version JSR 268 in mid-2007. The GridSphere portal was developed from the GridLab project funded by the EU IST program in 2002–2005 to be similar to the commercial WebSphere portal from IBM. GridShere, according to the developer, was designed to be compatible with WebSphere. The collaboration portal is based on the standard Microsoft Office SharePoint Portal platform. Kopal provides services offered by Java API, which could be imported directly in the applications.

The goal of this step is to conceptualize and implement an interface between both portals, and to import the kopal functionalities given the results of the first step regarding security. To save the principles of a user-oriented portal, special focus has to be placed on:

- Maximum synergy for the scientist to allow the use of the services in both portals without extra effort
- Simple portal principles of single sign on
- User personalization and different contents on one screen aggregation possibilities.

Application integration

While one main task of MediGRID is developing a grid middleware integration platform enabling e-Science services for biomedical life science, the other task is to gain knowledge to implement applications on this infrastructure. An integration pipeline process was planned from the beginning of the MediGRID project. Currently, the knowledge gained in the first 'gridifying' steps is helping to accelerate the implementation of applications (see Figure 3).

The applications within new research networks that intend to access (Medi)grid resources have to be analyzed and categorized. Non-grid applications can be integrated as simple services outside the grid portal. More demanding applications can be integrated as grid services allocating and using grid resources. The new medical focus may demand new analysis methods not implemented previously. Therefore, access to NLM resources as well as to caBIG open-source code and applications is of paramount interest. Some of these applications are ready to be deployed on grid infrastructure, which means a saving in development costs.

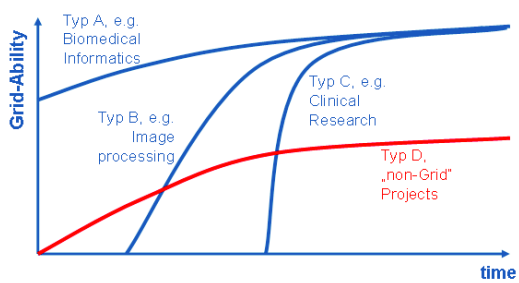

Figure 3 - The pipeline process in MediGRID: type A projects are prepared for grid computing. Other projects can be 'gridified' using the experience of the first projects (type B). Type D projects should be avoided

Discussion and conclusion

In this paper, we have discussed the different projects being conducted by the Department of Medical Informatics at the University Hospital of Goettingen, and the necessary steps to merge the IT infrastructures of these different projects starting from the point that access to resources uses a higher level portal access to the resources and aiming to keep the access process as simple as possible.

Our objectives in this study were to:

- Keep costs as low as possible
- Maximize the usability
- Save implementation time and effort.

These objectives reflect the triangle of cost, quality and resources. Our analysis shows that a three-step procedure should be performed and successfully completed to achieve the mentioned goals. These three steps are:

- Proving and interfacing the security policies and technologies between the different project/research networks
- Harmonizing the different portal-access methods to have one GUI
- Integrating all applications and services as portlets in the suitable portal, where the necessary resources can be accessed.

By building such an interface, the different medical research groups could work together more easily and could use the advantages of the available IT infrastructure more efficiently.

Taking into account the complexity of portal integration, it becomes clear that the integrated solutions have to be developed and tested by major centers. In a second step, end-users can customize their specific solutions in the developed system. However, smaller research consortia have no chance to develop such infrastructure by their own.

Acknowledgments

This work was funded by the MediGRID grant of the Federal Ministry of Education and Research in Germany (BMBF) e-science-initiative program under the promotion number: 01AK803H, the BMBF Competence Network congenital heart diseases (KN AHF) project under the promotion number: 01GI0210, and the BMBF Competence Network Dementia (KND) project under the promotion number: 01GI0428.

[b] *Department of Medical Informatics, University Medical Center Freiburg, Germany*

Abstract

In this paper we want to describe how the promising technology of biomedical data mining can improve the use of hospital information systems: a large set of unstructured, narrative clinical data from a dermatological university hospital like discharge letters or other dermatological reports were processed through a morpho-semantic text retrieval engine ("MorphoSaurus") and integrated with other clinical data using a web-based interface and brought into daily clinical routine. The user evaluation showed a very high user acceptance – this system seems to meet the clinicians' requirements for a vertical data mining in the electronic patient records. What emerges is the need for integration of biomedical data mining into hospital information systems for clinical, scientific, educational and economic reasons.

Keywords:

hospital information systems;
natural language processing; information storage and retrieval; medical records systems, computerized

Introduction

Hospital Information Systems (HIS)

Hospital Information Systems are widely adopted as a valuable and indispensable tool in the healthcare domain: they integrate patient information and improve efficiency and quality of care [1-3]. Hospital Information Systems usually focus on patient-centered, "intra-patient" issues, like storage of laboratory results, medical reports, discharge letters, coded diagnoses and procedures, and other clinical documents: Waegemann [4;5] defines the Electronic Health Record (EHR) as a *computer-stored collection of health information about one person linked by a person identifier*. Another aspect of the EHR is defined by the Healthcare Information and Management Systems Society (HIMSS) [6]: *The Electronic Health Record (EHR) is a secure, real-time, point-of-care, patient centric information resource for clinicians.* […] *The EHR also supports the collection of data for uses other than direct clinical care, such as billing, quality management, outcomes reporting, resource planning, and public health disease surveillance and reporting*.

According to those definitions and to individual patient care, access to the medical information contained in current Hospital Information Systems is mostly horizontal, i.e., patient-centered (figure 1): by opening a patient's electronic record the doctor gets all information about him. The HIMSS definition suggests more scenarios of use by aggregating information in the vertical view of all electronic patient records. This information relies usually on structured entries like billing information, coded diagnoses and procedures, structured laboratory or microbiology results – it easily can be selected using appropriate and well-known database and data warehouse technologies.

For the clinician, non-structured, heterogeneous information like discharge letters, anamnesis, reports of particular investigations and other narrative data are of high relevance for patient care – the more information is stored in the HIS, the more interesting are its vertical, i.e. inter-patient interdependencies.

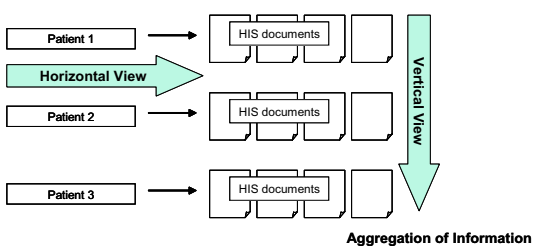

Figure 1 - Views on the HIS

Some questions the doctor could pose:

- "What patients did I treat that had the same disease?"
- "What was the outcome of that treatment?"
- "What were the adverse events of that treatment?"
- "Did I have patients with disease *xy* and symptoms *ab*?"
- "I'd like to get some typical cases with images of disease *xy* with symptoms *ab* for my students."
- "How was the name of the patient with symptoms *ab* that I treated three weeks ago?"
- […]

Although several promising technologies like the Clinical Document Architecture [7-10] and medical terminologies have been developed in order to standardize and structure clinical information, there is still a gap between this clinical need and today's practice. Furthermore, structured information like ICD Codes is often less accurate compared to text.

Narrative data cannot be selected using traditional database-driven technologies due to several limitations. Natural Language Processing (NLP) has developed efficient tools and new approaches to improve text mining mainly due to its paradigm shift from rule based methods to statistical and corpus based approaches [11]. The architecture of a medical text mining system may consist of three core functions [12]:

- Morphological analysis of words
- Structured analysis of sentences
- Semantical interpretation

To achieve basic results of text mining, it is not necessary to completely build all these components including the highly sophisticated semantic interpreter. We started with a medicine specific word analysis and focused on a solution of grammatical phenomena of word building severely impeding user friendly text retrieval:

- Inflection (lesion, lesions)
- Derivation (psoriasis, psoriatic)
- Abbreviations (LE=lupus erythematodes, SSM=superficial spreading melanoma)
- Synonyms (Sarcoidosis, Besnier-Boeck-Schaumann disease, Lupus pernio, benign Lymphogranulomatosis, Uveoparotid fever)
- Composition (leg ulcer, ulcer of the leg)
- […]

Data mining in the healthcare domain

In molecular biology, data mining technology has been successfully adopted to automatically summarize the immensely increasing scientific literature [13-17]. In the context of healthcare related information, natural language processing and data mining technology are often used in radiology findings [18-21].

At the University Medical Center of Freiburg, a comprehensive and flexible cross-language document retrieval engine ("MorphoSaurus") for the medical domain has been developed [22].

Biomedical data mining in dermatology

As a conclusion of the above, the document retrieval engine should be implemented into clinical routine, based on a large set of clinical data from a dermatologic university hospital, presented to those physicians, which actually generated the medical content.

These questions should be answered:

- How shall text mining be presented to the doctors?
- What features are important for clinical routine?
- What additional data can enhance doctors' compliance to this system?
- How useful is text mining for clinical routine as well as for scientific or educational purposes?

Materials and methods

Morpho-semantic indexing

At the core of this approach lies the MorphoSaurus text processing engine (an acronym for MORPHeme TheSAURUS). Its indexing technique is particularly sensitive towards cross-language morpho-semantic regularities. The system is centered around a new type of dictionary, in which the entries are subwords, i.e., semantically minimal, morpheme-style units. Language specific subwords are linked by intralingual as well as interlingual synonymy and grouped in terms of concept-like equivalence classes at the layer of a language-independent interlingua.

Morpho-semantic indexing starts from the assumption that neither fully inflected nor automatically stemmed words – such as common in many text retrieval systems – constitute the appropriate granularity level for lexicalized content description. Especially in the medical domain, a high frequency of do-main-specific suffixes (e.g. "-itis", "-ectomia") and numerous occurrences of complex word forms such as "pseudo | hypo | para | thyroid | ism" or "gluco | corticoid | s". To properly account for these particularities, the notion of subwords, i.e. self-contained, semantically minimal units had been introduced. [23]

Subwords are assembled in a multilingual dictionary and thesaurus, which contain their entries, special attributes and semantic relations between them, according to the following considerations:

- Subwords are listed, together with their attributes such as language (English, German, Portuguese) and sub-word type (stem, prefix, suffix, invariant). Each lexicon entry is assigned one or more morpho-semantic identifier(s) representing the corresponding synonymy class, the Morphosaurus identifier (MID).
- Semantic links between synonymy classes are added.

Figure 2 depicts how source documents (top-left) are converted into an interlingual representation by a three-step mor-pho-semantic indexing procedure:

- First, each input word is orthographically normalized in terms of lower case characters and according to language specific rules for the transcription of diacritics (top-right).
- Next, words are segmented into sequences of subwords or left unchanged when no subwords can be decomposed (bottom-right).
- The segmentation results are checked for morphological plausibility using a finite-state automaton which rejects invalid segmentations (e.g. segmentations without stems or ones beginning with a suffix).

- Finally, each meaning-bearing subword is replaced by an language independent semantic identifier, its MID, thus producing the interlingual output representation of the system (bottom-left).

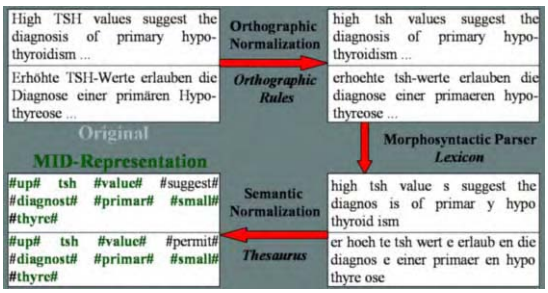

Figure 2 - Morpho-semantic indexing pathway

Having been successfully used for several scenarios [24;25], the impact on purely clinical data had to be tested in clinical routine.

Implementation

Clinical data set

Since the HIS [26] does not provide an interface, which could be used for implementing biomedical data retrieval, we had to extract all relevant information and to integrate it into a web-based user interface: Almost 30.000 clinical documents, which were stored in Rich Text Format (RTF) were extracted from the HIS database. These were mainly discharge letters, but also surgical reports, immuno-dermatological findings and different other narrative reports of clinical results. These documents originated from 2000 to 2006. The RTF-documents then were converted to plain text files that could be processed by the morpho-semantic indexing system.

Building the web interface

A web interface then had been developed based on Apache Lucene [27], a freely available open-source search engine which combines boolean searching with a sophisticated but highly efficient ranking model. It supports a rich query language like multi-field search, including more than ten different query operators. The web interface itself had been programmed in php [28] (figure 3).

Adding image repository

Since patient photographic images play an important role in dermatological record keeping and training [29], a large image repository, consisting of 90.000 photographs, had been patient-specifically linked to the web interface, in order to enhance the overall benefit of the system.

Evaluation

As the system should show the clinical impact of biomedical datamining, an evaluation engine was implemented. Users were intermittently encouraged to assess their benefit of the system and its further potential for their work. Search terms that were applied by the users were recorded anonymously.

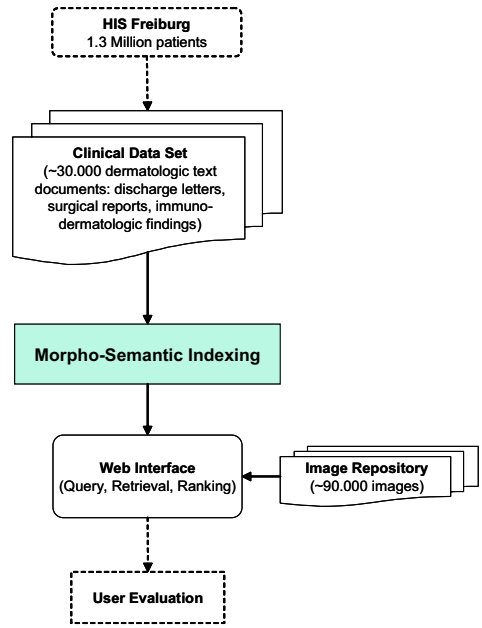

Figure 3 - Implementation

Results

Application interface

The main design principles for the web-based application interface were combining ease of use with specific search options according to clinical needs (figure 4): An edit box allows free-text search in all documents using the MorphoSaurus. Results can be ranked by relevance, date, patient name and date. In the results section, the relevant part of the underlying document is shown depending on the search terms. Search words or their derivations are highlighted. Information about the patient, the author and creation date of the document is shown in the respective context. The original document can be viewed as a PDF file that is linked to the record.

Another link opens the image library of the respective patient (figure 5), where all images are shown together with localization and creation date. This is particularly helpful for dermatologists, so they can analyze the images in the context of the underlying documents and vice versa.

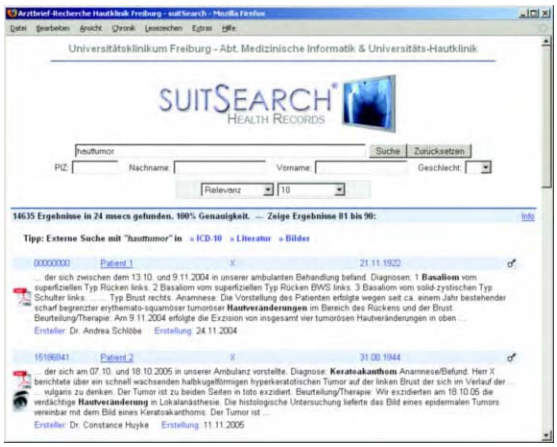

Figure 4- Web-based user interface

Figure 5 - Image retrieval

User evaluation

General acceptance

Users' acceptance of the data mining engine was remarkably high and enthusiastic from the beginning: For the first time, they had access to thousands of documents and images independently from the individual patient record. Three weeks after the introduction of the system, it was already used by three doctoral students in order to extract information for their doctoral thesis. Some even found unpredicted use scenarios, like searching good discharge letters as an example for their own letters they had to write.

Systematic evaluation

The use of the system has been systematically evaluated in three different major topics (clinical, scientific, educational impact), for each using structured questions as well as open free-text comments. Some preliminary results of that evaluation are given here.

The evaluation revealed 20 user evaluation data sets (15 physicians, 3 students, 2 information specialists). 82% stated that the system could enhance their clinical performance. Almost 89% thought that this kind of biomedical data mining and the integration of narrative text with dermatological images have a very positive impact on their scientific work. The impact on dermatologic education has been less estimated, only 52% of the users saw a potential benefit.

Users generally wished the integration of more clinical data, like radiology images and reports, laboratory results and other clinical findings.

Discussion

As long as Hospital Information Systems mainly contain narrative text, biomedical data mining seems crucial for enhancing clinical benefit in many ways. Although our system is currently successfully and regularly used in clinical routine by approximately 25 users, it has several limitations:

- Clinicians' search terms are not predictable; they vary from a single word to complex phrases, so a thorough analysis of the aggregated search history is necessary.
- A domain-specific dermatological MorphoSaurus dictionary has to be developed in order to enhance the response rate of their searches.
- Clinical data cannot be accessed in "real time", i.e. they have to be exported periodically from the HIS and indexed by the MorphoSaurus, before they can be retrieved.
- A direct integration into the HIS would be highly desirable and is planned in 2007.
- The integration of even more and also structured clinical data like laboratory results, histological findings, diagnosis and procedure codes etc. seems of broad interest.
- User acceptance and expectations towards biomedical data mining clearly has to be further evaluated in-depth.

Conclusion

Our experiences show that there is an emerging need for integration of biomedical data and text mining techniques into hospital information systems for clinical, scientific, educational and economic reasons. Nevertheless, structured data entry and storage mechanisms should be encouraged as well.

Acknowledgments

This work was partly supported by Deutsche Forschungsgemeinschaft (DFG), grant KL 640/5-1 and the European Net-work of Excellence "Semantic Mining" (NoE 507505).

We wish to thank all clinicians of the Department of Dermatology for fruitful discussions and evaluation of the system.

Abstract

*To achieve a safer future prescribing, the Swedish government has introduced a mandatory registration of all drugs dispensed at pharmacies. The medication history in the register may be accessed online by registered individuals, prescribers and pharmacists. After 15 months of action, the prevalence of individuals with dispensed drugs in the Swedish population was 71.0% (6,424,487/9,047,752); women 78.8% and men 63.1%. The incidence rate for individuals with dispensed drugs was estimated as 12.4 (1,000*111,960/9,047,752) per month and 1,000 inhabitants. The mean number of dispensed prescriptions was 12.1 (median 6, Q1-Q3 2-15) per individual. For the elderly (age group 80-89), the mean number of dispensed prescriptions was 27.8 during the study period (median 24, Q1-Q3 13-38); women 28.8 and men 26.1.*

When introducing a National Pharmacy Register, containing personal drug information for the majority of the population, issues on security, confidentiality and ethics have to be taken into consideration. The lack of widespread secure digital signatures in health care may delay general availability. To clinically evaluate individual medication history, the relatively high prevalence of dispensed drugs in the population, seems to justify the National Pharmacy Register.

Introduction

Since many patients have several health care contacts concomitantly at different institutions, physicians are often reduced to prescribing potent drugs unaware of each other's prescriptions. This might influence the effect of the therapy in an uncontrollable manner. Moreover, the polypharmacy, with accompanied risk for drug interactions [1-4], may be so profuse that a low degree of compliance to the prescribed therapy has been named 'intelligent non-compliance', indicating that it may be beneficial for patients not to adhere to the prescribed therapy [5].

One approach to improve the situation for prescribers has been to store information on the *prescribed* therapy in databases at institutions or within larger regional organisations, mostly as part of an electronic health care record. When prescribing, the physician will be able to check the patient history for polypharmacy, interactions and different kind of contraindications. Automated systems for interaction alert may also be integrated in these systems. Results of the alerts may be to refrain from prescribing, adjusting the dose or monitoring the plasma concentration of the drug. Discontinuation of previous prescriptions may also be relevant.

Another approach to provide prescribers with medication history is the new legislations in Denmark and Sweden allowing nationwide databases with information on *dispensed* prescriptions at the pharmacies. The information is accessible to the patients, and with the patients' conditioned consent, to prescribers and dispensing pharmacists (Fig.1). These databases comprise a large proportion of the national population and are subject to strict security regulations to ensure individual confidentiality.

In Sweden, all prescriptions dispensed at pharmacies, with the exception of drugs dispensed for in-patients at hospitals and OTC (Over-The-Counter) sales have been stored in a National Pharmacy Register since July 2005 [6-7]. Use of the medication history in this register is, by a special law, restricted to clinical use and documentation;

- achieving a safer drug prescribing for the registered person in the future,
- providing the registered person care or treatment,
- supplementing the registered persons health care record,
- assisting dispensing pharmacists and
- facilitating the registered persons drug utilization.

Aim of the study

The present study was conducted in order to describe the information content of the National Pharmacy Register.

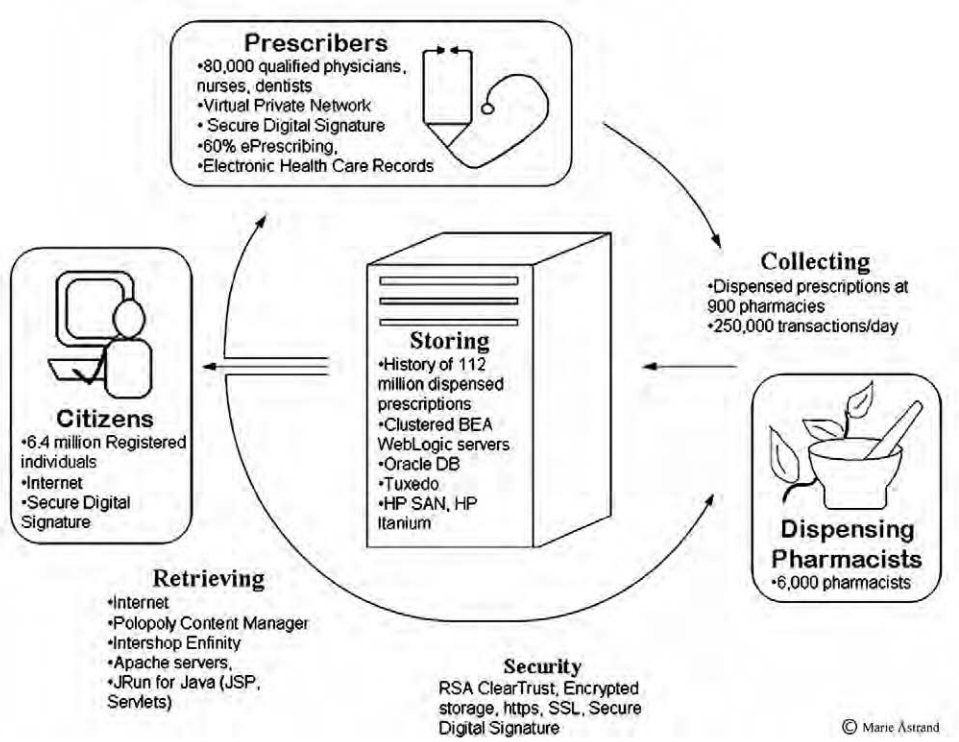

Figure 1 - Information model applied to the National Pharmacy Register

Materials and methods

The National Pharmacy Register

The National Pharmacy Register is individual-based and contains data from all dispensed out-patient prescriptions at all Swedish pharmacies from July 1, 2005, including multi-dose dispensed prescriptions and legal internet sales. Data collection from about 900 pharmacies and the National Pharmacy Register is administered by the National Corporation of Pharmacies, Apoteket AB [8]. The registered data is available for the registered individual at the pharmacy desk, with valid identification, and on the internet, with a secure digital signature. After conditioned consent from the registered individual, the register will be accessible on-line for prescribers and dispensing pharmacists. The registration is mandatory and includes the name and the personal identification number (social security number) of the registered individual along with day of dispensing, drug name, prescribed amount and dosage (Table 1). The information is stored in the register for a period of 15 months and thereafter cleared.

Table 1 - Information content in the national pharmacy register

Object	Variable
Patient	**Name** **Personal identification number***
Drug	**Name** **Amount** **Dose**
Pharmacy	**Data of dispensing**

All individuals (outpatients) filling prescriptions at Swedish pharmacies during the first 15 month period were included in our study. The measures used were number of individuals, number of dispensing dates and number of drugs. Epidemiological measures were used and defined; *prevalence* - the proportion of individuals filling prescriptions in the Swedish population during 15 months; *incidence* - the total number of new individuals filling prescriptions in the Swedish population per month, after a wash-out period of 12 months; *incidence rate* - number of new individuals filling a prescription*1,000/number of individuals at risk (the entire Swedish population); relative risk, RR – the ratio between risks in two groups for filling a prescription during the 15 month study period.

Calculation of sums, frequencies and ratios were aggregated and compiled from production data of the source database. All data processing in our study were done anonymously, without the personal identification number; only gender and year of birth, originally embedded in the personal identification number, were used. The study population was stratified by gender and age (10-year classes) on July 1, 2005. Results were compared to statistics on the number of individuals per gender and age group in the Swedish population on December 31, 2005 [9].

Results

After the first 15 months (July 2005 to September 2006) the register contained 6,424,487 individuals of the Swedish population of 9,047,752 inhabitants. Thus, the prevalence of individuals with dispensed drugs in the entire Swedish population was 71.0% (women 78.8%, men 63.1%) (Fig.2). The prevalence of individuals with multi-dose dispensed drugs was 2.4% (213,395/9,047,752). During the first month, 30.3% (1,946,885/6,424,487) of the registered individuals filled a prescription at a Swedish pharmacy. After four months, 2/3 (4,328,627/6,424,487) of the individuals were registered in the database (Fig.2). After a 12-month wash-out period, the incidence was estimated as 111,960 new individuals per month (Fig.3). Hence, the incidence rate of dispensing drugs on prescriptions per month and 1,000 inhabitants was estimated as 12.4 (1,000*111,960/9,047,752).

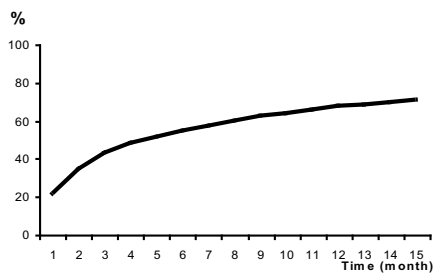

Figure 2 - Prevalence of individuals with dispensed drugs in the National Pharmacy Register during the first 15 months

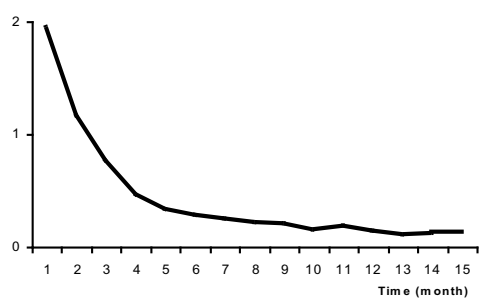

Figure 3 – Number of new individuals in the National Pharmacy Register during the first 15 months.

Most individuals in the register were women (56.0% women, 44.0% men), with a relative risk of 1.25 ((3,595,152/4,561,202)/(2,829,335/4,486,550)). The prevalence of individuals with dispensed drugs showed a positive linear relationship with age, with a higher prevalence for the elderly. Above 70 years of age, the prevalence was 92.1%, 94.9% and 94.3% in the respective age groups. For children 0-9 years of age, the prevalence was 62.8% (women 61.2%, men 64.3%). For women, the prevalence was 77% or more, for all age groups 20 years and above (Fig.4)

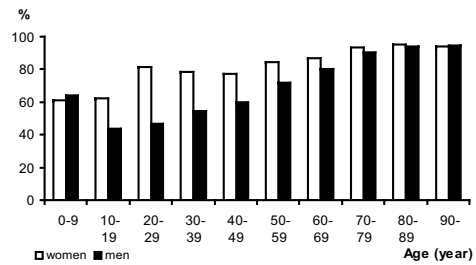

Figure 4 - Prevalence of individuals with dispensed drugs according to age groups and gender in the National Pharmacy Register during the first 15 months

During the 15 month study period the mean number of dispensed prescriptions was 12.1 (median 6, Q1-Q3 2-15) per individual, multi-dose dispensed prescriptions excluded; for the elderly above 70 years of age the mean number of prescriptions was 25.1 (median 20, Q1-Q3 10-34), 27.8 (median 24, Q1-Q3 13-38) and 24.8 (median 21, Q1-Q3 10-35) in the respective age groups, for children 0-9 years of age, the mean number of dispensed prescriptions was 3.7 (median 2, Q1-Q3 1-4). The overall mean number of dispensed drugs at each pharmacy visit (same date) was 1.88 (76,004,043/40,445,263), multi-dose dispensed prescriptions excluded.

Discussion

In the present study, less than 30% of the Swedish population did not fill any prescription, revealing that more than 2/3 of the population filled at least one prescription, during the study period of 15 months. The prevalence of dispensed prescriptions must be regarded as relatively high, since for elderly it was above 92% and for women over 20 years of age the prevalence was never below 77%. Even for children, a high prevalence of 63% was observed. The elderly filled more than twice as many prescriptions as the general population (24.8-27.8 vs. 12.1). Of those who filled a prescription, filled 15 or more prescriptions. As a rule, with the Swedish reimbursement model, the filling of one prescription covers consumption for a three-month period. We did not evaluate to what extent the prescriptions were intended for continuous use, rather than for a shorter treatment period. The relative risk of 1.25 for women may be explained by women's use of sex hormones and modulators of the genital system [7].

The prevalence and incidence of dispensed drugs may be viewed as indicators of the health status of a population.

However, drugs are not only used for curing and alleviating diseases but also for prevention and, more rarely, diagnosing. Moreover, we did not measure the actual consumption of the drugs, only the prescriptions dispensed at the pharmacy. The register does not contain information on OTC sales or drugs dispensed for inpatients in hospitals and institutions, with the exception of multi-dose dispensed drugs at pharmacies.

The Swedish health care system is tax financed and readily available for all and the patients are free to consult an unlimited number of physicians. To clinically evaluate individual medication history, the relatively high prevalence of dispensed drugs in the population, seems to justify the National Pharmacy Register.

Prescribed, dispensed and consumed

The patients' degree of *adherence* to the doctors' prescribed therapy has been described as *compliance* or more recently as *concordance*, indicating a more inclusive and less paternalistic view of the doctor-patient relationship [10].

Prescribing is not always equivalent to the amount of dispensed drugs or the actual drugs consumed by the patient. If the patient does not fill the prescription at a pharmacy a so-called *primary non-compliance* occurs. As a result of experienced or imagined side effects or otherwise unfulfilled patient expectations, the patient may choose, or just forget, not to continue a medication, although the prescriptions have been presented to a pharmacy and subsequently filled. This is referred to as *secondary non-compliance* and may result in early cessation of therapy, prescriptions not refilled or simply a reduced intake of the amount of the medication. Thus, as a measure of true drug consumption, prevalence and incidence estimates in the present study may be both over- and underestimated. Some of the filled prescriptions will never be used by patients, resulting in an overestimation. In contrast, additional sources like OTC sales, herbal remedies, in-hospital medications, and illicit internet sales will result in an underestimation of the true exposure.

Clinical aspects

In order to reduce polypharmacy, drug interactions and side-effects, the expected clinical benefits of the National Pharmacy Register would be to provide a correct and updated medication history for all patients, readily available whenever needed, and independent of who has prescribed the therapy. To what extent does the National Pharmacy Register fulfil these expectations? As a source for a national medication history, the register seems to be rather complete, exceeding 2/3 of the entire national population. While pilot tests are in an early phase, clinical experiences are anecdotic and not yet systematically evaluated. Lack of widespread secure digital signatures in health care may, however, delay general availability. The usability would also be improved if the information from the register were available within the framework of systems for electronic health care records, a technology still under construction.

