What kinds of noun categories do people talk about more, and does this distribution vary between adults and children or by whether generics or non-generics are involved? To answer this question, Figure 2 plots the percentage of each of the four noun categories within generics and non-generics, re-

[2]These numbers are as reported in Friedrich and Pinkal (2015). We did not re-implement their models.

[3]We would like to thank Susan Gelman, who graciously provided this data upon request.

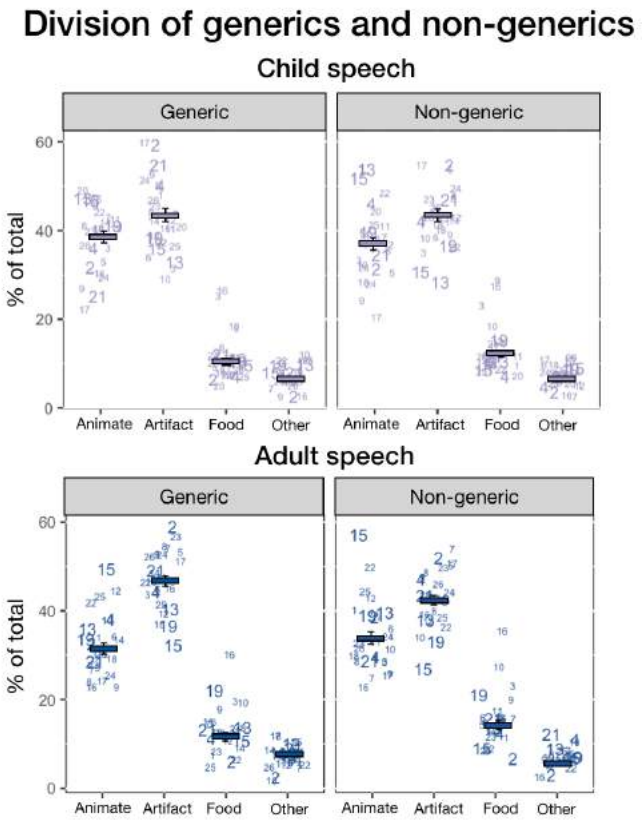

Figure 2: Proportion of generic and non-generic speech across categories. This figure shows the distribution of speech across the four noun categories, for both children (purple) and adults (blue). Lines show the mean when averaged by corpus; error bars indicate standard error. The numbers correspond to the relevant measure for each of the 26 corpora. The corpora from Gelman et al. (2008) are slightly larger and correspond to numbers 2, 4, 13, 15, 19, and 21. It is evident that there is high variability between corpora, but for the most part both children and adults speak about artifacts more often and that there is little difference between generics and non-generics in how they are distributed amongst the four noun categories.

spectively. The left panel thus shows the percentage of all of the generic nouns that are animates, artifacts, foods, or other; the right panel shows the same breakdown out of all of the non-generic nouns. We illustrate the variability in this distribution by plotting the results for each of the corpora individually. It is evident that there is substantial variability overall, and that at least some of that variability is corpus-specific: the correlation between adult and child speech by corpus is $r = 0.95$. This probably largely reflects the fact that children and adults co-create one another's linguistic environment.

This analysis also demonstrates that in general both children and adults talk about artifacts slightly more often than animates.[4] There is also no difference in the distribution of

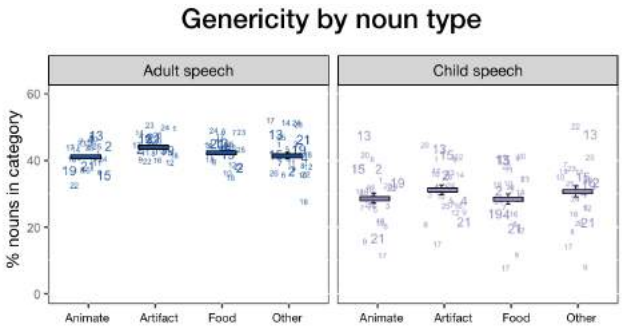

Figure 3: Proportion of generic speech within each noun category. For each of the four categories, this figure shows how often nouns in that category were generic. The large transparent bars indicate the aggregate proportion over all corpora, while the small boxes with error bars show the mean when averaged by corpus. The numbers correspond to the relevant measure for each of the 26 corpora. The corpora from Gelman et al. (2008) are slightly larger and correspond to numbers 2, 4, 13, 15, 19, and 21. There is high variability between corpora (especially for children). However, there is little difference in the pattern of generic usage across noun categories.

speech across noun categories as a function of genericity or speaker.[5] Generics and non-generics have similar distributions across different kinds of nouns, and this holds regardless of whether the speakers are adults or children.

Another way to explore the issue of whether children or adults use generics differently for different categories is to condition on category rather than on genericity. Figure 3 thus shows, for each of the four noun categories, what proportion of time it occurs as a generic in both child and adult speech. Although children are much more variable, we still see little difference in generic usage between noun categories. However, adults were more likely to use generics for artifacts than animates, as well as more overall.[6]

These results are rather surprising, since previous work has suggested that generics tend to be used more often with animate categories. What is going on?

One possibility might be that the six corpora used by Gelman et al. (2008) were outliers in some way relative to our larger set of 26. In order to investigate this possibility, we calculate how many corpora used a higher percentage of animate nouns than artifact nouns as generics. On this measure, the corpora from Gelman et al. (2008) appear to be slight outliers relative to the others. Of the 25 corpora with adult speech, only six used generics more with animates and three of those six were theirs: Bloom (2), Brown (4), and Kuczaj (13). Of the 26 with child speech, six used generics more with animates and four were theirs: 2, 4, 13, and Sachs (19).

[4]Bayesian t-test comparing artifact to animate percentage: For child generics, $BF_{10} = 2.4$ weakly in favour of a model that includes noun type; for child non-generics, $BF_{10} = 7.7$ moderately in favour. For adult generics, $BF_{10} > 10^6$ in favour of a model that includes nountype; for adult non-generics, $BF_{10} = 111$ in favour. All Bayesian analyses used the BayesFactor package in R (version 3.4.4) and compared the model of interest to an intercept-only null model. In also cases we also ran analogous frequentist tests, which always returned qualitatively similar results.

[5]Bayesian ANOVA: $BF_{01} = 10$ for the null model over a model including genericity and $BF_{01} = 10$ for the null over a model including speaker. This indicates strong support for the null model.

[6]Bayesian ANOVA: $BF_{01} = 14.3$ favouring the null model over a model including noun category; $BF_{10} > 10^6$ favoring a model including speaker. Bayesian t-test comparing artifact to animate generic percentage: for child speech, $BF_{01} = 1.9$ favouring the null model; for adult, $BF_{10} = 6.9$ favouring a model including nountype.

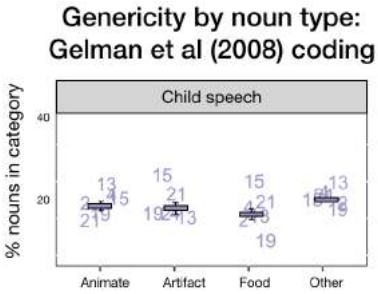

Figure 4: Proportion of generic speech within each noun category using the genericity identifications from Gelman et al. (2008). For each of the four categories, this figure shows how often nouns in that category were generic, using the six corpora and their classifications rather than the classifications from our model. Despite using their classifications, we replicate our previous result, suggesting that the difference between our findings and theirs did not arise due to poor classification performance by our model.

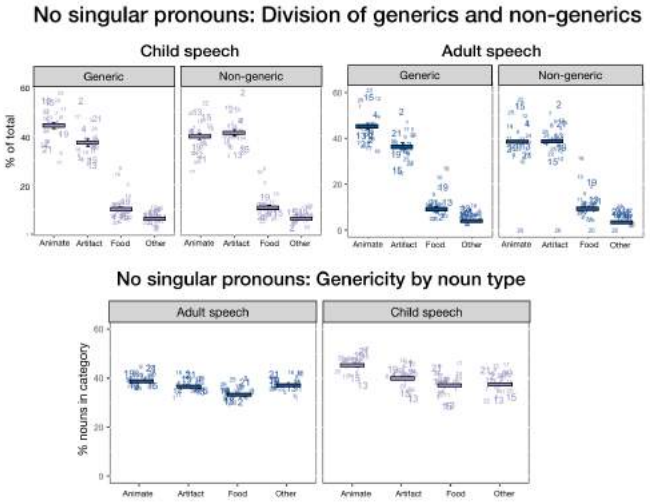

Figure 5: Proportion of generic speech across and within noun categories, on corpora without any singular pronouns. Since Gelman et al. (2008) excluded singular pronouns, we reran our analyses (using our classifications) on our corpora after excluding all singular pronouns. Results are now much more similar to their findings than ours. Generics but not non-generics are used more for animate than artifact categories (top); and for both adults and children, the proportion of generic utterances in animates is higher than in artifacts. This suggests that their exclusion of singular pronouns from the dataset may have driven their results.

These considerations suggest that at least part of the reason our results diverge so markedly from Gelman et al. (2008) is that their corpora were different. However, this cannot be the entire story: the magnitudes of the differences they found are much larger than the magnitudes we found on the same corpora in very similar analyses.

An obvious possibility is that our model is simply classifying many items very differently than they did. Our high accuracy and F-score against their coding scheme suggests that this is not the case, but we were able to test this hypothesis in a much more stringent way as well. For the six corpora in Gelman et al. (2008) that we have their classifications for (child speech only), we took the set of nouns that they identified as generic, assumed that they coded all of the others as non-generic, and applied the same analysis as in Figure 3 to that data. If the difference between our work is because our classifier is coding or identifying items differently than they did, we should find that using their classifications on their corpora replicates their results. However, Figure 4 reveals that we instead replicate our result: there is no difference in generic usage across the four noun categories.[7]

This outcome suggests that the point of divergence between our work and Gelman et al. (2008) must be less due to different decisions about what to code as generic, and more due to different decisions about what nouns to include in the first place. Our analysis included all nouns of any kind, which was straightforward to do since the model could identify them automatically. However, lacking this technology, Gelman et al. (2008) had to process the corpora by hand. They accomplished this by manually identifying potential generics by searching for any bare plurals, plural pronouns, mass nouns, and indefinite singular nouns and then hand-coding that set of nouns as generic (or not). This was justified on the grounds that the vast majority of generics fall into these categories, which is sensible if the goal is to understand the distribution of generics alone. However, if the goal is also to compare to non-generics, it is important to include even those nouns that tend to be non-generic. Their dataset excluded singular pronouns like *he, she, you, I*, and *it*. If singular pronouns tend to "cluster" (for instance, are more likely to be animate and non-generic) then excluding them might result in a mis-estimation of the overall distribution of generics relative to non-generics in different ways for different noun categories.

To test whether the inclusion or exclusion of singular pronouns drove the difference between our results and those of Gelman et al. (2008), we re-ran our original analyses after excluding all singular pronouns from our dataset. As shown in Figure 5, the results now replicate their findings rather than ours. The top panel shows that generics but not non-generics are used more for animate than artifact categories,[8] and the bottom panel shows that for both adults and children, the proportion of generic utterances is higher within animate categories than artifacts.[9] This suggests that Gelman et al. (2008) may have found that animate categories had more generics because they did not count a large number of non-generic animates like *he, she, you,* and *I*. Our other analysis show that once all nouns are included, the proportion of generics across noun categories evens up and if anything favours artifacts.

[7]Bayesian ANOVA: $BF_{01} = 2.6$ for the null over a model including noun category. Bayesian t-test comparing animates to artifacts: $BF_{01} = 2.1$ for the null over a model including noun category.

[8]Bayesian t-test comparing artifact to animate percentage: For child generics, $BF_{10} = 91$ in favour of a model that includes nountype; for child non-generics, $BF_{01} = 2.9$ for the null model. For adult generics, $BF_{10} = 206$ in favour of a model that includes nountype; for adult non-generics, $BF_{01} = 3.5$ for the null model.

[9]Bayesian ANOVA: $BF_{10} > 10^6$ favouring a model including noun category; $BF_{10} = 522888$ favoring a model including speaker. Bayesian t-test comparing artifact to animate generic percentage: for child speech, $BF_{10} = 2529$ favouring a model including nountype; for adult, $BF_{10} = 35$ favouring a model including nountype.

Discussion

This work makes several contributions. First, we present the first fully automatic model for generic identification which uses only synactic features, and demonstrate that it performs well relative to both the state-of-the-art and manual classifications from Gelman et al. (2008). Second, we apply this model to a much larger dataset of child speech than had previously been possible to analyse. Although we replicate the previously-observed developmental trend in generic usage, we find that neither adults nor children use generics more in categories that tend to be essentialised (like animates). Follow-up analyses suggest that our results differ from Gelman et al. (2008) not because of poor classification performance by our model, but primarily because we did not exclude singular pronouns from our dataset (as they did).

A natural question at this point is whether it is better to include singular pronouns or not. Any answer must be conditioned on considerations of what is realistically possible. Given the extreme amount of labour involved in hand-coding corpora, one can reasonably argue that the process for identifying nouns used by Gelman et al. (2008) was a necessary simplification. Other analyses excluded pronouns for other good reasons. For instance, Gelman and Tardif (1998) and Goldin-Meadow et al. (2005) excluded pronouns because of the need to compare English with Mandarin, a pro-drop language. Given these considerations, this too seems reasonable. However, it is possible that this decision is why they as well found a higher proportion of generics for animates.

Overall, we suggest that if the goal is to understand the distribution of generics relative to non-generics in the nouns children hear, it is important to include *all* of the nouns that children hear. Singular pronouns are very common and almost always non-generic; as such, an accurate comparison of generics to non-generics cannot exclude them.

One might also ask why our model identified a larger proportion of generics than previous work did (Figure 1). Part of the reason is probably that a manual identification of generics, as Gelman et al. (2008) had to do, would probably have erred on the side of under-counting them. Another part is that our model appeared to make less conservative choices in some cases. For instance, our model identified many generics that were preceded by the word *the*, as in sentences like *What do bears in the forest do in the day?*. Since our observed developmental trends are very similar and all of our other results hold even when we use the classifications from Gelman et al. (2008), we doubt that our overall higher rate poses a problem.

A final question is what our results mean for our initial question: to what extent does the linguistic environment support the difference in essentialisation of artifact vs animate categories? Our results suggest that this difference is not reflected in differences in generic usage, and thus lends less credence to the possibility that these domin differences in essentialism result from linguistic input. Although this finding is surprising given previous work, one nice aspect of it is that it removes the chicken-and-egg question that otherwise arises: *why* does the linguistic environment have this distribution in the first place? Much remains to be done, but we hope that our model and results offer a useful tool for better understanding how our early biases are shaped by the environment.

Online Phonetic Training Improves L2 Word Recognition

Abstract

High-Variability Phonetic Training (HVPT) has been shown to be effective in improving the perception of even the hardest second-language (L2) contrasts. However, little is known as to whether such training can improve phonological processing at the lexical level. The present study tested whether this type of training also improves word recognition. Adult proficient French late learners of English completed eight online sessions of HVPT on the perception of English word-initial /h/. This sound does not exist in French and has been shown to be difficult to process by French listeners both on the prelexical (Mah, Goad & Steinhauer, 2016) and the lexical level (Melnik & Peperkamp, 2019). In pretest and posttest participants completed an identification task as well as a lexical decision task. The results demonstrated that after training the learners' accuracy had improved in both tasks. The theoretical and applied implications are discussed.

Keywords: second language acquisition; lexical processing; word recognition; speech perception; phonetic training

Introduction

It is well known that producing and perceiving non-native speech sounds can be very challenging (for reviews, see Piske, MacKay & Flege, 2001; Sebastián-Gallés, 2005). In the realm of perception, much research has shown that with auditory training, the difficulty of perceiving even the hardest non-native sounds can be reduced. The most common training paradigm used to improve second language (L2) perception is High-Variability Phonetic Training (HVPT). HVPT uses multiple natural exemplars of the target sounds in a variety of phonetic environments. This variability enhances the process of building novel phonological categories. Importantly, perceptual training involves immediate corrective feedback that provides information to participants about their performance and promotes rapid learning by driving the learner's attention to the relevant phonetic cues of the sounds to be learned (Homa & Cultice, 1984; Logan, Lively & Pisoni, 1991). The effectiveness of this technique has been shown in many studies in a variety of languages, using several target contrasts and structures, including vowels (Carlet & Cebrian, 2014; Lee & Lyster, 2016), consonants (Kim & Hazan, 2010; Shinohara & Iverson, 2018), tones (Wang et al. 1999; Wang, Jongman, & Sereno, 2003), and syllable structure (Huensch & Tremblay, 2015). Moreover, both high- and low-proficiency speakers benefit from HVPT (Iverson, Pinet & Evans, 2012), and HVPT generalizes to new tokens and new speakers (Lively et al., 1994; Okuno & Hardison, 2016). Finally, it gives rise to long-term retention of the new categories (Lively et al., 1994), and it helps to improve L2 production (for a review, see Sakai & Moorman, 2018).

Although the effectiveness of HVPT is well studied, most previous work focused exclusively on prelexical perception, using identification or discrimination tasks. The difficulty with the perception of L2 sounds, though, is paralleled by less efficient lexical processing (e.g., Pallier, Colomé & Sebastián-Gallés, 2001; Weber & Cutler, 2004). Thus, truly successful training should also enhance performance at the lexical level. While prelexical processing only involves a phonetic analysis, lexical processing is more complex as it additionally requires mapping the incoming speech signal onto phonological representations stored in memory, and the performance gap between native and non-native listeners in L2 speech perception increases as the tasks have greater lexical involvement (Díaz et al., 2012).

So far, the only studies on the effect of prelexical auditory training on lexical processing focused on naïve listeners' ability to learn words in a tonal language (Cooper & Wang, 2011; Ingvalson, Barr & Wong, 2013). Both studies found that naïve English listeners' ability to learn words involving difficult tone contrasts improved after auditory training. To our knowledge, no studies have directly assessed the effect of auditory training on enhancing word recognition in L2 learners.

We focused on the perception of the English sound /h/ by intermediate French learners of English. As /h/ does not exist in French, French listeners – even those who are fluent in English – have difficulty perceiving the contrast between the presence vs. absence of /h/ in English stimuli (Mah et al., 2016). At the lexical level, proficient French learners of English tend to accept nonwords such as *usband* (cf. *husband*) and, to a lesser extent, *hofficer* (cf. *officer*), as real words (Melnik & Peperkamp, 2019). Thus, they have difficulty not only in perceiving the contrast between /h/ and silence, but also in distinguishing between words and nonwords that differ only in the presence vs. absence of /h/.

Importantly, there is an almost perfect one-to-one mapping in English of the grapheme <h> onto the phoneme /h/. Most French L2 speakers know how to correctly write /h/-initial words. They are also instructed that <h> is rarely silent in English and that it is pronounced as /h/. If after training learners start better perceiving /h/, they might thus be able to also improve their recognition of /h/-initial English words even if they have imprecise phonological representations of such words, since they can rely on the orthography.

In the current study we trained French learners on the perception of English /h/ in a pretest–training–posttest design. In pretest and posttest, participants performed an identification task aimed at testing their phonetic perception of /h/, and a lexical decision task aimed at testing their processing of /h/ at the lexical level. In the posttest, the identification task also tested for generalization to novel items. In the identification task we used /h/- and vowel-initial nonwords as stimuli. In the lexical decision task we used words and nonwords, where the test nonwords were created from /h/-initial and vowel-initial words by removing or adding /h/, respectively.

Training was administered on-line, and consisted of eight sessions of an identification task using minimal pairs of real words (such as *air*-*hair*), with corrective feedback.[1] We expected the training to enhance performance in the identification task at posttest, thus replicating the findings of previous studies on the effectiveness of HVPT in improving phonetic perception of L2 sounds. Moreover, if the effect of training extends to lexical processing, performance in lexical decision should likewise improve with training.

Method

Pretest-Posttest-Generalization: Identification

Stimuli

For the pre- and posttest we selected 100 pairs of nonwords. The members of each pair differed in the presence or absence of an initial /h/ (e.g. /hasp/ – /asp/). Forty pairs were monosyllabic, 40 dissyllabic and 20 trisyllabic. Ten English vowels (ʌ, ɒ, a, ɪ, ɛ, iː, ʌɪ, əʊ, eɪ, aʊ) were used in the first (or only) syllable, thus creating a large amount of variability in phonetic context.

An additional 30 pairs of nonwords (10 monosyllabic, 10 disyllabic and 10 trisyllabic, containing the 10 vowels mentioned above) were selected to test for generalization at the end of the posttest. Half of the pairs were recorded by a male, and the other half by a female native of American English.

Procedure

Participants were tested individually in a soundproof booth. In each trial they were presented auditorily with a stimulus; their task was to press as quickly as possible the key labelled "h" with their dominant hand if they thought the nonword started with the sound /h/, and to press the key labelled "no h" with their non-dominant hand if they thought it did not start with /h/. There were 194 trials divided over two blocks. Trials were presented in a semi-random order such that no more than four trials of the same type (vowel-initial or /h/-initial) and no more than three trials recorded by the same speaker appeared in a row.

The first block started with a practice phase of six trials, during which participants received feedback. In the case of an incorrect response or no response within 2500 ms, the trial was repeated until the correct response was given. During the test phase, participants received no feedback and if they did not give a response within 2500 ms the next trial was presented. An interval of 1000 ms elapsed between the participant's response or the time-out - whichever came first - and the presentation of the next trial.

At the end of the posttest only, 60 trials with the 30 additional nonword pairs were used to test for generalization.

Pretest-Posttest: Lexical decision

Stimuli

The stimuli were the same as in Melnik & Peperkamp (2019). They consisted of 80 English test words, 40 starting with /h/ (e.g., *husband*) and 40 with a vowel (e.g. *officer*), recorded by the same male American English speaker who recorded stimuli for the identification task. They consisted of nouns, verbs and adjectives, and contained between two and four syllables. The /h/-initial and the vowel-initial words did not differ in mean frequency in the Subtlex database (Brysbaert & New, 2009) or in mean number of syllables (both $t < 1$).[2]

Each word was paired with a nonword, created by deleting or adding /h/ at the beginning (e.g. *husband* → *usband*, *officer* → *hofficer*). In addition, there were 240 English control words (nouns, verbs and adjectives), none of which starting with /h/. They were matched for mean frequency and mean number of syllables with the test words. Each control word was paired with a nonword created by replacing, deleting or inserting one phoneme other than /h/.

The test and control minimal pairs were divided into two equal groups, one for pretest and one for posttest, respecting the matching in terms of frequency and number of syllables. The pretest stimuli were further divided into two counterbalancing lists: list A and list B. Each of them contained only one member of each pretest minimal pair. For instance, if the word *husband* was in list A, its nonword counterpart *usband* was in list B. The posttest stimuli were divided into lists C and D following the same principle. Thus,

[1] Training can be done either with nonwords (e.g., Yamada, 1991) or with real words (e.g., Logan et al., 1991). Here, we chose to use real words because repeated exposure to a large number of nonwords during training might have induced a bias to excessively accepting nonwords in the lexical decision task in pre- and posttest.

[2] The familiarity of these words was evaluated by a separate group of 45 adult French learners of English in an online rating questionnaire. The /h/- and vowel-initial words that were chosen for the experiment did not differ in mean familiarity ($t = 1.0$, $p > 0.1$).

no list contained both members of a given word–nonword pair. Each of the four lists contained 10 /h/-initial and 10 vowel-initial words, 10 /h/-initial and 10 vowel-initial nonwords, as well as 60 control words and 60 control nonwords. Finally, for a practice phase there were two additional words and two additional nonwords, none involving /h/.

Procedure

In pretest half of the participants were randomly assigned to one of the two pretest lists (list A or list B). In posttest, participants who previously heard the list A were given the list C, while participants who previously heard the list B, were now given the list D. Hence, participants heard only one of the members of each word-nonword pair throughout the whole experiment.

The procedure was identical to that in Melnik & Peperkamp (2019): Participants performed a speeded auditory lexical decision task. In each trial they heard a word or a nonword and had to answer if the item was an English word. They were instructed to use their dominant hand for "yes"- and their non-dominant hand for "no"-responses on a button box. There were 160 trials divided over two blocks, each containing the same number of test and control stimuli. Trials were presented in a semi-random order such that between one to three control trials appeared between two experimental ones, and that no more than four trials of the same type (word or nonword) appeared in a row.

The first block started with a practice phase of four trials with control items, during which participants received feedback ('correct' or 'wrong' written on the screen). In the case of an incorrect response or no response within 2500 ms, the trial was repeated until the correct response was given. During the test phase, participants received no feedback and if they did not give a response within 2500 ms the next trial was presented. An interval of 1000 ms elapsed between the participant's response or the time-out and the presentation of the next trial.

Training: Identification

Stimuli

We selected 59 minimal pairs of real words differing in the presence or absence of an initial /h/. Given the limited number of such minimal pairs, we used both frequent words (e.g. *hair-air*) and infrequent ones (e.g. *hosier-osier*) words. However, word frequency was not considered to have an impact, as the task used in training was prelexical.

Four different speakers, two men and two women, recorded the items. One of the male speakers and one of the female speakers were those who recorded the stimuli for the nonword identification task used in pretest and posttest, with the male speaker having also recorded the stimuli for the lexical decision task.

Procedure

The training consisted of eight high-variability phonetic training sessions. In the first four sessions participants heard one speaker per session. In the following four sessions they heard a pair of speakers in each session, such that all four male-female combinations were used.

All training sessions were run at the participants' homes through internet. The online training sessions were designed using the JsPsych library (de Leeuw, 2015) in JavaScript. Before each training session participants received by email a link to the corresponding training session webpage. Stimuli were presented at a comfortable listening level, set individually. The details of each training session (e.g., participant details, day and time of completion, RTs and responses) were automatically sent to the MySql database after the completion of each session. Participants could only do one session per day and there could be no more than one day in between two sessions. Thus, the whole course of training was completed in eight to fifteen days.

In each trial participants first saw the two response alternatives written on the screen (e.g. "hair – air"). The word starting with /h/ was always displayed on the left, and the word without /h/ always on the right. The auditory stimulus was played 800 ms later. The task was to press as quickly as possible the left arrow key if the word started with /h/ and the right arrow key otherwise. When the participant pressed the key, the corresponding word was highlighted in bold. If the response was correct, the word "Correct" written in green appeared in the middle of the screen, in between the two alternatives. If it was incorrect, the word "Wrong" written in red appeared on the screen, followed after 1000 ms by auditory feedback of the form: "*The word was not: XXX. It was: YYY*", spoken by the same speaker as the stimulus itself. For instance, if the stimulus played was the word "hair" but the participant chose instead the word "air", the word "Wrong" was displayed on the screen and the phrase *"The word was not: air. It was: hair"* was played.

If no response was given within 2500 ms, the words "Too slow" appeared on the screen. An interval of 1000 ms elapsed between the participant's response or the time-out - whichever came first - and the presentation of the next trial. There were 118 trials in each session, and trials were presented in a random order. Each session lasted from 15 to 20 min, depending on the accuracy of the participant.

Participants

Participants were French intermediate learners of English, recruited from among university students (about half of which in an English department). In order to avoid ceiling performance or insufficient knowledge of English vocabulary, only participants whose accuracy in pretest was below 80% in the identification task and above 70% on control items in the lexical decision task went through the training and posttest. Of the 51 participants who did the pretest, 25 satisfied these criteria, out of whom a total of 24 completed the study and were included in the data analysis. Among these participants, there were 12 women and 12 men, aged between 19 and 32 (mean: 22.3), who had started

learning English at school. They filled in a questionnaire to self-evaluate their speaking, listening, reading, vocabulary and grammar skills in English and French, on a scale from 1 to 10. The overall mean score was 6.4 (SD = 1.6) for English and 9.4 (SD = 0.9) for French.

None of the participants reported a history of speech or language problems. They received a small payment after the pretest, and those who underwent training received a second, larger, payment when they came back to the laboratory for the posttest.

Results

Pretest-Posttest-Generalization: Identification

Prior to analysis, we discarded responses with a reaction time of 0 ms. Figure 1 displays the identification accuracy of participants in pretest, posttest and generalization. As the identification task is a signal detection task, we used the A' statistic, which provides a non-parametric, unbiased, index of sensitivity (here: to the difference between words and nonwords), with 0.5 indicating chance performance and 1.0 perfect performance. A repeated measures ANOVA by participant with the factor Session (Pretest vs. Posttest vs. Generalization), revealed a main effect of Session ($F(2,46) = 26.75$, $p < .001$), with the accuracy improving from an average A′ score of 0.74 in pretest to 0.86 in posttest and 0.86 in generalization. Bonferroni-adjusted pairwise t-tests revealed that there was a significant difference between pretest and posttest ($p < .01$), as well as between pretest and generalization ($p < .01$). There was no difference between the performance in the posttest and in the generalization ($p = .82$).

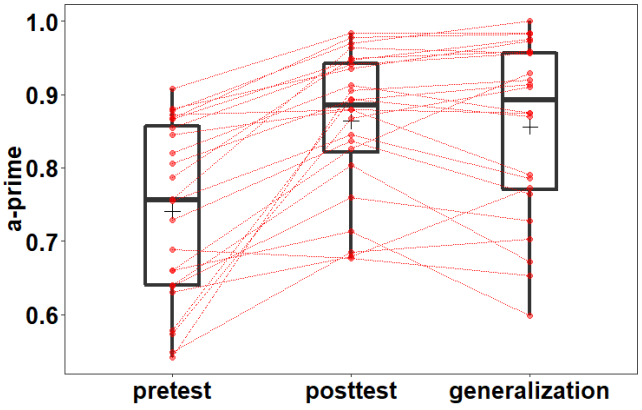

Figure 1. Boxplots of A′ scores in the identification task in pretest, posttest, and generalization. The red dots represent individual participants; the lines link each participant's performance in the three sessions. The black cross marks indicate mean A′ scores in each session.

Pretest-Posttest: Lexical Decision

Prior to analysis, we discarded responses with 0 ms reaction time. Figure 2 displays the accuracy of participants on the test items in pretest and posttest. As the participants had a strong bias for 'yes'-responses (shown by their low accuracy scores on test nonwords), we used the A' statistic as in the analysis of performance in the identification task.

We carried out a repeated measures ANOVA by participant with the factors Session (pretest vs. posttest), Condition (test vs. control) and Lists (AC vs. BD), as well as an interaction between Session and Condition. We found main effects of Session ($F(1, 23) = 39.36$, $p < .001$) and Condition ($F(1, 23) = 73.93$, $p < .001$), and a Session X Condition interaction ($F(1, 23) = 30.87$, $p < .001$). Pairwise t-tests revealed that the interaction was due to the fact that in control items, the effect of Session was not significant, while in test items, there was a significant difference between pretest and posttest ($p < .001$), with the accuracy improving from an average A′ score of 0.62 in pretest to 0.82 in posttest. There was no effect of the counterbalancing factor Lists.

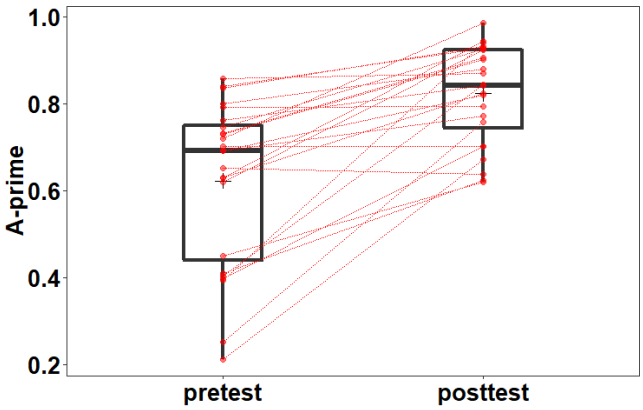

Figure 2. Boxplots of A′ scores in the lexical decision task in pretest and posttest. The red dots represent individual participants; the lines link each participant's performance in both sessions. The black cross marks indicate mean A′ scores in each session.

Discussion

The present study examined if phonetic training can enhance the recognition of words that contain a difficult non-native sound. We tested French learners with intermediate proficiency in English on both their prelexical perception and their lexical processing of stimuli containing /h/. This sound does not exist in French, and French listeners tend to confuse it with silence (Mah et al., 2016). The participants underwent eight sessions of High-Variability Phonetic training, and were tested in pretest and posttest by means of an identification and a lexical decision task.

We found that participants improved in both tasks in posttest compared to pretest. For the identification task, we also observed generalization to new items. The results for this task are in accordance with results from previous studies that used HVPT. Concerning the lexical decision task, this is the first piece of evidence that HVPT can improve not only prelexical but also lexical processing. As mentioned in the

introduction, successful word recognition depends on the correct decoding of the speech signal and the matching of this percept to the phonological representation stored in long-term memory (Pisoni & Luce, 1987). If listeners have difficulty with at least one of those aspects, then word recognition might be less effective. Evidence that this is the case is shown by the fact that in the lexical decision task during pretest, the test items involving the difficult sound /h/ yielded higher error rates than the control items. Note that performance on control items was very good in both pre- and posttest (mean A′ score 0.94). As the test and control items were matched in frequency, this indicates that the difficulty participants encountered with the test items was caused by the presence of /h/ and not by a lack of English vocabulary. Importantly, this difficulty was clearly reduced after training, as in posttest participants made less errors on the test items with /h/ than in pretest, while their performance did not change on control items.

Our findings have both theoretical and practical implications. From a theoretical point of view, they shed light on the relationship between prelexical and lexical processing in L2 learning. It is generally agreed upon that speech processing involves several stages, ranging from auditory processing, phonetic and phonological analysis, to word recognition and lexical access (Pisoni & Luce, 1987). In a study on Dutch L2 learners' processing of the English /æ/-/ɛ/ contrast, Díaz et al. (2012), found that the performance gap between native and non-native listeners increases as the tasks have greater lexical involvement. This is likely due to the fact that different perceptual tasks tap into different processing levels, thus requiring different skills and involving different amounts of cognitive load. Our finding that improvement in prelexical perception is paralleled by an improvement in lexical processing suggests a bottom-up sequential order in learning. Although at a specific time point in learning the proficiency in prelexical perception might be ahead of that in lexical processing, a rapid improvement in the former might give rise to change in the latter. This is in accordance with the Automatic Selective Perception model (Strange, 2011), which proposes that L2 phonological processing is less automatic and therefore requires more attentional resources than phonological processing in L1. Consequently, while the performance of learners might be good on relatively simple prelexical tasks, where they can exclusively focus their attention on crucial phonetic cues, the same performance level might not be obtained in tasks requiring the processing of more complex stimuli and attention to other information, such as word meaning. According to this model, the processing of simple tasks becomes more automatic and nativelike as proficiency grows. Thus, in our study, training possibly rendered the prelexical processing more efficient, thus allowing participants to allocate more cognitive resources to the lexical level of processing.

A similar finding on the benefit of phonetic training for higher processing levels was reported in a study on the perception of L2 speech in noise (Lengeris & Hazan, 2010). Adverse listening conditions such as a high signal-to-noise ratios (SNRs) have been shown to involve increased cognitive load and to have greater negative effects for speech perception in non-native than in native listeners (for a review, see Lecumberri et al., 2010). In this study, it was shown that HVPT in quiet improves the perception of a difficult L2 sound in noise.

On the practical side, the current findings could have implications for language teaching. The above-mentioned aspects of speech processing – lexical perception and perception of speech in noise – are inherent elements of "real life" language processing. The fact that they can be improved by relatively short HVPT is encouraging. Moreover, our training was administered online and not in a well-controlled laboratory setting; it can thus easily complement traditional language teaching methodologies. Finally, we note that participants of our study reported that being trained on real words was very motivating, as they had the occasion not only to enhance their perception but to learn new words as well.

To conclude, we showed that even short online HVPT can improve both prelexical and lexical processing of a difficult L2 sound. Future research should test if these improvements are retained in the long term. Furthermore, although we observed significant improvements, only some participants were at ceiling in posttest. Thus, further studies should look at the effect of training length on learning outcomes. This would help us understand if there is an upper limit of improvement in lexical processing that training can induce.

Explanatory Considerations Guide Pursuit

Abstract

Evidence is typically consistent with more than one hypothesis. How do we decide which hypothesis to pursue (e.g., to subject to further consideration and testing)? Research has shown that *explanatory considerations* play an important role in learning and inference: we tend to seek and favor hypotheses that offer good explanations for the evidence we invoke them to explain. Here we report three studies testing the proposal that explanatory considerations similarly inform decisions concerning pursuit. We find that ratings of explanatory goodness predict pursuit (though to a lesser extent than they predict belief), and that these effects hold after adjusting for subjective probability. These findings contribute to a growing body of work suggesting an important role for explanatory considerations in shaping inquiry.

Keywords: explanation; pursuit; abduction; active learning

From belief to pursuit

"Faced with tracks in the snow of a certain peculiar shape," writes (Lipton, 2003), "I infer that a person on snowshoes has recently passed this way." This form of inference, familiar from both science and everyday life, is known as *inference to the best explanation* (IBE). Harman (1965) explains that in drawing this inference to an explanatory hypothesis, one infers, from the premise that a given hypothesis would provide a better explanation for the evidence than would any other hypothesis, to the conclusion that the given hypothesis is true (Harman, 1965).

Recent work in the cognitive science of explanation has confirmed and helped characterize the role of IBE in human cognition: both children and adults tend to prefer some explanations over others, and these preferences affect which hypotheses they favor (Lombrozo, 2016; for factors that might affect these preferences, see Colombo, Bucher, & Sprenger, 2017). For example, in Douven and Mirabile (2018), participants read about two possible explanations for six realistic events: a target "best" explanation (that had on average received higher quality ratings in a previous experiment) and an alternative explanation (that had received lower ratings). One group of participants was asked to rate the explanatory quality of both explanations (how well each explained the event) and a second group of participants rated the probability of each explanation, additionally indicating whether they accepted the target explanation as the true one. They found that the mean goodness ratings of the first group were better predictors of the acceptance rate of the target explanation by the second group than the probability ratings of that same group.

Findings like these suggest that explanatory considerations play an important role in guiding belief – indeed, in some cases a stronger role than that played by probability (see also Douven & Schupbach, 2015). But they also raise an important puzzle that has been a perennial challenge for advocates of IBE: why treat explanatory considerations as a good guide to what is true? After all, the world may not be simple, elegant, or otherwise conform to a good explanation. This challenge is especially acute when explanatory considerations diverge from probabilistic considerations (see van Fraassen, 1989).

One possibility is that the practice of favoring hypotheses that offer better explanations is a good epistemic policy in the sense that it has positive epistemic consequences, even if it doesnt *directly* result in an inference to a hypothesis that is more likely to be true. Along these lines, Wilkenfeld and Lombrozo (2015) introduce the idea of "Explaining for the Best Inference," whereby the practice of explaining (and of seeking *good* explanations) might improve our epistemic standing through a suite of downstream cognitive effects. Indeed, seeking and evaluating explanations facilitates the discovery of subtle patterns (e.g., Williams & Lombrozo, 2010; Walker & Lombrozo, 2017), even when the generated explanations are inaccurate (Walker, Lombrozo, Legare, & Gopnik, 2014). Explaining also encourages processes such as comparison (Edwards, Williams, Gentner, & Lombrozo, 2019), abstraction (Walker & Lombrozo, 2017), and metacognitive calibration (Rozenblit & Keil, 2002), which can be beneficial even if the agent fails to make an inference to a true explanation.

In the current paper, we turn our attention to the idea of IBE as an effective epistemic policy that could guide learners over time. Rather than focusing exclusively on the role of explanatory considerations in making an inference to (or evaluating the probability of) a given hypothesis at a given time, we consider whether and how explanatory considerations affect the decision to *pursue* one hypothesis over another – that is, to subject a hypothesis to further consideration or testing.