Epidemiological research

The register is intended for prescribers, pharmacists and the registered individuals for clinical use and documentation. The equivalent information is also collected and distributed to the Swedish National Board of Health and Welfare for statistical, epidemiological and scientific purposes, stored without any time restrictions, with new opportunities to explore drug and disease associations and the risks, benefits, effectiveness and health economical effects of drug use [11].

Quality and security

The development in Sweden of medical information systems for the physician office launched the first electronic transfer of an ePrescription in 1983 [12-13]. In December 2006, 62% (intra-county range 33-81%) of all prescriptions were transferred as ePrescriptions, with a steadily growing trend. Thus, the prescriber is entering prescription information into electronic health record systems that will subsequently be used, not only for the dispensing of new prescriptions and refills, but also as an information source for future prescriptions by other prescribers, which is one of the main objectives of the National Pharmacy Register. In order to prevent medical errors, it will be of utmost importance to monitor and improve the quality of prescriptions.

For authorization of prescribers a secure digital signature is required; in Denmark by law and in Sweden by regulation of authorities. Until now, these were not readily available in health care and will present a constraint for making the register available to all prescribers in the near future. The register is protected against unauthorized access by laws, rules, written agreements, authorities' inspection, technical and physical procedures. The data collection procedure is presently done batch-wise overnight, but should be altered to online and momentarily, ensuring constantly updated and accurate information in the register.

Ethical considerations

Individuals may benefit from the register being complete and correct at all times but may at the same time be cautious about the confidentiality of their personal health information. To solve this dilemma, the approach in the national pharmacy dispensing registers in Denmark and Sweden, has been to mandatory collect and register the information in the national database, but also to give the patient the right to restrict the accessibility of the information to certain individual health care professionals. In addition, the patient is offered full transparency to who has accessed the information. According to national laws, unauthorized access might be subject to a lawsuit. As an exception, prescribers may, in emergencies, have access to the register without a conditioned consent.

Future improvements and studies

If feasible, it would be beneficial to include all drugs in the register, e.g. OTC sales and drugs used for inpatients in hospitals. Also, to increase the clinical usability of the information in the register, information on the actual prescriber of each prescription should be included.

A coordinated nationwide pilot plan is presently being conducted within several Swedish health care organisations and pharmacies. For the registered individuals' access to the register on the Internet, about 40,000 accesses have been registered (March – December, 2006). Evaluations are conducted by the e-Health Institute, University of Kalmar, Sweden.

The National Pharmacy Register has a clinical objective, namely to improve drug utilization. Future studies should evaluate the availability and the deployment in health care as well as to what extent the intended benefits have been reached.

The results in our study raise many research questions on the utilization of drugs on a population level. For further studies the pharmacoepidemiological database at the National Board of Health and Welfare opens new prospects for researchers.

The register can also serve as a model for coming health care services for individuals on the Internet. The Swedish government has published a National Strategy for eHealth, with the objective to facilitate access to information across organisational boundaries; making information and services easily accessible to citizens [14].

Conclusions

The Swedish National Pharmacy Register provides prescription dispensing information for the majority of the population. The medication history in the register may be accessed online, to improve drug utilization, by registered individuals, prescribers and pharmacists in a safe and secure manner. Lack of widespread secure digital signatures in health care may delay general availability. To clinically evaluate individual medication history, the relatively high prevalence of dispensed drugs in the population, seems to justify the National Pharmacy Register.

The Use of Existing Low-Cost Technologies to Enhance the Medical Record Documentation Using a Summary Patient Record [SPR]

Dr S. Bart[a], Dr T.Hannan[b]

[a,b] *Department of Medicine, Launceston General Hospital, Launceston, Tasmania, Australia*

Abstract

The Institute of Medicine has described the Electronic Medical Record [EMR] as an essential technology for health care that improves patient safety and the quality of care when compared to traditional paper-based records. [1,2,3] Despite major financial expenditures on health information technology related to EMRs in developed countries such as North America, Britain and Australia, success rates for successful implementations have been low. One specific domain of information management relates to the communication of health care between those involved in the care process. Summarization of patient histories is a core component of EMR systems and assists in the communication of health care. This paper demonstrates how the utilization of simple technologies, can lead to the successful implementation of the Summary Patient Record [SPR] component of an EMR system.

Keywords:

summarization, communication, technology

Introduction

In 1991 the Institute Of Medicine [IOM] published a review stating that computer-based technologies are the essential technologies for improving health care delivery. [1] Subsequent publications from the IOM on aspects of health care delivery and the quality of care, affirm the critical role of the Electronic Medical Record [EMR] in reforming the health care processes. [2, 3]. No clear definition of the EMR exists but it is essentially a pre-birth to post death electronic record which meets the record-keeping requirements for any setting -whether intensive care or primary care, whether obstetrics or gynecology.

Despite this knowledge on the importance of the EMR, implementation of such systems has been slow. The urgency EMR implementation has recently been emphasised by the American Medical Informatics Association [AMIA] [4]. This organisation has devised a plan to facilitate the implementation of a national EMR in the United States. [4] The impetus for this plan is the continuation of poor quality of care, adverse patient outcomes and expanding health costs. [2, 3, 5]

Review of the Integrated Area [Advanced] Information Management System [IAIMS] by Stead in 1997, showed that implementers of health information systems were more concerned about the cost of computer resources than information management tools. [6] He indicated the issues we needed to address relate to our current costs of information management and how can we obtain timely, reliable and complete clinical information? [6]

EMR definitions describe core functional elements, and one of these is Summarization, [creation of a summary of the patient's medical record] as a tool for effectively communicating health care between professionals. Benefits of Summarisation of the EMR have been shown by Whiting-O'Keefe in 1980 and Fries in 1984. [7, 8]

Utilising the experiences of one of the authors [TH] in the successful implementation of an electronic medical records in resource poor and developed nations, [9, 10, 11] we decided to explore the feasibility of implementing a Summary Patient Record [SPR] in an ambulatory Diabetic Clinic in a regional hospital in northern Tasmania with the aim of improving the documentation and communication of patient care information.

Materials and methods

Setting

The Launceston General Hospital [LGH], is a 300 bed regional teaching hospital in northern Tasmania. The Diabetic Clinic sees approximately 50-100 patients per week. Clinic staffing is by a Specialist, training registrars, diabetes educators, social worker, nurses etc.

Information use prior to the study

The institution does use an EMR. It has a robust intranet infrastructure that links health care institutions within the State of Tasmania. This system provides hospital-wide Internet access, email facilities and in each ward, doctors offices and nursing stations there is computer access to the internet and electronic laboratory data, radiology reports and in 2006 radiology images.

The ancillary patient data is recorded and stored electronically in separate non-communicating systems. All results are printed and stored in the paper record. Radiology has two separate systems, one, which stores digital images, and the other text reports on these images.

Current record documentation in the clinics is by dictated, free-text, typed letters with no clear structural continuity. These letters may be a brief summary of a given visit or an

attempt to repeat and record the whole of that patient's medical history.

The standard process for managing records in the Diabetic Clinic is independent of the SPR system, and all notes are hand written and the and used in conjunction with the current records. This usually includes the paper Diabetic Clinic Record and the separate previous paper In-Hospital Record. For a patient on dialysis or undergoing oncology therapy these records are not available in the Diabetic Clinic. Laboratory and text Radiology reports are available on-line and in printed reports. In general the printed formats are used to assess the patient's results.

Normally, the patient is seen by the clinician who dictates a letter which is delivered to and typed in a typing pool, approximately 2-3 weeks later the letter is returned for editing and signing by the clinician. If corrections are required then the process is repeated. If correct, it is mailed to the referring practitioners. All correspondence is then integrated manually into the Clinic's paper file.

Methods

For this study we performed a prospective study of 100 consecutive patients in the Diabetic Clinic in the LGH. All patients had a SPR Template completed by one author [TH] for both initial and follow up visits. The SPR was stored in MS Word format on a password protected directory on the hospital network. The initial SPR Template was completed using the information recorded at the patient's last visit. This created the core historical SPR. Using this process we could verify the accuracy and content of the information and update any new clinical information that may have been recorded since the previous visit. Information relevant to the current encounter was then recorded in the SPR.

For an initial encounter the SPR Template was completed at the end of the visit and before the arrival of the next patient. If the visit was a follow up and the patient had an existing SPR, then the visit information and management was entered directly into the SPR with the patient in the clinic room. Each Follow Up encounter Table was inserted into the record using macro key functions [two key strokes]. The patient was then given a printed copy or had it emailed to them at the time of the visit. If the patient was travelling near to their Primary Care Practitioner then they would be offered the option of taking it directly to that person. If the clinician did not have an email address or chose not to receive an electronic format of the SPR, a hard copy was sent by post.

For Follow Up visits the record was also printed, posted or emailed in the same manner as the original with the current copy replacing all previous versions of the SPR. Records were emailed using the guidelines described by Delbanco. [12] All email communications between any of the recipients of the SPR were stored electronically in the follow up section by date and time.

Access to radiology or laboratory data during the patient encounter required a single click of the pre-defined SPR *Hyperlink* making these results available in seconds. Use of the Back arrow on the Toolbar returned the user to the contents of the SPR.

Some patients preferred to document and email their Finger Stick Blood Sugar Level [FSBSL] results in a Microsoft Excel file. These were stored in a separate directory under a unique identifier and accessed from within the SPR through the *Hyperlink* tool. One author [TH] had created the Excel with formulae so that all FSBSL readings were averaged over time as were the HbA1c readings. The FSBSL readings were emailed the clinician [TH] and all updated files were stored in a specific computer directory. The standard procedure for FSBSL assessment in the Clinic was a weekly [or longer] review of the FSBSL recorded on a paper from phone conversations and these recordings continue to be hand written.

Outcome measures

We chose the following parameters as outcome measures.

- Turnaround time of documents. This was the time taken to create and transmit the SPR to the relevant people involved in the care process. This included the time to create the SPR at the patient visit and the time taken to send to the appropriate referrers.
- Accessibility of laboratory and ancillary services information. This is the time taken to access the last known data recorded on the patient. We attempted measure the time it took to find the relevant information in the paper record compared to accessing the information on line from within the SPR.
- Accuracy and completeness of information. This based on the content and completeness of the information recorded at the last visit of the patient prior to the use of the SPR. Both authors independently screened the last communication within the paper record for allergies, medications, surgical and diagnostic procedures, the presence of duplicate records and for record validation through the clinicians' signature.
- Patient accessibility to their clinical record. Here we measured how many patients had a copy of any part of their clinical record either the SPR or original Clinic record.
- Timeliness of communication of relevant information. In this assessment we evaluated the availability of the record at future visits or patient encounters with the clinic and also the use of emailed FSBSL readings to the diabetic educators and clinicians.

Results

- Turnaround time of documents.

  The previous record documentation required a minimum of 2-3 weeks. With workloads on the typing pool or with inaccuracies in the typing requiring retyping, this turnaround time for record completion could take up to six weeks. Using the SPR initial history recording by one author [TH] took approximately 10 minutes [usually less] based on clock monitoring. The SPR is printed immediately, given to the patient, and sent

referrers. If email facilities were available the SPR was sent instantaneously to the relevant person.

For Follow Up encounters this process required less than five [5] minutes.

- Accessibility of laboratory and ancillary services information.

  If available the paper-printed reports from laboratories, radiology and other ancillary support systems were filed in the patient's paper folder. Alternatively, Laboratory and Radiology results are accessible in seconds from within the SPR using the *Hyperlink* function.. This occurred during the patient encounter, and did not require sorting through pages of results, and the results could be discussed with the patient while visualising the screen information together. Return to the SPR record required only a click on the Back arrow button on the control panel. If results were required to be stored within the SPR then the *Cut & Paste* function in Word could be used.
- Accuracy and completeness of information.
- We evaluated this by having the authors [SB, TH] review the first 100 records independently using the last formal communication printed in the paper notes. The following list shows the percentage of each of these measurements and represents similar findings for each author. Formal statistical analysis of the evaluations was not performed.
  - Duplicate records-98%
  - Incomplete medication list-63%
  - Incomplete diagnosis-68%
  - Incomplete documentation of procedures-88%
  - Incomplete allergy list-86%
  - Unsigned document-50%
- Patient accessibility to their clinical record.
- Prior to the use of the SPR a patient was rarely provided access to their medical record. In our study every patient was provided with a printed or emailed copy of their SPR at each visit. Updated records were printed or emailed and replaced the previous versions of the document. We found that 35% of patients used email for this communication and 17% of these were over 65 years of age. All these patients chose to receive their SPR by this form of communication. Any comments or corrections made by patients on their record were stored as text in the last Follow Up table. The only negative comments came from a Primary Care practitioner who did not like the format of the SPR.
- Timeliness of communication of relevant information.
- The turnaround for record documentation and distribution time was dramatically shortened from weeks to minutes. 100% of patients had a copy of their record always available immediately. The SPR in electronic format was immediately available for review by authorised persons or transmission to another location e.g. the hospital or to the individual patient if they were travelling long distances. If the patient was subsequently admitted then a copy was in the existing Diabetic Clinic record. Each patient was encouraged to carry the record with them or bring it when admitted. The need for redundancy of copies of the SPR in the notes was because this record format was new and those with access to the patient's record were not familiar with this new format of record documentation. Reports from laboratories and radiology were available from any terminal in the hospital for those who had authorised access to the SPR.

  The emailing of FSBSL readings they would save up to 5 hours in waiting time to make phone contact with the Diabetic Educators in the clinic. We did not evaluate the effect on Diabetic Educators time. Some Educators preferred to use the older hand written charts and record the readings over the phone stating they could interpret the data better in the older format rather than the new graphical displays. Emailed FSBSL measurements were evaluated at the time they were received and a response [included in the SPR] was emailed back to the patient and updated in the existing paper record.

Discussion

The availability of timely, reliable, complete health care information within the medical record is fundamental to good clinical care. The use of paper-based systems in modern health care makes this virtually impossible. [1, 2, 3] Since 1994 it has been shown that the current forms of communication between hospitals and Primary Care practitioners is poor and of low quality. [13]. There has also been a greater focus on technology costs than on information management costs. [14]

Hannan and Fraser have demonstrated that even in resource poor environments complex clinical information systems can be implemented with beneficial outcomes. [9, 11]

Through the use of standard, affordable technologies such as word processing, email and internet connectivity, we have demonstrated that a low technology effective SPR can be implemented in resource rich environment. The SPR in the LGH provides timely, reliable and legible information on patient care. Patients have now become more involved in their health care with up to date information. This fits with the philosophical approach outlined by Weed in 1989. He stated that patients "*must be given the right tools to work with. They are the most neglected source of better quality and savings in the whole health care system. After all, they are highly motivated, and if they are not, nothing works in the long run anyway. They do not charge and they even pay to help. Also there is one for every member of the population.*"[15]

The SPR described here is now used in a General Medicine clinic [TH], another General Physician is trialling it as a model for his records, Outpatient Clinic nursing staff anecdotally report that they have time savings of up two hours per nurse per clinic per day by using this SPR. Inpatient discharges are more timely and accurate on specific patients [TH]. The SPR is used for peri operative manage-

ment for co-morbid states such as diabetes, venous thromboembolism and hypertension. It is hoped that this SPR will become a model for the hospital. Its adaptation with internationally standardized data formats such as ICD10, SNOMED and LOINC, will facilitate data capture for patient care and research.

A New Approach in Nursing Documentation: Community Nursing Case

Uros Rajkovic[a], Olga Sustersic[b], Vladislav Rajkovic[a], Vesna Prijatelj[c]

[a] *Faculty of Organizational Sciences,University of Maribor, Slovenia*
[b] *College of Health Studies, University of Ljubljana, Slovenia*
[c] *Clinical Centre Ljubljana, Slovenia*

Abstract

This paper presents the development of electronic documentation for community nursing using a system approach. Documentation is viewed as an information model for organizing and managing processes. The community nurse plans the nursing process after gathering and evaluating information on the patient's health and his/her family status. Documentation is thus considered to be a basis for the successful work of the health team and as a way of ensuring quality in nursing. The paper describes a prototype software model for e-documentation in community nursing together with its evaluation in practice.

Keywords:

information system, nursing, community nursing, documentation, software solution

Introduction

A system approach in the organizational and informational context brings specific challenges in terms of the complete management of complex systems. Systems in healthcare, of which nursing is a part, similarly belong within this framework [1, 2]. Along with the system approach, it makes sense to use the potentials of contemporary information and communications technology (ICT) and to study the possibility of adding value in managing complex systems, especially in terms of the effective use of resources and quality assurance.

E-documentation of any process is an information model, which uses ICT for organizing and managing the process according to established goals. Nursing documentation consists of patient and family data. Nurses use these data to plan the nursing process, which in short covers assessing patient's nursing problems, making nursing diagnoses, implementing nursing interventions and evaluating the work [2, 3]. The documentation of the nursing process is the basis for the successful work of a nurse, and also represents an element of quality assurance in nursing [1, 2].

We wish to propose a model that will serve for the reengineering of classical documentation into e-documentation. With a suitable object-oriented organization and use of contemporary ICT it is thereby possible to achieve a higher level of quality especially in regard to integral treatment of the patient. The active computer model itself supports the work of the nurse and, at the same time, reduces the possibility of mistakes at work.

This paper is based on findings and models developed within the framework of a Project for preparation of a model tool for establishing quality with the aid of documentation in nursing at the Ministry of Health of the Republic of Slovenia. Below are presented the elaboration and implementation of the proposed model, as well as testing of the prototype software for community nursing.

Analysis of existing documentation in nursing

Using the survey research we first analyzed the current state of documentation in nursing in selected health organizations in Slovenia. The sample included three old people's homes, Ljubljana Health Centre with five units, Clinical Centre Ljubljana and Maribor General Hospital. We distributed 386 questionnaires, of which 286 (response rate of 74.1%) were returned.

From the results of the survey on the use and suitability of nursing documentation we can conclude both the actual state of the documentation itself and the process of documenting, and also the perception (opinions, considerations) of existing problems and possible solutions on the part of those surveyed.

The majority of documents (86%) are prescribed on the level of the institution. The only exceptions are community nursing and old people's homes. Documentation for community nursing is prescribed and unified throughout the country, while old people's homes have a uniform computer supported information system. Rather less than 13% of documents are computer supported. Among the types of documents, the following were most frequently listed: nursing care plan, referral/discharge document, continuation notes and variance report, admission document and report on an undesired event.

It can be concluded that those five most frequently used documents should be unified firstly, taking into account the specificities of individual services. Given that with contemporary ICT we can generally provide effective support to documentation and increase the use of computers.

From the perspective of content, a process method of work is only used in 32% of nursing documentation. Over 52%

use only a fragmented process approach. It appears that existing documentation is to a large extent at fault for this, since the majority uses only those elements that the documentation enables. It is therefore sensible to reengineer the documentation in a way that will enable documenting all phases of the nursing process.

Minimal data set on patient are recorded by three quarters of survey participants. One of the reasons that the percentage is not higher is unsuitability of existing documentation.

Discussions with the patient, observation of the patient and measurements are sources of data for completing documentation in more than half of cases. Slightly less than half have also stated nursing documentation as a regularly used source of data. It is sensible to consider links between other health documentations and nursing documentation.

In the opinion of the surveyed nurses, they see the purpose of documentation or documenting mainly in the continuity of nursing, security for members of the nursing team and patient and an account of the work of individual members of the nursing team. The content thus supports the work, with emphasis on the legal security of members of the nursing team and the patient.

Among reasons for the non-use of nursing documentation, according to a quarter of nurses, are understaffing and insufficient knowledge of the nursing process, and among unspecified reasons, the fact that existing documentation is unsuitable was most often noted.

In terms of the influence of nursing documentation, the following are highlighted: the quality of nursing, uniform doctrine of work and reducing the possibilities of mistakes. With improved documentation we expect most changes in the quality of collaboration inside the health team and in the distribution of work and responsibilities among nurses and other health team members.

The results have shown that reengineering documentation using ICT can and should positively influence on the quality of nursing care. Because of unified documentation in the community nursing we have decided to begin the reengineering of documentation in community nursing.

Process method of work in nursing

The basis for developing e-documentation is the nursing process. Figure 1 shows a schematic presentation of the process method of work in the IDEF1 standard. The division in the figure differs from the literature [1]. A major difference is in the stage of evaluation due to standardization restriction. IDEF1 standard does not allow any process to appear in the scheme more than once. There is also a difference due to the cybernetic feedback loops, which are of crucial importance from a systemic point of view for system management, in this case of nursing.

The user interface of the prototype supports this process method in the nurse's job sequence. Only a few elements must be added, which are specific for community nursing [4]. These are elements such as entering referrals for community care visits to patients or families and for planning dates of home visits. Home visits can only be planned on the basis of referrals received from the general practitioner and on the basis of instructions for implementing community nursing. Later on the same steps apply for each home visit as in the already mentioned process scheme.

Database model

The base for a software solution is a database that enables data archiving and accessing data. Critical analysis of nursing documentation was a starting point in the database design process [5].

In paper form, the documentation is often mainly unstructured. Thus words in sentences can be entered. A problem occurs when seeking data in a longer text. The legibility of the writing often presents additional difficulty. Similarly, the statistical processing of data for research, education and other purposes can become unreasonably difficult [6, 7].

The higher level of data structuring in electronic form enables a higher usability of acquired data. The nurse is reminded with the entry fields, of all data that are desired in the documentation. The nurse is also forced to gather and record important data in the compulsory fields. This results in electronic form of data that enable electronic processing.

Additional fields for entering comments and data that were not envisaged in the original structure are also important. These fields serve in the prototype solution also as information for further development – which data must be additionally structured for electronic processing.

For ease of overview, we have grouped similar data according to their semantic relations. Tables 1 and 2 show tree structured data for describing a patient and a family.

A relational database suitable for storing data in electronic form was developed. It enables simple entry of data, reduces duplication of data and provides fast extraction [8]. The entity-relationship diagram of the proposed database is shown in Figure 2.

It is worth highlighting some particularities in the database diagram. The nursing diagnosis is directly bound to the subject of nursing. In the nursing diagnosis we record to which basic living activity (BLA) it is bound, and we are aware that after the evaluation of the nursing care plan, it may remains in the care plane throughout one or more of the following visits.

The subject of nursing can be a patient or a family. In the case of a visit to a family or a visit to a patient living with other family members, we also see a list of all family members who live together. From this list, we can access data on an individual member or on the whole family.

We see elements of the diagnostic therapeutic program as a list of previously determined nursing interventions, which must be carried out independently in relation to the established nursing problems, nursing diagnoses or nursing goals.

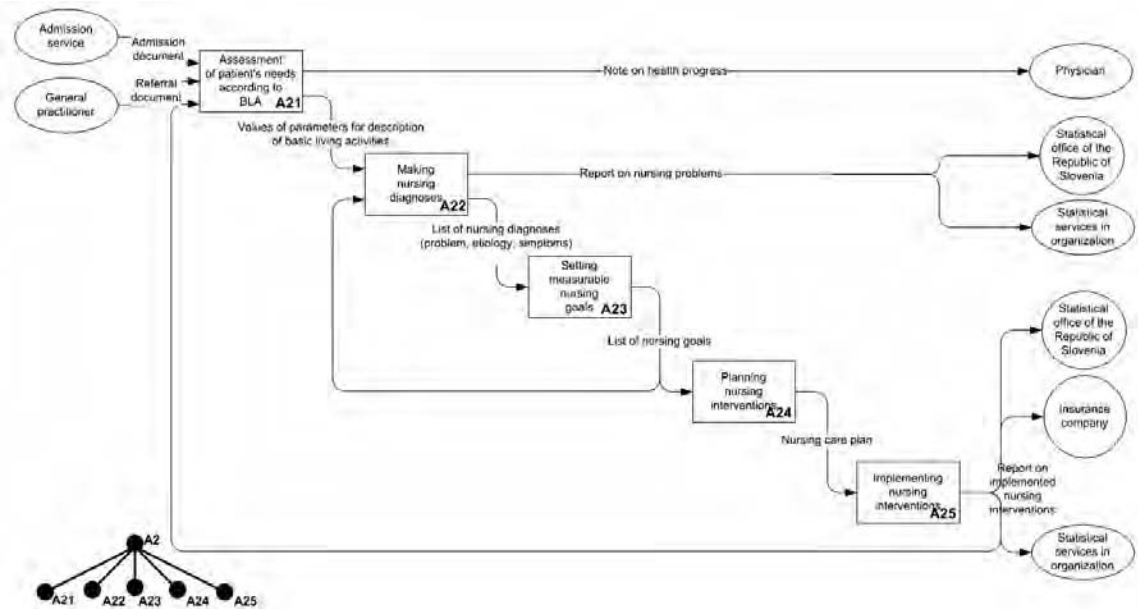

Figure 1- Schematic presentation of the process method of work in nursing according to the IDEF1 standard

In electronic documentation a user uses a password protected log-in. While it was necessary to sign some of documents in paper form, in electronic version data on the user are automatically recorded. For example, when the user records that an individual nursing intervention has been carried out, it is automatically recorded who entered the data for the individual activity and when.