Pursuing explanations

Pursuing hypotheses is an important part of any search for explanations: doctors order medical tests before establishing a diagnosis, detectives interrogate suspects and verify alibis, and scientists collect evidence to assess their theories. Decisions

about pursuit are especially critical in science: not only must we justify to academic peers, funding agencies, and sometimes the general public why a given hypothesis is worthy of pursuit, but this very investigation can also serve as a "criterion of demarcation" between scientific and non-scientific endeavors. According to Popper (2005), a hallmark of science is the generation of theories that can be submitted to a method of critical testing: scientific theories should make predictions that can be falsified by empirical evidence.

However, both in principle and due to time and resource limitations, we are unable to investigate all hypotheses, even all *good* hypotheses: we must instead decide which hypotheses are worth pursuing, and which hypotheses are worth pursuing first. Nyrup (2015) argues that the justification of pursuit is the most legitimate use of IBE – more legitimate even that the justification of belief. His core idea is that a hypothesis that offers a good explanation has higher "epistemic value" if true than its salient competitors, and that this justifies giving it priority when deciding which hypotheses to pursue first.

Formal analyses additionally support the idea that a policy of favoring better explanations could pay off downstream, even if it does not lead to an accurate inference right away. Specifically, Kelly (2007) introduces a formal notion of simplicity, and contends that simple hypotheses should be preferred because adopting simple rather than more complex hypotheses will reduce to a minimum the number of necessary reversals of opinion before arriving at the true hypothesis, and therefore allow us to converge to the truth more quickly. Douven (2016) shows that under certain conditions, artificial agents using update rules that favor better explanations (defined according to a particular measure of "explanatory power") converge faster on the truth than artificial agents with probabilistic (Bayesian) update rules. Evaluating the goodness of an explanation might therefore be a key consideration when deciding whether to pursue it.

In the present research, we report three studies designed to address the following four questions. First (Q1), are people more likely to pursue one hypothesis over another to the extent it offers a good explanation for the data? Second (Q2), is this evaluation partially comparative, such that the explanatory goodness of alternatives will also matter, with a given hypothesis more likely to be pursued to the extent its alternative offers a poor explanation? Third (Q3), does explanatory goodness have an effect on pursuit that is not reducible to the effects of subjective probability on pursuit? Based on the findings from Douven and Mirabile (2018) concerning belief, we expect positive answers to these questions. However, we also expect pursuit and belief to diverge, given their differential costs (in terms of both requisite resources, and the consequences of getting things right vs. wrong). This prompts our final question (Q4): Does explanatory goodness differentially affect pursuit versus belief?

Study 1

In Study 1, we address Q1 - Q4 using materials adapted from Douven and Mirabile (2018). In a within-subjects design, participants were shown six vignettes that each described a disruptive event. They were presented with two possible hypotheses that might explain the event, and asked to rate the goodness and probability of each hypothesis. They also indicated which hypothesis they would recommend investigating first ("pursuit"), and which hypothesis they were more inclined to believe ("belief"). This allowed us to examine the link between perceived explanatory goodness and pursuit, as well as its relationship to probability and belief.

Method

Participants Participants were 72 adults recruited from Amazon Mechanical Turk (33 female, 39 male, ages 20-69, M = 35). Participation was restricted to MTurk workers with unique IP addresses in the United States who had completed at least 1000 HITs with a minimum approval of 99%. An additional 35 participants completed the study, but were excluded from analyses for failing one or more attention checks (described below).

Materials Six vignettes were lightly adapted from the stimuli used by Douven and Mirabile (2018). In these vignettes, experts (scientists, detectives, doctors) are attempting to explain a disruptive event (e.g., the flooding of a village, a murder, or a patient's symptoms), and they have generated two possible explanatory hypotheses, where these hypotheses are independent and are not jointly exhaustive. For instance, in one vignette, participants read about a womans murder, where one hypothesis is that the murder was committed by her jealous husband, and another hypothesis is that the murder was committed by a coworker trying to prevent her from sharing incriminating evidence. Based on the ratings of explanatory goodness provided by participants in Experiment 1 of Douven and Mirabile (2018), one of the hypotheses was classified as offering what we expected to be perceived as the *best explanation*, and the other as offering the *second best explanation*. These designations were used in analyses, but were not presented to participants.

Procedure Each participant received all six vignettes, with the order of the two hypotheses in each vignette randomized across participants. The study consisted of three phases: goodness and probability ratings, belief and pursuit decisions, and distraction questions, which doubled as attention checks. The distraction questions always appeared between the other two phases, which appeared first or last (randomized across participants).

In the goodness and probability ratings phase, participants received all six vignettes, and for each rated the two corresponding hypotheses on *explanatory goodness* and *probability*, with order randomized across participants. For explanatory goodness, participants were asked: "How good do you think each of these hypotheses is as an explanation for why *[the*

event occurred]?", with the corresponding event specified in the stimuli participants saw. Responses were collected on a continuous scale from 0 to 100, where 0 meant that an explanation was very bad, 50 meant that an explanation was neither good nor bad, and 100 meant that an explanation was very good. For probability, participants were asked: "How likely do you think each of these hypotheses is?" Responses were collected on a continuous scale from 0 to 100, where 0 meant that the hypothesis had 0% probability of being true, 50 meant that the hypothesis was equally likely to be true or not true, and 100 meant that the hypothesis had 100% probability of being true. We also included an attention check in which participants were instructed to select zero on the two continuous scales.

In the pursuit and belief decisions phase, participants received all six vignettes, and for each rated the two corresponding hypotheses for pursuit and belief, with order randomized across participants. For the pursuit decisions, participants were told: "The [experts] only have enough resources to investigate and test *one of the two* hypotheses before deciding on an explanation. They could also decide to save their resources and not investigate or test either of the two hypotheses. What do you think they should do?" Participants could select either hypothesis or indicate that they didn't think either of the hypotheses should be investigated. For the belief judgment, participants were asked: "Which of the two hypotheses are you more inclined to believe is the true explanation of why *[the event occurred]*?", (again, the corresponding event was specified in the stimuli participants saw). Participants could select either hypothesis or indicate that they were not inclined to believe either of the hypotheses.

The distraction phase consisted of two questions that doubled as attention checks. Participants read a list of words and, depending on a randomly assigned condition, copied into a text box the first word from that list that referred to an animal, a fruit, or a season. Participants also counted the number of animals in a picture.

After completing these three phases of the study, participants provided demographic information.

Results & Discussion

To examine whether and how explanatory considerations affect pursuit (Q1 and Q2), we fit a logistic binomial mixed-effects model (Q1/Q2 model) predicting participants probability of deciding to pursue the (antecedently defined) best explanation, as opposed to the second best explanation or neither explanation. Our choice of model and dependent variable allowed us to parallel the analyses in Douven and Mirabile (2018), where acceptance of the target "best" explanation was used as a dichotomous dependent variable. Explanatory goodness ratings for the best explanation and for the second best explanation were both centered on 50 and included as fixed effects. Vignette was included as a group-level random effect.

This model found a positive coefficient for the goodness of the best explanation ($p < .001$), with a 5.2% increase in the odds of choosing to pursue an explanation for each one-point increase in goodness. It also found a negative coefficient for the goodness of the second best explanation ($p < .001$), with a 5.2% *decrease* in the odds of choosing to pursue the best explanation for each one-point increase in the goodness of the second best explanation. These results provide a positive answer to Q1: explanatory considerations did predict pursuit. They also provide an answer to Q2: while the goodness of the better hypothesis mattered, the goodness of the alternative mattered as well.

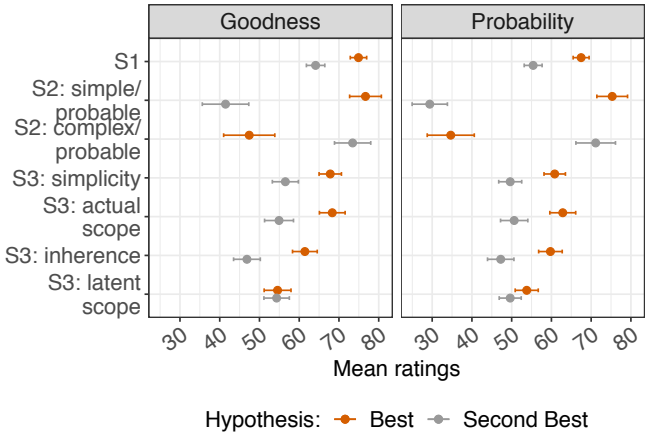

Figure 1: Mean ratings of goodness and of subjective probability for the two hypotheses for Study 1, Study 2 (Simple/Probable and Complex/Probable conditions) and Study 3 (Simplicity, Actual Scope, Latent Scope and Inherence conditions). Error bars represent 95% CI.

We next considered whether there were effects of explanatory considerations on pursuit that were not reducible to the effects of subjective probability on pursuit (Q3). To this end, we fit a logistic binomial mixed-effects model (Q3 model) predicting participants probability of deciding to pursue the best explanation, but in addition to the predictors included above, we also included a fixed effect for the probability assigned to the best explanation, and a fixed effect for the probability assigned to the second best explanation. Vignette was also included as a group-level random effect. There was a positive coefficient for the best explanation ($p < .001$), with a 4.8% increase in the odds of choosing to pursue the best explanation for each one-point increase in probability. There was also a negative coefficient for the second best explanation ($p < .001$), with a 4.9% *decrease* in the odds of choosing to pursue the best explanation for each one-point increase in the probability of its alternative. However, in this model, goodness ratings were not significant predictors. This suggests a negative answer to Q3: there was not evidence of effects of explanatory goodness on pursuit that were not reducible to the effects of subjective probability on pursuit. This result is potentially surprising in light of the findings from Douven and Mirabile (2018), which used essentially the same materials, but could be because goodness and probability were

collected within-subjects and highly correlated: 0.73 for the best explanation, and 0.78 for the second best explanation. One aim of Study 2 is to more successfully tease apart goodness and probability ratings.

Finally, we evaluated whether explanatory goodness differentially predicted pursuit vs. belief (Q4). We fit a logistic regression mixed-effects model (Q4 model) predicting the probability of selecting the best explanation, with goodness rating for the best explanation, goodness rating for the second best explanation, and judgement type (belief vs. pursuit) as fixed effects, as well as interactions between judgement type and each goodness rating. We also included vignette as a group-level random effect. This model found that goodness ratings had a significant effect when predicting pursuit, and that this effect was significantly larger when predicting belief. A one-point increase in the goodness of the best explanation increased the odds of deciding to pursue by 5.1% ($p < .001$), and of deciding to believe by 11.5% ($p = 0.005$). On the other hand, a one-point increase in the goodness of the competing explanation *decreased* the odds of deciding to pursue by 5.0% ($p < .001$), and of deciding to believe by 7.3% ($p < .01$). Explanatory goodness thus had significant and differential effects on pursuit vs. belief, with the impact on belief larger than that on pursuit.

Study 2

Study 2 had two primary aims. First, we sought to revisit Q1-Q4 with materials that induced a weaker correlation between goodness and probability. Second, we sought to vary explanatory quality along a recognizable and objective dimension for which people's explanatory preferences have already been experimentally established: simplicity, defined as the number of unexplained causes invoked in an explanation (Pacer & Lombrozo, 2017). As in Study 1, participants were shown a vignette describing an unusual event with two possible explanatory hypotheses. Each hypothesis was either simple or complex, and described as either probable or improbable. By introducing simple/improbable and complex/probable hypotheses, we hoped to drive apart ratings of goodness and probability.

Method

Participants Participants in Study 2 were 135 adults recruited through Amazon Mechanical Turk as in Study 1 (56 female, 79 male, ages 19-72, M = 37). An additional 25 participants completed the study but were excluded from analyses for failing one or more attention checks.

Materials Two vignettes were created following the same structure as the stimuli used in Study 1. In these vignettes, scientists seek to explain an unusual event (either a change in the reproductive pattern of squirrels, or low crop yields in a given county), and they have generated two possibles hypotheses. One of these hypotheses was simple in the sense that it appealed to a single cause (exposure to one toxin, contamination by one pest), and the other was more complex in that it required the conjunction of two independent causes (two toxins, two pests). In addition, one of the hypotheses was described as being "quite probable" based on the data available to the scientists, and the other hypothesis was described as being "quite improbable."

Procedure The study had a between-subject design (2 vignettes x 2 probability conditions). Each participant received one vignette, with the order of the two presented hypotheses randomized across participants. Participants were randomly assigned to one of two probability conditions. In the simple/probable condition, the simple hypothesis was described as probable and the complex hypothesis as improbable. In the complex/probable condition, this pairing was reversed. In the main part of the study, participants responded to the same questions as in Study 1. They also responded to an attention check and completed one of the distraction tasks from Study 1 midway through the study.

Results & Discussion

First, we verified that Study 2 successfully reduced the high correlations between perceived goodness and probability observed in Study 1. We found correlations of 0.60 and 0.65 between goodness and probability in the simple/probable condition for the simple and complex explanations, respectively, and correlations of 0.58 and 0.76 in the complex/probable condition for the simple and complex explanations respectively. While these correlations remained strong, they were more modest than those in Study 1.

We next conducted the same analyses as those described in Study 1. To examine how explanatory considerations affect pursuit, we fit the Q1/Q2 model, but did not include vignette as a group-level random effect[1]. This model found a positive coefficient for the goodness of the simple explanation ($p < .001$), with a 9.8% increase in the odds of choosing to pursue an explanation for each one-point increase in goodness. It also found a negative coefficient for the goodness of the complex explanation ($p < .001$), with a 8.1% *decrease* in the odds of choosing to pursue the simple explanation for each one-point increase in the goodness of the complex explanation. These results again provide a positive answer to Q1: explanatory considerations did predict pursuit. They also provide an answer to Q2: while the goodness of the better hypothesis mattered, the goodness of the alternative mattered as well.

We next analyzed whether there were effects of explanatory considerations on pursuit that were not reducible to the effects of subjective probability on pursuit (Q3). There was a positive coefficient for the goodness of the simple explanation ($p < .001$), with a 7.9% increase in the odds of choosing to pursue the simple explanation for each one-point increase in goodness. There was also a negative coefficient for the goodness of the

[1] All analyses in Study 2 were first fit using mixed-effects models, with vignette as a group-level random effect. However, the regression analyses indicated a singular fit, so we fit the models again excluding the group-level random effect to ensure that the estimates were stable. Estimated coefficients in the fixed-effects and mixed-effects models were identical.

complex explanation ($p < .035$), with a 5.0% *decrease* in the odds of choosing to pursue the simple explanation for each one-point increase in the goodness of its alternative. However, in this model, subjective probability ratings were not significant predictors. This points to a positive answer to Q3: we found effects of explanatory goodness on pursuit that were not reducible to the effects of subjective probability. These findings could differ from those of Study 1 because goodness and probability were not as highly correlated as in Study 1, or because explanatory goodness was manipulated in the form of simplicity.

Finally, we evaluated whether explanatory goodness differentially predicted pursuit vs. belief by fitting the Q4 model. This model found that goodness ratings had a significant effect when predicting pursuit judgements, and that this effect was not significantly different when predicting belief. A one-point increase in the goodness of the simple explanation increased the odds of a participant deciding to pursue by 9.8% ($p < .001$), and a one-point increase in the goodness of the competing explanation *decreased* the odds of deciding to pursue by 8.1% ($p < .001$). Unlike Study 1, this suggests a negative answer to Q4.

Study 3

Studies 1-2 provided consistent answers to Q1 and Q2: participants were more likely to pursue one hypothesis over another to the extent they judged that hypothesis a good explanation, and its alternative a poor explanation. However, the answers to Q3 and Q4 were more variable across studies. In Study 3, we sought to revisit Q1-Q4 using a larger sample and more varied experimental materials.

Specifically, we varied explanatory quality along four dimensions suggested by prior research to elicit reliable patterns of preferences in people's judgements. The first dimension was simplicity, defined in terms of the number of unexplained causes invoked in each explanation (e.g, explaining an illness with one toxin or the conjunction of two toxins). The second dimension was actual scope, defined as the number of observed effects explained (e.g., explaining all aspects of how a space shuttle had deviated from its trajectory or only some of them). The third dimension was latent scope, defined as the number of *unverified* effects predicted (e.g., one hypothesis predicts that prior to the volcano's irruption, the magma should have been relatively cool and the second predicts that a wider ranger of magma temperatures was possible–however, data on magma temperature prior to the irruption is not available). The fourth dimension was inherence, defined as an appeal to inherent/internal features versus extrinsic features (e.g., a flower's ability to wick off water is explained either by properties of its petals or by properties of the soil where it grows). Prior work has shown that with materials like those used here, people favor explanations that are simpler (Pacer & Lombrozo, 2017), broad in actual scope (Williams & Lombrozo, 2010), narrow in latent scope (Khemlani, Sussman, & Oppenheimer, 2010), and inherent (Cimpian & Salomon, 2014). While simplicity and actual scope are often defended as explanatory virtues, latent scope and inherence are typically assumed to reflect unwarranted biases. The procedure, materials, data collection plan, main predictions, and analyses for Study 3 were preregistered on the Open Science Framework platform prior to data collection and are available at `https://osf.io/6b58k/`.

Method

Participants Participants in Study 3 were 875 adults recruited from Amazon Mechanical Turk as in Studies 1-2 (446 female, 424 male, 2 non-binary/other and 2 who preferred not to respond, ages 18-87, M = 40). Following our preregistration, 1000 participants completed the study, with exclusions (N=125) based on failure to pass one or more attention check(s).

Materials Twelve vignettes were created following the same structure as the stimuli in Studies 1-2. In these vignettes, scientists generate two possible hypotheses to explain an unusual event. The two hypotheses in each vignette differed along a single dimension (simplicity, actual scope, latent scope, or inherence), with three vignettes targeting each dimension. The simplicity vignettes were similar to those in Study 2. In the actual scope vignettes, the best hypothesis explained all aspects of the explanandum, and the second best hypothesis explained only a subset. In the latent scope vignettes, the best hypothesis accounted for the *explanandum* without making unverified predictions, while the second best generated a prediction that it was not possible to verify. In the inherence vignettes, modified from Horne and Khemlani (2018), the best hypothesis invoked an inherent feature of the *explanandum*, and the second best invoked an extrinsic feature.

Procedure Each participant received one vignette, with the order of the two hypotheses randomized across participants. Aside from the fact that this study had a between-subjects design (4 dimensions of explanatory quality x 3 vignettes), the procedure was identical to that of Study 1.

Results & Discussion

To address Q1-Q4, we followed the analyses described in Studies 1-2[2]. We first fit the Q1/Q2 model. This model found a positive coefficient for the goodness of the best explanation ($p < .001$), with a 5.6% increase in the odds of choosing to pursue an explanation for each one-point increase in goodness.

[2]In our preregistered analyses, we planned to fit logistic binomial mixed-effects models that included as predictors the goodness and probability ratings of the best explanation and differences in goodness/probability ratings between the best and the second best explanation. However, upon analyzing the data, we found a high (>0.89) correlation between differences in goodness ratings and differences in probability ratings. Because high correlations between predictors in linear regressions can make the estimated coefficients unreliable, we replaced the difference predictors by the goodness and probability ratings of the second best explanation. The correlation between goodness and probability ratings ranged from >0.8 for the actual and latent scope virtues, to >0.82 for simplicity and >0.94 for inherence.

It also found a negative coefficient for the goodness of the second best explanation ($p < .001$), with a 4.1% *decrease* in the odds of choosing to pursue the best explanation for each one-point increase in the goodness of the second best explanation. These results again provide a positive answer to Q1: explanatory considerations did predict pursuit. They also provide an answer to Q2: while the goodness of the better hypothesis mattered, the goodness of alternatives mattered as well.

We next analyzed whether there were effects of explanatory considerations on pursuit that were not reducible to the effects of subjective probability by fitting the Q3 model. There was a positive coefficient for the goodness of the best explanation ($p < .001$), with a 2.7% increase in the odds of choosing to pursue the best explanation for each one-point increase in goodness, and a positive coefficient for the subjective probability of the best explanation ($p < .001$), with a 3.4% increase in the odds of choosing to pursue the best explanation for each one-point increase in probability. There was also a negative coefficient for the goodness of the second best explanation ($p = .0026$), with a 1.8% *decrease* in the odds of choosing to pursue the best explanation for each one-point increase in the goodness of its alternative, and a negative coefficient for the subjective probability of the second best explanation ($p < .001$), with a 2.9% *decrease* in the odds of choosing to pursue the best explanation for each one-point increase in the goodness of its alternative. Like study 2, this provided a positive answer to Q3: the effect of explanatory considerations held even when the effect of probability judgements was also taken into account.

Next, we evaluated whether explanatory goodness differentially predicted pursuit vs. belief by fitting the Q4 model. This model found that goodness ratings had a significant effect when predicting pursuit judgements, and that this effect was significantly larger when predicting belief: a one-point increase in the goodness of the best explanation increased the odds of a participant deciding to pursue by 5.6% ($p < .001$) and of deciding to believe by 13.6% ($p < .001$). On the other hand, a one-point increase in the goodness of the competing explanation *decreased* the odds of deciding to pursue by 4.1% ($p < .001$), and of deciding to believe by 10.4% ($p < .01$). As in Study 1, explanatory goodness thus had significant and differential effects on pursuit vs. belief, with a larger impact on belief.

Finally, we repeated the three analyses just described for each of the four sets of vignettes corresponding to each virtue. These analyses revealed the same patterns of answers to Q1-Q2 as in the full data set, but some departures for Q3 and Q4. Specifically, we found a negative answer to Q3 for simplicity and actual scope, and a negative answer to Q4 for latent scope.

General Discussion

Across three studies, we find evidence that explanatory considerations affect pursuit: participants were more disposed to pursue a hypothesis to the extent it offered a good explanation, and to the extent its competitor offered a poor explanation. In Studies 2-3, we also found that the effect of explanatory considerations on pursuit were not reducible to the effects of subjective probability on pursuit. Finally, in Studies 1 and 3, we found that explanatory goodness had a larger impact on belief than on pursuit. Discrepancies across the three studies could have resulted from the high correlations between ratings of goodness and of subjective probability, but it is notable that Study 3–which had the largest sample–found positive answers to all four of our guiding questions. However, it is important to note that these results raise open questions about the direction of a potential causal relationship between explanatory considerations and pursuit, and indeed they do not rule out the possibility that pursuit decisions might be causing judgements of explanatory goodness, rather than the reverse.

Why might explanatory considerations affect pursuit? As suggested in the introduction, pursuing good explanations could facilitate learning (Lombrozo, 2016), have higher expected epistemic value (Nyrup, 2015), or provide a more efficient route to the truth (Kelly, 2007; Douven & Schupbach, 2015). The pursuit of good explanations might therefore improve our overall epistemic standing (Wilkenfeld & Lombrozo, 2015), even if the true hypothesis is not the most explanatory. If these ideas are correct, they provide a justification for IBE that side-steps many of the traditional worries concerning its application to belief.

Interestingly, however, the impact of explanatory goodness on pursuit was smaller than that on belief. In a context where unjustified pursuit is more costly (given limited resources) than erroneous belief, participants might be more reluctant to recommend pursuit on the basis of explanatory considerations alone. Moreover, decisions to pursue might be more sensitive to pragmatic considerations that compete with explanatory goodness, or to the goal of reducing uncertainty by maximizing expected information gain.

Several limitations are worth noting. First, participants reasoned about relatively abstract and unfamiliar material. Second, participants did not pursue explanations themselves (e.g., through further consideration or evidence gathering). Future work could investigate decisions to pursue (vs. believe) with more realistic materials, and testing a richer set of pursuit-relevant behaviors. It would also be fruitful to investigate whether the role of explanatory considerations changes as a function of the relevant consideration (as we began to explore in Study 3), in different environments (e.g., with different cost structures), and as a function of the learners goals (e.g., to achieve truth vs. avoid error).

More ambitiously, future research should investigate how pursuit and belief are integrated into a broader model of truth-seeking behavior that involves explanation generation, pursuit, the collection of evidence, hypothesis revision, and ultimately belief. Our findings suggest that explanatory considerations affect this process at two important stages, belief and pursuit, but leave open how they shape everyday and scientific inquiry more broadly.

What information shapes and shifts people's attitudes about capital punishment?

Abstract

Although most Americans support capital punishment, many people have misconceptions about its efficacy and administration (e.g., that capital punishment deters crime). Can correcting people's inaccurate attitudes change their support for the death penalty? If not, are there other strategies that might shift people's attitudes about the death penalty? Some research suggests that statistical information can correct misconceptions about polarizing topics. Still, statistics might be irrelevant for some people because they may support capital punishment for purely retributive reasons, suggesting other argumentative strategies may be more effective. In Studies 1 and 2, we examined what attitudes shape endorsement of capital punishment and compared how two different interventions shifted these attitudes. Altogether, our findings suggest that attitudes about capital punishment are based on more than just retributive motives, and that correcting misconceptions related to its administration reduces support for capital punishment.

Keywords: capital punishment; coherence; open science

Introduction

In October 2018, Washington state became the 20th state to overturn capital punishment on the grounds that it is unconstitutional, stating that death sentences have been "imposed in an arbitrary and racially biased manner" (Johnson, 2018). Although capital punishment has come under scrutiny at the state-level, a recent poll indicated that 55% of adults in the United States still favor the death penalty for a person convicted of murder (Jones, 2017). However, many people who support the use of capital punishment have misconceptions about its efficacy and administration. For instance, many people believe that capital punishment is an effective deterrent against violent crime, that innocent people are not sentenced with the death penalty, and that it is administered in a fair and unbiased manner (see Manski & Pepper, 2013; DPIC, 2018; Baldus, Woodworth, Zuckerman, & Weiner, 1998). The Death Penalty Information Center (DPIC) and the Innocence Project have publicly impugned these assumptions to better educate the public by releasing informational brochures and short educational videos. Given that people have misinformed attitudes about issues integral to the administration and efficacy of capital punishment, can correcting their misconceptions shift their support for the death penalty, and if not, are there other argumentative tactics that could be used to shift people's attitudes about the death penalty?

Ideally, we could affect attitude change by simply providing people with accurate statistical information—on the basis of this information, people may still support the death penalty, but it would not be based on misconceptions about its efficacy and administration. On the other hand, there is some reason to think that statistics-interventions like these may not be effective at changing people's moral attitudes. In a now classic study, Lord, Ross, and Lepper (1979) found that when people were presented with statistical evidence about capital punishment—especially when that evidence was "mixed" (providing some evidence consistent with and inconsistent with the death penalty)—this led to belief polarization. People who were strongly opposed to or strongly in favor of the death penalty attended to the information that confirmed their position and ignored the information that was inconsistent with their position. These results have led many researchers to conclude that providing statistical information is not an effective tactic for correcting people's misconceptions (e.g., Thaler & Sunstein, 2008; Janis & King, 1954; Gawronski & Bodenhausen, 2006).

More recently, however, some research suggests that statistical information, especially when carefully presented (e.g., using visual aids) can correct misconceptions about polarizing topics like climate change and anti-vaccine attitudes (see Lewandowsky, Ecker, Seifert, Schwarz, & Cook, 2012; Horne, Powell, Hummel, & Holyoak, 2015). These results are some cause for optimism, but they do not establish exactly what interventions are most effective at changing people's attitudes about the death penalty. For example, statistics might be irrelevant to some people's support of capital punishment. For moral reasons alone, people may support the use of capital punishment, not because they believe it deters crime or is more cost effective, but because they think criminals should get what they deserve and that it is the morally right thing to do. Consequently, providing statistics about deterrence, cost, wrongful convictions, and other relevant issues may do little to alter these attitudes about the death penalty.

Current research suggests that even if attitudes about the

death penalty are driven entirely by the desire for retribution, or because it is perceived as the right thing to do, it may still be possible to shift their moral attitudes. A recent line of work has examined how moral attitudes change when related attitudes are manipulated (e.g., Horne, Powell, & Hummel, 2015; Holyoak & Powell, 2016). In the law, coherence is an important theoretical virtue (e.g., Dancy, 1984). Moral theories that are incoherent are generally considered "nonstarters" and inconsistencies in influential moral theories are often the topics of entire books (e.g., Lyons, 1965; Gewirth, 1978; Rawls, 1980; Sen & Williams, 1982; MacIntyre, 2007). These considerations do not appear to only be the concern of academics. For example, Horne and colleagues (2015) found that when people are presented with a situation (e.g., a moral dilemma) that elicits a judgment inconsistent with a general moral principle (e.g., utilitarianism), tension arises due to an internal conflict among participants' attitudes about the dilemma and the general moral principle. This tension induces belief revision because people desire to restore coherence in their network of attitudes (e.g., Festinger, 1962; Holyoak & Powell, 2016). We call this a coherence-based intervention.

Altogether, people may support the use of capital punishment for reasons like deterrence and the cost of execution, which may suggest that presenting accurate statistical information could change people's minds (e.g., Cochran & Chamlin, 2005). On the other hand, the death penalty is a moral issue importantly linked to attitudes about just desserts—this may suggest that coherence-based interventions would be more persuasive than raw statistical information.

In the present studies, we sought to answer two questions: First, what kinds of interventions—statistics or coherence-based—will shift people's support for capital punishment? Second, what might this tell us about what attitudes are most malleable and most central to people's endorsement of the death penalty? In Study 1, we compared the efficacy of two interventions by investigating how statistics versus coherence-based interventions changed people's attitudes about capital punishment. However, because we have reason to think that the effectiveness of these distinct arguments likely depends on the reasons people have for supporting capital punishment, and because of our results in Study 1, we sought to investigate what other related attitudes might be predictive of support for the death penalty in Study 2.

Study 1

Method

Preregistration The data collection plan, predictions, and analysis scripts for our study were preregistered through the Open Science Framework. Data, analyses, and supplemental materials are available at https://osf.io/ek4fh/.

Participants We recruited 504 participants through Amazon Mechanical Turk. Our sample size was determined by conducting a power analysis to detect a Cohen's d of .25 with 80% power. We used an optional stopping procedure by computing a Bayes Factor on the parameter estimating the effect of condition (that is, the parameter of interest). Specifically, we determined that we would continue data collection until the Bayes Factor (BF_{10}) was greater than 100 or less than .01, at which point we would stop data collection (Rouder, 2014). After excluding participants who failed attention checks, 405 participants remained for our final sample (46% female, M_{age} = 36 years old). Each participant was compensated $0.70 for completing the study.

Procedure We developed statistics and coherence-based interventions aimed at countering three common attitudes people have for supporting the death penalty. These attitudes were: (1) People who commit serious crimes, such as murder, deserve to be put to death (retribution), (2) The death penalty discourages people from committing crime (deterrence), and (3) The death penalty is cheaper than life-imprisonment (cost). Participants were randomly assigned to either the statistics or coherence-based intervention, in which they saw either three statistical arguments or three coherence-based arguments in a between-subjects design.

The study proceeded as follows: Participants first were asked to rate how much they agree with three pretest statements (one statement for each commonly-held belief about capital punishment). Then participants received either the statistics or coherence-based intervention, which consisted of statistical or coherence-based arguments designed to counter attitudes about deterrence, cost, and retribution as motivations for supporting the death penalty. After reading these arguments, participants completed the post-intervention measure which captured participants' attitudes about retribution, deterrence, and cost, and their overall attitudes towards capital punishment. Participants then were asked to provide general demographic information. These measures and interventions are described in more detail below. Complete materials for this study can be found in the Supplementary Online Materials (SOM).

Pretest Measure Participants were asked to rate their agreement with three pretest statements about the death penalty. Each of these statements measured three common motivations for supporting the death penalty on a 7-point Likert scale (1 = Strongly disagree, 7 = Strongly agree). For example, the item that measured attitudes about deterrence was, "The death penalty makes criminals think twice before committing murder." These statements were developed based on our post-intervention capital punishment measure.

Interventions As noted, participants were randomly assigned to either the statistics or coherence-based intervention, in which they read three statistical arguments or three coherence-based arguments against each belief for supporting the death penalty.

The statistics intervention was composed of brief summaries of empirical research taken from the Death Penalty Information Center (DPIC). This research contradicts

common misconceptions about capital punishment. For instance, the statistical argument for deterrence summarized information about criminology experts' and researchers' conclusions regarding the efficacy of capital punishment as a deterrent. Excerpts from this argument stated that "88% of these experts rejected the notion that the death penalty acts as a deterrent to murder", and that "studies claiming that the death penalty has a deterrent effect on murder rates are fundamentally flawed."

The coherence-based intervention consisted of brief persuasive arguments adapted from widely-cited law papers. In these papers, authors attempt to persuade readers through coherence-based arguments why the typical reasons taken to support the death penalty are inconsistent with other attitudes they otherwise strongly hold. Therefore, these arguments did not provide information about a belief being objectively false, but rather demonstrated ways in which the reason underlying a belief was incoherent with their other attitudes. For example, the coherence-based argument for cost demonstrated that determining whether someone should live or die based off of financial considerations is not a practice people generally condone and thus, it should not be considered a good reason in the case of capital punishment either. For complete intervention materials, see Table S2 and S3 in the SOM.

Posttest Measure The posttest items measured participants' attitudes about retribution, deterrence, and cost, along with their attitudes towards the death penalty in general. Participants were asked how much they agreed with 13 statements, adapted from the Death Penalty Attitudes Questionnaire (O'Neil, Patry, & Penrod, 2004). An example of a general death penalty item (general items labeled G1 - G4 in Figure 2) was, "I think the death penalty is necessary." Other items concerned attitudes about retribution (labeled R1 - R4 in Figure 2), deterrence (labeled D1 - D3), and the cost of the death penalty (labeled C1 - C2). For example, one item was "Society has a right to get revenge when murder has been committed."

Results

We tested whether statistical or coherence-based arguments would be more effective at changing people's attitudes towards capital punishment. Further, we aimed to understand how the effectiveness of each intervention varied as a function of the specific attitudes, or reasons people have for supporting capital punishment. In order to test this, we performed Bayesian ordinal mixed-effects modeling, predicting post-intervention attitudes towards the death penalty on the basis of condition (1 = statistics, 0 = coherence-based), and participants' pretest attitudes, which we modeled as a monotonic effect. This model treated both participants and scale items as group-level effects, allowing for heterogeneity in the intercept for each participant and question. The model is specified in the syntax of `brms` (Bürkner, 2018):

```
Model 1 <- Response ~ Condition +
mo(PreRetribution) + mo(PreDeterrence) +
mo(PreCost) + (1|Question) + (1|Subject)
```

Bayesian analyses formulate model parameters as probability distributions wherein the posterior distribution for a parameter θ is computed via the prior and the likelihood of θ. To model the joint probability distribution of responses, we specify regularizing priors over the possible effects each parameter could have on the response variable. Model 1 priors are shown below:

$$\beta_{Intercept[1]} \sim \mathcal{N}(2.19, 1)$$
$$\beta_{Intercept[2]} \sim \mathcal{N}(2.94, 1)$$
$$\beta_{Intercept[3]} \sim \mathcal{N}(3.17, 1)$$
$$\beta_{Intercept[4]} \sim \mathcal{N}(3.47, 1)$$
$$\beta_{Intercept[5]} \sim \mathcal{N}(3.89, 1)$$
$$\beta_{Intercept[6]} \sim \mathcal{N}(4.59, 1)$$
$$\beta_{\forall Pretest\ Beliefs} \sim \mathcal{N}(6, 1)$$
$$\beta_{Condition} \sim \mathcal{N}(0, 1)$$
$$\text{Group-level effects} \sim t(3, 0, 10)$$

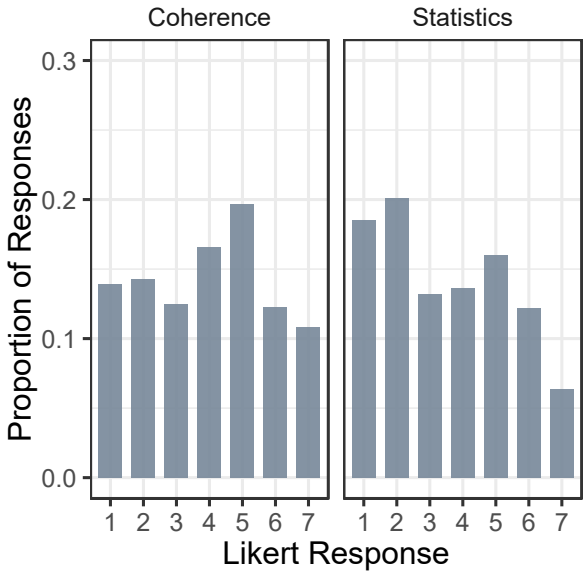

Figure 1: A histogram of the proportion of responses at a given Likert scale point (1 = Strongly disagree, 7 = Strongly agree) in the Coherence and Statistics conditions in Study 1. The figure indicates that participants were less likely to agree with pro-death penalty statements in the Statistics condition than the Coherence condition.

This analysis revealed that the statistics intervention reduced overall support for the death penalty relative to the coherence-based intervention, $b = -0.58$, 95% CI [−0.80, −0.35], $BF_{10} > 100$ (see Figure 1). Models interacting pretest beliefs with condition did not account for additional variance.

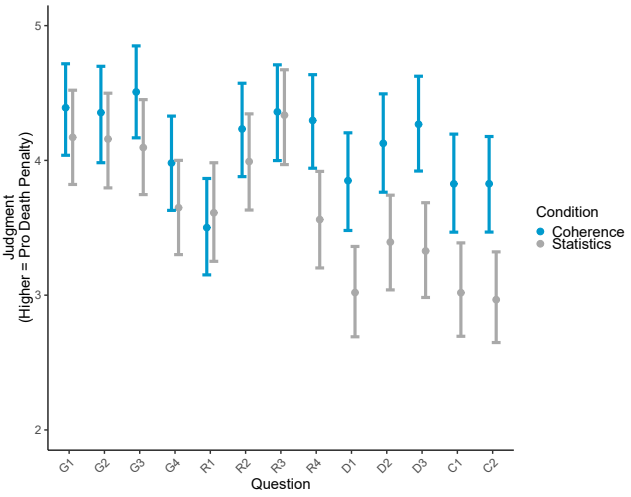

Figure 2: Death penalty attitudes for each scale item in the Coherence and Statistics conditions. Both conditions presented arguments against pro-death penalty beliefs. Error bars represent 95% Credible Intervals. Participants in the Statistical condition were less likely to endorse the death penalty than participants in the Coherence condition, but this effect varied as function of the question under consideration.