Table 1 - Tree structure of data groups on a family

```

Software solution

The steps that comprise the desired course of work of the community nurse (CN) required for each home visit are in accordance with the process method of work in nursing. When the CN selects a patient or a family and one of the planned home visits, a screen picture is shown for the individual home visit. In the upper part are shown data on the selected patient or family, and below the individual steps of the nursing process supported through four tabs: nursing anamnesis, assessment of patient's/family's need, planning and implementation. We will describe later how the evaluation phase is supported.

We have grouped criteria for an overall assessment of patient's need in a tree structure based on the fourteen BLAs [9, 10, 11]. It is a professionally accepted and well-known division as it has been confirmed in our survey. A list of parameters opens for each BLA of which we wish to remind the CN for gathering relevant data. These parameters are taken from the profession, and in nomenclature we

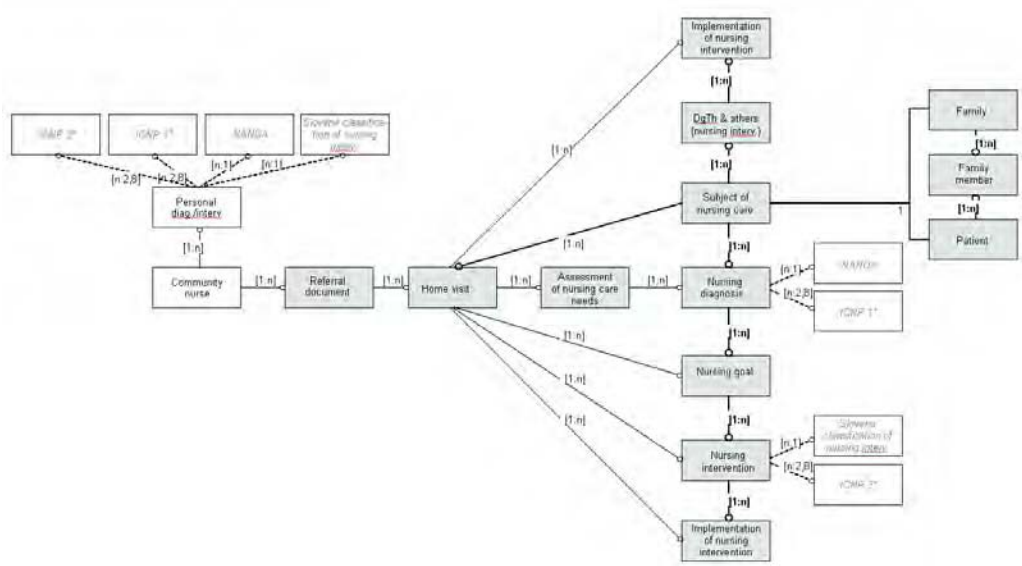

Figure 2 - Entity-relationship diagram of the proposed database

followed the Slovene translation of the International Classification of Nursing Practice, version beta 2 (ICNP) [12].

With each parameter there is a free text field for entering the values (e.g., with the parameter of excessive body weight we can insert the body mass index). In addition, for each parameter a CN also determines the degree of a problem using a five-point scale (no problem, minor problem, medium problem, major problem, very severe problem). Degrees are chosen in relation to the assessed state with individual nursing subjects.

From the values describing degrees of problems for parameters under the same BLA, the degree of problem for an individual BLA is calculated. These calculated values are then shown in the phase of planning. We will later show how we have supported evaluation with these grades. For example, the value of the parameter "appetite" has an impact on a BLA "diet and drinking" which affects the "physical BLA" and, consequently, the overall assessment of the patient. Values of higher-level parameters in the tree structure are calculated. The CN records values only for parameters on the tree leaves. After a simple calculation, we then obtain the grade of nursing problem for individual BLAs and the total overall assessment.

Under the tab planning we compose a nursing care plan in a tree structure. At the first level we see a list of BLAs and with each a calculated degree of a problem. On the second level we can add an arbitrary number of nursing diagnoses to each BLA. To each nursing diagnosis at least one nursing goal must be added, and to each nursing goal at least one nursing intervention (Figure 3).

The nursing diagnosis is made according to the PES system (Problem, Etiology, Symptoms). In denoting a problem, the nurse can use ICNP or the classification of the North American Nursing Diagnosis Association (NANDA) [3, 12].

Nursing interventions are described by name and frequency of performing them. Nurses denote interventions with the aid of the Slovene classification of nursing interventions and the ICNP beta 2.

The nurse can store her most often used nursing diagnoses and interventions in her personal directory. This can be simply supplemented with the catalogues that International Council of Nurses propagates as lists of the most often used nursing diagnoses and interventions for individual fields of nursing.

Under the implementation tab are shown all planned nursing interventions, those carried out need only to be marked. For the needs of evaluation, we can record comments on individual nursing interventions, e.g., ongoing evaluation or values of measurements, materials and time used.

After carrying out nursing interventions it is necessary to reassess the condition at the end of the visits. Assessments

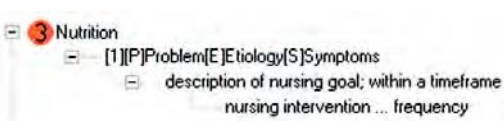

Figure 3 - Schematic presentation of nursing care plan in tree structure with explanation of individual levels

of the condition between two visits can also be compared. The evaluation phase is supported with the following visualization elements: comparison of overall assessments that shows progress for every parameter, a progress graph for a selected parameter throughout all previous visits. CN uses these measurements of changes in patient's needs to evaluate nursing goals and other elements in the nursing care plan.

When comparing assessments, we can compare the grade of nursing problem for the recorded and calculated criteria for two entries of overall assessments. We can thus compare two home visits, analyze the condition in the time between visits, or compare the overall assessment before and after visits are made, and analyze the impact of the intervention carried out on the change of condition. Where we have a number of assessments, it is also possible to show a time series of levels of nursing problem for an individual parameter – what sort of level of nursing problem was shown through all assessments of the condition e.g., appetite.

With these elements we wish to support the evaluation phase. The result of the evaluation phase is reflected in the changed nursing care plan. This means in practice to seek inappropriate elements in the nursing care plan, supplement them, exchange or remove them, and plan a new part of the nursing care plan for the new focus of problems.

The tabs are similar for home visits to the family, differing only in the parameters by which we describe the overall assessment. Instead of BLAs, we divided the parameters of families into the following groups: socio-economic state, health anamnesis, relations within the family and with the wider environment and functions of the family.

Computer support is provided by a completed prototype software solution. The solution used is a type of client-server and enables the use of laptop computers, which the CN can use directly in the field.

User's manual contains organizational and informational instructions for the direct use of the prototype software. It is basically intended as an aid to the work of the CN in using the software.

Testing the model in practice

We wanted to check the following categories in testing the proposed solutions:

- Success in implementing the nursing process in accordance with individual phases,
- Strengths and weaknesses of the use of hierarchical models of BLAs in the process,
- Suitability of the structure of data in nursing documents with an emphasis on the nursing care plan,
- Accordance of the data model and links among data with the current method of work or existing documentation,
- Interface with other processes.

In the alpha phase of testing, after completing the writing of the manual, we checked the operation of the program in compliance with the manual using simulation of real data. This was first carried out by the programmer and then by two working groups.

Beta testing of the software took place in the community nursing units of Ajdovscina Health Centre and Ljubljana-Bezigrad Health Centre. In total 8 nurses were involved. At both locations we placed software of a client-server type. Each participant in the testing, a CN, thus had available her own computer supported worksite. Data inserted at locations was gathered on the server.

At each location we had an introductory seminar covering:

- Presentation of the program in accordance with the process method of work,
- Presentation of the manual and annex and
- Test entry of data.

The CNs were then given a month time to become familiar with the program. During this time their questions related mostly to the terminology, the new model of the process and software solution. During this month they were asked to enter test data each day (at least one visit). This was the introductory period, which was intended to make a significant contribution to CNs being able to carry out the extensive plan of testing.

As a last step, we presented a detailed plan of testing. More than 80 entries in the period of one month provide the framework for testing various subjects with various needs and difficulty of work. At a new meeting, we then discussed possible difficulties and proposals of improvements and examined the entered records.

A SWOT analysis was carried out, which we performed with the help of the participants of testing at a final meeting.

Advantages:

- Providing users with integral nursing of high quality;
- Timely recognition of dangers that threaten the patient;
- Systemically arranged data of a relatively large quantity providing an easy to view information picture;
- Encouragement to the CNs own professional development.

Weaknesses:

- Insufficient ICT equipment;
- Work norms of CNs are often exceeded leaving too little time for entering the data into a computer;
- Lack of professional knowledge;
- The question is raised as to whether we know and can suitably use the available data.

Opportunities:

- To be more attuned to the user by means of the available data and to offer a higher quality of nursing;
- Users can be better informed and educated;
- Timely recognition of conditions;

- Production of guidelines for professional treatment and higher quality services for users;
- Including family and others in the nursing process;
- Motivation of staff.

Dangers:

- Insufficient ICT equipment of community nursing services could hold back the use of the system;
- Lack of permanent professional training and willingness of nurses to change could negatively affect on the use of such system;
- Changes in existing methods of work often trigger resistance in staff;
- Commitment to the computer rather than the patient.

Although the model and its prototype are already suitable for use in practice, we will continue to take certain comments into account and make the necessary changes. Extended testing will follow, which means monitoring use of the model in practice in a larger number of community nursing institutions throughout longer period of time.

Conclusion

The presented model of e-documentation covers the treatment of patients and families both from the aspects of processes and data. On this basis, a prototype organizational and informational solution of nursing documentation for the community-nursing segment was developed and has been tested in practice and critically evaluated.

The added value that contemporary ICT can contribute to nursing was presented, deriving primarily from a structured information picture, which monitors the patient and the nurse in the nursing process. It is worth highlighting in particular the use of hierarchical models in the treatment of BLAs. The model of calculating the grade of nursing problem, which the computer carries out concurrently in relation to the condition of the patient, thus enables an integral overview of the patient and systemically links apparently separate problems. It is thus a direct contribution to reducing the possibility of overlooking something important. E-documentation relies on the nursing record of the patient as a part of the overall health record of the patient [2]. This way we avoid duplication of data and the associated excessive work and obtain an overall information picture, which significantly contributes to a greater security for the patient and members of the nursing team.

We will continue the work not merely by extending testing and analysis of this model, but also by developing a similar model for documenting nursing in hospitals and dispensaries.

Acknowledgments

The authors thank the Ministry of Health of the Republic of Slovenia for financing the research work. We are also sincerely grateful to all institutions and individuals who took part in the project.

A Survey of the Effects of the full Computerized Nursing Records System on Sharing Nursing Records among Health Professionals

Yukio Kurihara[a], Naho Asai[a], Eri Ishimoto[a], Shigeyuki Kawamata[a], Satsuki Nakamura[a]

[a] *Department of Nursing Science, Kochi Medical School, Japan*

Abstract

In the last decade computerized nursing records systems (CNRSs) have been implemented at many hospitals around the world. Several effects of the CNRS were expected; the improvement of the quality of medicine and nursing care, the increased efficiency and the reduction of the cost. This study focused on the effects of the CNRS on access and sharing of nursing records among various health professionals. Timely access and availability of nursing records should improve the quality of medicine and nursing care. In 2003, we conducted a survey of the effectiveness of the CNRS on access and availability of nursing records among health professionals. We found that the CNRS contributed to the multidisciplinary sharing of nursing records without increasing the overall time spent on nursing documentation at most hospitals. However, effective sharing of nursing records even among nurses through the use of the CNRS did not occur at many nursing divisions.

Keyword:

Computerized nursing records system, survey, technology assessment

Introduction

Nurses record various observations of patients and make documents of nursing care throughout the patient's entire hospital stay. Although documentation is a large and time-consuming task for the average staff nurse, nursing records are used to share important information about the patient's status and plan of care among nurses, doctors and ancillary staff. However, paper-based nursing records are not simultaneously available for multiple users and sharing important information is sometimes delayed.

A computerized nursing records system (CNRS) [1], in which nursing records are accumulated into a database, might be effective to solve these problems. In the last decade, the CNRSs have been implemented at many hospitals around the world. Besides increasing availability of nursing records, several other effects of the CNRS were expected: the reduction of documentation time, an increased awareness of errors, and the reduction of the costs. There are many assessment reports about the effects of the CNRS on documentation time [2-5]. Although the reduction of time is desirable from the nurses' standpoint, the access and timely sharing of nursing records is much more essential, because one of the primary functions of nursing records is the continuity of care. We investigated the effects of the CNRS on access and sharing of nursing records among health professionals (i.e., pharmacists, nutritionists, medical technologists, and radiological technologists). We also investigated the changes in the amount of time spent o n nursing documentation, because a large increase in documentation time is not desirable.

Methods

In August and September 2003, we surveyed the effects of the CNRS on accessibility and sharing nursing records among health professionals at Japanese hospitals. We sent four sets of questionnaires to the director of nursing at each hospital and requested answers from responsible nurses of four major nursing divisions. We expected that the four major nursing divisions would include the following: internal medicine units, surgery units, combined internal medicine and surgery units, and intensive care units (ICUs).

Selection of hospitals

In a national survey, the status and function of health information systems in all main Japanese hospitals were published every year on the Japanese journal Gekkan Shiniryo. We selected all hospitals listed in 2001, 2002 and 2003 [6] that used the CNRSs; questionnaires were sent to a total of eighty-nine hospitals.

Questionnaires

Demographic data was requested about the respondents (i.e., position and work experience), the hospital (i.e., number of beds) and the division (i.e., type of division, number of beds, and number of staff nurses).

The questionnaire included:

1. What nursing record contents were computerized in the CNRS?
2. Which professionals had access to the nursing records before and after the implementation of the CNRS?
3. How had time spent on nursing documentation changed for the following: assessment data, daily reports, graphs of vital signs, nursing summaries, nursing diagnosis and care plans, and end-of-shift reports?
4. What kind of computerized nursing documentation was done at the bedside?

Data analysis

First, we checked what nursing record contents were being accumulated in the CNRS. We did an in-depth investigation of the answers from divisions where the CNRS contained the main contents of nursing records: assessment data, daily reports, graphs of vital signs, nursing diagnoses, care plans, evaluations and summary reports. We designated this type of CNRS as the "full CNRS". Secondly, we checked the type and size of divisions. We excluded specialty divisions and small divisions which had less than twenty beds.

Finally, we investigated the changes of access and sharing of nursing records among health professionals before and after the implementation of the full CNRS.

At Japanese hospitals, the end-of-shift report is usually performed. If the full CNRS could make nursing records more readily available in a timely fashion the end-shift meeting could be omitted or the meeting time could be decreased. We investigated the effect of the bedside computer documentation on the end-of-shift report times because bedside documentation enables the real-time sharing of nursing records. We also investigated the changes of time spent on various types of documentation.

We used SPSS Version 11.0 for the statistical analysis.

Results

Description of respondents

We received responses from 153 divisions of forty-six hospitals. Since we sent questionnaires to eighty-nine hospitals and requested each hospital to return answers from four different divisions, the respondent rate based on the total number of hospitals was 51.7% and the average number of the respondent divisions at each hospital was 3.3 (3.3/4=83.2%). Twenty-six were mid-sized hospitals, equipped with a hundred to four hundred beds and twenty were large hospitals equipped with more than four hundred beds. Since we requested answers from the nurse manager of the division, The respondents were mainly nurse managers or assistant nurse managers at divisions (Table 1). Most respondents had sufficient length of work experience at the hospital to understand the overall activities of the divisions.

Description of CNRS

Table 1 – Position and work experience of respondents

Position	Number of respondents (divisions)	Averaged work experience at the present hospital
Nurse manager of division	100	17 ± 9 yrs
Assistant nurse manager of division	15	15 ± 7 yrs
Staff nurse of division	29	8 ± 6 yrs
Others	9	11 ± 9 yrs

Half of the divisions used the full CNRS (Table 2). About 20% of the divisions implemented the CNRS-1 (one of the main elements of the content was missing). The CNRS-1 mainly lacked inclusion of nursing diagnoses. One third of the divisions used incomplete or partial CNRS possibly because the development of the system may have been in progress. Since the lack of any one element could affect the effectiveness of the CNRS, we elected to analyze data from only divisions using the full CNRS.

Table 2 - Level of CNRS

Contents	Computerized contents					
	Full CNRS	CNRS-1*				incomplete CNRS
Assessment data	ya	ya	ya	ya	ya	more than two elements are not computerized.
Nursing diagnosis	ya	ya	ya	ya	**no**	
Care plan	ya	ya	ya	**no**	ya	
Daily record	ya	ya	ya	ya	ya	
Graph of vital signs	ya	ya	ya	ya	ya	
Evaluation	ya	ya	**no**	ya	ya	
Nursing summary	ya	**no**	ya	ya	ya	
Number of divisions	77	2	6	1	19	52

* CNRS-1 lacks one element of the contents.

Description of divisions

In Table 3, we show the type and size of divisions. Since the responses from seven divisions lacked data about the type and size of division, we excluded these seven from our analysis. Since the length of stay of patients in the ICU is shorter compared to the stay on general wards, we excluded ICUs from the analysis. Finally sixty-two questionnaires from twenty-eight hospitals remained for further analysis. Eighteen hospitals were mid-sized hospitals equipped with hundred to four hundred beds and ten hospitals were large-sized and equipped with four hundred to seven hundred beds.

Table 3 - Profile of divisions implementing full CNRS

Type of divisions	Number of divisions*			
	1 to 19 beds	20 to 39 beds	40 to 59 beds	more than 60 beds
Internal medicine	0	1	17	4
Surgery	0	2	17	3
Mixed division of internal medicine and surgery	0	4	5	1
Pediatrics	0	0	2	0
Rehabilitation	0	0	2	0
Long care stay	0	0	4	0

Changes of access to nursing records for various health professionals

In Table 4, we show the numbers of divisions sharing nursing records with various health professionals before and after the implementation of the full CNRS. Before the implementation of the full CNRS the nursing records were shared in most divisions among nurses and doctors, and at a limited number of divisions with other professionals. After the implementation of the full CNRS the professionals outside the division could access the nursing records at most divisions. In the Kruskal Wallis's ^{2} test, for the percentage of divisions sharing nursing records among health professionals we could not find any significant difference according to the different type and different size of divisions.

Table 4 - The divisions sharing nursing records among various professions (n=62)

Professional	before implementing full CNRS	after implementing full CNRS
Nurse	55 (89%)	62 (100%)
Doctor	54 (87%)	62 (100%)
Pharmacist	32 (52%)	60 (97%)
Nutritionist	18 (29%)	55 (89%)
Medical technologist	12 (19%)	49 (79%)
Radiological technologist	12 (19%)	47 (76%)

Changes in the end-of-shift report time

In Table 5, we show the numbers of divisions that had changes in the length of time for end-of-shift report (T_m), related to bedside documentation using the full CNRS. If we disregarded bedside computer entry, about half the divisions had Tm that were essentially unchanged. However, if we divided divisions into two groups according to those who used bedside computer documentation and those that did not, many divisions using bedside input decreased T_m or abolished the end-of shift report. In the statistical analysis, we found that the bedside input into the CNRS significantly contributed to decreasing the end-of-shift meeting time; Mann Whitney's U test, p-value 0.001.

Table 5 - The change of the Tm before and after implementing full CNRS*

The change of Tm*	Number of divisions		
	Bedside computer documentation	No bedside computer documentation	Sum
Increase	0	0	0
Minimal change	11	20	31
Decrease	17	6	23
Absence†	4	0	4
Sum	32	26	58‡

However, many nurses pointed out several problems of bedside documentation with the CNRS. The communication with the patients was interrupted because the nurses had to focus on the data entry; some nurses had an increase in documentation time because of poor keyboard skills. Also, there was an insufficient number of mobile computers and bedside PCs.

Changes of time spent on documentation of nursing records

In Table 6, we show the percentage of divisions having changes in the time spent on documentation of various nursing contents before and after the implementation of the full CNRS. There was a small portion of the divisions that had increases in documentation time and 75% of those divisions had only one or two contents increased in documentation time. There were relatively much divisions that had the increased documentation time of the assessment data. Many respondents pointed out that the increase of assessment items in the full CNRS contributed to this increase in the documentation time.

Discussions

In principle the full CNRS increases access to nursing records for all health professionals. As shown in the previous section, sharing nursing records among nurses and

doctors was common practice for all divisions. However, the health professionals outside the divisions still could not easily access the nursing records at about 20% of the divisions. Cost and policy might be two factors that hinder the sharing of nursing records. In order to enable all professionals to share the nursing records, we would have to modify the system and the access control would require increased security, therefore the cost would increase. Another factor is the policy of the individual hospital in determining who should have access to patient information and what type of information should each professional group is allowed to have. In order to enhance the quality of care, we recommend that sharing patient information among health professionals is essential.

Table 6 - The change of the documentation time of various contents before and after implementing full CNRS

The change of documentation time	**Percentage of divisions**						
	Assessment data	Nursing diagnosis	Care plan	Daily record	Graph of vital signs	Evaluation	Nursing summary
Increase	26%	6%	5%	15%	15%	8%	8%
Minimal change	23%	16%	8%	32%	15%	48%	34%
Decrease	51%	76%	84%	48%	70%	40%	56%
No answer	0%	2%	3%	5%	0%	4%	2%

If nursing records were readily available in a timely fashion through the use of the full CNRS, the end-of shift meeting could be eliminated or shortened. However at half of the divisions shortening the time for shift report did not occur. The bedside input of nursing records was conducted at 78% of the divisions abolishing or shortening the meeting. Bedside computer entry seems very effective for facilitating access to nursing records; however, it could be potentially difficult for nurses to enter all data into the full CNRS at the bedside. A small device, such as a PDA is usable for documenting vital signs; however a mobile PC would be more useful for documenting various nursing observations. Unfortunately, the mobile PC currently weighs more than 1 kg, and it is impossible for nurses to carry one as they deliver patient care.

Comments from respondents highlight concerns that the nurse's attention is taken away from the patient and redirected towards the computer. We have to consider various possibilities to overcome the problems of the bedside computer documentation. One possibility is to set a PC outside each ward, and then the nurse could immediately input a memo into the full CNRS. Another possibility is to use a PDA for short comments. Any alternative solution should allow entry of key information into the full CNRS as soon as possible.

Conclusion

The full CNRS clearly contributed to the enhancement of sharing nursing records among health professionals and did not increase the overall documentation time in most divisions. Bedside computer entry of nursing observations also facilitated the sharing of nursing records among nurses. However, the bedside documentation has several practical problems related to the present technology and various solutions that allow efficient and timely bedside data entry are necessary.

[d]Dept. of Cardiovascular Surgery, Yonsei Univ. College of Medicine, korea

Abstract

An electronic medical recording (EMR) system is enlightened as a solution for deciding which nursing diagnosis was selected on the basis of a computerized system; it can help collect and analyze lots of diverse data in an objective way. But there are few reports of successful electronic nursing diagnosis on EMR systems. This study was to develop the objective decision system prior to nursing diagnosis and to adopt it in the Severance EMR system. We adopt a new concept, situational variables, as the key elements of the nursing process, based on the items of nursing intervention. It enables appropriate nursing diagnosis through complex clinical objective data (laboratory results, vital signs, etc.). Through these elements between nursing intervention and nursing diagnosis, we can create reliable evidence-based nursing diagnoses successfully, and make possible fast settlement of nursing intervention in the various clinical fields.

Keywords:

EMR, ENR, nursing process, situational variables

Introduction

The academic concept of a nursing process is constructed on the serial thread of nursing diagnosis, nursing intervention, and outcome of nursing (Figure 1).

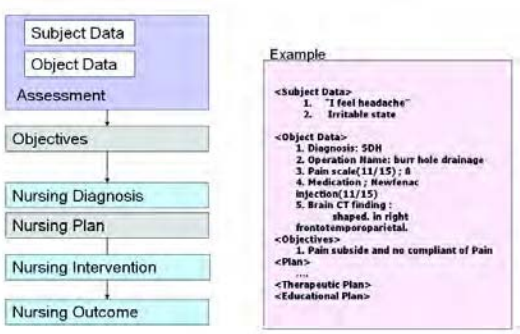

Figure 1 - Nursing process

The first step of this system is the nursing diagnosis, whether it is derived from medical diagnosis or the subjective decision from the experienced professional nurse who can judge the nursing diagnosis (Figure 2).

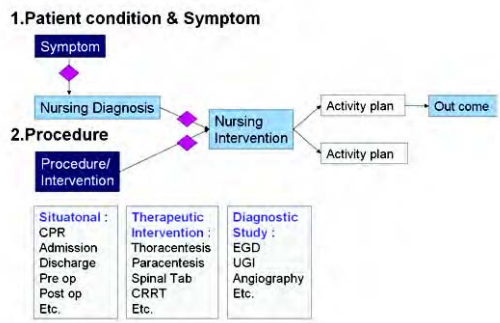

Figure 2 - Algorithm of nursing process

In real situation, Nursing diagnosis in the clinical field has been inevitably limited because of the inavailability of the experienced nursing professional with education and experience in nursing diagnosis.

An electronic medical recording (EMR) system is enlightened as a solution of nursing diagnosis because an electric nursing record (ENR) was expected that will help the implementation of appropriate nursing diagnosis with saving of the recording time and providing the standardization of the nursing records. However, there are few reports of successful nursing diagnosis systems. For the success of nursing diagnosis system, the decision of nursing diagnosis should be decided not in a subjective way but in an objective or evidence-based way. So, authors find out that the key point was based on the items of nursing intervention – so-called *situational variables* – instead of nursing diagnosis itself as a first step of the nursing intervention system.

To develop the objective decision system prior to nursing diagnosis, a new methodology was adopted in the Severance EMR system. Through this method we can create objective data based nursing diagnosis successfully, and it

makes possible fast settlement of nursing intervention in the various clinical fields.

Method

The steps of this study are shown in Figure 3.

Figure 3 - The steps of this study

The pre-existed items of nursing intervention protocol (NIC, 3rd edition) were used. NIC involves 1609 nursing activities with references to a translated version of the 2nd edition. The analysis was done in parallel way between above NIC items (1,800 items) and the items of intervention which was done in the real patient according to the medical diagnosis by doctors.

Through this comparison, the same item was categorized as a original NIC division, and the other related items from the real field was involved into the new created subdivision of the NIC items. This procedure can make a sophisticated set of nursing intervention items based on the specific situation and real activities.

This new set of nursing intervention item makes the relationship between nursing diagnosis(NANDA) and nursing intervention more concrete. From this new set of nursing intervention, we postulate and extract the situational variables. And then we create new set of situational variables which can decide nursing diagnosis automatically through the EMR system.

For processing of above procedure, all units of inpatient gathered the top 20 disease items that the hospitalization is required. Fianlly, total 125 disease items were selected and analyzed.

Results

The 46 nursing plans were postulated from 125 disease items as a prior step before decision of nursing diagnosis and the identification of items of nursing activities (Figure 4).

In the new set of nursing intervention (nursing activity), a total of 14,296 items were involved. Among them, 13,548 items were involved in the substructure of the NIC structure through a new methodology (Figure 5). Situational variables were extracted from the new set of nursing intervention for automatic extraction of nursing diagnosis (Figure 6). Initially, 118 sets of situational valuables were established in the Severance nursing record system for clinical nursing intervention. This set means that one set of nursing activities can determine specific nursing diagnosis, and in turn nurrsing diagnosis can determine more sophisticated nursing activities.

Ex) Gastro-Intestinal Medicine

Dx	Nursing Dx

Figure 6 - Nursing activity and situational variables

- Automatic nursing diagnosis; Successful
- Implementation of ENR system; Successful
- Construction of Nursing Terminology DB;
  - Nursing diagnosis ; 13 domains 92

- Nursing interventions ; 13,909
- Nursing activities with Order Treatment; 2,183
- Situational variables; 63
- Set of situational variables connected with nursing diagnosis; 118

1 year after adopted EMR system, we got those responses from the nurses of clinical field.

Usage of nursing diagnosis, Addition of nursing activities is more increased.

Request of creation of situational variables, request of changes of preset nursing diagnosis is also increased.

Conclusion

The study revealed that standardization of nursing activity based terminology can be established and can be evolved by itself.

An automatic nursing diagnosis system based on situational variables is a solution for realization of a Nursing Process based on 3N(NANDA, NIC, NOC). Automatic nursing diagnosis systems should be based on an objective, evidence based standpoint. Clinical Decision Support is also possible through automatic nursing diagnosis system.

Discussion

The nursing process is one of the most valuable concepts for effective and safe patient care [1-2]. However, its realization has been a questionable one, because of difficulty in adoption in the field for real-world use. Most nursing professionals think that the items of the NIC system can accomplish the thread of the nursing process [3]; we focused on whether the NIC system is able to express the interventional activities of the real practice in the field. If there is limitation of expression of real activities, it would indicate a disconnect between the conceptual items and their related activities.

So the trial of a process was done for the new connection between academic concept and real activities that can be involved in the academic concept. [2][4] All the currently used interventional activities should be gathered from the specified units. [4]

During these procedures we find that the meaning of the items of NIC is much broader than items from the real field. So, many items were found that can not be expressed by the items of NIC system in the real field, so we categorized additional items of nursing activities as a substructure of NIC items from the clinical disease base. This new structuring was the key point of establishing the successful nursing process.

From the set of situational variables, we decide the nursing diagnosis. This can be said as a kind of clinical decision support system in the real patient care field. The nursing process is impossible without first designation of nursing diagnosis in current concept. However the decision of nursing diagnosis is not an easy procedure for all the acting nurses. So, if there is no automatic creation or selection of nursing diagnosis, the realization of a nursing process would be only happen in the far future. To overcome this obstacle, the set of situational variables in Severance hospital was created and it reveals its effectiveness in real field(Figure 7).

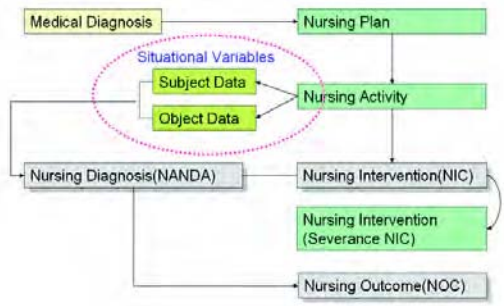

Figure 7 - New methodology of Nursing Process in Severance ENR

125 disease items may be a small percentage among all disease entities, however, we are sure these 125 high-frequency diseases can involve all the nursing intervention items, nursing diagnosis, and nursing plans. This hypothesis should be tested in terms of the rate of participation and reuse of nursing process in the field, and tested though 1 year's usage in Severance hospital. As another advantage of this system, the evaluation and validation of the activity based cost of the nursing activity will be enabled in every clinical activity. This kind of advantages would demonstrate the effectiveness or return on investment of this methodology.

For better nursing process, the contents of substructure of the intervention items should be reinforced with the concrete relationship with the nursing diagnosis and outcome systems. [2][3][4]

Abstract

The U.S. Veterans Health Administration (VHA) provides care to some 5.2 million patients spread across the continental United States, Alaska, Hawaii, Puerto Rico, and the Philippines. Sites of care include 157 medical centers, nearly 900 outpatient clinics, long-term facilities, and home care. Over the last 10 years, major changes in the nature of VHA healthcare have imposed a requirement for longitudinal electronic health records and integration of those records across the enterprise at the point of care. VHA has now evolved through three generations of applications that support such integration. This paper reports on the VHA experience, points out lessons learned, and outlines future directions for electronic health record integration in VHA.

Keywords:

Electronic Health Records, EHR, Longitudinal Records, Data Integration, VistA, Veterans Health Administration.

Introduction

Veterans health administration

The United States Department of Veterans Affairs (VA) provides benefits and services to the nation's veterans and selected family members ("To care for him who shall have borne the battle and for his widow and his orphan…" - Abraham Lincoln). The Veterans Health Administration (VHA) is the branch of VA that provides healthcare benefits.

VHA includes approximately 1,400 sites of care, including 157 medical centers, nearly 900 outpatient clinics, 135 long-term care facilities, and 88 home-care programs. VHA now treats some 5.2 million patients, with approximately 7.6 million enrollees. In 2005, VA workload included 587,000 inpatient admissions and some 52 million outpatient visits. 60% of US health professionals (70% of physicians) have some training in VHA. VHA has some 193,000 employees (approximately 14,000 physicians, 50,000 nurses, and 33,000 allied health personnel). VHA's budget in 2005 was $32.5B US.

In the last ten years, VHA has transformed itself from a loose federation of independent medical centers focused primarily on inpatient care into a fully integrated health care delivery system that promotes primary and ambulatory care. Between 1996 and 2005, the annual number of ambulatory care visits increased by 84%, the number of acute care hospital beds dropped by 68%, inpatient admissions dropped by 27%, and total bed days of care fell by 47%.

Aging of the veteran population is a major issue confronting the VA. Today, 9.6 million veterans are age 65 or older, representing 38 percent of the total veteran population. By 2030, the proportion of older veterans will increase to 45 percent of the total. As in the general U.S. population, those aged 85 or older (the "old-old") are the fastest growing segment of the veteran population, representing 3 percent of current veterans. The number of veterans age 85 or older is expected to nearly double from 764,000 to a peak of 1.4 million between 2003 and 2012.

In comparison with the U.S. Medicare population, the VHA patient population is older and sicker. 38% are over age 65. In comparison to age-matched Americans, VHA patients carry one additional mental health diagnosis and three additional non-mental health diagnoses. They are also less affluent: approximately 70% with annual incomes of less than $26,000 and some 40% with annual incomes less than $16,000. Demographics of the patient population are changing as older veterans die and veterans of more recent conflicts become eligible for care.

A progressively older population with more chronic diseases and increasing complexity of illnesses has resulted in involvement of more clinical providers (both primary and specialty care), more types of health care programs (inpatient, outpatient, and home care), and more diagnostic procedures done at geographically dispersed sites. In addition, restructuring of VHA into health care networks has increased patient travel and the number of institutions at which a given patient can be expected to receive care, which has in turn increased the medical and financial value of sharing information on patient care across sites on an enterprise basis.

VHA clinical information systems & electronic records

Veterans health information systems and technology architecture (VistA)

The Veterans Health Information Systems and Technology Architecture (VistA) supports day-to-day operations at VA health care facilities [1,2]. It incorporates both administrative and clinical applications; including a full suite of ancillary departmental systems as well as the Computerized Patient Record System (CPRS). A descendant of the Decentralized Hospital Computer Program (DHCP, circa 1982), VistA has been in continual evolution since 1996. It consists of more than 100 corporately developed applications as well as software developed at local medical facilities; it also includes support for integration of commercial off-the-shelf products. Historically, VistA has employed a decentralized architecture operating at the medical center level; applications and national databases derived from locally generated data that reside in VA's centralized corporate data center lie outside the scope of VistA. VistA employs a client-server architecture: applications are written in M (also known as MUMPS) on the server side and in Delphi on the workstation side; VHA is in the early stages of a major technology migration that will shift application development to Java and relational database systems. VistA has been used by a number of private and public health care facilities in the United States and around the world.

Computerized patient record system (CPRS)

CPRS is the electronic "clinical practice environment" for VA clinicians and all members of the healthcare team; it is a single, integrated clinical information system used throughout the organization in all healthcare settings (Inpatient, Outpatient, Long-term care). CPRS provides a longitudinal medical record as well as active functionality covering all aspects of patient care and treatment, including: electronic order entry and processing; entry and retrieval of clinical documents such as narrative notes and discharge summaries; display of results for laboratory, imaging, and diagnostic procedures; consult management and reporting; alerts of abnormal results; clinical reminders; problem list management; inpatient and outpatient medication management. It also serves as an enterprise integration platform, giving clinicians the ability to see electronic records from any other VHA facility where the patient has received care. As shown in Table 1, CPRS is heavily used.

Table 1 - CPRS usage as of December, 2006

Content category	Total count	Average daily volume
Documents (Progress Notes, Discharge Summaries, Reports)	874 M	638 K
Orders	1.6 B	912 K
Images	591 M	884 K
Vital measurements	1.0 B	729 K
Medications Administered - Bar Code Medication Administration	850 M	607 K

VHA has gone through three approaches to enterprise integration: WebTop, CPRS Remote Data Views, and VistA Web.

Materials and methods

WebTop

Motivation: Development of WebTop began in 1996 as a centrally-funded research project to explore the feasibility of extracting and displaying data from a VistA system using browser-based technology, with an emphasis on use of XML, Java technologies, and linkage of patient data to external resources. A follow-on project focused on integration of data across sites was undertaken in 1997, and the resulting application was brought to operational status in VISN 1 (VA New England) in 1998. Other VISNs adopted the technology, and at its peak, WebTop was deployed in 16 of 22 VISNs. WebTop development preceded that of CPRS, and was thus unable to take advantage of some of the foundations of the latter application.

Architecture: WebTop provided browser-based access to VistA clinical data using a combination of client-side and server-side software controlled and organized by a middleware server. (See Figure 1.) The middleware retrieved clinical data from multiple VA Vista systems and formatted it into a consolidated display. The middleware also supported retrieval of data from other intranet or internet information resources, such as knowledge bases, using patient data to construct a search query. Deployment was based on a regional model, with one WebTop instance per VISN; the architecture allowed for cross-VISN connectivity to produce integrated data sets covering multiple regions, but this approach was never generally adopted due to both technical and organizational obstacles at the time.

WebTop middleware was based on Java servlets, which handled log-on, patient look-up, clinical data retrieval, and traversal of links to other network resources. In keeping with the focus on web technology, HTTP was initially the sole choice for connectivity; when CPRS was implemented, the set of transport layer protocols was expanded to include Remote Procedure Calls (RPC).

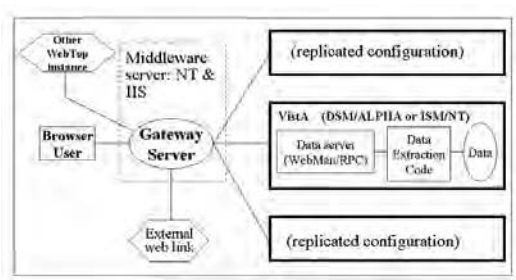

Figure 1 - WebTop architecture

Operational model: Users connected via browser to the WebTop middleware server, which validated the user's access codes against a selected VistA system. Once validated, the user was assumed to have access to data that resided on any Vista system participating in the WebTop domain (see discussion of business rules below). After selecting a patient, the user could browse the patient's record, selecting individually the type of data desired (e.g., lab results, progress notes, etc.). The middleware server processed such user requests, retrieved data from the individual VistA databases and aggregated it for display by applets running on the user's workstation.

CPRS remote data views

Motivation: Development of CPRS Remote Data Views (CPRS/RDV) began in 2001. Its objective was to support on-the-fly remote data views of patient information within VHA's mainstream clinical application. Because CPRS deployment was ubiquitous, CPRS/RDV offered the first opportunity for true enterprise-wide integration of the longitudinal electronic health record in VHA.

Architecture: Traditional CPRS architecture was based on communication between a client CPRS workstation and a VistA server using remote procedure calls (RPCs). Security concerns, desire to avoid additional servers, etc. led to implementation via server-to-server communication rather than client-to-servers or client-to-middleware. (See Figure 2.) To add this new capability to CPRS, changes were made to both the CPRS application and the underlying infrastructure; the RPC Broker was enhanced to provide the Server-to-Server RPC support required, and HL7 messages were encapsulated and exchanged within RPC messages.

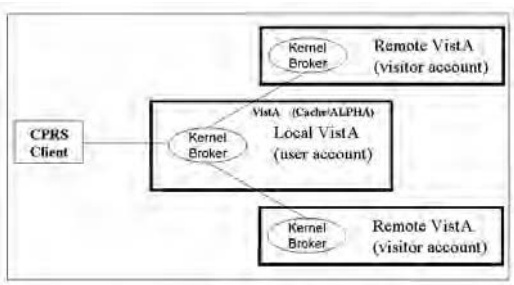

Figure 2 - CPRS Remote Data Views architecture

Operational model: Since CPRS RDV is part of CPRS, user logon, authentication to VistA system, and selection of a patient are all accomplished in the normal CPRS context. CPRS knows the sites at which a patient has data courtesy of the VHA enterprise Master Patient Index; information on the sites applicable to a specific patient is kept as part of the local patient record, and a user asking for remote data can limit the sites queried if desired. Once a type of data is chosen, the sequence is as follows: RDV asks the local VistA for remote data; the local VistA system adds a user identifier to the request and passes it on to the remote VistA systems; the local VistA returns a handle to CPRS; while the remote VistA systems assemble the date, CPRS iteratively asks the local VistA if the data is ready yet; when all the data has been returned from the remote VistA systems, the local VistA answers CPRS's next query with a YES, and CPRS issues the third and final RPC to get the data. The data is then displayed in spreadsheet form or tabs of narrative text, much like the approach taken with WebTop. At the remote sites, RDV uses "visitor" accounts that have no access or verify codes, no menu options, and are aliased as "VISITOR". However, the identity of the user originally requesting the data is passed to each remote VistA system and entered in an access log.

VistA web

Motivation: VistAWeb was initially developed within one of VHA's regional networks as an exploration of alternatives to WebTop and CPRS Remote Data Views. It also explored user interface alternatives, including alternative ways to deliver graphical information such as ECG or DICOM images.

Architecture: VistAWeb uses Medical Domain Objects (MDO) as its data abstraction layer, and MDOs handles all connectivity to VistA. On one side an MDO communicates with various data sources such as VistA, HL7, DICOM, XML, and SQL. On the other side, it delivers to the client a uniform, well-defined suite of objects from the medical domain (e.g., patient, provider, progress note, lab result, etc.) MDO delivers the same object regardless of the data source. So, to the client software, a progress note from VistA looks and behaves exactly the same as a progress note from an arbitrary source via HL7 or SQL or XML. All functionality is read-only.

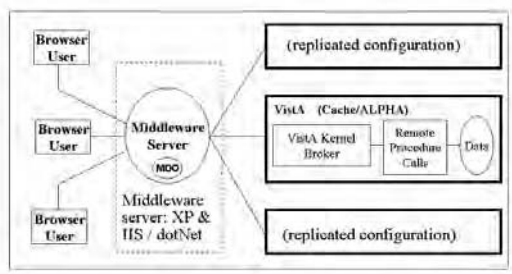

Figure 3 - VistAWeb architecture

Data Access Objects (DAO) are used to carry out communication. In the general case, DAOs would exist for different access protocols: VistA, HL7, SQL, DICOM, or XML. MDO is an ongoing project; the DAOs currently operational are for accessing VistA systems via RPC and the HDR via HL7.

Operational model: Users authenticate to VistAWeb via standard VistA credentials and are then able to browse the clinical record. Connections are made to sites determined by MPI data stored with the patient. If necessary, a new visitor identity is created at remote sites to support auditing of remote data access. Users are warned if they select a deceased or sensitive patient (e.g., patient as employee, patient as high-profile patient, etc.); a check is also made to prevent users from accessing their own records. User

requests for a specific type of data are sent to DAOs, one DAO per site, each of which communicates directly with its associated VistA system. MDO acquires data from VistA using the same RPCs that CPRS uses; the data returned is labeled with a site tag, collated, sorted, and returned to the user's browser as a standard HTML page – data displayed is patient-centric instead of geo-centric.

Results

WebTop: Deployed in 1998, WebTop employed a user interface that was different than that of CPRS and required an independent user authentication step and invocation of a separate application (i.e., a web browser) to view an integrated set of patient data. In addition, as a field-developed product that required local or regional implementation effort over and above mainstream systems, WebTop never achieved enterprise-wide deployment. As a result, some users were reluctant to invest in learning how to use it. However, WebTop provided a compelling proof-of-concept, and demonstrated that clinicians were willing to make compromises on data normalization across sites (e.g., variability in drug or lab test names) in return for the ability to see data integrated across sites. WebTop undoubtedly succeeded at the regional level in meeting its fundamental objective of providing clinicians with the ability to access the equivalent of a single clinical repository containing all data on a patient. It quickly become a part of the daily life of clinicians in the VISNs in which it was implemented, as evidenced by the rapidity with which clinicians were heard from when there was any problem with the system.

CPRS/RDV: Implemented in April, 2002, CPRS/RDV rapidly supplanted WebTop due to its availability within the CPRS user interface as well as its national scope. As a corporate product it had advantages over field-developed products (e.g., inserting a stub in the user file to support tracking of access to patient data). It is interesting to note, however, that until WebTop was finally decommissioned, there remained a core of users who preferred its speed and simplicity in spite of its constraints. Implementation of CPRS RDV was a watershed event in terms of making data available across an entire healthcare enterprise of major size and scope, and it continues as a core function of the clinician interface. While it is clear from observation and anecdotal reports that CPRS RDV is used extensively, the application is unfortunately not instrumented so as to allow reporting on actual usage volume and on the types of data being retrieved.

VistAWeb: Released to the field in March of 2005, VistAWeb combines aspects of WebTop and CPRS, and adds major innovations of its own. What began as a local project to explore alternatives to a mainstream corporate application became, in turn a corporate product itself. In the process, important foundations were established: use of web services, a simplified model for clinical data, and return to a model for access to data from VistA sites not based on VistA-to-VistA communication. VistAWeb is in production use in VHA an alternative to CPRS RDV; it is slated to replace the Reports tab of CPRS in an upcoming release, providing a convenient integrated view of data from within the context of the CPRS interface.

Discussion

The industry press is replete with accounts of both successful and unsuccessful attempts to introduce clinical information systems into clinical care. Consideration of the factors which have led to VHA's successes in this arena over a quarter century is beyond the scope of this paper: suffice it to say that a major factor has been a tradition of large-scale involvement of clinical users in defining requirements and functionality of clinical systems. Another is reflection in spending patterns of belief in clinical systems. Until very recently, VHA never had a budget line item for IT – it was paid for out of health care dollars, thus assuring that investments made were perceived as having high value in clinical care.

Beyond such broad considerations, however, VHA has learned a number of useful lessons from the series of projects described in this paper which should be of use to other organizations taking on the challenge of data integration across a healthcare enterprise.

- It is essential to achieve a compromise between perfection, in terms of normalization of vocabularies and forms of representation, and practical utility. As the saying goes, "Don't let the perfect be the enemy of the good". VHA's experience clearly demonstrates that the human brain remains capable of smoothing over discontinuities that could otherwise prevent a project from getting started at all.
- Clinicians favor working in a single application over multiple applications or multiple browser windows, and value incorporation of functionality such as data integration with applications that are part of their primary workflow.
- Day-to-day operation of an integration framework depends on changing the traditional attitude that access to patient data at one medical center by staff at another is suspect. Thus, an enterprise or consortium intending to implement such a framework must be willing to implement business rules such as the following: a provider who has access to a given patient's data at one medical center has access to that patient's data at all participating sites; authentication of a provider's credentials at one site is sufficient to authenticate that provider's access at all sites; a locally acceptable indication of right to access patient data is an acceptable surrogate for permission to access patient data at all sites.
- Regardless of whether an organization has an inclination toward research, it is important to instrument applications so that usage patterns can be studied and understood. This has not been adequately appreciated in our own organization, and we have regretted it a number of times.
- While long-term success requires that an enterprise eventually establish standards for what data each site must commit to collect electronically, sites just begin-

ning the process must educate providers to have realistic expectations for what data will be found in the base systems, and thus the integrated data set.

- While corporate information technology programs are essential to the widespread deployment and sustained operation of sophisticated systems, investigative projects and local innovation continue to be the well-spring of watershed projects that lead to major advances in the use of information systems in clinical practice.

Future plans

While VistA is a tightly integrated suite of applications, VHA's current facility-level systems represent islands of data in an enterprise sense bridged by a series of integration applications. Desire for a patient-centered, "gold standard" legal electronic record and a more tractable approach to making computable data available for decision support have motivated VHA to undertake migration to a new environment, referred to as "Health*e*Vet", a core component of which is a health data repository (HDR) at a national level. Although the transition from VistA to HealtheVet will of necessity be gradual (akin to building an airplane in flight), the HDR will eventually serve as the source of a patient's electronic health record, providing a superset of the integration available today and obviating the need for applications such as CPRS/RDV and VistAWeb. As a corollary activity, VHA is embarking on a major data standardization and data modeling effort which will support application re-engineering. A major long-term implication of this undertaking is the positioning of VHA as a single national health information organization (NHIO) interacting through a National Health Information Network (NHIN) with other public- and private-sector entities delivering care to VHA patients.

Conclusions

VHA has demonstrated the feasibility of an enterprise-wide integrated patient record in a very large healthcare organization of national scope. While others have reported on clinical data integration projects, most are still in a formative stage and few if any have the breadth or depth of VistA and its current integration platforms [3]. Trends in healthcare and efforts at all levels encouraging the development of partnerships for sharing electronic health records have had major impact on requirements for cross-site data integration: practical technical and economic models are still being developed. It is interesting to observe that the majority of the concepts first proposed in the initial paper from the Institute of Medicine on electronic health records [4] are only emerging now, some 15 years later.

We close this paper with an anecdote that illustrates the value of the applications described here. VHA was severely affected in the coastal Southeastern states when Hurricane Katrina hit on August 29 of 2005. Multiple sites were affected: as an example, the New Orleans VA Medical Center was submerged to the second floor (where the computer room was) and was closed, with most inpatients going to Houston, Texas. Outpatient services in affected areas were dislocated. The "RecoverAll" emergency response team was dispatched on September 1, and the New Orleans computer system was replicated in Houston in twenty-four hours, with all records restored. It is estimated that it required about 100 hours to restore EHR capability for all affected facilities.

In the days following Hurricane Katrina patients started to appear at medical centers outside the affected area, initially at other VA medical centers in the Southeast and later at hospitals as far away as Puget Sound, in the far Northwest. The high number of refugees precluded normal access through CPRS/RDV. The solution was to grant temporary special user privileges to all VistAWeb users which gave users the ability to do patient lookup at other sites, and thus get VHA-wide data on any patient from the affected VISNs regardless of whether they were registered in the provider's local VistA system. Thus, electronic health records – and beyond that the integration of data across sites – played a major role in continuity of health care through a massive natural disaster.

Abstract

Providing high-quality HIV/AIDS care requires high-quality, accessible data on individual patients and visits. These data can also drive strategic decision-making by health systems, national programs, and funding agencies. One major obstacle to HIV/AIDS care in developing countries is lack of electronic medical record systems (EMRs) to collect, manage, and report clinical data. In 2001, we implemented a simple primary care EMR at a rural health centre in western Kenya. This EMR evolved into a comprehensive, scalable system serving 19 urban and rural health centres. To date, the AMPATH Medical Record System contains 10 million observations from 400,000 visit records on 45,000 patients. Critical components include paper encounter forms for adults and children, technicians entering/managing data, and modules for patient registration, scheduling, encounters, clinical observations, setting user privileges, and a concept dictionary. Key outputs include patient summaries, care reminders, and reports for program management, operating ancillary services (e.g., tracing patients who fail to return for appointments), strategic planning (e.g., hiring health care providers and staff), reports to national AIDS programs and funding agencies, and research.

Keywords:

edical record systems, computerized; HIV; acquired immunodeficiency syndrome; developing countries; Africa south of the Sahara; Kenya.

Introduction

More than 38 million persons are currently living with human immunodeficiency virus (HIV) worldwide, 25 million (63%) in sub-Saharan Africa where only 1 million (<10%) of those eligible for antiretroviral drugs (ARVs) are receiving them [1]. To respond to the HIV crisis in Kenya, in 2001 Indiana University, Moi University, and Moi Teaching and Referral Hospital created AMPATH – an Academic Model for the Prevention And Treatment of HIV/AIDS [2,3] to leverage the power of universities to establish systems of care, train multidisciplinary providers of HIV/AIDS care, and research innovative methods for enhancing the quality and outcomes of care. As shown in Figure 1, initial grown in AMPATH's care programs was slow until mid-2004 when major funding was obtained. By mid-2007, more than 45,000 patients have been enrolled, 1500-2000 new patients being enrolled per month.

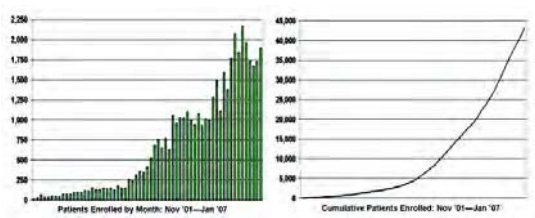

Figure 1 – Monthly and cumulative AMPATH enrollment

Hindering the ramping-up HIV/AIDS treatment programs is the lack of timely and accurate data on (1) the number of HIV-infected patients receiving care, (2) the number eligible for ARVs, (3) the number receiving ARVs, and (4) the positive and negative outcomes of treatment. Funding agencies often deny major program funding unless programs can document the number of patients treated and their outcomes. Paper-based record systems can only meet such information needs for small numbers of patients. The lack of EMRs has slowed the delivery of HIV care despite availability of funds for treatment from the U.S. [4], World Health Organisation [5], and philanthropic foundations [6]. This "Digital Divide" [7] has likely resulted in thousands of unnecessary deaths.

In this paper, we describe how a simple EMR implemented in a single Kenyan rural health centre in 2001 was transformed into a comprehensive, scalable EMR capable of

supporting large (even national) multifaceted HIV/AIDS care programs.

Methods

We describe the process used to initiate the Mosoriot Medical Record System (MMRS) and briefly listing its components, implementation, and use. We then describe how the MMRS was expanded in size and scope into the AMPATH Medical Record System (AMRS). We describe the data model and types of data stored and how the AMRS ultimately failed to support data input/management/output as enrolled patients exceeded 10,000, visits topped 100,000, and the needs of the clinical and funding programs demanded more data flexibility.

We then describe the evolution of the AMRS from its initial implementation as a set of linked spreadsheets into an object-oriented data management system. Finally, we describe how AMRS data serve clinicians, ancillary programs, strategic planning, and reporting to the Kenyan national AIDS control program and international funders.

Results

Initial implementation of the MMRS

In 1999, 3of the authors (WMT, JKR, TJH) visited the six adult and pediatric clinics at the Mosoriot Rural Health Centre to design an EMR as part of the Indiana University-Moi University's NIH-funded medical informatics program. After several days studying local care, redundant data entry in logbooks, and handwritten reports for national reporting, they held discussions with local providers and managers to design the MMRS [8], modeled loosely after the Regenstrief Medical Record System [9]. The MMRS had a 1-page paper encounter form, designed by Kenyan clinicians and used to include a minimum dataset for each visit. After each visit, these data were entered into a computer by a checkout clerk. The MMRS had modules for patient registry, clinical data, reports, and a concept dictionary defining data elements.

The MMRS was programmed in MS-Access® as a set of spreadsheets for clinical observations, laboratory tests, and drugs, all linked by patients' unique ID# (with check digit) and visit date. Data were entered using checkboxes, drop-down menus, or partial name lookup of dictionary terms. The dictionary included term names, synonyms (to ease data entry), term classes (to aid reporting), and charges for drugs and tests. A report module printed standard reports required by the Ministry of Health and for local management activities.

Created and pilot tested in 2000, the MMRS was implemented in 2001 (Figure 2) [10]. Initial use was slow. Adding a second data entry computer (connected by a network cable), closing a clinic exit, and directing patients to the checkout window resulted in use of the MMRS for 100% of visits. Two months later, the logbooks were discontinued. Prior to 2001, creating monthly reports required a half-time clerk. With the MMRS, it took less than an hour. Mosoriot became the #1 health centre in Kenya. Managing drug inventory improved, and quantifying unpaid (charity) increased Ministry of Health funding.

The MMRS also allowed nurses to identify hidden problems: Monthly reports showed a village with few vaccinations (a nurse was sent to educate villagers and vaccinate children). A rabies cluster was identified (the rabid dog was found and shot). A cluster of sexually transmitted infections was noted (the index man was found and treated). A formal time-motion study showed a 10 minute (23%) reduction in patient visits and a tripling of providers' free time from 15% to 46% of the workday. Since 2001, Mosoriot has doubled its patient and visit load but needed no additional staff.