Next we investigated how condition interacted with the question to examine whether the statistics intervention affected some reasons for supporting the death penalty more than others. This model is specified below:

```
Model 2 <- Response ~  Condition*Question
+ mo(Deterrence) + mo(Cost) +
mo(Retribution) + (1|Subject)
```

Model 2 Priors:

$$\beta_{Intercept[1]} \sim \mathcal{N}(2.19, 1)$$
$$\beta_{Intercept[2]} \sim \mathcal{N}(2.94, 1)$$
$$\beta_{Intercept[3]} \sim \mathcal{N}(3.17, 1)$$
$$\beta_{Intercept[4]} \sim \mathcal{N}(3.47, 1)$$
$$\beta_{Intercept[5]} \sim \mathcal{N}(3.89, 1)$$
$$\beta_{Intercept[6]} \sim \mathcal{N}(4.59, 1)$$
$$\beta_{\forall_{Pretest\ Beliefs}} \sim \mathcal{N}(6, 1)$$
$$\beta_{Condition} \sim \mathcal{N}(0, 1)$$
$$\beta_{\forall_{Questions}} \sim \mathcal{N}(0, 3)$$
$$\beta_{\forall_{Condition \times Question\ Interactions}} \sim \mathcal{N}(0, 1)$$
$$\text{Group-level effects} \sim t(3, 0, 10)$$

The analysis interacting question with condition indicated that the statistics intervention was more effective at changing people's general death penalty attitudes (i.e., G1 – G4), people's attitudes about the efficacy of capital punishment at deterring crime (D1 – D3), and the cost of capital punishment (C1 – C2) compared to retributive attitudes (R1 – R4), $BF_{10} > 100$, (see Figure 2). This result is consistent with the intuition that for some attitudes, perhaps those that are *particularly* moral in nature, statistical information is irrelevant. When predicting only general attitudes towards the death penalty on

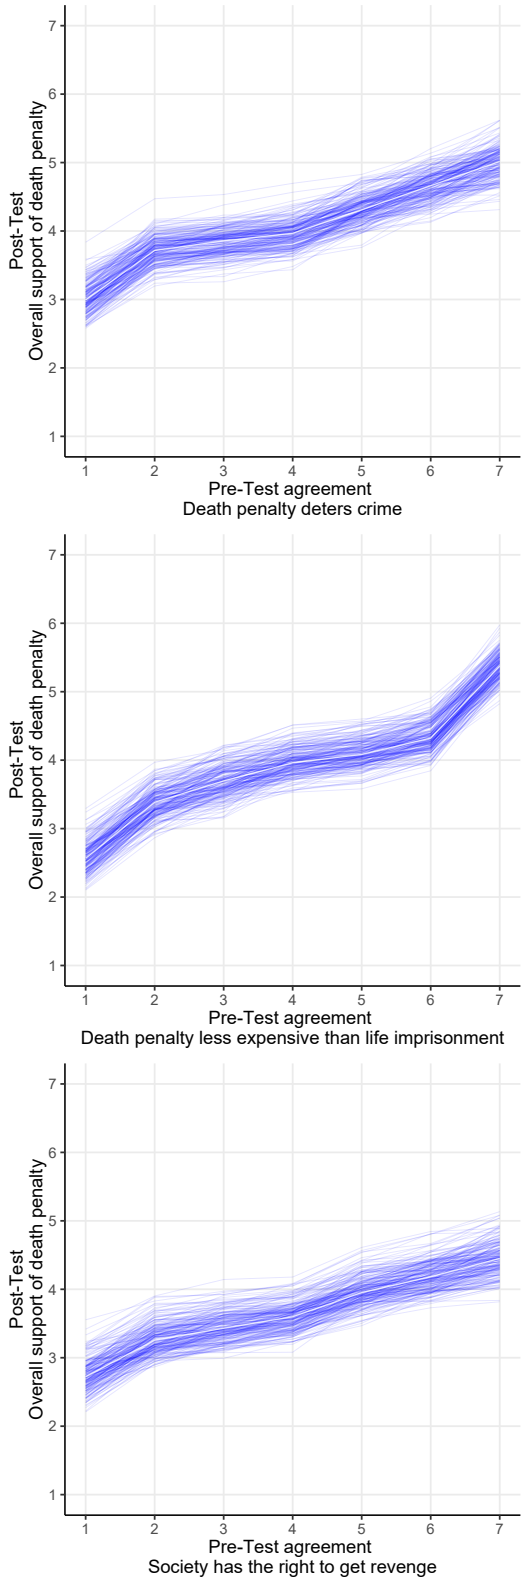

Figure 3: Spaghetti plot of post-test death penalty attitudes predicted by pre-test deterrence (top), cost (middle), and retribution (bottom) attitudes, which were treated as monotonic effects. Each regression line represents a draw from the posterior distribution.

the basis of condition, statistics were still more effective than coherence-based interventions, b = –0.49, 95% CI [–0.88, –0.08].

The nature of our design prohibited us from testing how effective each intervention was at changing every posttest death penalty attitudes because we could not compute a difference score for every item. However, three items were repeated across pretest and posttest. Therefore, we examined whether the coherence-based condition affected these items and how these change scores compared to the statistics condition. This analysis revealed that the statistics and the coherence conditions both decreased posttest endorsement for the three pro-death penalty beliefs, M = –0.68, 95% CI [–0.78, –0.57] and M = 0.25, 95% CI [–0.35, –0.16], respectively. However, for these items alone the statistics intervention was still more effective than the coherence-based intervention.

We followed up on these analyses by conducting a series of exploratory analyses examining how deterrence, cost, and retribution attitudes predicted overall posttest death penalty attitudes. This model regressed posttest death penalty attitudes on each pretest question, allowing us to measure the unique relationship each attitude accounts for in predicting posttest attitudes. Because of the ordinal nature of our predictors, we again treated each as a monotonic effect. These analyses indicated—to our surprise—that attitudes about the cost of the death penalty (b = 3.65, 95% CI [3.11, 4.18]) was more strongly related to people's death penalty attitudes than were beliefs about deterrence (b = 2.52, 95% CI [2.01, 3.03]) and the desire for retribution, b = 2.16, 95% CI [1.60, 2.73] (see Figure 3). Given that cost attitudes are most easily targeted by statistics interventions, and that these interventions proved more effective than a coherence-based intervention, this is further evidence that policy makers interested in shifting attitudes towards the death penalty might focus on the relevant statistics rather than moral imperatives.

Still, the results of Study 1 raised questions about what attitudes, beyond those that have been previously assumed to be relevant, are most strongly related to overall death penalty attitudes. Previous research assessing people's views about the death penalty have predominantly focused on people's retributive and utilitarian motives (i.e., people's desire for retribution and belief in the deterrent effect of capital punishment). Furthermore, some studies have used only a few items or a single dichotomous item to measure death penalty attitudes, even though public opinion polls and other research have shown that people's attitudes about this issue are complex and often dependent on the circumstances of the situation (e.g., Murray, 2003; Roberts & Stalans, 1997). Consequently, relatively simple measures such as these are unlikely to provide substantial insight into why people endorse the death penalty, and what beliefs and motivations underlie their attitudes. This is not to deny that attitudes about retribution and deterrence are central in shaping their attitudes about capital punishment. Rather, in Study 2, we aimed to understand what other understudied factors might also play a significant role in shaping people's attitudes towards capital punishment. For instance, people may not be familiar with the rate at which innocent people are sentenced to death, or they might not know that most other industrialized countries have abolished the death penalty. If these beliefs are related to support for capital punishment, and could also be changed more easily than beliefs about retribution, then researchers could develop more effective interventions using this information (Powell, Weismann, & Markman, 2018).

Study 2

In Study 2, we tested what attitudes are most strongly related to people's general support of the death penalty–what are the most relevant reasons people support capital punishment? We conducted an exploratory correlational study examining the relationship between previously-theorized attitudes (e.g., retribution and deterrence, Finckenauer, 1988; Carlsmith, Darley, & Robinson, 2002) and other understudied attitudes (e.g., the importance of wrongful convictions and perceptions of execution methods) that we hypothesized may be most strongly related to people's general death penalty attitudes.

Method

Preregistration Our sample size and study materials were preregistered through the Open Science Framework at https://osf.io/ek4fh/.

Participants We recruited 249 participants through Amazon Mechanical Turk. After excluding participants who failed attention checks, 184 participants remained for our final sample (45% female, M_{age} = 37 years old). Participants were paid $0.70 for participating in the study.

Procedure Participants were asked to rate how much they agreed with statements which composed 12 scales about capital punishment, the criminal justice system, and other related topics. These attitudes are described in more detail below. After answering these questions, participants provided demographic information.

Death Penalty Attitudes Measure We measured 11 attitudes (54 items total) that we hypothesized would be relevant to people's death penalty attitudes, many of which were suggested by previous studies but not included in most death penalty measures. We again measured attitudes about *retribution*, *deterrence*, and *cost*. The other attitudes we included were: (1) Providing rehabilitation programs for offenders is a good idea (*Rehabilitation*), (2) Innocent people are sometimes sentenced to death and this is a major concern with using the death penalty (*Innocence*), (3) People who are wrongfully convicted of serious crimes must have done something wrong to be in that situation (*Victim Blame*), (4) The death penalty is barbaric (*Barbarity*), (5) The United States has a great deal of crime (*Crime*), (6) America's execution methods are humane (*Humane*), (7) Other countries similar to America have the death penalty (*Common*), and (8)

Torture is acceptable in some cases (*Torture*). Our scales and items were adapted from the Death Penalty Attitudes Questionnaire (O'Neil et al., 2004), the Violence-Related Attitudes and Beliefs Scale (Brand & Anastasio, 2006), and a study by Jiang and colleagues (Jiang, Lambert, Wang, Saito, & Pilot, 2010). Participants rated how much they agreed with each statement on a 7-point Likert scale (1 = Strongly disagree, 7 = Strongly agree; Cronbach's α for all scales were > .70). For the complete list of materials and scales, see the SOM.

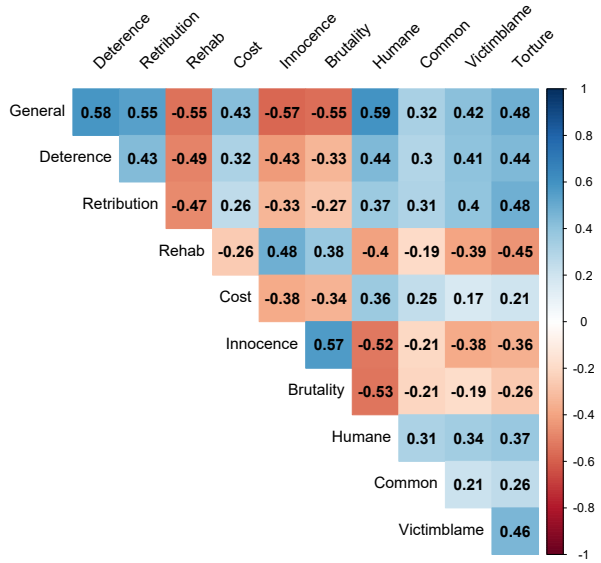

Figure 4: Kendall's tau correlation coefficients of death penalty attitudes in Study 2. Shades of blue indicate a positive correlation and shades of red indicate a negative correlation between two attitudes.

Results

We predicted that each of the 11 attitudes measured would be related to people's overall support for capital punishment, and as expected, all attitudes were correlated with participants' overall death penalty attitudes (see Figure 4). Deterrence, retribution, and the importance of innocence were among the most highly correlated attitudes with general endorsement of the death penalty. However, other attitudes exhibited surprisingly strong relationships with general support of the death penalty as well. For example, participants who endorsed the death penalty were also more likely to think that exonerated people were still nonetheless guilty or partially responsible for them being wrongfully convicted (Victim Blame; τ_b = .42). Strikingly, 28% of participants agreed, at least somewhat, with the idea that wrongfully convicted people on death row were responsible for their conviction (> 4 = Somewhat agree). Taken together, these results suggest that support for capital punishment may be more multidimensional than initially thought and provide further guidance for the development of interventions for correcting misconceptions about the administration of capital punishment.

General Discussion

Over half of the United States supports the use of the death penalty today yet are unaware of the statistics surrounding the deterrent effects and cost of the death penalty. Furthermore, there have been few systematic investigations of the attitudes, both proximal and remote, that may shape people's support for the death penalty. In Study 1, we examined how different types of interventions shift people's attitudes about the death penalty. We found that statistics interventions reduced support for the death penalty, and that these effects were largest for general death penalty attitudes, and attitudes about cost and deterrence. Furthermore, we found that statistics interventions were ineffective at changing attitudes motivated by retribution. Because retribution falls unambiguously within in the moral domain, people likely think statistics are irrelevant to the questions of whether criminals should get what they deserve. Study 1 also revealed that retribution is not the only relevant factor driving people's death penalty attitudes—beliefs about deterrence and cost were also strong predictors of overall endorsement of the death penalty. The results of Study 1 led us to examine what other attitudes, which have perhaps gone unexplored, may shape attitudes towards the death penalty (Powell et al., 2018). Study 2 revealed that many relatively "remote" attitudes were strongly correlated with endorsement of the death penalty. Of note, we observed a relationship between general death penalty attitudes and the belief that people wrongfully sentenced are to some degree responsible for their wrongful imprisonment. From an interventionist perspective, Study 2 also uncovered that many of the attitudes associated with support for the death penalty—for instance, beliefs about innocence and commonality—can be directly addressed by citing statistics. No moral imperative is required. Altogether, these findings highlight new avenues by which researchers can correct and shift people's attitudes about the death penalty.

How much to purchase? - A cognitive adaptive decision making account

Percy K. Mistry (pkmistry@uci.edu)
Department of Cognitive Sciences, University of California Irvine

Abstract

Repeated purchase decisions often violate assumptions of standard economic or rational choice models, such as demonstrating asymmetric or unstable responses to changes in underlying policy, price, or tax variables. I propose a novel framework for how such decisions can be interpreted through the lens of a cognitive process model. This provides psychologically interpretable characterizations of individuals or population groups. It incorporates mental accounting, hedonic adaptation, confirmation bias, and the influence of perceived trust and fairness. It shows how sequential experiences and contextual aspects such as political affiliation, are mediated by this cognitive process to produce evolving consumption patterns. This novel approach can account for empirically observed violations of conventional choice models. The model is quantitatively fit to experimental data for individual purchase decisions and demonstrates improved descriptive, predictive, and inference capabilities. A proof-of-concept analysis using this model to account for real world consumption trends is also demonstrated.

Introduction

Decisions on what quantity (Q) of a particular item to purchase over time depend on individual preferences, expected benefits from purchasing the item, and associated costs (prices, taxes, etc.). Elasticity (ε) is a canonical economic concept that defines the influence of a unit change of an underlying independent variable (e.g. prices or taxes) on the purchase quantity. Typical choice models assume that elasticities are stable at a population level over relatively long periods of time (controlling for income effects, i.e. the influence of higher levels of income on purchasing power), and that elasticities are symmetric (i.e. respond equally to increases versus decreases). They thus assume that observed changes in purchase quantities (∂Q) in response to changes in underlying variables such as prices and taxes (∂p) can be used to estimate empirical elasticities which in turn can be used to accurately forecast future changes.

Standard choice model: Standard economic models of choice assume that decision makers select the optimal quantity (Q) to purchase by maximizing the net benefit stemming from the utility (U_Q) of owning Q units of an item, less the costs of purchase (pQ), where p is the unit price (equation 1).

$$Q = arg\ max_x \{U_x - px\} \tag{1}$$

Without loss of generalizability, the utility function in equation 2 is assumed for the rest of the paper. This is one of a standard set of utility functions used in behavioral and econometric literature (e.g. Chetty, Looney, and Kroft (2009)). Solving for Q using equations 1 and 2, then taking logs, defining $\varepsilon_p = 1/b$, $(\varepsilon_p > 0)$ and $A = -\varepsilon_p\ log(a)$, we obtain equation 3. This is in the form of a log-linear model with a corresponding difference equation 4, with log price elasticity ε_p (a standard economic representation). As per this model $log(Q)$ decreases at a rate of ε_p as $log(p)$ increases and vice versa. Once ε_p is empirically estimated, equation 4 can be used to make forecasts.

$$U_x = \left(\frac{ax^{1-b}}{1-b}\right) \tag{2}$$

$$log(Q) = A - \varepsilon_p\ log(p) \tag{3}$$

$$\partial\ log(Q) = -\ \varepsilon_p\ \partial\ log(p) \tag{4}$$

Evidence against conventional assumptions: There is strong evidence however that elasticities (including, but not limited to, price elasticities such as ε_p described above) may not be stable even in the short run (Hughes, Knittel, & Sperling, 2006; Goodwin, 1992), may not be symmetric (Villas-Boas, Berck, Stevens, & Moe-Lange, 2016; Gately, 1992), may show significant heterogeneity, even directionally, (Chetty, Friedman, Olsen, & Pistaferri, 2009; Ayyagari, Deb, Fletcher, Gallo, & Sindelar, 2009; Fletcher, Frisvold, & Tefft, 2015), and may be easily manipulated by extraneous factors. Whilst these violations are acknowledged, no theory provides a robust and quantitative account of how elasticities evolve over time.

Psychological characterization of dynamic elasticities: In this paper I propose that dynamic characteristics of elasticities can be explained by examining purchase decisions through the lens of a sequential cognitive process. Let $\bar{p}$ define a sequential history of the underlying variable such as prices or taxes, Ψ represent stable cognitive characteristics of an individual or a population (these are elaborated on in subsequent sections), and Δ represent contextual factors (e.g. the measure of political climate or affiliations). Then equation 4 can be replaced with equation 5. Here, $\bar{p}$ and Δ are observable, and cognitive characterization Ψ can be empirically estimated (similar to ε).

$$\partial\ log(Q) = f(\Psi, \bar{p}, \Delta, \partial\ log(p)) \tag{5}$$

Cognitive framework

In this section, I develop a novel cognitive process model to structurally define $f()$ in equation 5, for a sequence of repeat purchase decisions over time. This model is parameterized by psychologically interpretable characteristics Ψ, which interact with sequential history $\bar{p}$ and environmental context Δ to shape continuously evolving patterns of purchases and elasticities. This model is based on bringing together and quantitatively specifying some novel and some previously explored psychological conceptualizations, as elaborated below:

Mental Accounting: Transaction Utility

Thaler (1999, 2008) proposed that consumption quantity (Q) choices were driven by a process of mental accounting that considered a combination of acquisition utility (similar to that defined in equation 2) and transaction utility. Transaction utility reflects the "value" of the deal, typically evaluated against some expectation or reference point, and adds or detracts from the acquisition utility. For this paper, transaction utility is defined by equation 6[1], reflecting the difference between the price p and the expectation or reference price θ.

$$T(Q,p,\theta) = (\theta - p)Q \tag{6}$$

The transaction utility can be positive or negative depending on whether expectations were exceeded. Thus the optimal purchase quantity can now be given by equation 7. This replaces equation 1 of the standard model. The mental accounting theory proposes that the acquisition and transaction utilities are separately evaluated, and may be accorded different weights. Here, δ is a salience weight that emphasizes or reduces the effect of the transaction utility component.

$$Q = arg\ max_x \{[U_x - px] + \delta\,[T(x,p,\theta)]\} \tag{7}$$

Salience Weight: Rational, Hedonic, or Altruistic?

The salience weight δ characterizes the nature of decision making. A rational choice would imply $\delta = 0$, since the transaction utility is driven purely by whether or not internal expectations are exceeded, and should not play any role in objective decision making. Applications of the mental accounting framework typically assume $\delta > 0$. This implies that individuals act hedonically in self-interest to maximize the utility they derive from exceeding their internal expectations. In that sense, $\delta > 0$ implies a reference-point that reflects 'the maximum they should be charging me'. Any price lower than this is treated as a positive utility and vice versa. However, some consumption decisions may involve conflicting considerations, such as those of fairness (Xia & Monroe, 2010). For instance, the decision to purchase goods that damage the environment, the decision to evade taxes, or the decision to purchase mandatory health insurance, may result in a conflict between hedonic utility on one hand, and a moral obligation on the other. Such moral obligations can give rise to utilitarian or altruistic concerns (Greene, 2007, 2009) that are concerned with the fairness of policies and redistribution goals. An altruistic reference point may thus reflect 'the bare minimum I should be paying'. For choices involving such moral obligations, if people do indeed demonstrate altruistic concerns, the salience weight may be $\delta < 0$, for at least a non-trivial subset of the population. A price lower than the reference point would reduce transaction utility and vice versa. While this may seem counterintuitive, an example that makes this comprehensible is the case of purchasing goods that are not environmentally friendly. Paying a price higher than the expected reference point may act as a moral justification, and in fact increase the transaction utility and resulting demand by reducing the associated guilt.

Hedonic reference point adaptation

Transaction utilities may be evaluated positive or negatively against a reference point. However this reference point is not typically constant. I propose that the reference point evolves over time (n), motivated by principles of hedonic adaptation (Frederick & Loewenstein, 1999). At time point n the reference point (θ_n) moves closer to the recently experienced values under consideration (e.g. price p_{n-1}), modulated by a hedonic adaptation rate L_h, as shown in equation 8.

$$\theta_n = \theta_{n-1} + L_h(p_{n-1} - \theta_{n-1}) \tag{8}$$

Hedonic adaptation implies that this mechanism serves to increase satisfaction and reduce dissonance created by any large difference between actual prices and expected reference points. This serves to condition people towards recent levels of p. The hedonic adaptation rate L_h may vary by individual or population - higher values of L_h close to 1 imply smaller transaction utility and rational consumption behavior.

Confirmation Bias: Asymmetric adaptation

Confirmation bias, where people place asymmetrical weights on information that confirm rather than contradict their beliefs and actions has been shown to be pervasive over many cognitive processes (Nickerson, 1998; Jones & Sugden, 2001; Palminteri, Lefebvre, Kilford, & Blakemore, 2016). The rate of hedonic adaptation L_h is proposed to be asymmetric, and depends on whether the prospective movement of the reference point supports or inhibits current behavior. Let m reflect a bias that reduces the rate of adaptation ($0 \leq m \leq 1$) when adaptation would serve to inhibit current behavior. This bias is introduced in equation 9. Here, I is an indicator function, with $I = 1$ if ($p < \theta$ under hedonic salience weight $\delta > 0$), or if ($p > \theta$ under altruistic salience weight $\delta < 0$), and 0 otherwise. These situations reflect a inhibition of current behavior based on prospective adaptation, and hence manifest as a lower adaptation rate mL_h. Confirmation bias will thus manifest as a consumption bias, slowing down adaptation that inhibits consumption.

$$\theta_n = \theta_{n-1} + L_h(p_{n-1} - \theta_{n-1})\ (mI + (1-I)) \tag{9}$$

[1]Note that this assumes a comparison of expectation and realization of the price, however a transaction utility can similarly be expressed based on expectations versus realization for the utility U_x. The framework and model in this paper can be applied without any loss of generalizability to such utility based reference points as well.

Trust based adaptation

Additionally, the reference points are proposed to increase when there is a perception of fairness or trust in the counter-party, and drop otherwise. For example, when considering tax changes and related reference points for tax rates, the government is the counter-party. A reference point for taxes may increase when the government is trusted (e.g. its wealth redistribution goals are considered fair, when political affiliations are in power, and hence higher taxes are more acceptable) than when it is not. Similar considerations may be at work when it comes to prices for goods, and whether people trust a certain brand, or when a brand signals quality, etc. This perception of trust is coded as $\pi = 1$ (trust), $\pi = -1$ (distrust)., or $\pi = 0$ (agnostic). Rate of adaptation in response to these perceptions is governed by L_π, and captured in equation 10. Updating is assumed to occur at every time point n when there is a consumption decision or a change in underlying policy.

$$\theta_n = \theta_{n-1}\,(1+\pi_n L_\pi) + L_h(p_{n-1} - \theta_{n-1})\,(mI + (1-I)) \quad (10)$$

Combined Cognitive-Econometric Model

Here, we replace the standard model in equation 3 by using equations 6, 7, and 10.

Case 1: Purchases Quantity and Price Changes

Equation 7 can now be re-written under the cognitive framework as equation 11, and solved. The log linear demand equation 3 then changes to equation 12. Note that these equations contain the term θ_n given by equation 10[2]. The fully expanded version of equation 12 would thus include the parameters π, L_π, L_h, and m.

$$Q_n = arg\ max_x \left\{ \frac{ax^{1-b}}{1-b} - p_n x + \delta(\theta_n - p_n)x \right\} \quad (11)$$

$$log(Q_n) = A - \varepsilon_p\ log(p_n - \delta(\theta_n - p_n)) \quad (12)$$

Case 2: Purchase Quantity and Tax Changes Next, consider the case where the key variable of interest is how purchase demand may change in response to changes in tax rates t, with the reference point θ being a reference point for what is considered a fair tax rate. There is a lot of evidence to show that there are considerable differences between price and tax elasticity, even when they would have objectively identical impact on consumers (Chetty, Looney, & Kroft, 2009; Chetty, 2015). Following the logic in the previous section, but adding terms for an excise tax rate t that is applied as a percentage on the cost price, so that effective cost would be increased by a value pxt, we obtain equation 13. This considers a situation with constant price p and only changes in the tax rate t and hence a reference point for tax rates only.

$$log(Q_n) = A - \varepsilon_p\ log(p) - \varepsilon_p\ log\big(1 - \delta(\theta_n - t_n)\big) \quad (13)$$

[2]Mathematicaly, extremely high values of the reference point would result in infinite utility, inducing people to spend all resources and maximize the units of consumption. Such reference levels are however *psychologically implausible*, and a mathematical bound for psychological plausibility of θ can be derived in terms of p and δ, such that the $log()$ term in equation 12 never turns negative, implying utility never increases to ∞.

Model Simulation Results

Figure 1 illustrates how different assumptions about the confirmation bias (low or high, governed by m) and mode of processing (hedonic versus altruistic, governed by δ) give rise to systematic deviations from the standard choice model, under different price trend situations (see figure caption for more details). When the predictions from the cognitive model shown in figure 1 are used to infer back what the interpretation of such data would have been under the standard choice model, the resulting inferences reflect highly unstable and variable shifts in conventionally measured elasticity from sub-period to sub-period, as well as asymmetry between elasticity during increasing and decreasing price trends, just as has been reported in literature discussed in the introduction. Such apparent instability and asymmetry is readily explained and generated by stable cognitive characteristics.

Application to Experimental Data (price)

Data: I consider a published experimental dataset from the work reported in Sitzia and Zizzo (2012, 2015). 384 participants made a series of 20 sequential decisions on how many units of a particular lottery to buy. Participants were provided experimental units of currency, and could spend as much of it as they wanted on the lotteries. At the end, the unspent currency, as well as any winnings based on the lotteries were added and converted to real monetary payouts. The lottery remained fixed across all trials, but the purchase price per lottery was varied sequentially. Participants were split into 5 conditions as shown in the left panel in figure 2, where the stimulus (price) patterns for the 5 conditions are represented in different colors. Participants in each of the 5 conditions start with either extremely high (EH), high (H), moderate (M), low (L), or extremely low (EL) levels of prices for the first 10 trials which constitute the "shape" block. All the participants observe the same moderate price levels in the last 10 trials, the "compare" block. The right panel in figure 2 shows the average response (average units bought) for each condition. Key observations made by Sitzia and Zizzo (2012) were that participants with higher initial price purchase more units in the "compare" block than those that have observed a lower initial price. This, as well as the dynamics of many individual patterns of how participants switch purchasing behavior over trials represents a challenge for the standard economic model.

Modeling Results: A standard choice model, as described in the introduction, as well as the cognitive model based on hedonic and asymmetric adaptation (equations 9 and 12) is quantitatively fit to this data, using a Bayesian MCMC framework (JAGS, Plummer et al. (2003)). Since this is an experimental setup, the concept of trust based adaptation is not included in the model. A measure of descriptive fit is evaluated. Additionally, the models are separately tested by providing the first 15 trials for each individual to the models, and obtaining predictions for the last 5 trials. Model comparison using deviance information criteria (DIC, a combined measure of model fit and complexity) was significantly better

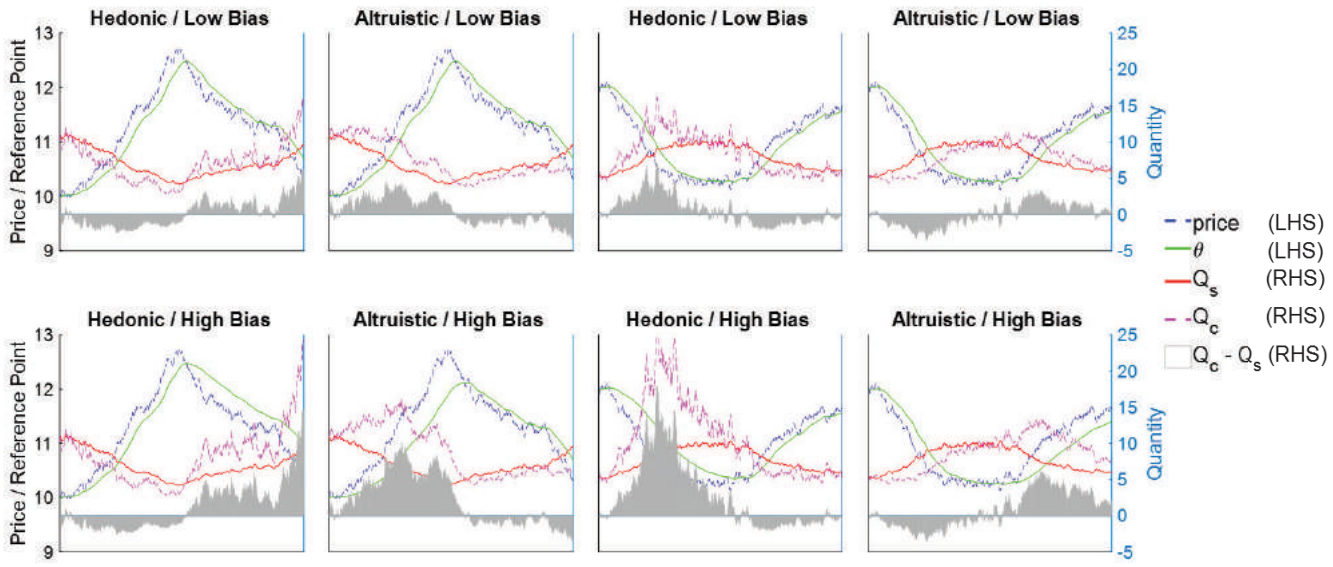

Figure 1: **Model Simulation:** Columns 1 and 2 show price trends that are first increasing and then decreasing. Columns 3 and 4 show price trends that are first decreasing and then increasing. Four parameter combinations reflecting Hedonic ($\delta > 0$) versus Altruistic ($\delta < 0$), and low confirmation bias (high values of m) versus low confirmation bias (high values of m) are compared under each scenario. The blue lines reflect the price changes. The x-axis reflects time, a hypothetical weekly data spread over a 10 year period. The red line gives the purchase quantity based on the standard choice model and typical assumptions about elasticity. The green line reflects the reference point based on the cognitive model assumptions. The pink line reflects the purchase quantity based on the cognitive model that assumes the same base elasticity as the standard model. The gray bars reflect differences between the cognitive model and the standard model quantities predicted. Price and reference points should be read of the left (LHS) axis and quantities off the right (RHS) axis. High bias parameterizations generally produce higher purchase quantity as expected. More interesting is the asymmetry produced by the cognitive model, which is typically seen in real world scenarios, which can be seen in the relative asymmetry between the gray bars in the first and second half of each simulation - reflecting asymmetries involved in responses to increasing versus decreasing prices.

(lower DIC is better) for the cognitive model (DIC = 21,276) compared to the standard model (DIC = 23,871). Figure 3 compares both the fit and prediction errors (RMSE) between the standard and cognitive models. It shows that for a huge majority of individuals, the cognitive model produces better descriptive fits (better for 86%) and better predictions on unseen data (better for 80%).

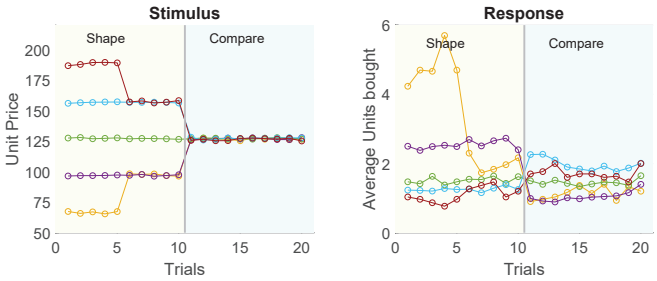

Figure 2: **Stimulus and Responses:** Experimental data from Sitzia and Zizzo (2015)

Illustration of how the model works: Figure 4 shows the latent model inferences about how the reference point evolves, and its relation to consumption patterns for 2 of the participants in the experimental tasks, to illustrate how the model is accounting for behavior. The figure shows the trial by trial stimulus price (red line), the response purchase quantity (black bars) and the latent reference point inferred by the model (green line). For the subject in the left panel, the prices are initially high and then fall. In the second half of the experiment, even though the price stays in the same range, the consumption levels falls as the difference between the latent reference point and the price narrows over time. For the subject in the right panel, the consumption remains almost constant from trials 6-17 even though the price increases after trial 10. This stability when the price is changing significantly is on account of the almost constant difference between the price and the evolving reference point. The standard model finds it difficult to explain these kind of behavioral patterns.

Inferences from the model parameters: Table 1 summarizes the parameter inferences for the cognitive model showing the mean, standard deviation, and the correlation between the parameters and purchase quantities in the "compare" block (trials 11 to 20, where the prices were identical for all 5 conditions). All participants demonstrated con-

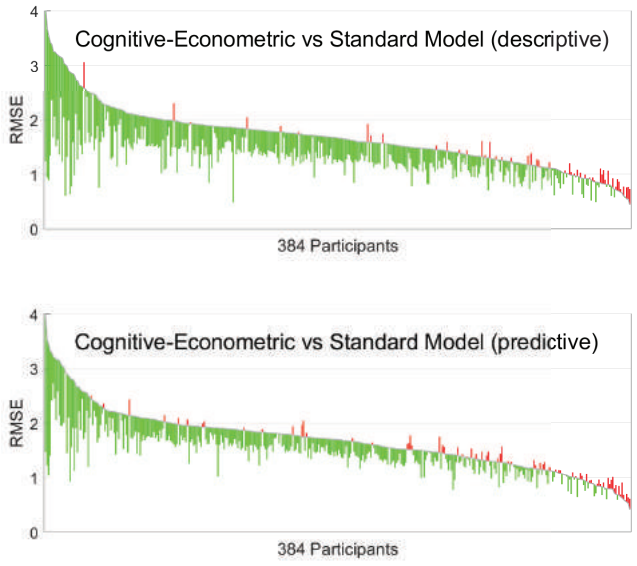

Figure 3: **Comparison of model fit errors:** Significantly better fit (upper panel) and predictions (lower panel) by the cognitive model. Each bar in the figure represents an individual, with the gray line showing the error from the standard model (participants sorted in order of reducing error based on the standard model). The green bars show an improvement (bar going downwards) on account of the cognitive model and red bars show deterioration (bars going upwards).

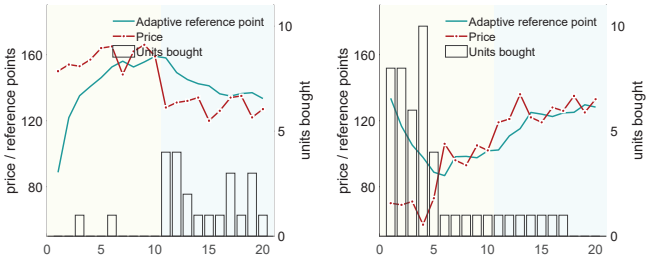

Figure 4: **Illustration of model mechanics:** Examples of the latent model inferences about the reference point trajectory for 2 participants. These behavioral patterns cannot be easily explained by the standard model.

sumption bias ($m < 1$, lower values of m indicate higher consumption bias). The mean value of m of 0.43 indicates that on average, people shifted their reference points twice as much when the price was higher than expectations, than when it was lower than expectations. As intuitively expected, m (lower values = higher consumption bias) is strongly correlated with consumption in the second half of the experiment ($r = -0.75, p < 0.00001$). Most participants show high salience weights δ on the transaction utility, but also individual differences, and higher salience weights are strongly correlated to higher consumption ($r = 0.68, p < 0.00001$). The rate of hedonic adaptation (L_h) did not show strong individual differences, but was consistently less than 1, indicating that adaptation was slower than rationally expected, leading to consistent deviations from the standard model.

Table 1: Key cognitive parameters (Ψ) capturing individual differences in the experimental task.

Characteristics	Mean	std	corr with $Q_{compare}$
m	0.43	0.15	-0.75
δ	1.59	0.71	0.68
L_h	0.48	0.10	0.27

Application to real world data (taxes)

Data: This section provides a brief proof-of-concept for applying this cognitive model to real world population level consumption behavior. Panel data from Chetty, Looney, and Kroft (2009) is used, that includes per capita consumption of beer by state in the US for a period of 34 years, along with the corresponding price and tax changes. As a proof of concept illustration, analysis for 3 states is provided below.

Modeling: A basic standard model[3], and the cognitive model based on equations 10 and 13, that is, including the trust based adaptation, are implemented within a Bayesian inferential framework. The models are fit by providing them with data about consumption changes for 20 years, and then checking model predictions (based on 1000 generated samples for each state for each year) about consumption changes for the last 13 years. The top panels of figure 5 show the changes in tax rates for 3 states over the 34 year period (note the different tax change profiles for the 3 states). The bottom panels show the distribution of prediction errors. The cognitive model produces significantly lower errors ($p < 0.05$ for comparison of error distributions for all 3 states).

Figure 6 shows the influence of the trust based adaptation on reference points (and hence eventually on consumption). The dotted lines show political party regime changes. The three states seem to show graded political affiliations, with the influence of trust switching between high and low (note how the green and blue lines cross over at each regime shift). This is in fact, an inference about the between state differences in trust in existing political regimes, and thus an indicator of state level political affiliation, that was inferred purely from tax rate and beer consumption data. This is an example of the Δ variable suggested in equation 5.

Conclusions

Repeat purchase and consumption decisions are reliant on multiple cognitive processes, and how people respond to

[3]It should be noted that there exist other, more sophisticated and customized econometric models for describing this data. The standard model is used as a baseline comparison to compare the generalizability of standard choice versus cognitive based models.

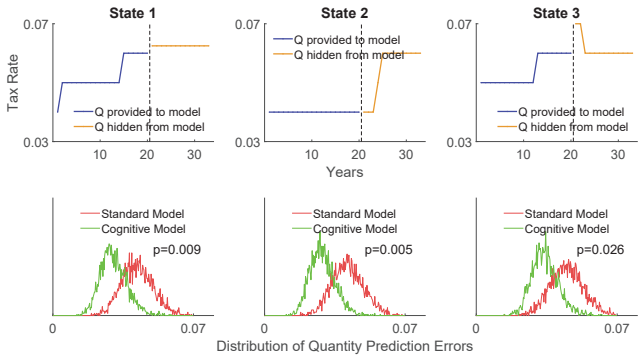

Figure 5: **Application to real world data:** Top panel - Changes in tax rate; Bottom Panel - Prediction error about consumption quantity from standard and cognitive models.

changes in prices, taxes, and other policies may deviate significantly from rational models of choice. This paper highlights the importance of a structural model that captures how people's internal expectations may evolve over time, and how capturing this cognitive characterization can help the descriptive and predictive quality of psychological and econometric models. Future work will apply the models to a wider range of experimental and real world data, including identifying heterogeneous sub-population clusters within a larger population (Bell & Lattin, 2000). It will explore the implications for economic predictions, policy implications, and our basic understanding of how adaptive human behavior evolves over time.

Abstract

Developmental theory considers action prediction as one of several processes involved in determining how infants come to perceive and understand social events (Gredebäck & Daum, 2015). Action prediction is observed from early in life and is considered an important social-cognitive skill. However, knowledge about infant action prediction is limited to evidence from screen-based eye-tracking tasks. Little is known about action prediction in real-life action contexts. Our aim in the current study was to provide new evidence on whether and how infants anticipate actions in free-flowing parent-child interaction. Using dual head-mounted eye-tracking, we analyzed infants' visual anticipations of their parents' reaching actions while they played with objects together. Findings reveal that infants anticipate their parents' actions at a rate higher than would be expected by chance.

Keywords: dual head-mounted eye-tracking; action prediction; parent-child interaction; social-cognitive development

Introduction

Action prediction refers to the ability to anticipate the outcome or endpoint of another person's goal-directed action (Flanagan & Johansson, 2003). This ability serves several important perceptual and cognitive functions: in a noisy and dynamic environment, anticipation allows the observer to direct visual attention to where important events will occur next (Gredebäck, Johnson, & von Hofsten, 2010). Action prediction also facilitates smooth, coordinated interactions. For instance, a simple interaction such as passing an object to another person requires planning a motor response at a precise moment in time and space to grasp the object successfully. Anticipating the other person's action and gazing to the location their hand will go next allows this kind of joint coordination to take place (Knoblich & Sebanz, 2012). For infants, whose developing system is solving the challenge of integrating their motor and visual systems, action prediction is an emerging skill (Falck-Ytter, Gredebäck, & von Hofsten, 2006; Kanakogi & Itakura, 2011; Monroy, Gerson, & Hunnius, 2017). In the current study, we investigated action prediction in 9-month-old infants, who are at the cusp of acquiring new fine motor skills and demonstrating rapid growth in their social-cognitive skills.