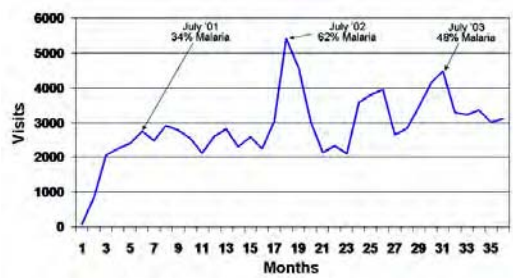

Figure 2 - Visits with data stored in the MMRS, by month

Expanding the MMRS into the AMPATH Medical Record System (AMRS)

In November of 2001, Moi University and Moi Hospital created AMPATH and opened its first 2 HIV clinics. Comprehensive HIV care requires more data and reports to the Ministry of Health and funding agencies. AMPATH directors designed 4 detailed encounter forms for initial and return visits for adult and pediatric patients. As at Mosoriot, data at the point of care were entered onto paper because there was inadequate electricity and funds for computers or hand-held devices. The AMRS' initial visit forms (5 pages long) captured demographics, family/social history, HIV risk, symptoms, prior hospitalizations and medications (ARVs, other antibiotics), alcohol use, physical exam, WHO stage, test results, problem lists and treatments (HIV- and non-HIV-related), and next visit [11]. The 2-page (1 sheet) return visit form collected a subset of the initial data: no symptoms, a limited exam, medication adherence, problems and treatments, and next visit. Importantly, the visit forms were designed by AMPATH clinicians and clinic managers to serve their needs, balancing the amount of data desired and the time it took to record them. Compromises and multiple iterations yielded a consensus minimum dataset [12].

As shown in Figure 3, most AMRS data were entered as checkboxes while the rest used menus and partial name lookup of dictionary terms. Text comments written on the encounter forms were transcribed into AMRS text fields. The data model behind the initial AMRS was the same as the MMRS: a series of MS-Access spreadsheets linked by patient ID# and visit date. The MMRS dictionary was expanded to include additional terms needed to count and describe enrolled AMPATH patients and report what care they received, and report their care and what outcomes occurred [11].

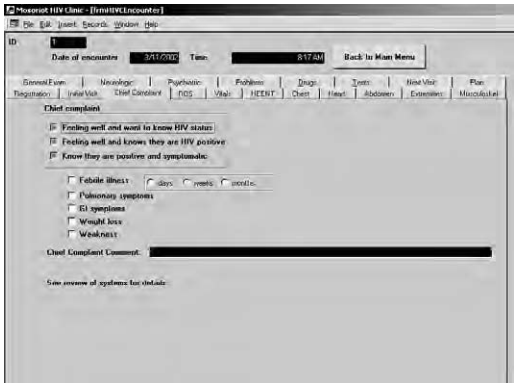

Figure 3 - Initial AMRS data entry screen

Failure of the initial AMRS

Initially, the MS-Access AMRS worked adequately, recording data and providing clinical summaries for providers and reports for AMPATH program managers and funding agencies. However, once the number of patients exceeded 10,000 and visits topped 100,000, the system bogged down. Most symptoms and exam findings were negative, yet an empty field was stored in the AMRS database. The limit of 256 fields per table caused major problems. Variables appearing on multiple forms had to be redefined each time they were used. Patients could only have one AMPATH number, which caused problems when patients visited more than one AMPATH clinic. It was impossible to extract sets of data, such as all patients on ARVs: each drug had to be extracted separately. Thus the MS-Access AMRS became huge, unwieldy, and limiting.

Transforming the AMRS into a Scalable EMR

To deal with these limitations, Regenstrief developers evolved the AMRS data model into one more tightly aligned with the Regenstrief Medical Record System [9]. Written in MySQL, the new, enhanced AMRS [13] has the following components:

Encounter forms

These continue to be defined by the data needs of AMPATH clinicians and managers, led by 3 of the authors (WMN, SK, JJM), They have evolved with changing data and reporting needs. By using checkboxes, menus, and numeric data, the AMRS return visit form takes 1-2 minutes to complete. (Page 1 of the 2-page form is shown in Figure 4, left.)

Patient registry

This defines "who" is providing care. Patients are registered and assigned AMRS numbers. They can have multiple names (e.g., get married, have aliases) and multiple AMPATH numbers: each clinic assigns a local number with a check-digit for ease of filing charts. This database also contains demographics and a history of funding sources. Patients can be linked in families for social, economic, and nutrition interventions.

User registry

This defines "by whom," persons who record, enter, and manage and report AMRS data. Each system user is registered, given a number (with check digit), and provided access and data management privileges needed for his/her required tasks.

Concept dictionary

This is the database of concepts that controls all data entry and extraction. It consists of both terms (e.g., chest xray, diagnosis) and findings (e.g., infiltrate, pneumonia). It defines the format of a term (e.g., coded text, numeric) and the allowable codes or numeric ranges. Terms can be sets (e.g., ARVs) or elements of sets (e.g., AZT) to facilitate data extraction. Term classes include tests, drugs, diagnoses, vital signs, etc.

Encounter site database

This stores "where" care is provided. Each site has a code, and by using the patient identifier, date, and encounter site, an episode of care can be recreated. These codes allow reports to be generated separately for each AMPATH clinic.

Observation database

This stores "what happens" and is the AMRS' heart. Each observation on the encounter forms (other than patient registry data, user ID#, and encounter site) is entered into this database and has 3 components: term ID#, date entered, and result (defined by the dictionary term linked to the data entry screen).Unlike MS-Access, there are no empty fields.

Data lookup

With this program, clinicians and managers look up data on individual patients for making patient and practice decisions.

Data entry

The encounter form is the official medical chart. Once entered into the AMRS, these data serve multiple clinical and managerial needs. Efficient data entry screen mirror the encounter forms which also allows them to be used for direct data entry at the point of care. Figure 4 below shows page 1 of the adult return visit form (filled in) and its AMRS data entry screen.

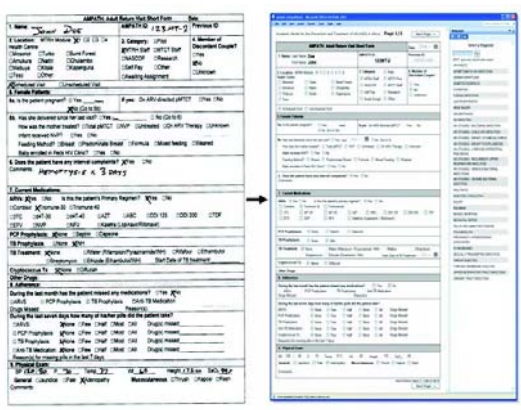

Figure 4 - Paper and electronic AMRS encounter forms

Arden query and reporting system

Using the if/then/else logic of the Arden Syntax [14], this query system provides standard and custom reports such as patient summary flowsheets and reminder reports. Knowledge of clinical medicine, the AMRS database and concept dictionary, and hierarchical data (observations within visits, visits within patients, patients within providers, and providers within clinics) is necessary to generate useful reports [15].

Patient summary and reminder reports

After receiving data for a visit, the AMRS prints out a report that contains diagnoses (with date recorded), WHO HIV stage, drug therapy, drug adherence, serial weight and test results, and reminders (e.g., "Order 6-month CD4 count") [11]. This summary/reminder report is placed in the patient's chart for viewing by clinicians during and between visits.

Non-clinical databases

AMPATH includes programs to prevent HIV infection, provide social and nutritional support, follow-up missed appointments, etc. To enhance efficiency, data security, and avoiding redundant data collection, the AMRS stores data for all ancillary programs and link with clinical data as needed.

Data management

Kenya has limited electricity and Internet access in urban and rural settings. Completed encounter forms are carried by courier to AMPATH's data center where clerks enter data into the AMRS. Data accuracy is enhanced by a financial incentive program. The forms and summary/reminder reports are then returned to the clinics. The AMRS currently contains 10 million data items for 45,000 patients and 400,000 visits to 19 AMPATH clinics. The encounter form is the only medical record, and data are entered into AMRS for virtually all visits. Moving forms between clinics and the data entry centre takes time (~2 days) and petrol. AMPATH will soon move to on-site data entry and printing. Data will be sent to the central database by flash drive or (where available) wireless Internet.

Costs and sustainability

Costs of computers, data entry, and data management are sustained by the agencies that fund HIV/AIDS care. Although originally resistant, these agencies now realize that complete, believable, timely data are essential providing high-quality care and monitoring and evaluating this care and its outcomes.

More constraining is the expertise needed to implement, maintain, and evolve EMRs. For AMPATH, the U.S. and Kenyan partner universities provide sufficient expertise to make this arrangement sustainable. It would be most appropriate for Kenyans to be wholly responsible for managing EMRs supporting care in Kenya. However, the requirements and costs of most medical informatics training programs are currently beyond the reach of most Kenyans. Hence, academic partnerships such as Indiana/Moi can help sustain EMRs in developing countries while training Africans to manage their EMRs.

Uses of AMRS data

Clinicians use the forms and patient summaries and computer reminders [16] for every day patient care. Clinic managers use monthly reports to assess productivity and anticipate personnel needs. For AMPATH, data managers report AMRS data to governmental and funding agencies. Ancillary programs use AMRS data as well: Outreach workers assess no-shows in their homes and facilitate visits. Med nurses assess reasons for non-adherence and counsel patients. Social workers assess financial needs and send patients to AMPATH's economic development program. Nutritionists refer underfed patients to AMPATH's nutrition program, with sufficient foodstuffs from the World Food Program and local farms to feed 30,000 persons/week. Prevention workers help pregnant mothers and newborns to lower HIV risk, caring for those who become infected. Researchers and quality improvement officers assess and improve processes and outcomes of care [17,18].

Expansion beyond Kenya: The OpenMRS Consortium

AMRS developers are committed to improving HIV/AIDS care in developing countries beyond Kenya. In 2004, they teamed up with Partners in Health [19] to expand the AMRS data model into OpenMRS, a free open-source EMR and an international collaboration of implementers [20]. OpenMRS has been implemented in Kenya, Rwanda, South Africa, Tanzania, Uganda, and Lesotho and is being installed in other developing countries. As a result, the Regenstrief Institute is WHO's first Medical Informatics Collaboration Centre. OpenMRS aims to enhance the productivity and accountability of HIV care programs. Key is independence and sustainability of local EMRs. Since early 2006, OpenMRS meetings have been held in Kenya and South Africa, attracting developers from more than two dozen countries. Information about OpenMRS, training, and downloads of programs and encounter forms can be found at www.openmrs.org. Widespread use of OpenMRS, which uses standard messaging formats and data coding, will enhance interoperability between HIV/AIDS providers, enhancing their ability to manage and improve care within and between provider systems.

Discussion

The AMRS has evolved from a simple MS-Access EMR serving a single rural health center in Kenya into a comprehensive, scalable, sustainable, multinational EMR capable of supporting multicomponent HIV/AIDS care. It has succeeded because it meets the needs of clinicians, who need the most data. Others (practice managers, Ministries of Health, funding agencies) need a small subset of clinicians' data. AMRS is the sole medical record; thus clinicians will complete the encounter forms, as they are meeting their own information needs.

The AMRS has succeeded where national HIV/AIDS registry systems have failed, largely because registries–which require completed visit forms to be sent to the Ministry of Health–do not provide any useful information to the clinicians or their practices. Clinicians thus have no incentive to complete these registry forms, and they often do not. Yet to date, many Ministry of Health officials in developing countries are not convinced that the expense of EMRs will

be offset by increased efficiency of care, as was shown with the MMRS [10].

Lack of training in medical informatics for EMR developers and managers will continue to limit the expansion, independence, and sustainability of EMRs in developing countries. Unfortunately, most medical informatics training programs in the U.S. cannot provide stipends to trainees who are not U.S. citizens or permanent residents. This problem needs urgent attention: capacity building will depend on funding from either non-governmental sources in the U.S. (e.g. philanthropic foundations) or governmental sources outside of the U.S.

The AMRS currently uses paper at the point of care. Personal computers, tablets, and other hand-held devices might yield efficient and effective data collection efficiently and accurately. Better Internet accessibility will further enhance connectivity. This should facilitate data collection and management, although even in developed countries, EMRs often use paper forms at points of care [9].

By creating, implementing, and evolving effective data collection and management systems, EMR developers contribute to care by magnifying the abilities of clinicians and managers to care for patients – especially those with HIV/AIDS – who so desperately need it. In no other way can these developers contribute so meaningfully to the battle against HIV/AIDS and other medical miseries that afflict the developing world.

São Paulo City Health Information System – A Case Report

Cláudio G A Costa[a], Beatriz F Leão[b], Lincoln A Moura Jr[b]

[a] *São Paulo City Department of Health, São Paulo, Brazil*
[b] *ZILICS – Health Information Systems, São Paulo, Brazil*

Abstract

São Paulo is the largest city in Brazil and one of the largest in the world. In 2004, São Paulo City Department of Health decided to implement a Healthcare Information System that would support managing healthcare services and provide an ambulatory health record. The system was designed to build on from national standards that identify healthcare workers, organizations and the relationships among them and reuse as much as possible existing concepts and software. At the same time, the system should reduce fragmentation, not only by integrating existing redundant or competing systems but also by providing a framework in which new modules would be naturally integrated to each other. Today, the web-based system, known as SIGA Saúde, runs in more than 370 healthcare units, processes some 8 thousand appointment scheduling daily and more than 10 thousand high-cost procedure authorizations monthly. This paper profiles the São Paulo City and its needs and describes the project, obstacles and results so far.

Keywords:

healthcare information systems, systems integration, information management

Introduction

SUS – the Brazilian health system

SUS, the Brazilian National Health System was created in 1998 when the Brazilian Constitution was approved in general elections. However, SUS is an evolving project whose history stretches back to as far as the Seventies [1]. SUS is required to provide free-of-charge health services based in principles: universality, integrality, and equity, meaning that all individuals are equally entitled to integral treatment. SUS has a complex organization, but it suffices to say it is funded and run jointly by the three levels of Government: federal, state and municipal. Under SUS, ideally, health services will be delivered and managed at city level, according to pre-defined and agreed programs, which are constantly monitored by the three levels.

Brazil has a long tradition of using Health Information Systems, and SUS data collection is impressive [2, 3]. However, the history of healthcare information systems has been characterized by system fragmentation as most application systems were developed to sort out specific problems, thus using specific vocabularies, patient and workers IDs. As a result of that some reports have counted more than 200 health information systems of different complexities without any integration whatsoever [2, 3].

That scenery started to change when, in 1999, the Ministry of Health proposed the National Health Card Project whose main objective was to define standards for uniquely identifying the individual, the health organization and the healthcare worker as well as to define a core patient data-set for registering the healthcare encounter in the country [3].

In parallel and using the same common ground, SUS started devising means to control patient flow. Patient flow control is currently regarded as the cornerstone to optimizing health resources and ensuring equity of access to health services. Essentially, patient flow control means ***intelligent scheduling*** of specialized consultations, exams and inpatient admission, including emergency. Intelligent scheduling means that allocating resources to answer to an individual's needs takes into account all relevant factors, such as distance, effectiveness, budget and cost. Although all treatment under SUS is offered free of charge, several procedures have to be authorized beforehand. Therefore, part of patient flow control relates to authorizing procedures and inpatient admissions alike.

Patient flow should follow a three-layer model, as depicted below. On the entry layer, lies primary care; on the second specialized treatment and, on the third layer, lies high-complexity treatment. Patient flow to the second and third layer follows recommended regional pathways, thus creating the reference-counter-reference model.

In 2000, the Health Ministry commissioned the development of SisReg – a patient flow control system – that use similar but unfortunately not the same data models of the National Health Card Project.

Both SisReg and the National Health Card projects were moderately successful but their evolution lacked continuity as governments changed hands. Nonetheless, these projects had major impact on how Health Information Systems become to be regarded. By the beginning of 2003 it was clear to most public health services managers (all pertaining to SUS) that national standards are vital, that patient flow control is an essential tool if SUS is ever to become a reality throughout the nation. It had also become

clear that, without proper Health Information Systems, no healthcare service can be operated properly [4].

São Paulo city health system

São Paulo is one of the largest cities in the world, with 10.3 million people in the city and some 18 million in the Metropolitan Area.

In June 2003, São Paulo Public Health came to operate as a "full managed-care" city, which means that resources from the National Health Fund are transferred directly to São Paulo City Department of Health (SPCDH) on a capitation basis. In exchange, the city agrees to meet certain production and quality goals, and has to send monthly reports that allow the Ministry o Health to assess if those criteria are being met.

By becoming a "full managed-care" city, São Paulo Dept of Health came to manage the following yearly figures:

- 10 million primary care consultations
- 8.5 million specialized consultations
- 550 thousand hospital admissions

São Paulo decided that investing in an Information System that would support Patient Flow Control and provide an Electronic Health Record System [5]. The core conditions that underlined the project can be summarized as:

- The information system would not only be fully compliant with all National Standards; but also help promote them;
- Open standards and open source-code should be used at all levels, whenever feasible;
- Whenever possible the project should use the results of previous projects, existing technologies and concepts;
- São Paulo City would receive source-code and consulting support from the Health Ministry and, in return, would send back to the Ministry all deliverables from the project;
- Finally, and most importantly, the system should be fully integrated and provide a framework for continuously embodying new functions in an easy and natural way.

The requirements and concepts summarizes above were described at length in a Term of Reference prepared by São Paulo City Department of Health. The Term of Reference defined 4 major sub-projects that should result in one and only Information System:

Municipal health register, whose objective is to handle and process the identification data for health care users, workers and organizations, as well as the relationships among them. The Register is the prime data source for all other modules, as no operation can be carried out unless its actors are registered.

This subsystem also stores and processes all standard vocabularies in use within SUS. All data within the Municipal Health Register are fully compliant with SUS

Patient flow control handles all requests for health care services (consultations, procedures, inpatients admission and emergency) and finds the best possible match, based on criteria such as budget, distance, availability and waiting time. This module also processes authorization requests for high-cost high-complexity procedures. This is standard-procedure under SUS Also handles exceptions, i.e. whenever resources use exceed predefined limits or are unavailable, an accredited doctor handles the exception, either by extending the budget, finding available resources or holding the request for some time, if that is the case.

It also processes patient flow control within the health care unit and copes with waiting lists, either local or in other reference layer.

Ambulatory electronic health record collects an essential dataset from the encounter and triggers related actions, such as notifying diseases or work-related diseases, when such conditions are met.

Role-based access control system is a single sign-on system that identifies the user and its user profile, thus enabling or disabling access to system's functions. Of course, all users have to be recorded in the Register, before being authorized to access the system. Initially, some 40 profiles were defined. Through system usage the Dept of Health decided to delete some and created other profiles, totaling more than 60 profiles currently.

To develop the project, SPCDH hired several companies that, under its management, focused on specific subprojects or on threads such as hosting, communications, equipment, software development, training and support.

Methods

In order to achieve the proposed goals, five main topics were considered:

Project management

From the very beginning, management was recognized as the most important aspect of the project. In order to cope with that task, three management committees were put together. At the topmost level, the Strategic Committee included the Health Secretary and the top management of all threads. The main purpose of the Strategic Committee was to build consensus among players and made decision on strategic issues such as overall budget, timing and political issues that involved organs or activities that went beyond the Information System's borders. The Managing Committee was formed by SPCDH IT Manager and from representatives from the several threads,. The Committee met together regularly to review progress and take the required action. Finally the Executive Committee formed by project coordinators that would look after every thread's development. Each thread was developed using its own methods that have been submitted and approved by the Managing Committee. Decision has always been taken by consensus. Whenever one level failed to reach consensus, the decision was taken to the upper level, so that eventually it would become a Secretary's decision.

From time to time, workshops and meetings would be held to celebrate major progress or to inform of important decisions or course changes.

Technology

The project was based on open-standards and free-software open-source paradigm. Java Technology was chosen from the first moments for its ability to generate systems that run on any platform; to make extensive use of object-oriented analysis, and to create reusable software components. Although the system should run on a variety of equipment, a basic platform was defined with Linux as the standard operating system, JBoss as the application server and Oracle as the database management system. The only proprietary piece of software chosen was Oracle, as for the foreseen volumes no free-software database management system was considered suitable for the task. The system was developed in three-layers as depicted in Figure 1.

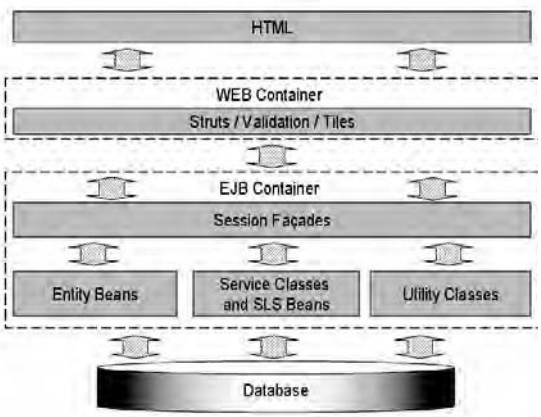

Figure 1 - System architecture overview

System specification

System's functionality was specified using the Unified Process, heavily based on use cases. Users and experts were assembled in forums to review and improve old use cases as well as propose new ones. A trained health informatician led the forum meetings with the aim of identifying and recording all necessary use cases. Throughout the project, use cases' granularity has been chosen to match basic system's functions and associated software components, in such a way that reusability is improved. Once implemented, use cases were validated by comparing their actual operation with use case's description.

In order to allow for full information integration, a Conceptual Information Model was devised to cope with the complexity of the Domain. The Model is described elsewhere, but its schematic representation can be seen in Figure 2.

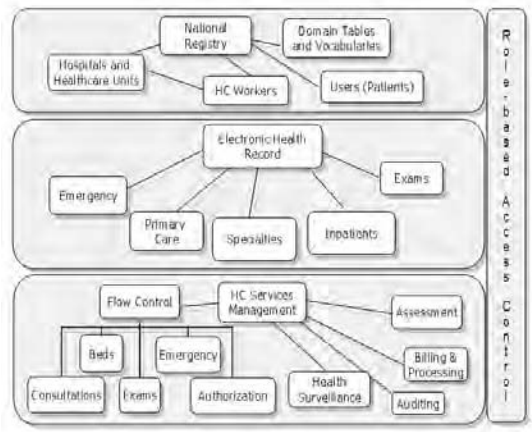

Figure 2 - Health information conceptual model

Human resources

Training was one of the most important aspects to consider, as the number and variety of human resources to be conquered and trained was enormous. The approach to training and HR involvement was based on replication, meaning that the company hired to develop the system gave training to some 20 Dept of Health staff members that, in turn, trained final users. Training was associated with the several subprojects, or modules, described above, so that blocks of similar functions were taught at each time. Additionally, assisted operation took place as equipment was deployed at the health care units. Some 700 computer science students were hired and trained to help end-users at the point of care, for as long as 5 weeks.

System deployment

Deployment of such a huge system was devised as a vertical-to-horizontal process, in which the system was to be fully implemented in one of São Paulo City Health Regions and, as it became stable, it would be rolled out to other regions. However, as a new City administration was elected and took office in January 2005, the deployment method was changed to completely horizontal. In other words, the modules related to registering patients, health care workers and health care units in all health units before moving to new functionalities. As that was a very slow process since it depended on all health units using the system at the same level, the process was reviewed once again, so that a mix of horizontal and vertical process are in place.

Figure 2 shows a schematic representation of the system as it has been deployed. Web-machines at point of care are connected via ADSL to the São Paulo City Datacenter. Via Internet authorized users have access to the system, which is represented in its major modules.

Figure 3 - Schematic representation of system deployment

Results

The system thus developed came to be known as "SIGA Saúde" which means "following health" and is an acronym for "Integrated System for Health Care Management".

As of this writing, SIGA Saúde is in use in 372 primary care units for a) registering patients, workers, health units and their services; b) scheduling local appointments.

The actual numbers of SIGA deployment as of November 6 to 12, 2006 as informed by São Paulo City Health authority are described in Table 1, below.

Table 1 - SIGA Saúde production, October 2006

Item	Amount
Primary Care Units Using SIGA Saúde	372
Primary Care consultations scheduled	1,657,023
Specialized Consultations scheduled	35,250
High-Cost Procedures Requests Processed	223,225
Patients Registered	8,357,863

Figure 4 shows the evolution in number of overal appointmens made using SIGA Saúde for the 5 São Paulo Regions, since October 2004, when the system was launched. Figure 5, in turn, shows the actual number of consultations performed for the same Regions in the same period.

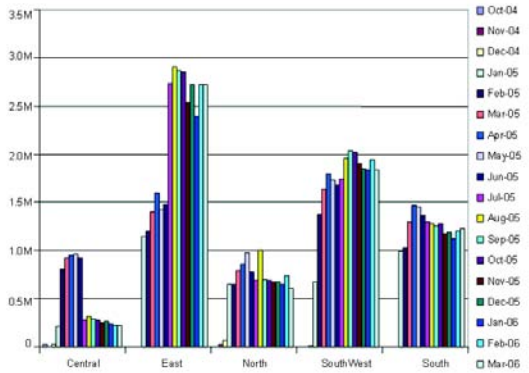

Figure 4 - Evolution of SIGA Saúde use for appointment scheduling, in São Paulo's 5 regions

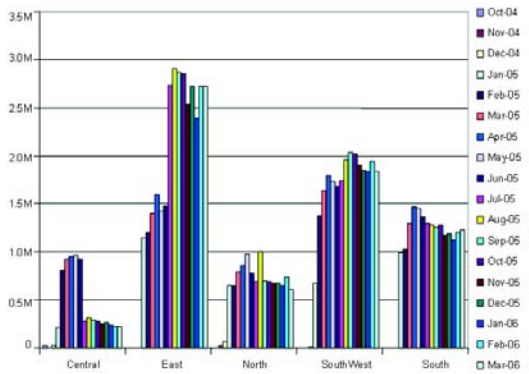

Figure 5 - Evolution of actual number of consultations delivered in São Paulo's 5 regions

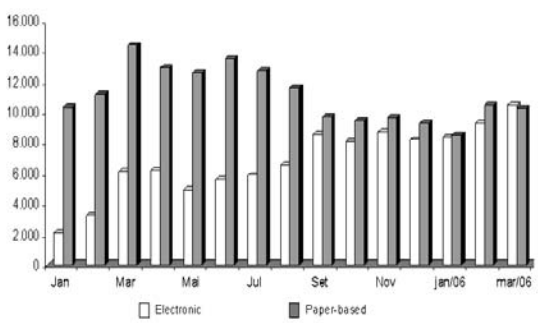

Figure 6 - Evolution of the number of high-cost procedures requested on paper and electronically since SIGA Saúde came to place

Discussion and conclusions

Impact data related to using SIGA Saúde is still under collection. However, a preliminary assessment reveals that outpatient services productivity has increased about 35%.

Patients' perception has changed for better, as patients have stated they can schedule appointments within the same month, against a three-month wait that was typical before SIGA Saúde. The Brazilian Press, usually very critical of public IT services published an opinion article stating their view that SIGA Saúde was a major contribution to the Bazilian Health System [6]. The project has also won a Duke's Choice Awards, granted by JavaOne 2005 Conference Meeting [7].

SIGA Saúde architecure is very innovative. By being fully web-compliant and using public Internet for providing safe role-based access to the system, SIGA Saúde can easily be deployed in other cities or regions. Also, as SIGA Saúde is fully compliant with all Brazilian standards and SUS practices, it is a tool to be used to help SUS itself be implemented throughout Brazil. Finally, São Paulo City's dimensions and complexity are so evident that taking SIGA Saúde to other cities and states requires simplification rather than new functionalities.

SIGA Saúde is a joint property between the Health Ministry and São Paulo City Department of Health, that are willing to share SIGA Saúde with other Public Service organizations, within the country or abroad.

SIGA Saúde architecture has several advantages when compared to conventonal client-server systems:

- The datacenter model allows that all complexity, such as backup, data model maintainance and system evolution, be kept away from the end-user, who accesses the system via a standard browser;
- All the health care unit needs is an Internet access and a browser. No local server is required at health units. When a point-of-care web-computer breaks down it is simply replaced by another one;
- The system can be shared by several cities in what has become increasingly common in Brazil, which are City Consortia. One single server can attend several cities that share services and or patients;

Next steps

SIGA Saúde has also been installed in São Paulo State Dept of Health to help identify and control the flow of hemophilic patients and hemodialisys. According to SUS model, the management of those aspects are responsibilities of States. At the moment, the major effort is to integrate State and Municipal databases. The problem is more of organizational than technological complexity.

São Paulo City Department of Health aims at putting together a communitiy of cities and states that use SIGA Saúde, so that furthere development can be carried out in a shared fashion, thus reducing costs. As SUS is very similar throughout Brazil, that is a feasible task. However managing shared development is a very complex task, as strong methods are required to deal with distributed object-oriented development based-on software components. Although SIGA Saúde has been built using a Development Framework that embodies such concepts, it is not true that cities and states are ready for such an enterprise.

At the moment, SIGA Saúde is being integrated to the information system of 3 clinical analysis labs that provide services to the Public Health System, using HL7 v3 and LOINC. With that, all lab orders and their results will be available on-line at the point of care.

Abstract

The challenge of scaling up HIV treatment in Africa has led to a new emphasis on improving health systems in impoverished areas. One aspect of this is the development and deployment of electronic medical record systems to support HIV and TB treatment. In this paper we describe the design and implementation of a new medical record architecture to support an HIV treatment program in rural Rwanda. The architecture is called OpenMRS and it has been developed to address the problem of configuring EMR systems to suit new sites, languages and diseases. OpenMRS uses a data dictionary called the concept dictionary to represent all the possible data items that can be collected. This allows new items to be added to the system by non-programmers. In addition, there are form creation tools that use drag and drop web technologies to simplify form construction.

The OpenMRS system was first implemented in Kenya in February 2006 and then in Rwanda in August 2006. The system is now functioning well and we are developing extensions to improve the support for the clinic. These include improved, easy to use reporting tools, support for additional clinical problems including nutrition and child health, better database synchronization tools, and modules to collect laboratory data and support the pharmacy. The system is also in use in South Africa and Lesotho and is being deployed in Tanzania and Uganda.

Keywords:

electronic medical records, developing countries

Introduction

The HIV epidemic centered in Africa is probably the greatest medical challenge facing the world today. Currently about 40 million people are infected with the virus and nearly all will die in the next decade without anti-retroviral (ARV) treatment. Real progress is now being made in ARV treatment for patients in impoverished developing countries spearheaded by the WHO 3x5 initiative[1] and supported by the Global Fund to Fight AIDS, TB and Malaria, the US PEPFAR program, EC countries and other government and private funds. Partners in Health (PIH) pioneered the treatment of HIV in the extremely impoverished environment of the Central Plateau of Haiti in 1999 and has now provided ARV treatment to over 3000 HIV patients in that country. Beginning in May of 2005 PIH started an HIV treatment program in some of the poorest rural areas of Rwanda[2]. There are now 3400 patients being monitored and over 2000 patients receiving ARV treatment. All patients on treatment have a baseline assessment of their clinical status, weight and CD4 count. Those patients with CD4 counts below 350 or who have evidence of opportunistic infections are promptly started on triple ARV therapy. Pregnant women who are HIV positive are also started on triple ARV therapy in the 3rd trimester. All treatment is directly observed by a community healthcare worker who visits the patient's home daily. This is to ensure excellent compliance and alert the clinic of any problems that occur between the monthly clinic visits. Patients with malnutrition are given food supplementation monthly.

To support the process of finding patients, initiating therapy and monitoring the patients' treatment we have set up a web-based electronic medical record system in Rwanda. This is used for all the HIV patients, with a focus on those that are on active ARV treatment. It is based on the OpenMRS electronic medical record architecture jointly developed by Partners In Health and Regenstrief Institute in Indiana. The OpenMRS system has now been implemented in Kenya, South Africa and Lesotho as well as Rwanda. We describe here the OpenMRS system, the implementation in Rwanda and the future plans for the OpenMRS system in that country and around the world.

Background

Electronic medical records (EMRs) are becoming accepted as an important tool to support high quality healthcare in the US, Europe and other developed countries. This approach has been driven by evidence that the use of EMR systems improves quality of care[3] and reduces medical

errors[4] and unnecessary medical investigations[5]. Experience in the use of EMR systems in developing countries is much more limited but there is now considerable interest in medical information systems to support the treatment of HIV and TB in Africa, Latin America and Asia. The Regenstrief Institute in collaboration with Moi University in Kenya developed the Mosoriot Medical Record System (MMRS) to record clinical data on general patient visits to clinics in western Kenya[6]. This system was built using Microsoft Access and was subsequently modified to support the care of several thousand HIV patients[7]. However, the design and technology was not easily extendable to cover new diseases or larger numbers of patients. Baobab Health in Malawi have developed an EMR system using innovative, low power touch screens for data entry and display[8]. This system is now used to support the care of more than 7000 HIV patients in the Lighthouse clinic in Lilongwe and is being assessed by the national HIV program for use throughout the country. Careware® an HIV medical information system developed for US patients has now been deployed in Uganda[9] and is planned for use in other African countries and in Latin America. Another system called SmartCare (and based on smart cards) is operational in Zambia. Medecins Sans Frontieres has deployed a system called Fuchsia to clinics where they provide HIV treatment.

The PIH-EMR system

In 2001, Partners In Health developed the PIH-EMR[10] a web-based medical record system to support the treatment of patients with multi-drug resistant TB (MDR-TB) in Peru. That system was based on an Oracle database and uses the Apache web server, Java server pages and the Tomcat servlet engine. It now has records on over 15,000 patients, more than 6000 of who have started or completed treatment for MDR-TB. The system is designed to collect data on the baseline patient assessment, bacteriology test results, drug regimens and patient outcomes. It includes extensive tools for data analysis and drug consumption forecasting as well as communication tools to improve the quality of laboratory data and reduce delays in starting patients on the correct treatment. The PIH-EMR has been evaluated in several studies that have shown that it can reduce: data errors[11], delays in data access and communication, and the workload of documentation and reporting[12]. The PIH-EMR is also used by an MDR-TB treatment program in the Philippines[13].

The HIV-EMR system

In 2002 the PIH-EMR was modified to support the treatment of HIV in rural Haiti[14] as part of the expansion of care funded by the Global Fund. The HIV-EMR is now used in 9 clinics in rural Haiti and collects data on patients' clinical history and examination, drug regimens, lab tests including CD4 counts, and follow-up data including opportunistic infections and medication side effects. The HIV-EMR is accessed by satellite Internet access in each of the clinics in Haiti. It is used to generate reports on patient treatment for the Global Fund and PEPFAR programs and to detect patients whose treatment may be delayed or incorrect. An additional component to the HIV-EMR allows staff to enter data while offline and then synchronize the data when the Internet connection is available. A particularly important extension to the EMR is a web-based pharmacy tracking system that tracks all medications and supplies for the clinics (not just for HIV patients) that handled almost 1.8 million patient visits in 2006.

In 2005, the HIV-EMR was set up to support patient care in our new clinic in Rwinkwavu, Rwanda[15]. The system was modified to match the local conditions including clinic details and Rwandan reporting requirements. A team of data entry staff and a data manager was hired and trained, and data were entered on over 1500 HIV patients taking ARV medication. This implementation was successful in less than one year, though it had the benefit of a full-time programmer on-site in Rwanda. It was clear from the experience in Rwanda and the Philippines that our existing architecture was challenging to set up and modify to suit new projects.

Motivation for a new EMR architecture

As there is a great need to provide software to support new HIV and MDR-TB treatment projects, we needed to develop a system that was very flexible and scalable, but that did not require expert programming to add new forms or tailor it to new sites, languages or diseases. Such a system would ideally use open source code to make it as widely accessible as possible by sites with limited funding. It would also benefit greatly if it could be developed by multiple programmers and groups, to share ideas and programming efforts. This would provide an avenue for other projects to contribute to the system and become part of the team rather than just passive recipients of the code. We believed that the system should retain the clear benefits of a web-based system while allowing local "offline" data entry. It should also provide excellent tools for data analysis and reporting, with the option of exporting raw data for further analysis using standard tools such as statistical packages.

We looked at existing EMR systems and found none that fulfilled these requirements. Most commercial medical record systems are closed, proprietary and, typically, expensive. They are not designed to be extended by the sites that use the system and it is often difficult to extract data for analysis or to upload to other systems. It was essential the system used was open to modification for different languages and local requirements. The small number of open source EMR systems do not have the characteristics required for projects with limited equipment, bandwidth and technology support. A particular requirement was for a data model that explicitly modeled medical concepts and data and that could be viewed and updated by experienced users, not just programmers.

Progress to date

OpenMRS system development

The approach we chose was to create an open source electronic medical record architecture through collaboration between Partners In Health and Regenstrief Institute and,

subsequently, the South African Medical Research Council. The system that came from that collaboration is OpenMRS[16]. The critical difference between OpenMRS and most other systems, such as those previously used by both PIH and Regenstrief (in Kenya), is the use of a comprehensive data dictionary for all clinical data. This allows new data items to be added to OpenMRS without programming or modifying the underlying database structure. All patient data apart from basic name and demographics are coded as concepts in the data dictionary. Data entered into the EMR are added to an observation table along with the date and time of entry. Orders such as drug prescribing are added to an orders table in a similar way. The concepts can be linked to existing coding systems such as LOINC and SNOMED, and can be shared between forms or between different projects. The dictionary also simplifies the process of translating data into different languages and creating libraries for different diseases or clinical problems. Data types supported by concepts include numeric, text and date/time. The OpenMRS concept dictionary allows concepts to be grouped together into concept sets to represent more complex relationships than single concepts alone. We are developing tools to create derived concepts that link together concepts with rules created in Arden syntax[17]. A derived concept could perform calculations on age and weight, for example. In addition, the Arden syntax interpreter will simplify creation of sophisticated decision support rules to drive alerts and reminders.

The OpenMRS system is built in Java using the Spring application framework and the Hibernate object-relational persistence system on top of a MySQL database back-end. (MySQL could be replaced by any RDBMS supported by Hibernate, including Oracle, MS SQL Server, and PostgreSQL.) OpenMRS's web front-end is served by the Tomcat servlet container, and is built in Java Server Pages with JSTL, with a liberal use of AJAX (implemented with DWR), and JavaScript widgets implemented in Dojo. All of these applications and libraries are open-source. We also use an XML-based form creation tool from Microsoft for certain data entry forms. OpenMRS has an API that allows software modules to be added to the core system, simplifying the creation and additional of new functionality. The technologies used for OpenMRS have been described in detail[16] (see also: www.openmrs.org).

The OpenMRS system was first implemented in Kenya in February 2006 with data entered from paper forms by the data entry team. Over 10 million observations have been entered on 48,000 ARV patients and the data are now being used to support the clinical care process and reporting. With their experience in using the web-based HIV-EMR, PIH staff use the EMR in a more interactive way and required extra tools for data entry, viewing, and analysis.

Implementation in Rwanda

We started with the HIV-EMR installation that had been running for one year[15] and developed a tool to migrate the data to the OpenMRS system. The OpenMRS was customized to use a look and feel, and navigation specific to the PIH project in Rwanda. We devised new intake and follow-up forms for use in the clinic, first on paper, and then converting them into the OpenMRS format using the Form Builder tool[16]. We then created the necessary reports in a reporting module so that we could generate output for national-level reporting, clinical support, administrative overviews, and research. Finally, we added custom modules for items such as batch data entry (to speed up repetitive tasks) and one-page clinical patient summaries. We are also creating forms and reports to support related treatment programs not included in our previous systems such as malnutrition and home visits.

The OpenMRS system is now running on a server in Rwinkwavu, Rwanda and is in daily use across six ART sites. Data are entered by a total of 11 data entry staff and reports and patient summaries are printed for doctors, nurses and other staff. While three of the sites (including Rwinkwavu) enter data from their respective sites, data from the three clinics without Internet connectivity are being entered in Rwinkwavu. We next plan to set up replicating servers in the other five sites that report back to the server in Rwinkwavu.

Laboratory data collection application

We have developed a simple laboratory data collection application using MySQL database and programmed in Java for use in Rwanda and similar sites. It allows users to search for a particular patient by name or ID and can show all of that patient's lab orders and results. Results can also be viewed in a register format to assess activity in a given time period. It can run as a "stand alone" system, but it can also be set up to send out alerts about critical results to those who subscribe. Using a simple module that connects to Skype™, these alerts can be sent as an SMS message to a clinician's mobile phone. We are currently refining the HL7 API to allow the data to be automatically uploaded to the OpenMRS system. Third party laboratory systems that can support HL7 data export should also be able to work with OpenMRS.

Reporting tools

To be useful to a wide range of staff it is essential that the reporting and analysis functions of OpenMRS are easy to use and flexible, while also providing access to the full expressiveness of the data model. This involves providing simpler user interfaces and pre-defined reports for some users, and richer user interfaces, user-defined reports, and raw data exports for more sophisticated users. The OpenMRS reporting tools consist of five distinct components: 1) a cohort definition tool, 2) a data set definition tool, 3) a data export tool, 4) a report designer, and 5) report generation modules.

1. *The cohort definition tool* is built into the OpenMRS API and web interface, and allows users to perform analysis on patient groups, based on patient characteristics, observational data, orders, program enrollments, or more complicated rules written in Java (and soon Arden syntax). It also allows users to save cohorts for future use, define them ad hoc, and generate predefined reports such as patient summaries for upcoming visits.

2. *The data set definition tool* is also built into the OpenMRS API and web interface and is closely tied to the OpenMRS concept dictionary. It allows users to specify the data columns (e.g. OpenMRS concepts) needed to implement a report. Data set definitions will be used to specify the data requirements for a report at the report design stage and will also be used by the data export tool at the report generation stage.
3 *Multiple data set definitions* can be defined per report. This allows users to define different data sets for each of the elements in their report. This is useful in scenarios where a single report may require different types of data (e.g. a graph showing enrollment data by age and gender and a table containing data about encounters at a specific clinic). Rather than requiring a user to define a single, monolithic data set which can only be used for that particular report, this feature allows users to define specific data sets for reuse in other reports.
4. *The data export tool* is also built into the OpenMRS API and is similar to the data set definition and cohort definition tool. This tool allows users to choose a cohort and data set definitions and export data in a format that will allow them to perform analysis within a wide-range of reporting and analysis tools. OpenMRS currently supports data export as a CSV (Excel) file, the most commonly used data export format. In the future, it will be extended to provide support for other formats, such as XML and tab-delimited files, as well as data export formats that are implemented through custom modules. The data export tool is also used to interface with the report generation modules (discussed below) to provide seamless data integration at the report generation stage.
5. *Report generation* is implemented within OpenMRS as a separate module. This allows OpenMRS to support a wide range of reporting frameworks, including open-source projects such as Pentaho, JFreeReport, JasperReport, and Eclipse BIRT. The first report generation module implementation will use the BIRT reporting framework. The reason we chose to initially support BIRT was based on its easy-to-use and flexible report designer and support for complex reporting features, such as cross-tabulation, joined data sets, and multiple data set support. In addition, since the BIRT tool is based on the Eclipse platform, OpenMRS developers can implement plug-ins to add new functionality. We also plan to implement an Open Data Access driver that interfaces with OpenMRS and acts as a JDBC-like driver to retrieve concepts and data through the OpenMRS API.

Implementing modules for each reporting framework allows OpenMRS to extend the functionality of the core reporting components without tying it to a particular reporting framework.

Pharmacy data

A critical use of EMR systems is tracking the drugs required for the group of patients for the next six to twelve months. In addition, to forecasting drug requirement from the drug regimen data we also need to track shipments of drugs to our warehouses and pharmacies and the weekly consumption of medications. We added a component to the HIV-EMR for Haiti to allow pharmacy staff to enter medication transactions in electronic stock cards[14]. The system now tracks all movements to and from the warehouses and allows staff to order drugs from the central depot and check on their order status online. Weekly reports are generated automatically that warn of any impending stockouts or excessive stock in each site. This system is separate from the OpenMRS system but is being linked to allow regimen data from the OpenMRS system to drive the dispensing of medications in the pharmacy for each patient. As with the lab system, other pharmacy software should function with OpenMRS if it supports standard data exchange protocols.

Future plans

Data synchronization

A key challenge in using an EMR in a developing country setting is that sites need local copies of data, due to slow and unreliable internet connectivity, while data from all sites needs to be combined in a central repository to allow tracking of transferred patients, project-wide reporting and reliable backup of data. We are currently designing tools to synchronize data and handle data entry conflicts, to allow seamless use of local OpenMRS servers that replicate and provide offline access to a parent OpenMRS repository.

Managing data on a range of diseases

Due to the urgency of this work and the resources available, the first installations of the OpenMRS focused on HIV and TB treatment projects, but it is designed to collect data on any medical care issue. In Rwanda we are already working with our *food distribution program*. Over the course of the next few months, we will continue to expand the use of OpenMRS to other PIH programs that were only indirectly related to HIV care, and were difficult to integrate into our previous EMR system (which lacked OpenMRS's concept dictionary and report designer). These include the *home visit program*, the *malnutrition program*, the *infant formula feeding* program and the *POSER program* (which constructs better homes for patients in desperate need). For each of these programs we will work closely with heads of department to devise effective forms for information intake. We will then work at length to come up with the reports those programs need to generate, both for external funders and for internal program management. The end goals are (1) to improve patient care by automatically providing lists of patients who have missed appointments or need special attention; (2) to make our hard-working staff's jobs easier, particularly by automating reporting that must currently be done manually; (3) integration of data so we can use OpenMRS's analysis tools to easily answer cross-program questions. We plan to study what happens to the clinical status of patients who stop receiving food support (and provide early warnings of patients who deteriorate after leaving the food program), and to assess the effect on patients' health once they have a better roof over their head. In Peru and Lesotho we are setting up OpenMRS to

track patients with TB and MDR-TB with support from WHO. Colleagues in Tanzania have developed concepts and forms for an oncology care version of OpenMRS.

Better integration with the hospital and clinic

We want patient information to be more available and encourage more interaction with the system by clinic staff. In addition, to adding more computers that can access the web-based EMR, we will be implementing a touch-screen interface for usage around the clinic and hospital. This will give clinicians easy access to patient histories, orders and lab data.

New interface tools

Date entry at present mainly occurs via forms implemented with Microsoft Infopath. This tool was used to simplify form design and speed up development but does not work perfectly with Linux, and requires a license fee. We are designing a new open source form creation tool using Java server pages, with help from students at the University of KwaZulu-Natal, South Africa. In addition, we are working to link the OpenMRS system to PDAs and Notepad PCs. Communication of data from the interface to OpenMRS is via the HL7 data exchange standard, simplifying the process of building links to other interface devices and software.

Conclusions

This project and those described earlier illustrate the capability that a system like OpenMRS has to help a clinic in a developing country to manage their data effectively and efficiently. By combining the functionality for patient data recording and display, reporting, and quality control in one system we are able to reduce the cost and complexity of setting up and maintaining the data management processes. The OpenMRS is now in operation in Kenya, Rwanda, South Africa, and Lesotho, with pilot implementations underway in Tanzania and Uganda. We are developing the Spanish language version for HIV and TB treatment in Peru, and there are plans to develop a Portuguese version for use in Africa and Brazil. We believe that the collaborative nature of the development of OpenMRS has not only magnified the resources available to build the software, but has greatly aided our ability to anticipate problems in new sites. We look forward to collaborating with other projects in Africa and other resource poor areas.

Acknowledgements

We thank the WHO and the CDC for supporting the development of the OpenMRS system. We thank the Clinton foundation, the Global Fund for AIDS, TB and Malaria and the US PEPFAR program for supporting clinical care.

Abstract

Most essential information contained in the electronic medical record is stored as text, and this imposes several difficulties on automated data extraction and retrieval. Natural language processing is an approach that can unlock clinical information from free texts. The proposed methodology uses the specialized natural language processor MEDLEE developed for the English language. To use this processor on Portuguese medical texts, chest X-ray reports were machine translated (MT) into English. The result of serial coupling of MT and NLP is tagged text that needs further investigation for extracting clinical findings. This experiment's objective was to investigate normal reports and reports with device description on a set of 165 chest X-ray reports. We obtained sensitivity and specificity of 1 and 0.71 for the first condition, and 0.97 and 0.97 for the second. The reference was formed by the opinions of two radiologists. The results of this experiment indicate the viability of extracting clinical findings from chest X-ray reports through coupling MT and NLP.

natural language processing, information storage and retrieval, thoracic radiography, machine translation

Introduction

There has been gradually been a change in the storage of medical information from paper to a digital medium in the form of electronic medical record (EMR). One of the greatest advantages of digital storage is the possibility of searching and consulting the stored information. However, a great part of the clinical information is stored as free text in the EMR, which makes searching, analyzing and comparing documents difficult.

Natural language processing (NLP) refers to a set of computational techniques whose objective is narrative text analysis for information extraction, classification and data comparison. This approach is highly effective in extracting and retrieving medical text information in several languages, including English [1, 2].

We decided to use machine translation (MT) associated with NLP in a serialized form for extracting and retrieving medical text information in Portuguese. The machine translates medical texts from Portuguese into English in a controlled way; that is, based on the utilization of a specialized translation dictionary in the chosen domain. Therefore, we would be able to employ a natural language processor, MEDLEE, which had been developed for medical texts in English and already validated for this domain [3]. Consequently, MT would work as a pre-processing stage to normalize and adjust the text before it was submitted to NLP. As the English language is so dominant in medical knowledge, we could assume there would t be expressiveness and representativity loss in the texts content in performing this translation. A general overview of methodology is shown in Figure 1.

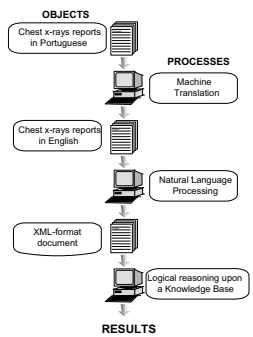

Figure 1 - General overview of proposed methodology

The chosen domain for this project was chest X-ray reports to investigate several clinical findings present in this kind of document. We show the primary results of this methodology in two clinical conditions: radiographic normality and the presence of devices. The results of this processing were binary responses indicating whether these two situations were present, and would be compared to the opinions of two specialist observers (radiologists).

Background

Information retrieval of medical texts using NLP has been successful in languages such as English, Dutch, German, Japanese and French [2]. Recently, a project in Portuguese was described [4]; however, it has obtained limited results. MEDLEE is one of the most successful systems for extracting information from medical texts. Initially, it was developed as a decision tool for X-ray reports but its coverage was extended to a wide variety of medical texts. The processing result is a XML document composed of clinical

Selected for best paper award.

primary findings with modifying elements. One of the most important results was obtained in the processing of 889.921 reports of thorax X-rays [5]. A sample analysis showed a sensitivity and specificity of 81% and 95% respectively on retrieval of documents describing the most important chest radiology diagnoses.

Materials and methods

The MT was performed with the software application SYSTRAN Premium version 5.0 [6]. This application performs rule-based translations and requires a specialized dictionary to process medical texts. Two were configured. The first one was a user's dictionary composed of a unidirectional table of source and destination terms associated with attributes; the most important is category, a mixture of syntactic and grammatical class. The elaboration of this dictionary followed a specific methodology [7]. The terms that constituted this dictionary were taken from chest radiography reports of articles' summaries from specialized literature [8], RADLEX [9], and UMLS [10]. A translation memory was also elaborated that of a pre-translated sentences table suitable to translate those of frequent occurrence. In this case, it was configured to process sentences related to normal findings.

Some 1362 chest radiography reports in Portuguese developed at the Instituto do Coração de São Paulo in 2003 and 2004 were chosen for MT training. Out of these reports, 930 unique sentences were obtained and submitted to MT using the dictionaries described above. Translations were manually revised and adjustments were carried out in the dictionaries. Parallel studies of performance evaluation were also conducted [11,12].

For the experiment, 165 reports performed in January 2006 were randomly selected. In any report, no data was obtained in a way that would identify patients or any clinical information. All incidences were included and there was no distinction if the data referred to radiographies performed with portable equipment on a bed. The only constraint was the presence of a report produced by the radiologist. The professional who developed the report was not identified.

Each report was marked with a unique numeric identifier and its content was located in a text file. Then, it was submitted to MT using the application SYSTRAN configured with the dictionaries described above. The report that had been translated into English was then submitted for processing through MEDLEE [3] and the processing result was stored in a XML file.

The XML-format result needed additional processing to determine the presence of the findings being investigated. To accomplish this, we developed a methodology based on an ontology created with the software PROTEGE [13] and that was submitted to first order logic queries with the Algernon Abstract Machine (AAM) [14].

The ontology was created from the specialized vocabulary in radiology RADLEX. Its hierarchical structure renders the building up of an ontology. Each RADLEX element of the super-classes' 'anatomic location', 'morphologic and physiologic processes', 'diagnoses and etiologies', and 'visual features' was incorporated into the ontology (each one as a class). The RADLEX original hierarchical structure was preserved.

The processing commenced with the inference rules loading. These included lexicon equivalence rules between MEDLEE and RADLEX, and the clinical relation rules shown in Tables 1 and 2.

Table 1 - Simple terms equivalence rule from MEDLEE to RADLEX as pseudocode

if MedLee term is lung then Radlex term is lungs

Table 2 - Example of pseudocode rule that establishes an affect relation between an anatomic structure and a disease

if pneumonia is true then lung instance is true and normal is false

Table 3 - An example of some logical assertions obtained from a processed report, shown as AAM code

(tell ((:add-instance (?x sentence)(tipo ?x "problem") (tipo_value ?x "osteophytosis")(suid ?x "s1.1.1") (value2 ?x :TRUE))))
(tell ((:add-instance (?x sentence)(tipo ?x "problem") (tipo_value ?x "enlarged") (bodyloc ?x "auricle") (suid ?x "s1.1.6") (certainty ?x "no") (value2 ?x :FALSE))))
(tell ((:add-instance (?x sentence)(tipo ?x "finding") (tipo_value ?x "free") (suid ?x "s1.1.2") (region ?x "recess") (value2 ?x :TRUE))))

Then the data derived from the reports were loaded. These data were those contained in the XML file transformed by XSLT into logic instructions in the AAM syntax. To transform a MEDLEE result in XML into logical instructions, a simplification was adopted. Table 3 shows some logical assertions obtained from a processed report after the transformation of the MEDLEE result. These assertions create instances in the ontology that discharge the rules previously loaded, thus creating new instances. The last stage was performing queries through searching instances created in the target classes using a binary response (yes or no) to indicate the presence of the findings. Table 4 shows one of the queries related to devices.

In this experiment, we looked for two fundamental radiological findings. The first was the normal reports that can be defined as those whose sentences report only radiological findings compatible with normal standards. The second related to implants, catheters, probes, equipment, foreign bodies and other implements of surgical nature, such as sutures or clips. Such elements will be generically called devices.

Table 4 - Query performed to search device instances, shown as pseudocode

```
if device is true then print "1" on output file
```

The 165 investigated reports were compared to the reference elaborated by the two radiologists who did not belong to the institution where the reports came from. The reference variability had been measured with the kappa index. System performance was accessed globally and only the final result was evaluated, and not the intermediate stages. Accuracy in the report retrieval was measured by the calculating specificity, sensitivity, and true positive and true negative fractions, including confidence intervals [15].

Results

A personal computer was used in the translation, transformation and logical inference operations, whereas MEDLEE processing was performed by a remote server via the Internet. The whole operation lasted about 90 minutes. The prevalence of the investigated findings according to the employed methodology on the 165 reports is shown in Table 5.

Table 5 - Prevalence of investigated conditions (n=165)

Conditions	Quantity	Prevalence
Normal Report	36	22%
Device	26	18%

True positives were defined when there was agreement between the system and the human reference on positive cases. The following contingency table (6) shows the methodology results compared to human reference in relation to normal reports.

Table 6 - Contingency table related to normal reports

Methodology	Reference		Total
	Positive	Negative	
Positive	36	27	63
Negative	0	102	102
Total	36	129	165

We show the results relating to reports with a description of devices in Table 7.

Table 7 - Contingency table related to reports with device description

Methodology	Reference		Total
	Positive	Negative	
Positive	26	4	30
Negative	3	132	135
Total	29	136	165

Tables 8 and 9 show the accuracy of the methodology compared to human observers on finding normal reports and reports with device description respectively. The inter-observer agreement measured by kappa index is shown in table 10.

Table 8 - Accuracy measures from normal reports

Measure	Observed value	95 % Confidence interval	
		Inferior	Superior
Sensitivity	1	0.88	1
Specificity	0.79	0.71	0.86
True Positive	0.57	0.44	0.69
True Negative	1	0.95	1

Table 9 - Accuracy measures for device reports

Measure	Observed value	95 % Confidence interval	
		Inferior	Superior
Sensitivity	0.9	0.72	0.97
Specificity	0.97	0.92	0.99
True Positive	0.87	0.68	0.96
True Negative	0.98	0.93	0.99

Table 10 - Agreement between observers measured by kappa index

Condition	Observed kappa	95 % Confidence interval	
		Inferior	Superior
Normal Reports	0.9652	0.9172	1.0132
Device	0.921	0.818	0.9862

Discussion

Natural language processing is an effective method of clinical information extraction and retrieval directly from free medical texts, and it is particularly useful when investigating a large number of reports [5]. The unpublished methodology described here connects a machine translator to a natural language processor in English to investigate clinical situations present in reports in Portuguese.

This paper does not intend to evaluate the isolated performance of the various stages of methodology. To achieve**,** this we would have had to evaluate each stage independently and controlled the various influences. We decided to perform a global evaluation of a complete methodology and only evaluated the final result and not the intermediate phases. The results described here are the first using this methodology. To study the feasibility of this approach, we decided to evaluate only normal reports and the presence of device description. Since we obtained favorable results, we will expand our rules and queries to the major chest X-ray diagnoses and conditions.

The main innovation of this methodology is the use of the MT associated to NLP. A similar methodology for information retrieval of medical texts had not been described previously. We hypothesize that a loss of expressivity and representativity of semantic content after translation will not occur. This is based on the fact that English is the most important language in the spread of technical knowledge. Moreover, the semantic content of medical knowledge has a global character based on what has been published in medical literature in English. This makes English the *lingua franca* of medicine [16].

Another aspect determined the elaboration of this methodology. There is no satisfactory medical natural language processor for Portuguese texts The experiment described by Martha [4] obtained sensitivity of less than 50% on information retrieval medical texts. This performance is inferior to that obtained by MEDLEE alone or by coupling with MT as described in this paper.

MT is certainly the most critical aspect of this methodology. The best MT results were obtained in the processing of technical texts [17]. The morphological errors observed in the English texts might be of various types. The first refers to words that present orthographic errors in the Portuguese source text. The machine translator SYSTRAN offers the option of orthographic correction. This correction worked suitably**,** taking into account the fact that accent differences between the terms of the text and the dictionary were ignored and correctly translated by the system. This orthographic corrector thus allows SYSTRAN to eliminate mistakes relating to accent use and other special characters normalizing the text. Another kind of error occurred when the original word did not exist in the MT dictionary. This situation can lead to two situations: the presence of untranslated words in the destination text, or the use of words out of context. An example of the latter kind of error was observed during the training stage when the word *lobo* was translated as *wolf* instead of *lobe*.

The next stage of the methodology involved subjecting the translated text to MEDLEE processing. For instance, in this stage of development and training, an error was observed that was associated with the interpretation of the finding 'linear opacity'. Translated as 'dense line', it was interpreted by MEDLEE as vascular access like 'venous line'.

MEDLEE result present a multilevel hierarchic structure that was simplified to a single level. MEDLEE describes entities in a structured form with various XML elements, whereas the RADLEX-based ontology used in the inference mechanism describes each entity through a single element. In the present experiment**,** this was the major cause of errors and it led to several clinical situations not being identified and jeopardized the normal findings. Improvements will be implemented in the next stage of the project through augmentation of the MEDLEE captured structure.

The next stage was logical reasoning. NLP results are composed of data that need further interpretation for the presence of the investigated clinical states to be established. Here, we utilized a logical inference mechanism based on an ontology that was juxtaposed with the use of the other described methodologies. Specifically for MEDLEE use, an inference system was implemented based on rules to NLP results processing. This approach used Arden Syntax for Medical Modules that accept the coded findings as entries and use a set of rules to determine the presence of selected clinical findings [18]. Our approach used these same data to create instances in an ontology which, in turn, will be queried afterwards.

The hierarchy of anatomic structure classes and findings, as well as their relations rules, is essential to this process of logical reasoning. Queries were loaded to aim at finding instances of investigated classes and subclasses. Table 4 shows the instruction in pseudocode that searched for instances of the 'device' class. This reasoning model was able to check for the presence of investigated clinical situations based on given assertions.

A study compared five types of expert systems in the interpretation of NLP results [19] for the investigation of pneumonia in comparison with three human observers (two radiologists and one clinical). The systems were rules elaborated by specialists, two kinds of Bayesian nets, a decision tree and a search for words. The latter aside (which performed poorly), differences were not observed with the human reference when deciding on the presence of pneumonia in the NLP result.

The accuracy of methodology was higher for devices location than for normal reports. This stemmed directly from the way the logical inference was performed. Normalcy is the initial state of the report. The inference system task was to find out clinical situations described in the report. The system's failure to point out the presence of several findings ensured that no normal reports were construed as normal. This derived from the project development stage. Until that point, only devices findings had had all their rules defined, which was evident from the performance. In the next stage of development**,** rules for other findings will be refined. In doing so, this methodology will be able to investigate a larger range of clinical findings, and therefore reduce the number of false positive normal reports observed in this experiment.

The MEDLEE output has a five-step scale of certainty varying from no to high certainty. The current rules that transform this output into logical assertions capture only two states. When certainty is no**,** it indicates a false assertion. On the other hand, the assertion is considered true, even on low certainty. Another aspect that needs to be mentioned is that the status tag of a MEDLEE output is not captured by this transformation. However, both aspects of logical transformation have contributed to false positive results.

NLP already represents a consistent approach in information retrieval from medical texts. Here, we presented a methodology that permits this information retrieval through a multilingual approach using MT. The feasibility of the hypothesis that it is possible to machine translate texts in Portuguese and submit them to NLP through the MEDLEE tool was demonstrated. This work was innovative in the sense it used MT as pre-processing to realize natural language processing. Another feature that deserves to be mentioned is the use of a logical inference mechanism based upon ontology, which is different from previously described methods for interpreting NLP results from medical texts.

Acknowledgments

We would like to thank to thank Dr. Carol Friedman for permitting the use of MEDLEE. MEDLEE is supported by the grants

R01 LM007659 and R01LM008635 from the National Library of Medicine (USA). This work is also supported by grant 55.2026/2002.6 from CNPQ (Brazil).

Abstract

We propose an approach to multilingual medical document retrieval in which complex word forms are segmented according to medically relevant morpho-semantic criteria. At its core lies a multilingual dictionary, in which entries are equivalence classes of subwords, i.e. semantically minimal units. Using two different standard test collections for the medical domain, we evaluate our approach for six languages covered by our system.

Keywords:

Information storage and retrieval, multilingualism, natural language processing.

Introduction

The main challenges for the architecture and implementation of medical document retrieval systems and their underlying search engines are inherently linguistic. Additional complexity emerges from the multilingual dimension of information retrieval applied in the medical domain [1]. While clinical documents are typically written in the physicians' native language, searches in scientific databases require sophisticated knowledge of (expert-level) English medical terminology which most non-English speaking physicians do not have. Hence, some sort of bridging between synonymous or closely related terms from different languages has to be realized to make use of the information that these databases hold.

Furthermore, the user population of medical document retrieval systems and their search strategies are really diverse. Not only physicians, but also nurses, medical insurance companies and patients are increasingly accessing these resources, with the Web adding an even more scattered group of searchers. Hence, mappings between different jargons and sublanguages are inevitable to serve the needs of such a heterogeneous searcher community. Therefore, the simplicity of the document content representation, as well as automatically performed intra- and interlingual lexical mappings or transformations of equivalent expressions become crucial issues for an adequate methodology of medical information retrieval.

This work presents the MORPHOSAURUS system [2] which is intended to meet the particular challenges of medical language processing, especially for medical information retrieval. Its main component is a dictionary, in which entries constitute equivalence classes of *subwords*, i.e., semantically minimal units. These equivalence classes capture intralingual as well as interlingual synonymy. As equivalence classes abstract away from subtle particularities within and between languages, and reference to them is realized via a language-independent conceptual system, they form an interlingua.

Morpho-semantic indexing

Within the MORPHOSAURUS framework (an acronym for MORPHeme theSAURUS), subwords are assembled in a multilingual lexicon and thesaurus, with the following considerations in mind:

- Subwords are listed with their attributes such as language (English, German, Portuguese, Spanish, French, Swedish) or subword type (stem, prefix, suffix, invariant). Each lexicon entry is assigned one or more morpho-semantic identifier(s) representing its equivalence class, the MID.
- Semantic links between synonymy classes are added. We subscribe to a shallow approach in which semantic relations are restricted to a paradigmatic relation *has-meaning*[1], which relates one ambiguous class to its specific readings, and a syntagmatic relation *expands-to*[2], which consists of predefined segmentations in case of utterly short subwords.

Figure 1 depicts how source documents (top-left) are converted into an interlingual representation by a three-step procedure. First, each input word is orthographically normalized in terms of lower case characters and according to language-specific rules for the transcription of diacritics (top-right). Next, words are segmented into sequences of subwords from the lexicon (bottom-right). Finally, each

1 For instance, {head} {zephal,kopf,caput,cephal,cabec,cefalg} OR {leader,boss,lider,chef}

2 For instance, {*myalg*} {*muscle,muskel,muscul*} + {*schmerz, pain,dor*}

meaning-bearing subword is replaced by a language-independent semantic identifier, the MID. It unifies intralingual and interlingual (quasi-) synonyms, thus producing the interlingual output representation of the system (bottom-left). In Figure 1, bold-faced MIDs co-occur in both text fragments.

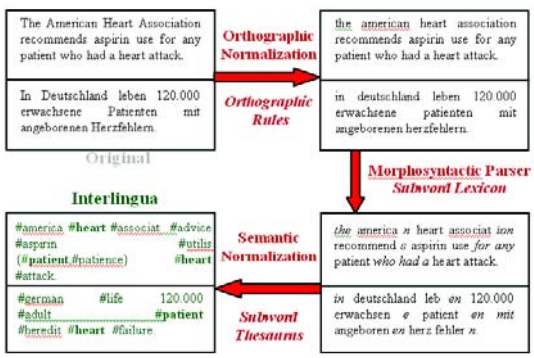

Figure 1 – Morpho-Semantic Indexing (MSI): Ambiguity is represented by the sequence of multiple MIDs in curly brackets. The German sentence can be translated to "In Germany, 120,000 adult patients live with a hereditary heart failure".

The combined subword lexicon currently contains 99,781 entries, with 22,953 for English, 24,357 for German, 15,158 for Portuguese, 13,390 for Spanish, 9,924 for French, and 13,981 for Swedish. All of these entries are related in the thesaurus by 22,707 equivalence classes.

Subword sense disambiguation

In the subword thesaurus, entries can be attributed to different senses (via the *has-meaning* relation). Consider, e.g., the English lexical item "patient", which has (at least) two different meanings. As a noun it refers to a human (*#patient* in Figure 1, bottom left), as an adjective it has a completely different meaning (*#patience*). In order to resolve ambiguities that can occur during the morpho-semantic indexing process, a simple probabilistic model is used [3]. It accounts for co-occurrence information from large textual resources. To illustrate this for the English document sample in Figure 1, the reading *#patient* should be preferred over *#patience*, since *#patient* as well as the context identifier *#heart* also occur in the representation resulting from the processing of the German document (the word *"Patient"* in German is unambiguous).

In earlier experiments on bilingual information retrieval (English and German, cf. [2]), we have shown the usefulness of representing medical documents on an interlingual layer. In this paper, we extend this evaluation by the other languages that are covered by the system. Furthermore, the effect of the disambiguation module attached to the morpho-semantic indexing procedure is analyzed in detail.

Information retrieval experiments

The experiments were run on the OHSUMED corpus [4], which constitutes one of the standard IR testbeds for the medical domain, and the 2006 corpus of IMAGECLEFMED (cf. [5]).

OHSUMED is a subset of the MEDLINE database. Considering the title and abstract field (if available) for each bibliographic unit, the set contains 348,566 documents and 26,705,691 tokens (whitespaces), thus, the average document length is 76.6 tokens. Since the OHSUMED corpus was created specifically for IR studies, 106 queries are available, including associated relevance judgments (actually 105, because for one query no relevant documents could be found). The average number of query terms is 5.2. The following is a typical query: *"Are there adverse effects on lipids when progesterone is given with estrogen replacement therapy?"*

IMAGECLEF is the cross-language image retrieval track which is run as part of the Cross Language Evaluation Forum (CLEF) campaign. IMAGECLEFMED evaluates the retrieval of medical images described by text captions based on queries in different languages. The main goal is to improve the multimedial retrieval of medical images from heterogeneous and multilingual document collections containing images as well as text. In IMAGECLEFMED 2006, the multilingual image retrieval task is based on a dataset containing images from different types (radiology and pathology images, clinical case descriptions related to nuclear medicine). Considering English annotations only, there are 40,709 image descriptions with a highly variable quality within and between the collections. The number of tokens is 1,130,419, thus, the average document length is relatively small compared to OHSUMED (27.7). There are 30 queries for which relevance judgments are available. For English queries, the average number of query terms is 5.8. A typical example is: *"Show me images of a frontal head MRI"*.

The OHSUMED corpus and the IMAGECLEFMED subset considered here contain only English-language documents. This raises the question of how these collections (or, e.g. MEDLINE, in general) can be accessed from other languages as well. It is a realistic scenario, because, unlike in sciences with English as a *lingua franca*, among medical doctors native languages are still dominant in their education and everyday practice. English medical sublanguage capabilities are often quite limited. In order to solve this problem, medical practitioners might resort to translating their native-language search problem to English with the help of current Web technology, e.g., an automatic translation service available in a standard Web search engine. Its operation might be further enhanced by lexical resources as available from the U.S. National Library of Medicine in support of various non-English languages, e.g. the UMLS Metathesaurus (which currently supports, with considerable differences in coverage, German, French, Spanish, Portuguese, Swedish and many others). Relying on the quality of the translation, this procedure

then reduces the cross-language retrieval problem to a monolingual one.

As an alternative, MORPHOSAURUS is used as a cross-language approach. In our experiments, both scenarios will be evaluated on the same query and document set. As the baseline, a retrieval system is provided operating with the Porter stemmer[3] and language-specific stop word lists so that the system runs on English documents with English queries.

In the following experiments, the original English queries were translated into Portuguese, German, Spanish, French and Swedish by medical experts (native speakers, with a very good mastery of both general and medical English).

QTR approach: Machine translation based on bilingual dictionaries

Machine translation based approaches to Cross-Language Information Retrieval (CLIR, cf. [6] for an overview) either translate native-language queries into the target language of the document collection to be searched, or contrariwise, translate the entire set of documents into each (supported) query language [7]. Since the latter is a resource intensive task, query translation (QTR) can be regarded as a standard experimental procedure in the cross-language retrieval community.

For evaluation, the manually translated queries were re-translated into English using the GOOGLE TRANSLATOR.[4] Admittedly, this tool may not be particularly suited to translate medical terminology (in fact, 13% of the German, 7% of the French, and 19% of the Portuguese and Spanish query terms were not translated, while Swedish is not supported at all). Hence, bilingual lexeme dictionaries derived from the UMLS Metathesaurus were used additionally. If no English correspondence could be found, the terms were left untranslated.

Just as in the (English-English) baseline condition, the stop words were removed from both the documents and the automatically translated queries and potential suffixes were stripped off.

MSI-approach: Language independent morpho-semantic indexing

As an alternative to QTR, the approach which is based on the morpho-semantic indexing procedures was probed, as introduced above. Unlike QTR, the indexing of documents *and* queries using MSI (after stop word elimination) yields a language-independent, semantically normalized index format.

Search engine

For an unbiased evaluation, several experiments were run with LUCENE,[5] a freely available open-source search engine which combines Boolean searching with a sophisticated statistical ranking model. Furthermore, this search engine has another advantage: it supports a rich query language like multi-field search, including more than ten different query operators.

Evaluation scenarios

Three different basic test conditions can now be distinguished for the retrieval experiments:

- **BASELINE**: The baseline of the experiments is given by the OHSUMED and IMAGECLEFMED corpus both in terms of their Porter-stemmed English queries, as well as their Porter-stemmed English document collection.
- **QTR**: In this condition, German, Portuguese, Spanish, French and Swedish queries are automatically translated into English ones (using the GOOGLE TRANSLATOR and the UMLS Metathesaurus), which are Porter-stemmed after the translation. These queries are evaluated on the Porter-stemmed OHSUMED and IMAGECLEFMED document collections.
- **MSI**: This condition stands for the automatic transformation of the English, German, Portuguese, Spanish, French and Swedish queries into the language-independent MSI interlingua (plus lexical remainders). The entire OHSUMED and IMAGECLEFMED collections are also submitted to the MSI procedure. Finally, the MSI-coded queries are evaluated on the MSI-coded corpora, both at an interlingual representation level. In this scenario, two different categories can be further discriminated:
  - **MSI**: experiments without incorporating the disambiguation module
  - **MSI-D**: experiments incorporating the disambiguation module

Measurements

Two measurements are taken in comparing the performance of QTR and different MSI. The first one is the average of the precision values at all eleven standard recall points (0.0, 0.1, 0.2, ..., 1.0). While this data is computed with consideration to the first 200 documents under each condition, the exact precision scores for the top 20 ranked documents are also taken into account.

Results

Considering the different test conditions and languages, Table 1 contains the exact numbers for the OHSUMED collection, and Table 2 for the IMAGECLEFMED collection (best results for each language marked bold).

OHSUMED results

For the OHSUMED collection, as depicted in Table 1 (first row), the English-English baseline achieves an 11pt average of 0.19 (Column 3). Running the experiment by MSI-indexing the original corpus and queries, the baseline condition can be exceeded by 16% for English. Additionally using the disambiguation module, 100% of the baseline up to 121% is reached for Portuguese, German and English. For the other languages considered, this scenario (MSI-D) also yields best results, ranging from 79% (French and Swedish) to 84% (Spanish) of the baseline. On the other

3 The stemmer is available on http://www.snowball.tartarus.org
4 http://www.google.de/language_tools
5 http://jakarta.apache.org/lucene/docs/index.html

hand, the QTR approach scores far lower than any MSI condition, reaching 37% of the baseline for Swedish and a maximum of 63% for Spanish. This results in 21 percentage points difference for Spanish up to 53 percentage points for German (QTR compared to MSI-D).

Table 1 - OHSUMED Results: Average and exact precision scores (% of baseline in brackets)

Language	Condition	11pt	Top 20
English	Baseline	0.19	0.27
English	MSI	0.22 (115.8)	0.29 (107.4)
	MSI-D	0.23 (**121.1**)	0.31 (**114.8**)
German	QTR	0.11 (57.9)	0.17 (63.0)
	MSI	0.20 (105.3)	0.27 (100.0)
	MSI-D	0.21 (**110.5**)	0.28 (**103.7**)
Portuguese	QTR	0.11 (57.9)	0.15 (55.6)
	MSI	0.17 (89.5)	0.23 (85.2)
	MSI-D	0.19 (**100.0**)	0.25 (**92.6**)
Spanish	QTR	0.12 (63.2)	0.16 (59.3)
	MSI	0.16 (**84.2**)	0.22 (**81.5**)
	MSI-D	0.16 (**84.2**)	0.22 (**81.5**)
French	QTR	0.10 (52.6)	0.16 (59.3)
	MSI	0.12 (63.2)	0.15 (55.6)
	MSI-D	0.15 (**78.9**)	0.20 (**74.1**)
Swedish	QTR	0.07 (36.8)	0.10 (37.0)
	MSI	0.15 (**78.9**)	0.22 (**81.5**)
	MSI-D	0.15 (**78.9**)	0.23 (85.2)
Average	QTR	0.12 (63.2)	0.17 (63.0)
	MSI	0.17 (89.5)	0.23 (85.2)
	MSI-D	0.18 (**94.7**)	0.24 (**88.9**)

The uneven investment of effort in constructing the different lexicons (see lexicon sizes above) is well reflected in the results. In any case, it seems worth noting that at *no* recall point QTR values were higher than MSI values.

However, there may be considerable variation regarding the actual numbers behind these average values. Medical decision-makers under time pressure are often interested in a few top-ranked documents. Thus, the exact precision scores for these documents are more indicative of the performance. Considering only the top 20 ranked documents (Column 4), precision does not fall below 74% of the baseline for MSI-D. In contrast, QTR does not exceed 63%, which means that MSI-D clearly outperforms QTR in any language condition. Again, focusing on the (English) monolingual retrieval setting, MSI-D gains 15% compared to the baseline.

By averaging over all languages and adding the English baseline condition to the values of the QTR approach for the other languages, query translation has a mean average precision of 0.12, thus reaching 63% of the baseline. MSI achieves 90% while MSI-D performs best with 95%.

IMAGECLEFMED results

Table 2 depicts the results for the IMAGECLEFMED corpus. Unlike the OHSUMED collection, which documents consist of coherent texts (MEDLINE abstracts), IMAGECLEFMED contains short captions of medical images, often only consisting of noun phrases with many acronyms. This might be the reason why the overall-performance is not comparable to OHSUMED for all scenarios, including the baseline condition.

Table 2 - IMAGECLEFMED Results: Average and exact precision scores (% of baseline in brackets)

Language	Condition	11pt	Top 20
English	Baseline	0.17	0.36
English	MSI	0.15 (88.2)	0.35 (**97.2**)
	MSI-D	0.16 (**94.1**)	0.35 (**97.2**)
German	QTR	0.10 (58.8)	0.22 (61.1)
	MSI	0.13 (**76.5**)	0.33 (91.7)
	MSI-D	0.13 (**76.5**)	0.34 (**94.4**)
Portuguese	QTR	0.13 (**76.5**)	0.22 (61.1)
	MSI	0.10 (58.8)	0.31 (**86.1**)
	MSI-D	0.12 (**70.6**)	0.30 (**83.3**)
Spanish	QTR	0.13 (**76.5**)	0.22 (61.1)
	MSI	0.13 (**76.5**)	0.32 (**88.9**)
	MSI-D	0.13 (**76.5**)	0.32 (**88.9**)
French	QTR	0.10 (58.8)	0.18 (50.0)
	MSI	0.11 (64.7)	0.30 (83.3)
	MSI-D	0.12 (**70.6**)	0.32 (**88.9**)

Language	Condition	11pt	Top 20
Swedish	QTR	0.06 (35.3)	0.08 (22.2)
	MSI	0.12 (70.6)	0.32 (88.9)
	MSI-D	0.13 (**76.5**)	0.34 (**94.4**)
Average	QTR	0.12 (70.6)	0.21 (58.3)
	MSI	0.12 (70.6)	0.32 (88.9)
	MSI-D	0.13 (**76.5**)	0.33 (**91.7**)

However, the advantage of MSI compared to QTR is still observable. While, in average, QTR yields 71% of the baseline regarding 11pt average, the MSI-D condition performs best with 77%. On the other hand, considering only a few top ranked documents, MSI-D outperforms QTR by 34 percentage points, reaching 92% of the baseline.

Of course, considering only 30 queries, the IMAGECLEFMED collection has only limited value for the evaluation of information retrieval systems. However, since this collection focuses on an important medical field (medical imaging and picture archiving systems) and results are in-line with those using the more elaborated OHSUMED collection, additional evidence for the excellent performance of the MORPHOSAURUS system in a Cross-Language Information Retrieval setting is available.

Discussion

After more than a decade of intensive research, cross-language information retrieval (CLIR) has produced considerable achievements. From a methodological point of view, the field is divided into dictionary-based *vs.* corpus-based approaches [6]. Since corpus-based approaches depend on the availability of large parallel corpora, which is mostly not the case for domain-specific sublanguages, most efforts in CLIR are centered on either query translation or document translation [7].

The success of dictionary-based CLIR depends on the coverage of the lexicon, tools for conflating morphological variants, phrase and proper name recognition, as well as word sense disambiguation. Within the MORPHOSAURUS system, the lexical coverage is optimized by limiting the lexicon to semantically relevant subwords of the medical domain. This also helps in dealing with morphological variation, including single-word decomposition. Since the latter is a frequent requirement for processing highly compounding languages (but also medical terminology in general), this partially explains the poor results for German in the SAPHIRE medical text retrieval system which uses the UMLS Metathesaurus for semantic indexing [8].

The UMLS is also the lexical basis of the approach pursued by the MUCHMORE project [9]. Although good results are communicated, these are not comparable to those presented here because the authors use a home-grown document and query collection and diverge in the construction of their baseline.

Eichmann *et al.* [10] report on cross-language experiments for French and Spanish using the same test collection as used here (OHSUMED), and the UMLS Metathesaurus for query translation, achieving 71% of their baseline for Spanish and 61 % for French (contrasted to 84% and 79% for MSI-D). With the vector space engine they employ, their overall 11pt performance (0.24) is far above the approach pursued here (0.18). On the other hand, when focusing on exact precision scores that have more explanatory power when thinking of a real world user scenario, the MORPHOSAURUS approach using a standard search engine turns out to be more advantageous. Eichmann *et al.* report precision values of 0.23 for Spanish (0.17 for French) for the top 5 ranked documents. Compared to these scores, the MSI approach (involving disambiguation) reaches 0.32 for Spanish (0.30 for French) for the top 5 ranked documents. Since query translation via the UMLS Metathesaurus was adopted in their work, it is not surprising that the QTR scenario yields comparable results by all means.

EHR Query Language (EQL) – A Query Language for Archetype-Based Health Records

Chunlan Ma, Heath Frankel, Thomas Beale, Sam Heard

Ocean Informatics Pty. Ltd, Australia

Abstract

OpenEHR specifications have been developed to standardise the representation of an international electronic health record (EHR). The language used for querying EHR data is not as yet part of the specification. To fill in this gap, Ocean Informatics has developed a query language currently known as EHR Query Language (EQL), a declarative language supporting queries on EHR data. EQL is neutral to EHR systems, programming languages and system environments and depends only on the openEHR archetype model and semantics. Thus, in principle, EQL can be used in any archetype-based computational context. In the EHR context described here, particular queries mention concepts from the openEHR EHR Reference Model (RM). EQL can be used as a common query language for disparate archetype-based applications. The use of a common RM, archetypes, and a companion query language, such as EQL, semantic interoperability of EHR information is much closer. This paper introduces the EQL syntax and provides example clinical queries to illustrate the syntax. Finally, current implementations and future directions are outlined.

Keywords:

openEHR reference model, archetype, query language, electronic health record

Introduction

The National E-Health Transition Authority of Australia (NEHTA) defines an EHR query as a formal user or system request for information to the EHR repository/ database that specifies the constraints on precisely what part(s) of the EHR content needs to be retrieved [1]. Due to the lack of any clear standards in EHR query services, NEHTA has identified it as a major area for review [2]. Easy accessibility of data from an electronic health record (EHR) is considered as one of the essential features of the EHRs that can enhance a hospital revenue cycle [3]. There are two major challenges commonly encountered in clinical data accessibility: one is that people who understand the clinical data best, such as health professionals, are not the ones most competent of querying the data; another challenge is that qualified SQL programmers or other query language programmers must spend much time on exploring the data, composing tedious code to provide the data that end user needs [4]. EHR data include thousands of facts to do with a patient's clinical status, which can be highly structured, semi-structured or non-structured, or most commonly, a mixture of all three. The lack of discipline commonly found in EHR data not only increases the difficulties in storing them, but particularly the difficulty in querying them.

The openEHR specifications have been developed to standardise the representation of an international electronic health record (EHR)[1]. Although there are implementations based on these specifications in development, experience with querying archetype-based EHR data is still limited, to the point where it is not clear what kinds of query language(s) are even appropriate for information systems based on archetypes.

Since the openEHR specifications intend to define a standardised EHR infrastructure, a query language for this infrastructure should aim to become an open specification as well. The query language described here will be submitted to the openEHR foundation as a candidate openEHR query language.

There are four requirements for an archetype-based query language. First, the query language should be able to express queries for requesting any data item from an archetype-based system, i.e. data defined in archetypes and/or the underlying reference model . Second, the query language should be able to be used by both domain professionals and software developers. Third, the query language should be portable, i.e., be neutral to system implementation, application environment and programming language. Lastly, the syntax should be neutral with respect to the reference model, i.e. the common data model of the information being queried. Particular queries will of course be specific to a reference model.

The current available query languages that might potentially be used to query openEHR data include the XML Query Language (XQuery) [5] and the Structured Query Language (SQL) . XQuery uses eXtensible Mark-up Language (XML) as its underlying data model. It has rich predefined functions and allows user-defined functions supporting the kind of clinical data requests required in the EHR context. It is platform independent. Nevertheless, its main strength is also its main flaw: it is limited to purely

1 http://www.openehr.org/

XML data environments. Direct use of XQuery for the openEHR EHR would require that all openEHR data must be represented in XML format. However, openEHR is designed as an object-oriented framework, and allows for a multitude of data representations, including as programming language persistent objects (e.g. in the form of Java objects in a product such as db4o[2]); as language neutral objects (such as in a database like Matisse[3]); as relational structures (governed by an object/relational mapping layer), and in various XML storage representations (e.g. XML blob or XML databases). XQuery is therefore problematic, because the query syntax is directly tied to the representational format of the data. Considerable efforts would be required to convert openEHR data in each deployment context to XML just for the purpose of querying; each such transformation may well be custom, requiring special work on the part of the system implementers.

A further disadvantage is that XQuery is a native XML programming language requiring intimate familiarity of both users (in this case, health professionals and software developers) alike with XML and XQuery, something that cannot be assumed.

SQL in its standard form is also not a viable candidate for querying archetype-based EHR data, because it does not support object-structured data, e.g. the data modelled in archetypes. It has been found that considerable intellectual efforts are required when using SQL to search and retrieve clinical data for both individual subject care and clinical research studies [6].

Object Query Language (OQL) is a query language for object-oriented databases. OQL was developed by the Object Data Management Group (ODMG[4]), which was disbanded in 2001. Comparing with XQuery and SQL, OQL would be the best candidate query language used for archetype-based EHR data. However, it is complex and as a result, it has not been widely implemented. For large object models, such as the openEHR RMs, OQL query statements can become extremely verbose. OQL uses an object programming style dot-notation to express object members, while an XPath-based syntax is specified by openEHR to locate archetype data elements. Using OQL with archetype-based EHRs would require the use and translation between these two notation styles.

To satisfy the aforementioned requirements of an archetype-based query language, a new language – EHR Query Language (EQL) is under development. This paper introduces the EQL features and syntax. Example clinical query scenarios are used to demonstrate the use of the EQL expression.

Methods

EQL was developed based on the analysis of a set of clinical query scenarios, the study of the current available query language syntaxes (including XQuery, SQL and Object Query Language), and the study of the archetypes technology, openEHR RM and openEHR path mechanisms.

What is EQL

EQL is a declarative query language developed exclusively for expressing the queries used for searching and retrieving the clinical data found in archetype-based EHRs. It is applied to the openEHR EHR Reference Model (RM) and the openEHR clinical archetypes, but the syntax is generic across applications, programming languages, system environment, and reference model. The EQL is designed as a common language used for expressing clinical data requests across multiple openEHR-based applications.

The EQL has two innovations: 1) utilizing the openEHR path mechanism to represent the query criteria and returned results; and 2) using a 'containment' mechanism to indicate the data hierarchy and constrain the source data to which the query is applied.

OpenEHR path mechanisms

OpenEHR path syntax is used to locate clinical statements and data values within them using Archetypes. An Archetype is a computable expression of a clinical concept in the form of structured constraint statements, based on some reference model [7], such as the openEHR RM which provides the support for clinical archetypes. Each archetype has a global unique identifier and each node of this archetype has a unique archetype node identifier. The openEHR architecture has a path mechanism that enables any node within a top level structure to be specified from the top of the structure using a "semantic" X-path compatible path. The availability of such paths radically changes the available querying possibilities with health information, and is one of the major distinguishing features of openEHR [8]. Consequently, it is possible to locate any node in an archetype, including leaf data elements by using the archetype and archetype node identifiers within openEHR paths.

Features of the EQL

The EQL features are listed below:

- Neutral expression syntax. EQL does not have any dependencies on the underlying RM of the archetypes. It is neutral to system implementation and environment. This is one of the distinguishing features of the EQL.
- Allows setting query criteria using archetype and node identifiers, data values within the archetypes, and class attributes defined within the openEHR RM.
- Allows the returned results to be top-level archetyped RM objects, data items within the archetypes or RM attribute values.
- Supports naming returned results.
- Support queries with logical time-based data rollback.
- Supports query criteria parameters.

2 http://www.db4o.com/
3 http://www.matisse.com/
4 http://www.odmg.org/

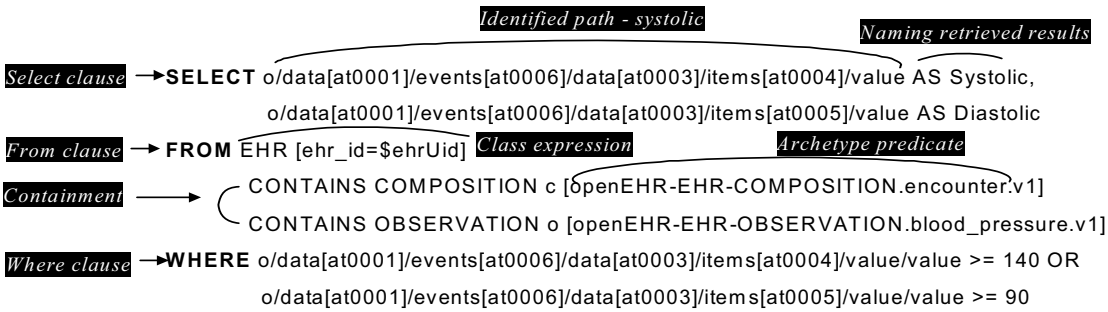

Figure 1 - A typical EQL statement

- Supports arithmetic operations (such as count, addition, subtraction, multiplication, and division), relational operations (>, >=, =, !=, <=, <) and Boolean operations (or, and, xor, not).
- Supports some functions that are supported in XQuery, such as current-date().
- Users could specify their preference on the retrieved data, such as ordering preferences, or total number of retrieved results.
- Supports the queries for individual clinical subjects at the point of care, administrative purposes and clinical research purposes.

EQL Syntax

Figure 1 shows a typical EQL statement, which would return all blood pressure values where systolic value is greater or equal to 140 or diastolic value is greater or equals to 90 within a specified EHR. EQL syntax is a synthesis of SQL structural syntax and openEHR path syntax. The SQL clauses SELECT, FROM, WHERE, and ORDER BY provide the basic structure of EQL. The SELECT clause specifies the data elements to be returned. The FROM clause specifies the result source and the corresponding containment criteria. The WHERE clause specifies data value criteria within the result source. The ORDER BY clause indicates the data items used to order the returned result set.

The openEHR path syntax [7], which is XPath compatible, is used in EQL to identify data items. Apart from the path mechanisms, EQL has a containment constraint, which specifies the hierarchical relationships between parent and child data items. The details of the EQL syntax are introduced below.

openEHR paths

The details of the openEHR path can be found elsewhere [7]. Herein, we briefly introduce its basic syntax.

A general pattern of the openEHR path syntax starts with a slash and followed by an attribute name of an object defined by the RM, and followed by another slash and attribute name and so on if there are multiple attributes involved, e.g. /ehr_id.

Another pattern of the path is a subset of the XPath syntax for predicates with a small number of short-cuts, i.e. archetype path. This path utilises an archetype ID or archetype node ID (i.e. at code, such as at0006) to identify an object. The example shown in Figure 1 uses the openEHR path syntax to locate both systolic and diastolic value in the blood pressure archetype.

Predicates

A predicate pattern is delimited by square brackets ([]). The path predicate has two operands and an operator. The operands are either an RM class attribute, an openEHR path or data value, such as a string or integer. A parameter name prefixed with a $ symbol can be used instead of a data value, which is substituted for a real data value at run time, e.g. ehr_id=$ehrUid shown in Figure 1. The operator can be =, >, <, >=, <=, or !=.

The archetype node ID predicates are a shortcut of a path predicate, which include either an archetype ID or archetype node ID. The archetype node ID predicates can also use a parameter name for the archetype node ID value, e.g. [$compositionArchetypeId]. The archetype node ID predicate shortcut is equivalent to a long-form path predicate with a left operand of archetype_node_id, and an operator of =. For example COMPOSTION c[openEHR-EHR-COMPOSITION-encounter.v1] shown in Figure 1 is equivalent to COMPOSTION c[archetype_node_id = 'openEHR-EHR-COMPOSITION-encounter.v1'].

EQL variables

All variables must have a RM class type assigned and they must be defined in the FROM clause, e.g. character c and o shown in the FROM clause of Figure 1 are EQL variables. EQL variables need to be declared when other clauses need a reference to them.

FROM clause

A FROM clause represents the data source for the query. It starts with the keyword – FROM, followed by a class expression indicating the RM classes, containment constraints and object identifying criteria used to constrain the data source for the query (refer to Figure 1).

For the openEHR RM, the classes declared in the FROM clause may include EHR, COMPOSITION, entry classes (e.g. OBSERVATION), and data structure class (e.g. ITEM_LIST).

Class expressions

An EQL class expression consists of a RM class name, an EQL variable (optional), and an optional class predicate. The class predicate further constrains the objects used as the query source and is normally applied to the archetype node ID or unique object ID class attributes.

Containment is indicated in EQL using the CONTAINS keyword between two class expressions. The left class expression indicates the parent object of the right class expression.

Identified paths

Identified paths are used to locate data items within an archetyped RM class. The identified path starts with an EQL variable that is declared within the class expression. This is followed by a slash and an openEHR path. The expression – o/data/[at0001]/event/…/value – shown in Figure 1 is an example of an identified path.

WHERE clause

A where clause is used to represent further criteria applied to the data items within the objects declared in the FROM clause. A WHERE clause starts with the keyword – WHERE, followed by a criteria expression. It consists of two operands and an operator. The operands may be an identified path or data value, such as a string or integer. A parameter name prefixed with a $ symbol can be used instead of a data value and substituted at run time. The operator can be =, >, <, >=, <=, or !=. Multiple criteria expressions can be combined using Boolean operators: AND, OR, XOR, and NOT.

SELECT clause

A SELECT clause starts with the keyword – SELECT, and followed by a set of identified paths. The set of paths are separated using a comma (see Figure 1).

Results naming

EQL allows users to rename the returned items specified in the SELECT clause. The keyword is AS, followed by the specified name, e.g. AS Systolic shown in Figure 1 SELECT clause.

ORDER BY clause

An ORDER BY clause starts with the keywords – ORDER BY, followed by a set of identified paths indicating the data items used to sort the returned result set. The keywords ASCENDING and DESCENDING (and abbreviations, ASC and DESC) can be used after each identified path as per SQL.

Arithmetic functions

A set of arithmetic functions, such as addition, subtraction, multiplication, and division can also be used in EQL. The use of these functions is the same as SQL, and is not described here.

TIMEWINDOW clause

TIMEWINDOW is an addition query clause used in EQL to constrain the query to data that was available in the system within the specified time criteria. This supports a time-based logical system rollback allowing a query to be executed as though it was performed at that specified time, which is essential for medico-legal reporting. It starts with the keyword – TIMEWINDOW, and followed by a string compatible with the ISO 8601 representation of time interval. The first example below constrains the query source to data committed to the system before 2006-01-01. The second example constrains the query source to data committed within the period of two years before 2006-01-01.

1) TIMEWINDOW /2006-01-01

2) TIMEWINDOW P2Y/2006-01-01

Clinical scenarios

To illustrate the use of the EQL syntax, this section provides the EQL expressions for two typical clinical scenarios.

Scenario one

Scenario description

Get the number of all patients with diabetes who have HbA1c results greater than 7.0 in last 12 months.

EQL expression