Prior research has demonstrated that infants exploit multiple cues to anticipate observed actions. For instance, infants can use kinematic cues from movement trajectories (Rosander & von Hofsten, 2011; Stapel, Hunnius, & Bekkering, 2012), the statistical regularities in familiar action sequences (Monroy, Gerson, & Hunnius, 2017), and knowledge about an actor's goal (Woodward, 1998). This ability develops within the first year of life: at 12 months, but not at 6 months, infants can anticipate unambiguous reaching actions (Falck-Ytter et al., 2006). By 9 months of age, infants can predict the endpoints of simple reaching actions based on motor cues from pincer and palmar grasps (Monroy et al., 2017; Senna et al., 2016).

The research described above is exclusively based on evidence from tightly controlled, yet artificial reaching paradigms. These paradigms have been useful in refining current theories about infants' action perception (Gredebäck & Daum, 2015). However, little is currently known about action prediction abilities 'in the wild', as infants interact with others while freely moving about in the environment. It is unknown whether infants' anticipatory behavior in laboratory contexts would generalize to the messier, more complex action contexts of real life. Here, we aimed to provide new evidence for whether and how frequently infants predict their parents' actions during free-flowing parent-child play.

In real-life contexts such as toy play, infants spend a great deal of time engaged with objects (e.g., almost 90% of the time; Yuan, Xu, Yu, & Smith, 2019) and their visual attention is characterized by long fixations to objects they are holding themselves (Yu & Smith, 2013). Based on these findings from recent head-mounted eye-tracking studies, our first question was whether infants do anticipate others' actions in real life, as they do in controlled laboratory contexts. If so, our second aim was to identify the frequency with which they do so and whether this frequency occurs at a rate higher than would be expected by chance. In the current study, we quantified the proportion of anticipated reaching actions during parent-child play and compared these to chance proportions.

To examine further the contexts in which action prediction can occur during parent-child play, we also analyzed infants' visual attention and manual activity during parents' reaching actions. For instance, to make a successful anticipation, do infants need to be disengaged from other

non-target objects? Do they exploit ostensive cues by attending to their parent's face (Senju & Csibra, 2008)? Given the limitations of infants' visual attention and their tendency to focus on their own manual actions at this age (Yu & Smith, 2017), one possibility is that infants demonstrate anticipations when they are less active themselves (i.e., better opportunity to anticipate) or when they are more socially engaged with their parent (e.g., more face looking).

Method

Participants

The sample consisted of 32 parent-infant dyads (mean age = 9.3 months, range = 9-9.7; 18 females). All children were born full-term and had no developmental diagnoses.

Procedure

Infants and parents were seated at a child-sized table across from one another. Both dyad members were fitted with head-mounted eye-trackers from Positive Science, LLC (Figure 1). Each eye-tracker has an infrared camera that records the right eye and a head camera that records the field of view. Two additional cameras recorded a third-person view of each dyad member. All six cameras recorded at 30Hz and were synchronized offline using custom-written Python scripts.

Figure 1: Experimental setup. A parent and her infant are seated across from one another playing with familiar objects. The crosshair indicates the estimated gaze direction.

To calibrate the eye-trackers, an engaging toy was placed in 15 unique locations on the tabletop to capture the infant's attention. Parents were instructed to attend as well. This phase was use for offline calibration using Yarbus software by marking the locations on the corresponding video frames when the eye was directed at the target.

Following calibration, participants were presented with six familiar, engaging toys (a car, cup, a train, a duck, a plane, and a boat). Toys were grouped into two sets of three, with each set containing one red, one green and one blue toy. Parents were instructed to play with their infants "as they normally would at home". Dyads played with each toy set twice for 90 seconds, yielding six possible minutes of interaction. The order of toy sets was counterbalanced across dyads.

Data processing

After offline calibration, gaze direction was superimposed onto the head camera recording with a crosshair, yielding an additional recording of the calibrated gaze. All camera recordings were then exported into a series of single frames. Each camera contributed a maximum of 10,800 frames per dyad (six minutes of recording at 30 frames per second).

Infants' gaze direction and parents' reaching actions were then manually coded frame-by-frame. For gaze, two independent coders used frames from the calibrated recording to determine whether the crosshair fell within one of four regions of interest (ROIs): the three novel objects and the parent's face. Frames were excluded whenever the eye-tracker failed to capture the eye (e.g., the child knocked the camera out of place), in between trials, or whenever the child was off-task. The second coder annotated a random 10% of the frames. Reliability ranged from 82-95% (Cohen's kappa = .81).

Additional coders annotated parent reaching actions: for each frame, the coder determined whether the parent was reaching for an object and, if so, which one. Reaching was defined as any movement towards an object that ended when contact was made. Right and left hands were coded separately and then merged to yield one data stream.

To identify infants' action prediction—anticipatory looks to the targets of their parents' reaching actions—the two data streams from the infant gaze and the parent reaching were aligned. Action prediction was defined as a gaze to an object that occurred after the onset of a parent reach to that same target, but before the reach was completed (Figure 2). This represents the time window in which the infant had enough information to predict the observed action, but before the hand reached the target. The number of anticipations per interaction was then summed and divided by the total number of valid parent actions to yield the proportion of anticipated actions.

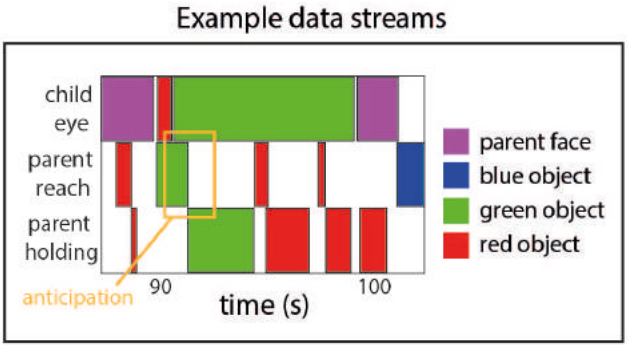

Figure 2: A sample of the aligned gaze and reaching data streams from a representative dyad. The yellow box highlights an example of an anticipation: the infant looks to the green object after the reach onset and prior to the end of the reach. Parent holding is included here for visualization purposes.

Not all parent reaches represented fair opportunities for anticipation. To estimate rates of anticipation out of the child's actual opportunities to anticipate—rather than total

number of reaches—we categorized all parent reaching actions as *valid* or *invalid* opportunities (Table 1).

Table 1: Criteria for categorizing parent reaches as *invalid* opportunities to anticipate.

	Criterion
1.	<200ms (to account for the time needed to program an eye movement)
2.	Subsequent contacts in cases of multiple object contacts (e.g., tapping or switching object from one hand to another)
3.	Infant reaching for the object at the same time
4.	Experimenter was reaching for or touching the object at the same time
5.	Both parent and object were entirely out of the child's view for the entire duration of the reach (e.g., child's eyes were closed, or object was underneath the table)
6.	Child threw or rolled the object to the parent and the parent simply received it[1]

Results

Action prediction

As a group, infants made 78 total anticipations out of 3640 gaze fixations. Per infant, they made an average of 2.44 anticipations throughout the interaction (range = 0-7, *SD* = 1.97). Parents made 1176 total reaching events, an average of 36.75 reaches per parent (range = 17-67, *SD* = 12.14). Of these, 563 represented valid opportunities to anticipate (average = 17.59 per parent, range = 7-33, *SD* = 5.08). The 78 total infant anticipations corresponded to valid reaches; there were no anticipations that corresponded to an invalid reach. Therefore, the mean proportion of anticipated reaches out of all valid reaches across infants was .13 (*SD* = .11).

These results indicate that infants do demonstrate action prediction at 9 months of age during free-flowing interaction, though infrequently (Figure 3). There was a substantial amount of variability among infants: while some infants never anticipated (*n* = 8, or 25% of the sample), others anticipated more than 40% of their parents' actions. After excluding infants who never anticipated, the mean proportion of anticipated reaches was .18 (SD = .09), which is consistent with the findings reported above from all infants.

Out of 563 total reaching events across all parents, in 94 of these events the infant was already looking to the target object when the parent initiated their reach. In these cases, the parent was most likely responding to the child's visual attention by reaching for what the infant is looking at. When these reaching events are removed from the total count—they can also be considered invalid opportunities to anticipate, since the child cannot anticipate a target they are already looking at—the average proportion of anticipated reaches increases to 0.16 (*SD* = 0.13).

Given the low frequency of this behavior, we tested whether infants' anticipations could have been due to chance overlaps between infant gaze and parent reaching behavior. For each infant, we created 1000 randomized time-series by shuffling the sequence of gaze fixations while preserving their overall duration. We then aligned each randomized gaze sequence with the sequence of parents' reaching actions, calculated the number of anticipations that could occur by chance, and averaged over these 1000 values to yield a baseline anticipation rate for each infant. This resulted in a mean of 1.31 baseline anticipations across infants (*range* = 0.31-3.33, *SD* = 0.65). A paired-samples t-test revealed that the average number of anticipations was significantly *higher* than baseline (*mean difference* = 1.13, $t(31) = 3.84$, $p = .001$). This result was the same when comparing the proportion of anticipated reaches with the chance proportion of .07, (*mean difference* = .09, $t(31) = 4.34$, $p < .001$). This finding reveals that infants' action prediction did not simply occur from chance overlaps between looking and parent reaching to the same object.

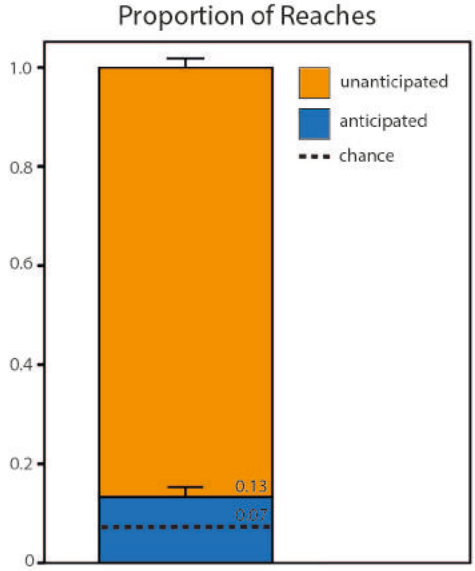

Figure 3: The proportions of reaching actions that were anticipated vs. unanticipated, with the dotted line representing chance. Error bars represent the s.e.m.

Infant visual attention and manual activity during parent reaching

To explore the characteristics of the parent-child interaction during reaching events, we examined the infant and parent behaviors that were occurring during each reaching event. Figure 4 illustrates the proportion of all valid parent reaches in which the infant was attending to or manipulating a different object from the target of the reach. Parents were also holding another object in their other hand during 37.5% of their reaches. In fact, there was not *one single* reaching event across all dyads with no concurrent

[1]Here, the child may be anticipating the causal outcome of their own action or the movement trajectory of the ball rather than their parents' action goal.

visual and/or manual activity to a non-target object from either the child or the parent.

Given this finding, we conducted an additional analysis on the rate of anticipation with the aim of only considering opportunities that did not overlap with infants' own actions. We therefore excluded reaches during which the infant was holding or reaching for a non-target object. In these instances, infants were occupied with planning their own manual actions, which requires vision. After excluding infants' manual activity, this resulted in 251 valid reaches actions across parents (*mean* = 7.84 per parent, *SD* = 3.62). The mean proportion of anticipated actions was 0.36 (*SD* = .31), which remained significantly higher than the chance level of 0.20 (*SD* = .12), $t(31) = 3.61$, $p = .001$. In other words, in a less demanding observation context (i.e., without competing goals from their own manual actions) infants will anticipate close to 40% of their parents' actions.

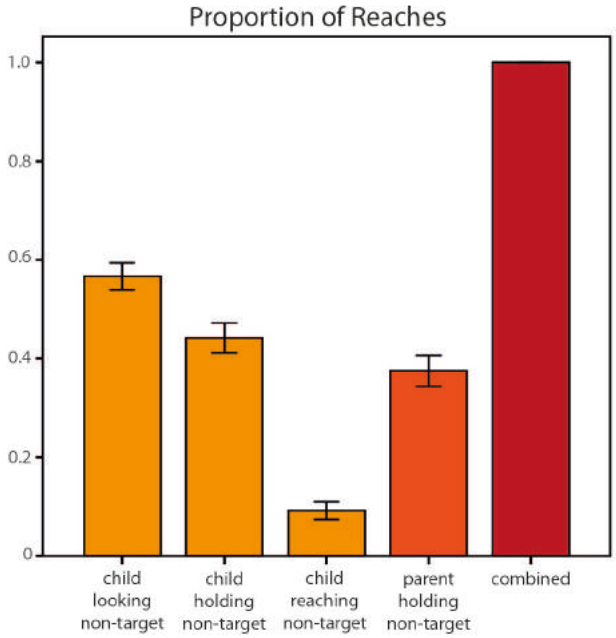

Figure 4: The proportion of reaching events in which infants or parents were concurrently attending to or manipulating a non-target object. From left to right, reaches during which 1) infants were looking at non-target object; 2) infants were holding a non-target object; 3) infants were reaching for a non-target object; 4), parents were holding a non-target object in their other hand, and 5) at least one of the above was occurring. (*Note:1-4 are not mutually exclusive and therefore add up to more than 1.*)

Anticipation latency

The mean duration of parents' anticipated reaches were 611.46ms (*SD* = 314.90, *range* = 200-1770). Figure 5 displays a bar chart of the time-course of infants' anticipations: the latencies between the onset of the reaching actions, infants' looks to the target object, and the contact with the goal (i.e., the end of the reach). The mean latency from the start of the reach to the moment the child looked to the target was 328.88ms (*SD* = 234.67). The mean latency from the gaze onset to the moment the hand reached the target was 282.58ms (*SD* = 282.31). In other words, on average infants required just over 300ms to detect and process their parents' movements and then anticipate. This includes the time required for infants to program an eye movement in response to a visual stimulus (Gredebäck et al., 2010). This finding suggests that movement cues were a strong cue for anticipation.

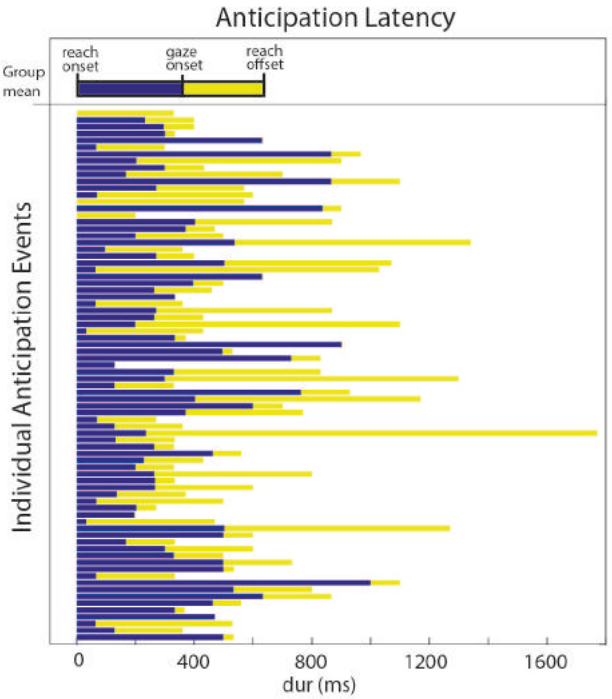

Figure 5: A histogram of the time course of infants' anticipations: blue bars indicate the latency between the start of the reach and the moment the child looked to the target; yellow bars indicate the latency between the child's look and the moment the parent's hand reached the target.

Looks to Parent Faces

If an infant is looking at their parent's face, they could be more likely to perceive the onset of their parent's reach and its trajectory. To determine whether attending to their parents facilitated anticipations, we calculated the proportion of anticipations that were immediately preceded by a fixation to the parent's face. Out of the 78 anticipations performed across all subjects, 18 were immediately preceded by a face look. For the remaining 60 anticipations, 42 of them did not have a face look within a 3-second window before or after the anticipation. This finding suggests that looking to parents' faces was not a strong cue for anticipation.

Discussion

The world of the developing infant is dynamic and constantly changing in both time and space. In the first year of life, infants become increasingly proficient actors and make rapid gains in their abilities to perceive and understand social events. Action prediction reflects an

important part of this social-cognitive process (Gredebäck & Daum, 2015; Hunnius & Bekkering, 2014) and has been widely studied using screen-based eye-tracking methods (Robson & Kuhlmeier, 2016). In the current study, we used dual head-mounted eye-tracking to investigate whether infants' predict their parents' object-directed reaching actions during free-flowing parent-child interaction.

Our primary finding is that, as a group, infants do anticipate their parents' actions at a rate that was significantly higher than what would be expected by chance. This finding demonstrates that infants' action prediction skills are not limited to the unambiguous, controlled action contexts that are typical in laboratory paradigms—they also demonstrate this ability during free-flowing parent-child play while they are also acting themselves.

On the other hand, the low rate of anticipation is also consistent with recent work investigating the real-time dynamics of parent-child interactions. New evidence from head-mounted eye-tracking studies have revealed, for instance, that infants actually rarely look to their parents' faces (Franchak, Kretch, Soska, & Adolph, 2010) and achieve joint attention through their own manual actions rather than through gaze following (Yu & Smith, 2016). The current study adds to this growing literature by revealing that infants also attend less to the goals of their parent's reaching actions. However, it is difficult to evaluate whether proportions of .13-.16 should actually be considered low, as there is no existing data to compare to these values. Future work could, for instance, quantify the rate of parents' anticipations of their infants' actions to provide a reference point.

A second finding was that infants anticipated their parents' actions on a rapid timescale—the mean latency after the reach onset was 328ms. In one recent study that also reported the "disengagement time"—i.e., the $reach_{onset}$ - $gaze_{onset}$ latency—on average infants required 344ms (SD = 209ms) to look to the target (Rosander & von Hofsten, 2011). These authors interpreted this finding as evidence that infants were able to use movement trajectories on a rapid timescale to accurately predict their parents' targets. In that study, infants were seated in a high chair and observed an experimenter move a small ball into a cylinder. Interestingly, infants demonstrated a similar timescale despite the increase in complexity of the toy play context.

A third finding that emerged is that there was not *one single* object-directed reaching action, in the entire sample, in which infants or parents were not simultaneously looking at or holding a different object than the target of the reach. Nevertheless, infants were still able to generate successful anticipations. One recent study may shed some insight into this finding. De Barbaro et al., (2016) investigated the qualitative shift from infant-guided object play to the triadic joint object play that emerges around 9-12 months of age. Their research highlights a "decoupling" between infant gaze and manual activity: in their studies, infants frequently directed their visual and sensorimotor attention to different objects (i.e., they do not look at what they are holding). Likewise, they frequently shifted their gaze from the objects in their own hands and those in their parents' hands. These authors propose that this "sensorimotor decoupling" in hand-eye coordination contributes to the emergence of triadic interactions, by enabling infants to manipulate objects while still attending to the objects in their parents' hands.

This finding also highlights the dissociation between screen-based action contexts and real life: infants rarely experience isolated, unambiguous moments without competing cues or distractors, unlike discrete trials in experimental studies. Although examining what infants can or cannot do in a controlled laboratory setup is an effective approach to understanding infant cognition, it is also critical to examine how behaviors emerge from complex contexts with competing goals. For example, in the toy play context examined here, infants need to efficiently control their visual attention on a rapid timescale to serve multiple tasks—guiding their own manual actions, predicting their partner's actions, and sometimes using gaze to send social signals to their partner. In such real-life contexts, the key question is how the infant cognitive system operates with multiple ongoing tasks and how they distribute cognitive resources (e.g., attention and memory) to coordinate and manage these tasks.