```
SELECT COUNT(e/ehr_id)
FROM EHR e
  CONTAINS
  (COMPOSITION c
       [openEHR-EHR-COMPOSITION.problem_list.v1]
    CONTAINS EVALUATION e
       [openEHR-EHR-EVALUATION.problem-
diagnosis.v1]
   AND
   COMPOSITION c1
       [openEHR-EHR-COMPOSITION.report.v1]
    CONTAINS OBSERVATION o
       [openEHR-EHR-OBSERVATION.laboratory-
hba1c.v1])
WHERE
  e/data/items[at0002.1]/value/value='diabetes
mellitus' AND
  c1/context/other_context/items[at0006]/
    items[at0013]/value > current-date() -P1Y AND
  o/data/events[at0002]/data/items[at0013.1]
   /value/numerator > 7
```

Scenario two

Scenario description

Get all HbA1c observations that have been done in the last 12 months for a specific patient.

EQL expression

```
SELECT o
FROM EHR e[ehr_id=$ehrId]
  CONTAINS COMPOSITION c
    [openEHR-EHR-COMPOSITION.report.v1]
    CONTAINS OBSERVATION o
     [openEHR-EHR-OBSERVATION.laboratory-hba1c.v1]
WHERE
c/context/other_context[at0001]/items[at0006]/
items[at0013]/value > current-date()-1PY
```

Scenario three

Scenario description

Get a patient's current medication list

EQL expression

```
SELECT c
FROM EHR e[ehr_id=$ehrId]
 CONTAINS COMPOSITION c
  [openEHR-EHR-COMPOSITION.medication_list.v1]
WHERE c/name/value='current medication list'
```

Discussions

This paper has introduced EQL – a declarative query language developed for querying openEHR-based EHRs by utilising the openEHR path mechanisms and unique containment syntax. However, the EQL syntax is not specific to the openEHR RM and can be used for any archetype-based information system. It could be used as a common query language for disparate archetype-based applications. The EQL will be submitted to the openEHR foundation as a candidate openEHR query language.

EQL implementation

Ocean Informatics Ptd Lty has implemented the components to process the EQL within the OceanEHR suite of EHR tools. These components include an EQL parser, the EHR query object model and a query processor. The implementation does not currently support all features of the EQL. However it has demonstrated the power and flexibility of using a common RM, archetypes and EQL, independent from the underlying system implementation, to retrieve any data set from an EHR.

The EQL is not easily understood by health professionals due to the computer-oriented openEHR path syntax used in EQL. An EQL query editor, which allows users to generate and edit EQL statements, has been developed to empower clinicians with fine-grained access to their EHR data. The query editor provides users with access to an archetype repository to build FROM containment constraints and a tree representation of RM attributes and archetype structures used to set WHERE criteria, SELECT data items and ORDER BY preferences. The tool can then execute the generated query and display the returned results without the user seeing or knowing how to write an EQL statement.

Future directions

The EQL continues to be developed based on requirements from additional clinical query scenarios. New EQL features may need to be provided, such as statistical, string pattern matching and user-defined functions. Existential (∃) and universal (∀) quantifiers may be also required.

Other research areas may include 1) exploring how the EQL supports clinical decision support technologies, e.g., clinical guidelines presentation; 2) investigating the integration of EQL with clinical terminology servers; and 3) conducting field trials using the EQL to represent common clinical queries to retrieve openEHR-based EHR data sets.

Conclusion

The use of a common RM and archetypes supports the sharing of EHR data, and with the addition of a companion query language, such as EQL, achieving semantic interoperability of EHR information is much closer.

Acknowledgements

We extend our thanks to Lisa Thurston for her support, including the development of the EhrView component – a generic EHR viewer – that uses EQL for retrieving EHR data.

Abstract

Giving clinicians and researchers the ability to easily retrieve and explore relevant fragments of patient histories would greatly facilitate quality assurance, patient follow-up and research on patient treatment processes. Established database query languages are inconvenient for such exploration, and may also be too complex for users with limited backgrounds in informatics. We believe that understandability can be increased in return for a sacrifice of some of the power of expression found in general query languages. In order to design a specialized query language, we have collected and synthesized a tentative list of requirements. Based on these requirements, we have designed and implemented Practice Explorer, a prototype for visual query of collections of patient histories, and evaluated the understandability of its query language by testing with medical students. The results indicate that parts of the language are intuitive enough for users to understand without demonstrations, examples, feedback or assistance. They also provide some lessons for future work in this area.

Keywords:

information retrieval. Data display. Medical record

Introduction

Clinicians and health researchers have a need for querying their patient records for relevant history fragments. Four tasks where this need may arise are:

1. Retrospective study of guideline compliance [1].
2. Re-consideration of treatment plans for groups of patients possibly affected by the discovery of new medical knowledge, such as the connection between H. pylori and peptic ulcers.
3. Selection of patients for scientific studies.
4. Development of research hypotheses through explorative search of patient records.

The text-based database query languages available in today's patient record systems are either too complex for users without informatics competence or has insufficient power of expression. As one of the sources in our requirements collection put it, "(...) I lack basic search functionality, mostly because of my own aversion against learning a programming language for searching (...)".

The research question this article addresses is: How can we design a system for formulating temporal queries against patient history databases that is easily understandable for users with little competence in informatics, but still satisfies most of their query needs? The contributions of this article are 1) a tentative list of requirements for the expressiveness of patient history query languages, 2) an outline of our design for a query system satisfying the requirements and 3) results, observations and lessons learned from understandability testing of a prototype implementing our design.

Related work

The system most closely resembling Practice Explorer is the very recent PatternFinder [2]. The most important differences are that Practice Explorer visualizes queries as hierarchical, directed acyclic graphs, whereas PatternFinder uses linear chains of forms, and that Practice Explorer's query language, prompted by the requirements described below and enabled by the more flexible query model, is also able to express queries with parallel and alternative branches. It would be interesting to compare a form-based and a graph-based visual query system to see which is more intuitive for users without a background in informatics. Also related is TVQL [3], a visual query language where binary interval relations are specified via sliders, and where multiple such relations can be combined via neighborhood and disjunction. Another related study [4] proposes three new notations (elastic bands, springs and paint strips) for interval relations and experimentally compares their understandability. It also provides a table comparing different approaches to visualizing temporal relations and specifying combinations of such relations with logical expressions. In our case, the query graph both specifies local temporal relations and conjunction and disjunction of sub-queries through the parallel and alternative branching constructs.

Our visual representation of branching and joining constructs is borrowed from UML activity diagrams [5], a flowchart notation for defining workflows. In fact, our

query graphs can be viewed as flowcharts, extended with some new constructs and given an alternative semantics suitable for matching against histories.

Materials and methods

Requirements collection

Through discussions with two general practitioners, a rheumatologist and a health researcher interested in clinical processes, and through a pilot study applying an early prototype to a general practitioner's database and letting him verbally specify queries to be executed by the developers, we collected example queries and synthesized the following list of requirements for patient history query languages. Queries should be able to find patterns consisting of:

1. A primitive history element, such as a patient encounter, lab test, prescription or correspondence event.
2. Results limited by the date or the age of the patient at a specific point in a pattern.
3. A time interval in which a medication has been prescribed, including overlapping prescriptions, or the start or end of such an interval.
4. Time periods of variable length, with the possibility of specifying that a specified pattern should, or should not, occur during the period.
5. Repetitive occurrence of a specified pattern.
6. Sequences of specified patterns.
7. Parallel occurrence of specified patterns.
8. Alternative occurrence of specified patterns.
9. The first occurrence of a pattern in the whole history.

It should also be possible to:

10. Specify encounter events and medication intervals at various points of abstraction in relevant coding hierarchies.
11. Perform union and intersection set operations on query results.
12. Save and re-use queries or their components.

Table 1 shows a natural-language specification of a query need that exemplifies many of the requirements.

Table 1 - Natural-language specification of a query need

Find all patients who initiated medication with an ACE-inhibitor for the first time in their histories without having any encounters coded as angina, myocardial infarction or heart failure in the preceding two-year period, and who had an en-counter coded as hypertension some time between the history's start and the initiation of the ACE-inhibitor medication.

Find all patients who initiated medication with an ACE-inhibitor for the first time in their histories without having any encounters coded as angina, myocardial infarction or heart failure in the preceding two-year period, and who had an encounter coded as hypertension some time between the history's start and the initiation of the ACE-inhibitor medication.

We have no illusions that our list of requirements is complete. In our experience, potential users are often not fully able to understand the possibilities offered by a temporal query system without having such a system available for use on their own data. Therefore, it will be necessary to iterate between developing prototypes and collecting more requirements.

Data source and data model

Our test case is a patient record database from a general practitioner's office. For the sake of query performance, Practice Explorer extracts relevant data from the database at startup and represents the patient histories in main memory as lists of events. Each event has a time stamp and is considered to last for 24 hours because the test case database does not contain accurate time information at smaller granularities than days. The types of events include patient encounters (with diagnosis codes), lab tests, prescriptions and correspondence. For prescriptions, cessation dates are, where possible, heuristically deduced from fields in the prescription. Events have various attributes, such as codes, values and text, depending on their type. Practice Explorer is currently only able to extract data from Profdoc Vision, a patient record system widely used by Norwegian general practitioners. In this system, encounter diagnoses are coded according to the International Classification of Primary Care (ICPC), and prescriptions are coded according to the Anatomical Therapeutic Chemical Classification (ATC).

Query language

The main idea behind Practice Explorer's query language is to visualize queries as directed acyclic graphs, with each vertex describing a part of the history and with the edges always directed to the right, towards the present time. A query defines what a segment of a history must be like to constitute a match for that query. The informal interpretation of a query is that, for a query to match a segment of a history, it must be possible to simultaneously walk from left to right through the query and the history segment, encountering a matching history part for every query element passed. An edge between two elements indicates that the match for the element on the right hand side must begin at the exact same time that the match for the element on the left hand side ends. In other words, edges do not represent passage of time, but connects temporally juxtaposed events. Figure 1 shows two very simple queries. The bottom query specifies that a contact with diagnosis code K86 must occur, immediately followed by a period of medication with beta blockers. The top query specifies the same situation, except that an unlimited amount of time, represented by the spring-like middle element, is allowed to pass between the contact and the start of the medication period.

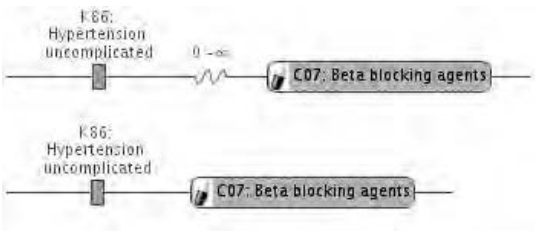

Figure 1 - Simple queries.

Table 2 - The central structure of the query language

```
<Q>        ::= <Point>
             | <Interval>
             | sequentialComposition(<Q>, <Q>)
             | parallelComposition(<Q>, <Q>)
             | alternativeComposition(<Q>, <Q>)
             | firstOccurrence(<Q>)
<Point>    ::= encounter(<IcpcCode>)
             | prescription(<AtcCode>)
             | medicationStart(<AtcCode>)
             | medicationEnd(<AtcCode>)
             | test(<TestType>, <TestValueRange>)
             | correspondence(<CorrType>)
             | dateControl(<DateRange>)
             | ageControl(<AgeRange>)
<Interval> ::= medicationInterval(<AtcCode>)
             | timeWindow(<Dur>, <Dur>)
             | timeWindowWith(<Dur>, <Dur>, <Q>)
             | timeWindowWithout(<Dur>, <Dur>, <Q>)
             | repetition(<Q>, <Int>, <Int>, <Dur>, <Dur>)
```

The user builds a query by dragging components from a menu to a panel containing the query graph under construction. Dialog boxes ask for necessary parameters as components are added. Figure 2 shows a moderately complex query graph.

The query language has a textual syntax, the central structure of which is defined by the grammar in table 2. A query is any derivation from <Q>. The visual representation of many of the elements can be seen in figure 2.

Space does not permit giving a full formal definition of the query language and its semantics. We will now informally describe the semantics of the query components given by the grammar.

Point queries, except for date controls and age controls, match events of the corresponding types satisfying the criteria in the parentheses. Date controls and age controls match all points in histories where the date or patient age could be successfully verified to belong to the specified range.

- Of the interval queries, medication intervals match any continuous time period where the patient is deduced, from prescription events, to be taking medication of the given code. The three types of time windows match time periods of duration between a given minimum and a given maximum, with a possible additional requirement that a given query must, or must not, match within the period. Repetition queries require that a given query gives repeating matches with upper and lower limits for the count and the duration allowed between repeats.

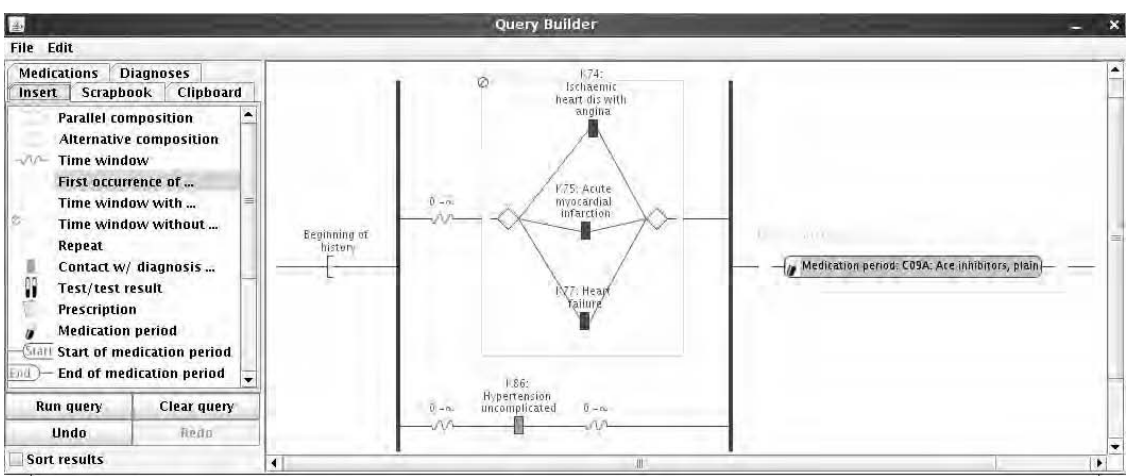

Figure 2 - Query building window showing a query satisfying the query need from table 1. From left to right, we see the following: an element matching the beginning of the history, followed by a branching into two parallel threads, along the upper of which the last two-year-period must not contain a contact with any of three codes and along the lower of which a contact with a given code must occur somewhere, followed by a re-joining of the parallel threads, followed by an interval of medication with a given type of drug, which must be the first of its kind in the entire history. (The query builder was constructed using the prefuse toolkit [6].)

- Sequentially composed queries require that the queries match, in such a way that the end of match of the first query coincides with the beginning of the match of the second query. This construction gives rise to the edges in the query graph.
- Parallelly composed queries require that the queries match, and in such a way that the start points of the matches coincide and that the end points of the matches coincide.
- Alternatively composed queries require that at least one of the queries matches.
- First-occurrence queries merely require that there is a match of the given query and that this is the first such match in the entire history. (This effect can be achieved with a combination of other elements, but the requirement was important enough to warrant support as a simpler formulation.)

The grammar gives the query graph an underlying tree structure where the matches of a node depends on how the matches of its children cohere with the rules and parameters for the node itself. The matches of a query graph are the matches of its root node. Execution of a query is performed with the leaf nodes scanning the history sequentially and the internal nodes iterating through the matches from their children.

The language elements described above straightforwardly satisfy requirements 1-10. Intersection and union of query results can easily be achieved by parallel and alternative composition of the queries, thus satisfying requirement 11. The recursive definition of the query language means that parts of queries, down to primitive components, are queries in their own right that can easily be collapsed, given names, saved and re-used, thus satisfying requirement 12.

Result visualization

Practice Explorer consists of two main windows. The query builder was described in the previous section. The history explorer, is shown in figure 3. It displays a number of vertically stacked horizontal bars, each providing a compact, very simple, LifeLines-like [7], explorable visualization of a history above a common time axis. The history explorer dynamically limits its view to the histories containing matches for the query given by the current state of the query builder, marks the hits of the query with red boxes and synchronizes the histories so that they are aligned on the first match.

Understandability testing

We performed 12 two-hour understandability tests, each followed by a brief questionnaire. The goal was not to test general usability, but to investigate the intuitive understandability of the underlying principles. We therefore simplified the query builder, keeping only the following query elements: encounter, history start, history end, date control, age control, time window, time window without ..., sequential, parallel and alternative composition. We applied the system to 2066 general practice patient histories of lengths up to 12 years. The test subjects were 4th- and 5th-year medical students.

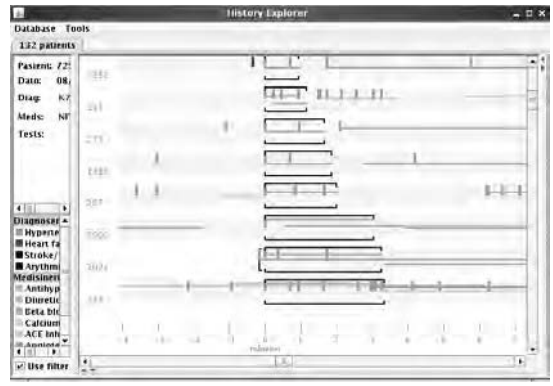

Figure 3 - Visualization of a query result

Tests 1-3 were informal, with demonstration and explanation provided during the test. In tests 4-6, the subjects were given a leaflet containing instructions and examples, as well as a number of query construction tasks to be performed. During tests 1-6 we made the observation that the learning process was greatly enhanced by the availability of examples, demonstration or interactive assistance. In particular, getting feedback on the correctness of one's queries improved ability to accomplish further tasks. We suspected that these factors could obscure issues related to our stated goal, which was to investigate the intuitive understandability of the underlying principles of the query system. Therefore, we devised a testing framework with the following rules: 1) The user will receive written instructions and query construction tasks to solve within an allotted time, 2) There must be no demonstration or assistance and 3) The instructions must contain no example queries. We carried out tests 7-12 in compliance with these rules. The subject was left alone for 105 minutes to read the instructions and attempt to solve the tasks, occasionally prompted via a loudspeaker to explain his or her thinking. Of the 25 tasks, the first 5 were point queries, the next 8 also involved intervals, the next 4 added branching constructs, and the final 8 required complex combinations of different types of elements, In the final 15 minutes, a developer interviewed the subject about the tasks that the test subject had failed to solve, and explained how those tasks should have been solved. Screen, video and audio were captured for further investigation.

Results

Figure 4 summarizes the correctness scores of test subjects 7-12 on the 25 query construction tasks. For an query to be classified as correct, it had to give the exact intended result.

From studying the users' actions on the screen, listening to them thinking aloud, and interviewing them afterwards, we made the following observations:

1. When a time window was specified as having a duration between an upper and a lower limit, for example 0 and 12 months, test subjects would often think of this as a fixed-length window from relative time point 0 to

relative time point 12 months, even though the instructions explicitly stated otherwise.

2. The test subjects made many errors where they seemed to assume that the query described the whole history and not just a fragment of it.
3. Test subjects frequently and successfully used the match-aligned result visualization to check if their queries were correct.
4. The test subjects made many errors related to not understanding that matches of parallel queries must cover the same time period.
5. On tasks requiring nested branching constructs, test subjects seemed to strain under the mental effort required. Some ceased serious efforts to find a solution.

Most of these observations either did not occur before tests 7-12, or occurred much more strongly in tests 7-12.

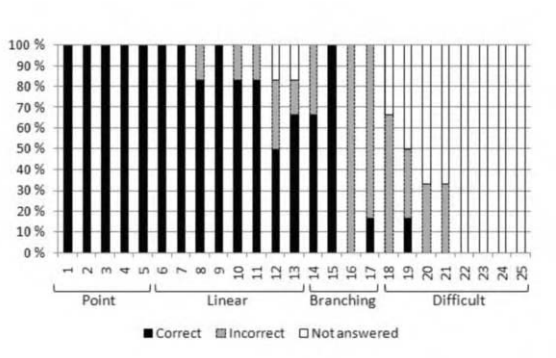

Figure 4: Scores for test subjects 7-12 on the 25 tasks.

On the questionnaire, which used a 5-point Lickert scale, 3 out of 12 marked “agree” or “fully agree” on the proposition “I think the visualization and building of the queries was easy to understand based on the instruction”. 9 out of 12 marked “agree” or “fully agree” on the proposition “I think the visualization and building of the queries was easy to understand based on the explanation given afterwards.”

Discussion

Studying figure 4, it appears that test subjects 7-12, even without examples, demonstration or assistance, arrived at a reasonably good understanding of the linear parts of the query language. The branching constructs appear to have been poorly understood. The survey answers indicate that explanation did help a lot on understanding. From the observations, we arrive at some lessons that may be helpful when designing this kind of system:

1. It seems much more natural for users to interpret a minimum and maximum number of time units as time points defining a constant-length interval rather than as bounds on the duration of a flexible interval.
2. Users may find it more natural to build a query describing the whole history rather than just a fragment.
3. Match-aligned result visualization can help users correct their own thinking and build correct queries.
4. Attention must be paid to make the visualization of branching constructs reflect their properties and reduce the effort required in reasoning about them.
5. Refraining from giving examples, demonstration, assistance or feedback may make testing more effective in uncovering problems.

Another question, partly addressed by our requirements collection, is whether the language is sufficiently expressive. On this topic we also note that, out of Allen's 13 primitive interval relations [8], our query language does not support *overlaps* or *overlapped-by*. The other 11 can be constructed with parallel composition and time windows. Supporting *overlaps*/*overlapped-by* would probably make the language more complex. Since we can match the start or end of a medication interval occurring during the match of another interval, we have not yet seen any query need requiring *overlaps*/*overlapped-by*.

Conclusion

We have designed, implemented and evaluated a temporal, graph-based query language based on our collected tentative list of requirements. Our understandability tests indicate that domain users relatively easily can construct point and interval queries, but not branching queries. Based on observations done during testing, we arrived at a list of lessons of potential relevance for the design of similar systems.

Abstract

Background: *The growing number of resources to be indexed in the catalogue of online health resources in French (CISMeF) calls for curating strategies involving automatic indexing tools while maintaining the catalogue's high indexing quality standards.* ***Objective****: To develop a simple automatic tool that retrieves MeSH descriptors from documents titles.* ***Methods:*** *In parallel to research on advanced indexing methods, a bag-of-words tool was developed for timely inclusion in CISMeF's maintenance system. An evaluation was carried out on a corpus of 99 documents. The indexing sets retrieved by the automatic tool were compared to manual indexing based on the title and on the full text of resources.* ***Results****: 58% of the major main headings were retrieved by the bag-of-words algorithm and the precision on main heading retrieval was 69%.* ***Conclusion****: Bag-of-words indexing has effectively been used on selected resources to be included in CISMeF since August 2006. Meanwhile, on going work aims at improving the current version of the tool.*

Introduction

Since 1995, the catalogue of online health resources in French (CISMeF)[1] has been selecting institutional and educational resources for patients, students and health professionals. The resources are described with a set of metadata and Medical Subject Headings (MeSH® descriptors[1]). Faced with a growing amount of resources to be indexed and included in the catalogue, the CISMeF team has recently adopted a new curation policy. The use of automatic indexing tools was deemed necessary to reduce the indexing back-log of about 7,000 resources. Considering the limitations of automatic indexing methods, it is necessary to distinguish clearly which resources in the catalogue are indexed manually and automatically [3]. In fact, the question arises at the time resources are considered for inclusion in the catalogue: the curation policy must define which resources should be indexed with the higher quality indexing produced manually and which resources may be given less attention and indexed automatically. At CISMeF, the decision was mainly based on two criteria: (a) the depth of indexing required and (b) the level of coverage of a given topic. High quality (manual) indexing must be available for all the topics covered in the catalogue, but when a reasonable level of coverage has been reached (about a dozen resources according to the curator) additional resources may be indexed automatically. Besides, we assume that automatic indexing is more suitable to cover only the central main concepts discussed in a resource whereas manual indexing will be necessary for in-depth indexing. In any case, in answer to an information query, manually indexed resources will always be displayed before automatically indexed resources. Moreover, the type of indexing (manual *vs.* automatic) will be shown to the user.

Teaching material (N=3629) and clinical guidelines (N=2978) are two vast categories of resources indexed in CISMeF. The average number of descriptors used to index a teaching resource is 9.89 +/- 10.87 vs. 13.64 +/- 15.69 for a clinical guideline. The difference is significant according to a Student test ($p<0.0001$) and illustrates the fact that clinical guidelines are indexed more in depth than teaching resources. In fact, for clinical guidelines, the curation policy for CISMeF is to be as exhaustive and as minute as possible: all clinical guidelines are to be indexed manually regardless of the current coverage in the catalogue. Teaching resources, on the other hand, may be given less attention once sufficient coverage has been reached, as they do not require in-depth indexing. To accommodate the difference between these resource types, a longer time is typically spent for indexing clinical guidelines[2] (about

1 MeSH is the US. National Library of Medicine (NLM)'s controlled vocabulary thesaurus. It consists of sets of terms naming biomedical related descriptors in a hierarchical structure. MeSH is used worldwide for indexing articles from the biomedical literature.

60 minutes *vs.* 15 minutes for teaching resources). Furthermore, CISMeF's curation policy is to use automatic indexing on teaching resources[3].

The VUMeF[4] project aims at increasing the amount of material available for French in the Unified Medical Language System. In particular, VUMeF participants agreed to make the development of automatic indexing tools a priority task of the project. It was addressed in two steps: first, automatically extracting a set of MeSH descriptors from online resources in French (which is discussed below) and secondly, in this set, selecting the major descriptors denoting central concepts discussed in the resource [2]. In the framework of VUMeF, the CISMeF team has been consistently researching and evaluating advanced automatic MeSH indexing techniques [3]. Although promising results have been obtained from a research prototype (see [4] for a comparative evaluation of CISMeF's MAIF and the NLM's Medical Text Indexer [5]), the integration of an operational system into the catalogue workflow is a lengthy process. For this reason, more readily available techniques are also investigated in order to speed-up the availability of automatic indexing tools and eventually complement other tools when they become available. Recent advances in Information Retrieval in CISMeF have resulted in the development of a query analysis algorithm designed to map free text to MeSH [7]. Moreover, new partnerships with health information providers accommodate the reception of resources to be included in the catalogue along with some metadata information such as the title, which previous research has shown to be significantly informative of the document content [3], [6]. In this paper we (a) assess the extent of the information contained in resource titles and (b) evaluate an automatic MeSH indexing approach based on bag-of-words indexing of resource titles in the specific context of teaching resources.

Materials and methods

Bag-of-words indexing algorithm

The algorithm used to extract keywords from the title of documents is similar to the query interpretation algorithm currently used in CISMeF [7]. We decided to use this algorithm for indexing based on the assumption that document titles for teaching resources are similar to information retrieval queries with respect to length and information content. In this experiment, teaching resources titles are processed in the same way as queries to extract MeSH descriptors which will then be used as candidate terms to index the teaching resource.

After the title has been normalized (accents are removed, all words are switched to lower case…) and stop words have been removed, a bag of words containing all the content words is formed. Each word is stemmed in order to account for some cases of word flexion and derivation. The "bag" thus obtained is sorted alphabetically and matched against a database of MeSH terms that have been processed in the same way. If no term is found, subsets of the original bag of words are processed. The size of the bags is decreased by one at each step of the process. In an effort to retrieve the most specific keywords, when a match is found, the corresponding content words are taken out of the bag before the next iteration. For a given bag size, when more than one match is found all candidates are kept. For example, the title "prevalence of hepatitis A and B" would yield both *Hepatitis A* and *Hepatitis B* when size-2 bags are considered, but not *Hepatitis* which would have been removed before size-1 bags were processed. If both MeSH main headings and subheadings are retrieved, all the legal[5] pairs are formed from both main heading and subheading sets.

Figure 1 illustrates the processing of a sample title[6] in the test corpus (see next section for corpus description). A bag of seven content words is obtained from the title "Tumeurs cérébrales chez l'enfant: particularités épidémiologiques, diagnostiques et thérapeutiques" (*Brains tumors in children : epidemiologic, diagnostic and therapeutic specificities*). No single MeSH term can be matched to it. Therefore, the size of the bag is gradually reduced. The two-word bag containing "cerebrales" and "tumeurs" yields the main heading "tumeurs du cerveau" (*Brain Neoplasms*). The two corresponding content words ("cerebrales" and "tumeurs") are taken out of the bag. Size-one bags containing the remaining words yield the main heading "enfant" (*Child*) and the subheadings "épidémiologie" (*epidemiology*) and "thérapie" (*therapy*). Finally, as both subheadings are allowable qualifiers for *Brain Neoplasm* but not for *Child*, a list of three indexing candidates is produced: *Child, Brain Neoplasms/epidemiology* and *Brain Neoplasms/therapy.* This particular example will be further commented on in the discussion section.

Test corpus

The algorithm was evaluated on a corpus of 99 teaching resources to be included in CISMeF that were selected for automatic processing. A professional indexer was asked to provide MeSH indexing sets for the corpus resources. First, the indexer was only shown the title of the resource and the indexing set automatically produced using the bag-of-words algorithm. His task was to revise the indexing set

2 Other cataloguing institutions may adopt different policies regarding time issues – e.g. at NLM, the average time spent indexing an article for Medline is 15 minutes regardless of the publication type.

3 e.g. a resource discussing drugs available for the treatment of thrombosis was selected for automatic processing because it consisted of lecture notes and the query "thrombosis/drug therapy" retrieved 31 manually indexed resources on 11/08/06

4 *Vocabulaire Unifié Médical Français* (French Unified Medical Vocabulary). Project sponsored by the French National Research Agency. http://www.vidal.fr/vumef/

5 For each main heading, MeSH defines a set of subheadings called "applicable qualifiers" that can be coordinated with it (e.g. */metabolisms* is applicable to *Amino Acids* but not *Hand*).

6 The original title ("Cancer de l'enfant: particularités épidémiologiques diagnostiques et thérapeutiques") was edited to illustrate an additional feature of the algorithm.

obtained automatically. Then, the indexer had access to the full text of the resource and was asked to index the resource as he would usually do, i.e. he selected MeSH descriptors to index the resource, and assigned to each a "major" or "minor" weight depending on how substantively the concept represented by the descriptor was discussed in the resource. As a result, each resource in the test corpus was manually annotated with two different sets of indexing terms: one based on the title only, and one based on the full text..

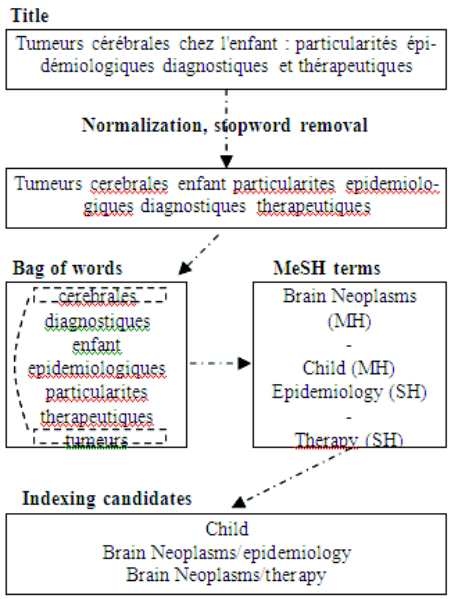

Figure 1 - Bag-of-words indexing of a sample title

It is important to stress that the annotations were obtained through an iterative process in which the quality of the indexing improved with every step, while being consistent [8] with the previous step: the automatic bag-of-words recommendations were revised to obtain manual title annotations. In turn, these were revised to obtain manual full text annotations.

In this evaluation, the indexer is not blind to the recommendations produced by the automatic tool. However our goal was to conduct an experiment reproducing real-life indexing settings where the recommendations of the automatic tool will be available to the human indexer when indexing a resource.

The revisions made by the indexer include adding a main heading, deleting a main heading, modifying the list of subheadings attached to a main heading. Table 1 shows the successive steps for a sample resource in the test corpus.

Evaluation measures

In this study we used precision and recall to compare a set of candidate indexing terms to a set of reference indexing terms. *Precision* corresponds to the number of terms present in both the candidate and reference sets over the total number of terms in the candidate set. *Recall* corresponds to the number of terms present in both the candidate and reference sets over the total number of terms in the reference set.

Table 1 - Processing of a sample corpus resource: overview of the indexing revision cycle

Title	Cancer de l'enfant: particularités épidémiologiques diagnostiques et thérapeutiques (*Cancer in children : epidemiologic, diagnostic and therapeutic specificities*)
Bag-of-words indexing (Title)	Neoplasms/epidemiology Neoplasms/therapy Child
Manual indexing (Title)	Neoplasms/diagnosis Neoplasms/epidemiology Neoplasms/therapy Child Pediatrics
Manual indexing (Full Text)	*Neoplasms/diagnosis *Neoplasms/epidemiology *Neoplasms/therapy Child Continuity of Patient Care Pediatrics/education

In addition, we considered three categories of terms:

- Descriptors: MeSH main headings or main heading / subheading pairs. In this category, subheading coordination is taken into account (e.g. *Pediatrics* does not match *Pediatrics/education*)
- Main headings: Any MeSH main heading. In this category, subheadings or stars (indicating major concepts) are not taken into account. (e.g. *Pediatrics* matches **Pediatrics/education*)
- Central-concept main headings: MeSH main headings that were marked as "major" using the star symbol "*" in the manual indexing based on the resource full text. In this category, subheadings are not taken into account. (e.g. **Pediatrics* matches **Pediatrics/education*)

Results

Information content of resource titles

Table 2 - Information content of resource titles

	Information Content Precision (%) – Recall (%)	
Descriptors	71	24
Main Headings (MH)	81	37
Central-concept (*MH)	78	78*

* Precision and recall figures are the same for central concepts because the indication of whether a term is central (major) is only available for manual indexing on the full text of the resource.

The extent of the information contained in teaching resource titles was assessed by comparing the manual indexing obtained from the title of the resource to the manual indexing obtained from the full text of the resource (see lines 3 and 4 in Table 1 for a specific example – in this case, the precision for *descriptors* indexing was 4/5=80% whereas the recall was 4/6=67%).

Performance of the bag-of-words indexing

The performance of the bag-of-words indexing was assessed by comparing the automatic indexing recommendations obtained by applying the bag-of-words algorithm on the resource title to the manual indexing:

- obtained from the resource title (overall results are shown in table 3; see lines 2 and 3 in table 1 for a specific example. In this case, the precision for *descriptors* indexing was 3/3=100% whereas the recall was 3/5=60%).

Table 3 - Performance of bag-of-words indexing (Title)

	Performance Precision (%) – Recall (%)	
Descriptors	62	56
Main Headings (MH)	69	64
Central-concept (*MH)	58	58

- obtained from the full text of the resource (overall results are shown in table 4; see lines 2 and 4 in table 1 for a specific example – in this case, the precision for *descriptors* indexing was 3/3=100% whereas the recall was 3/6=50%).

Table 4 - Performance of bag-of-words indexing (Full Text)

	Performance Precision (%) – Recall (%)	
Descriptors	54	16
Main Headings (MH)	66	30
Central-concept (*MH)	58	58

Discussion

Information content of teaching resources titles

According to table 2, overall, only 24% of the MeSH descriptors to index a teaching resource may be inferred from the resource title, however including 78% of the central concepts. This shows that, in our corpus, teaching resources titles contain explicit information as to the central content of the resource. In 81% of the cases, the main headings inferred from the title by the indexer were kept after reviewing the full text of the resources. For descriptors, this figure goes down to 71%. Some descriptors were discarded for not denoting concepts that were substantively discussed in the resource. The other descriptors were in fact main headings to which a subheading had to be attached – in the example presented in table 1, the subheading *education* had to be attached to *Pediatrics*, which was inferred from the title.

Bag-of-words indexing

Performance

According to table 4, more than half (58%) of the major main headings were retrieved by the bag-of-words algorithm and the precision on main heading retrieval was 69%. These results show that the algorithm is able to retrieve central concepts, while generating a reasonably low noise. However, the difference between the performance on descriptors and main headings (lines 2 vs. 4 in tables 3 and 4) indicates that the more difficult task of assigning subheadings to the main headings is lacking. The low recall for descriptors and main headings compared to the full text (table 4) reflects the amount of information that may be extracted from the sole title of the resource. For example, for main heading retrieval recall could not be higher than 37% (as shown in table 2), so 30% is comparatively a good performance.

Error analysis

Looking at sample revisions of the bag-of-words recommendations made by the indexer helps identifying the issues that need to be addressed in order to improve the automatic tool. Typical errors fall into the following categories:

- Stemming errors – in the example shown in table 1, the word « diagnostiques » was not stemmed properly and could not be mapped to the subheading *Diagnostic (Diagnosis)*. As a result, the pair *Neoplasm/diagnosis* was not retrieved
- Generic main headings – some MeSH terms that may appear in a resource title are so generic that they are rarely used for indexing. *Syndrom*, *Patient*, *Life* or *Health* are examples of such descriptors.
- Implicit indexing rules – through daily indexing practice, the indexers are able to infer descriptors that do not explicitly appear in the title of the resource. In the example shown in table 1, no cue from the title prompts the use of the main heading *Pediatrics*. However, *Pediatrics* is typically an appropriate descriptor to index a teaching resource discussing a particular disease onset in children (here, cancer).
- Level of specificity – some of the descriptors retrieved by the algorithm were sometimes related to descriptors selected by the indexers, although not identical. For example, *Hemorrhage/therapy* was retrieved instead of *Gastrointestinal Hemorrhage/therapy.*

Based on these observations, a « stop list » of common generic descriptors is currently being compiled and shall be used to reduce the noise of the algorithm. As such, the bag-of-words algorithm cannot be expected to retrieve descriptors that an indexer would *infer* rather than see in a resource title. For this reason, applying post-processing rules (such as described in [9]) to a set of main headings retrieved by the algorithm would be desirable in order to improve the automatic tool.

Although we anticipated that the loss of word order inherent to the "bag-of-word" approach may yield some noise, no errors related to word-order were observed on the test

corpus. This may be explained by the fact that teaching resources titles are generally short and to-the-point. Different results may be obtained when applying the algorithm to more lengthy and complex sentences as can be found in full text.

Limitations of this study

The bag-of-words indexing algorithm presented here was evaluated on a set of 99 teaching resources. The small size of the evaluation corpus is due to the amount of manual labour needed to produce the annotations of the title and full text of the resources. Moreover, the fact that the indexer was shown the automatic recommendations while he was producing his own set of descriptors may yield a bias in favour of the automatic tool.

Impact on CISMeF indexing procedure

The positive results of this study conducted in May 2006 prompted the effective use of bag-of-words indexing in the CISMeF catalogue as of August 2006. The original backlog of 6,832 resources was automatically processed with the bag-of-words algorithm. The automatic indexing for 1127 resources (including the 99 resources of our corpus) have been revised by an indexer and included with the manually indexed resources of the catalogue. For another 557 resources, manual revision is pending. Finally, the remaining 5148 resources are included with the automatically indexed resources of the catalogue (these resources had originally been classified as “low priority” and did not require in depth indexing).

Perspectives

Automatic indexing for CISMeF: In the near future, the automatic indexing of selected low-priority resources to be included in the CISMeF catalogue will no doubt consist of integrating the recommendations produced by the different methods studied by the CISMeF Team: MAIF (i.e. a combination of Natural Language Processing and Nearest Neighbors approaches) and the bag-of-words indexing presented here.

Other uses of bag-of-words indexing: Based on the results of this study, we are planning to adapt the bag-of-words algorithm to the coding of patient discharge summaries with ICD-10 [10], MeSH and SNOMED [11] and to the indexing of French FDA notices with the Unified Vidal Thesaurus (TUV). In this case, documents would be segmented at the sentence level and the algorithm would be applied to each sentence. Ultimately, our goal is to integrate these applications to produce a multi-terminology indexing tool able to process medical documents and extract concepts belonging to several terminologies (MeSH, SNOMED, ICD-10 and TUV).

Conclusion

We have presented a simple bag-of-words indexing method that retrieves MeSH descriptors from resource titles. An evaluation on a corpus of teaching resources shows good performance, in particular for central concepts. For this reason, bag-of-words indexing has been in use for selected CISMeF resources since August 2006.

Acknowledgments

This research was supported in part by VIDAL (http://www.vidal.fr/) and by an appointment of A. Névéol to the NLM Research Participation Program sponsored by NLM and administered by the Oak Ridge Institute for Science and Education. The authors would like to thank CISMeF indexers for their help in the study design and result analysis.

Abstract

General descriptions in medical records are so diverse that they are usually entered as free text into an electronic medical record, and the resulting data analysis is often difficult. We developed and implemented a template-based data entry module and data analyzing system for general descriptions.

We developed a template with tree structure, whose content master and entered patient's data are simultaneously expressed by XML. The entered structured data is converted to narrative form for easy reading. This module was implemented in the EMR system, and is used in 35 hospitals as of October, 2006. So far, 3725 templates (3242 concepts) have been produced.

The data in XML and narrative text data are stored in the EMR database. The XML data are retrieved, and then patient's data are extracted, to be stored in the data warehouse (DWH). We developed a search assisting system that enables users to find objective data from the DWH without requiring complicated SQL.

By using this method, general descriptions in medical records can be structured and made available for clinical research.

Keywords:

medical records system, template, structured data entry, data warehouse, XML

Introduction

Recently, electronic medical record systems have been implemented and are used in many hospitals [1,2]. The medical staff expects data entered into electronic medical records (EMR) to be linked with a knowledge base for decision support, or used for assessment of medical activities and clinical research [3-5]. Medical records include patient profile data, diagnosis, chief complaints, patient histories, physical examinations, progress notes, records of orders, examination reports, operation reports, summaries and so on. Some of the patient profile data, diagnosis, records of orders, and laboratory test results are originally structured data, and have thus been stored in the clinical data warehouse (DWH) and previously used for clinical research [6-8]. However, most general descriptions in medical records are diverse and complicated, thus they are entered as free text. The valuable data for clinical research (e.g. stage of cancer, tissue type, side effects of medicine etc.) are usually entered as free text. Analysis of data in free text format is difficult. If these data are not available, the data in EMR declines in value.

In order to analyze the entered data, it must be structured, i.e. the description should be expressed by the assembly of data elements that consist of item and values with codes [9-11]. To get data into this format, an input template is the most practical method [12]. By using input templates, the entered data can be stored in the database and made available for data analysis. The descriptions in medical records are so diverse and complicated, however, that the template method is difficult to adopt. To overcome this problem, we developed a tree-structured template named 'dynamic template', whose basic concept was reported in 1998 [13].

It is usual to adopt a strategy of making templates based on their own database files [14,15]. This strategy makes it possible to analyze the data easily. Because of the lack of productivity and flexibility, however, it is difficult to produce templates for any possible description that might arise within broad specialties.

In this paper, we report on the dynamic template module and the method for analyzing the entered data by the template. In our method, the contents of the templates are independent of the database schema, thus the template can be easily produced and freely revised. We have produced many templates in broad specialties in every department. Furthermore, any data entered by the templates can be searched through DWH with the assistance of the searching system.

Methods

Structure of descriptions in medical records

In this paper we term a cluster of descriptions a 'describing object', which is a record about a certain property of a patient at a certain point in time. A medical record can be

considered as an aggregate of describing objects about one patient. A describing object has the attributes of patient ID, object name, observation time, description time, writer, department, and contents. In our model, contents of a describing object are expressed by the assembly in tree structure of data elements consisting of items and values.

Template module

We developed the input template module to get the data in this structure. The template contents can be considered as a union of the possible descriptions of patients regarding a certain describing object, i.e. each description of a patient is a subset of the template contents. Thus the structure of the template must be the same as that of the describing object.