What are the functional consequences of action prediction? Anticipating the actions of their social partners may help infants form associations between other peoples' actions and their goals or intentions. This pathway has been proposed to provide a potential explanation for how infants transition from forming associations between the behaviors they observe and more complex social understanding skills within the first years of life (Hunnius & Bekkering, 2014; Ruffman, Taumoepeau, & Perkins, 2012). In fact, a related study in our lab found correlations between the frequency of infants' action prediction and their vocabulary size, both at the same age and up to 6 months later (Monroy et al., under review). This finding provides preliminary evidence that action prediction may not only reflect infants' current social information-processing skills (Gredebäck & Daum, 2015) but also provide learning opportunities that support their developing social-cognitive system.

Our study represents a first attempt to investigate action prediction in naturalistic parent-child play. In our experimental set-up, parents and infants engaged in unstructured object play limited to three objects. However, this paradigm is also limited in the kinds of information available to infants. For instance, parents' actions did not lead to any meaningful action goal, as our everyday actions do (e.g., making a sandwich or building a Lego tower). In addition, there were no regularities in parents' reaching actions that they could use to anticipate their next target, which is one cue that infants use to generate predictions (Monroy et al., 2017). In future work, we plan to investigate action prediction in a broader range of action contexts—for instance, when infants and parents are engaged in joint activities that feature structure and shared goals.

Acknowledgments

Thank you to Alexis Allard for data coding and to Steven Elmlinger, Melissa Hall, Charlene Tay, Charlotte Wozniak, Melissa Elston, and Seth Foster for data collection. We would also like to thank three anonymous reviewers for helpful comments on an earlier draft of this manuscript. Abstract

This study investigated how beat gesture and contrastive pitch accenting affect online contrastive reference resolution during spoken discourse comprehension. Evidence from gaze fixations indicated that beat gesture encouraged fixations to target referents of contrastive referring expressions and that contrastive accenting encouraged fixations to competitor referents of non-contrastive referring expressions. Notably, beat gesture and contrastive accenting acted independently, indicating that their effects are additive rather than interactive. Moreover, neither beat gesture nor contrastive accenting affected an observed tendency to anticipate contrastive referring expressions. Together, these results provide the first evidence that beat gesture, like contrastive accenting, is interpreted as a cue to contrast during online reference resolution in spoken discourse comprehension.

Keywords: beat gesture; pitch accent; reference resolution; discourse processing; visual world; eye tracking

Introduction

Successful discourse comprehension entails establishing relations between entities. One such relation is *contrast,* which refers to a contradiction between two themes (Myhill & Xing, 1996). An example can be seen in the distinction between referents in the following discourse: *The report isn't due on Tuesday; it's due on Thursday*. Although contrast can be discerned semantically, cues conveying prominence can be used to highlight it, strengthening the propositional representations of both the speaker and the listener. Two such cues are pitch accent—alterations in in speech fundamental frequency (f0), duration, and intensity (Ladd, 1996)—and beat gesture—simple rhythmic gesture (McNeill, 1992; 2005). Although processing of these cues has been studied in offline discourse comprehension (Kushch & Prieto, 2016; Llanes-Coromina et al., 2018), it is currently unclear how it affects *online* discourse comprehension. The current study uses eyetracking to examine how independently manipulating pitch accent and beat gesture affects online contrast interpretation in spoken discourse. In doing so, it provides insight into the individual and combined contributions of these cues to prediction and resolution of contrast in particular, as well as representation and processing of inter-entity relations more generally, in spoken discourse.

Cues to contrast

Two of the most prominent types of pitch accenting in English discourse are presentational pitch accenting (PPA), which is used to convey new, non-contrastive information, and contrastive pitch accenting (CPA), which is used to convey information contrasting with other mentioned information. These two pitch accents differ acoustically; PPA (H* in the ToBI framework) consists of a high pitch target and f0 high in the talker's range, whereas CPA (L+H* in the ToBI framework) consists of an initial low pitch followed by a sharp rise to a high target on the accented syllable (Beckman & Elam, 1997; K. Silverman et al., 1992). Previous work demonstrates that listeners are sensitive to the distinction between PPA and CPA, and this is reflected in both memory for discourse and real-time discourse comprehension. Referents with CPA are remembered better than referents with PPA, particularly when a salient contrasting item must be rejected (e.g., remembering *Scottish* rather than *British;* Fraundorf et al., 2010; 2012; Lee & Fraundorf, 2016; Lee & Snedeker, 2016; Sanford, Sanford, Molle, & Emmott, 2006). Moreover, CPA facilitates rejection of items contrasting with contrastively-accented referents (e.g., *dish* given *antenna*), but not objects with non-contrastive relations to those referents (e.g., *television* given *antenna*; Braun & Tagliapietra, 2010). Lastly, in eyetracking studies, CPA encourages anticipatory looks to objects contrasting with previously-mentioned referents (e.g., after hearing "red scissors," to purple scissors upon hearing "PURPLE"), even when the referent is subsequently revealed to be non-contrastive (e.g., *book*; Ito, Jincho, Minai, Yamane, & Mazuka, 2012; Ito & Speer, 2008; Kurumada, Brown, Bibyk, Pontillo, & Tanenhaus, 2014; Watson, Tanenhaus, & Gunlogson, 2008; Weber, Braun, & Crocker, 2006).

Like pitch accenting, beat gesture is used to emphasize important information in spoken discourse, such that it serves as a "yellow gestural highlighter" (McNeill, 2006). Indeed, both alone and in combination with pitch accenting, beat gesture enhances memory for information conveyed via discourse (Austin & Sweller, 2014; Igualada, Esteve-Gilbert, & Prieto, 2017; Morett, 2014; Vilà-Giménez, Igualada, & Prieto, in press). Moreover, some work indicates that beat gesture enhances memory for contrastive information in particular, especially when it occurs in conjunction with CPA (Kushch & Prieto, 2016; Llanes-Coromina et al., 2018). These findings suggest that beat gesture strengthens memory traces for information in spoken discourse by increasing its salience visually. In addition to their similarity in function, beat gesture and pitch accenting are closely related in timing. Indeed, beat gesture and pitch accenting are temporally aligned on both the sentential and syllabic levels (Esteve-Gilbert & Prieto, 2013; Leonard & Cummins, 2011), suggesting that the temporal relationship between these two cues to prominence is based on prosody.

Considered as a whole, these findings demonstrate that beat gesture and pitch accenting are closely related in timing and meaning. This suggests that beat gesture—as another cue

to prominence—might facilitate online processing of contrast in spoken discourse, as CPA does, Further, the functional similarity of beat gesture and CPA highlights the need to investigate their effects on online contrast processing not only independently but also *conjointly*.

Cue integration

Despite the similar function and close relationship of pitch accenting and beat gesture, relatively little research has examined how the presence—and absence—of these cues in relation to one another affects interpretation of contrast in spoken discourse. In a focus production task in which participants produced beat gesture and/or pitch accenting on one or both referents of a sentence (*Amanda goes to Malta*), referents produced with beat gesture alone had higher vowel formants and were more likely to be perceived as pitch accented than referents unaccompanied by beat gesture (Krahmer & Swerts, 2007). However, in a similar task that involved producing beat gesture in conjunction with contrastive corrections after hearing sentences (*Baba holds the baby? → Mumu holds the baby*), beat gesture production did not affect the articulatory or acoustic correlates of CPA (Roustan & Dohen, 2010). Moreover, in a focus comprehension task in which pitch accenting and beat gesture were independently manipulated in conjunction with the patients of transitive sentences (e.g., *Yesterday, Anna brought fresh lilies to the room*), pitch accenting elicited a larger N400 response when beat gesture was absent than when beat gesture was present, indicating greater inconsistency with predictions or difficulty of semantic integration in the former case (Wang & Chu, 2013). Taken together, these findings indicate that the co-occurrence patterns of pitch accenting and beat gesture affect their interpretation as cues to contrast in spoken discourse.

The influence of beat gesture on interpretation of pitch accenting is also evident in work indicating that information conveyed via spoken discourse accompanied by both beat gesture and pitch accenting is remembered better than the same information accompanied by pitch accenting alone. This result has been observed for memory of focal, non-contrastive information (Igualada, Esteve-Gibert, & Prieto, 2017; Kushch, Igualada, & Prieto, 2018; Morett, 2014; Vilà-Giménez, Igualada, & Prieto, in press) as well as contrastive information (Kushch & Prieto, 2016; Llanes-Coromina et al., 2018; Morett & Fraundorf, under review). With respect to memory for contrastive information, the authors' previous work indicates that, when both cues are manipulated independently in a within-subjects design, contrastive information with CPA is remembered better than contrastive information with PPA when beat gesture is present, but not when beat gesture is absent. When beat gesture is *never* present, however, contrastive information with CPA is remembered better than contrastive information with PPA, consistent with the findings of previous work demonstrating the same effect using similar paradigms presented only in the auditory modality (Fraundorf et al., 2010; 2012; Lee & Fraundorf, 2016; Lee & Snedeker, 2016; Sanford, Sanford, Molle, & Emmott, 2006). Considered as a whole, these findings suggest that beat gesture and CPA influence one another in offline discourse comprehension and memory. However, it is less clear whether and how these cues interact in online discourse processing.

To elucidate how beat gesture and CPA affect contrastive reference resolution in online spoken discourse, we examined differences in fixations to referents accompanied by beat gesture and/or CPA. To do so, we used a modified version of the visual world paradigm that included video. The visual world paradigm has been used successfully to examine how CPA affects online reference resolution (Ito & Speer, 2008; Kurumada et al., 2014; Watson, Tanenhaus, & Gunlogson, 2008), as well as how representational gesture is integrated with speech online (L. B. Silverman, Bennetto, Campana, & Tanenhaus, 2010). Based on these studies and the related work discussed above, we predicted that beat gesture and CPA would affect online reference resolution. Specifically, we predicted that, when referents contrasted only in color (e.g., *blue triangle* and *red triangle*), the presence of beat gesture alongside the color word would facilitate reference resolution, particularly in conjunction with CPA. By comparison, we predicted that when referents differed in both color and shape (e.g., *blue square* and *red triangle*), the presence of beat gesture alongside the color word would misleadingly suggest a color contrast and hinder reference resolution, particularly in conjunction with CPA.

Methods

Participants

Forty adult native English speakers (age range: 18-35 years; 29 females, 11 males) were recruited to participate in this study on a paid basis. All participants had normal hearing and normal or corrected-to-normal vision and were not colorblind. Additionally, participants were screened for factors affecting eye movements (e.g., psychiatric and neurological disorders, recreational drug use).

Materials

A total of 672 referring expressions conveying simple instructions were audio recorded (see 1a-2b for examples; 32 practice, 640 experimental). In both practice and experimental trials, half of referring expressions provided context, with standard PPA on both color and shape words. The other half of referring expressions provided continuation, consisting of half critical and half filler trials. In critical trials, the color word always differed from that of the preceding context referring expression, and the shape word was either the same (color-contrast; 1a) or different (both-contrast; 1b). In both types of critical trials, pitch accenting was manipulated by splicing color words with CPA or PPA into identical carrier sentences (in which original color and shape words had PPA) to control acoustic realization of the rest of the referring expression. Filler trials were created to represent the other possibilities, in which the color word was the same as that of the preceding context referring expression and the shape word either differed (shape-contrast; 2c) or was the same (no-contrast; 2d). In these trials, pitch accent was always felicitous, such that shape words in shape-contrast referring expressions always had CPA and shape words in no-

contrast referring expressions always had PPA. Sentences in filler trials were recorded wholesale and were not spliced.

1a. *Color-contrast:* Click on the blue triangle → red triangle.
1b. *Both-contrast:* Click on the blue square → red triangle.
2a. *Shape-contrast:* Click on the red square → red triangle.
2b. *No-contrast:* Click on the red triangle → red triangle.

840 videos of a talker producing the sentences described above were recorded to accompany audio recordings. 40 of these videos were used for practice trials, and 800 were used for experimental trials. 336 of these videos, which accompanied context sentences, did not contain beat gestures. In the other 504 videos, which accompanied continuation referring expressions, beat gesture was either present or absent alongside the color word (for critical trials) or shape word (for filler trials). Two videos were recorded to accompany each critical referring expression. In one of these videos, beat gesture was present alongside color words; in the other, beat gesture was absent. Videos recorded to accompany filler trials maintained the association between beat gesture and CPA present in natural speech; in videos accompanying shape-contrast referring expressions), beat gesture occurred alongside CPA-accented shape words, whereas beat gesture was absent from videos accompanying PPA-accented no-contrast referring expressions. A within-participants design was used such that each participant received all combinations of contrast type, beat gesture, and pitch accenting; however, combinations for individual trials were counterbalanced across participants (see Table 1 for experimental design summary). All videos were recorded separately from audio and were aligned temporally with it in post-production. Because beat gestures were produced with one hand, consisting of a single downward stroke with the palm oriented upward, horizontally-flipped duplicates were created for all videos in post-production.

A total of 64 objects (8 colors x 8 shapes) were created for inclusion in arrays accompanying audio and video stimuli. Videos were presented centrally with a circular mask, with objects positioned equidistantly (see Fig. 1). Locations in which objects appeared were counterbalanced to control for contingencies between them and beat gesture orientation.

Table 1: Experimental design (excluding practice trials).

Type	Contrast	Accent	Gesture	Trials
Critical	Color	CPA	Beat	20
Critical	Color	No CPA	Beat	20
Critical	Color	CPA	None	20
Critical	Color	No CPA	None	20
Critical	Both	CPA	Beat	20
Critical	Both	No CPA	Beat	20
Critical	Both	CPA	No Beat	20
Critical	Both	No CPA	No Beat	20
Filler	Shape	CPA	Beat	40
Filler	None	No CPA	None	40

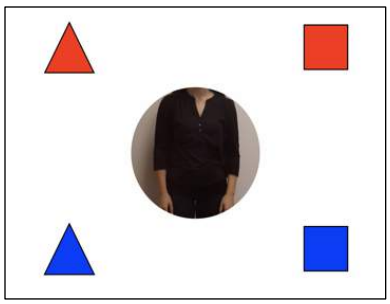

Figure 1: Schematic of screen configuration.

Procedure

Fixation data was collected remotely from the right eye at a 500 Hz sampling rate using an EyeLink 1000 eyetracker. Before beginning the experimental task, participants were seated 55-56 cm from the screen (35° 55' 0.32" visual angle). Gaze was calibrated to within 0.5° of visual angle using 13 points of reference. Drift checks and recalibrations were performed between experimental trial blocks.

At the beginning of the experimental task, participants were told that its objective was to test their ability to follow instructions. Participants were told to respond to all instructions issued in the paradigm by clicking on the appropriate object. The experiment was programmed such that participants who clicked on the wrong object were instructed to click on the correct object to proceed. However, all responses to critical referring expressions were correct. This was not surprising given that the task was simple and straightforward, as is characteristic of visual world tasks (Huettig, Rommers, & Meyer, 2011; Salverda, Brown, & Tanenhaus, 2011), and our intent was to assess the online processing of correctly-understood referring expressions.

To become familiar with the experimental task, participants first completed a practice phase consisting of 8 trials. Participants then proceeded to the experimental phase, which consisted of four blocks of 40 trials each. In both phases, critical and filler trials were randomly interleaved. In each trial, an array of objects appeared and a video began playing, and the context referring expression was presented aurally after a 200 ms delay. This configuration ensured that the apex of the beat gesture occurred 200 ms prior to the onset of the corresponding word, which is consistent with the timing of gesture production relative to speech in natural discourse (Morrel-Samuels & Krauss, 1992) as well as perceptual biases for the timing of beat gesture relative to speech (Leonard & Cummins, 2011). Following a correct response, the video disappeared and was replaced by a gray circular placeholder for 1000 ms while the object array remained on screen. Subsequently, the sequence repeated with the continuation referring expression and corresponding video. Following a correct response, the trial ended and, after a blank screen was displayed for 1000 ms, a new trial began.

Results

We examined fixations during two periods of the critical referring expression: *color word* (color word onset to shape word onset) and *shape word* (shape word onset to response

onset). To account for saccade planning, each period was shifted ahead by 200 ms. Two interest areas relevant to the main research question were defined: the *target object* referred to by the critical referring expression, and the *competitor object* that is temporarily consistent with the unfolding linguistic input. In color-contrast trials, in which the target object contrasted with the referent of the context referring expression only in color, the competitor object differed in both color and shape; in both-contrast trials, in which the target object differed from the referent of the context referring expression in both color and shape, the competitor object contrasted only in color. In addition, the *video* interest area was defined to confirm that participants were watching the video. Participants fixated the video more than target and competitor objects combined during both the color word (77.65% of fixations) and shape word (52.19% of fixations) interest periods.

To account for non-independence of samples, we summed fixations within each interest period in each trial and took the empirical logit (Barr, 2008). Because we were interested in how beat gesture and CPA facilitated and hindered reference resolution, empirical logit values were computed for fixations to target and competitor objects separately. These values were then entered into linear mixed effects models, which were fit using the *lme4* R package (Bates, Mächler, Bolker, & Walker, 2015) and evaluated via null hypothesis statistical testing using the *lmerTest* R package (Kuznetsova, Brockhoff, & Christensen, 2017). Each model implemented the maximal random effect structure permitting convergence, with beat gesture, CPA, contrast, and their interactions as fixed effects and participant and trial as random effects. To account for any effects of spatial orientation of the gesture, we also included gesture orientation and target object side as control variables.

Color Word Interest Period

For target fixations, we observed a main effect of contrast, indicating a higher likelihood of fixating target objects during color-contrast (M = -0.11, SD = 0.55) than both-difference critical referring expressions (M = -0.17, SD = 0.55; t = -3.57, p < .001); however, no interactions between contrast and either accent or gesture were observed. For competitor fixations, no main effect of contrast was observed (color: M = -0.16, SD = 0.54; both: M = -0.09, SD = 0.57; t = 1.62, p = .11). Moreover, there were no main effects or interactions of gesture orientation and target side for target or competitor fixations. Thus, although these results suggest a baseline bias towards contrastive interpretation of critical referring expressions, neither beat gesture nor CPA enhanced resolution of these expressions prior to disambiguation.

Shape Word Interest Period

We observed significant two-way interactions between orientation and target side for both target and competitor fixations (target: B = 0.48, SE = 0.08, t = 6.32, p < .001; competitor: B = -0.10, SE = 0.04, t = -2.58, p = .01), indicating a baseline tendency to fixate target objects and not to fixate competitor objects appearing on the side of the array congruent with the orientation of accompanying beat gesture.

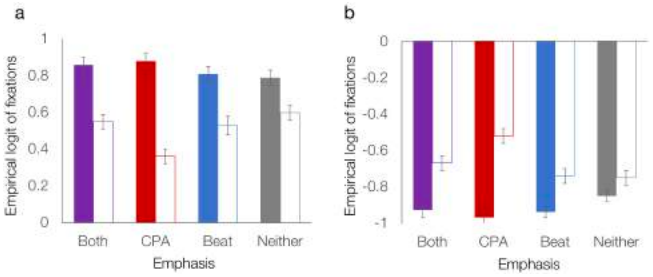

Figure 2: Fixations on (a) target and (b) competitor objects during the shape word period for color-contrast (filled) and both-difference (outlined) critical referring expressions by prominence cue (CPA, Beat, Both, Neither).

We also observed a continuation of the baseline color-contrast preference: There was a higher likelihood of fixating target objects and a lower likelihood of fixating competitor objects during color-contrast than both-difference critical referring expressions. Critically, this preference was qualified by interactions with beat gesture for target fixations (B = 0.13, SE = 0.06, t = 2.18, p = .03) and CPA for competitor fixations (B = 0.26, SE = 0.10, t = 2.51, p = .02; see Fig. 2). A simple-effect analysis revealed a greater likelihood of fixating target objects during color-contrast than during both-difference critical referring expressions when beat gesture was present (color: M = 0.84, SD = 0.80; both: M = 0.54, SD = 0.87; t = -2.01, p = .001) than when it was absent (color: M = 0.83, SD = 0.75; both: M = 0.48, SD = 0.86; t = -3.55, p = .047), indicating that beat gesture facilitated online resolution of contrastive critical referring expressions. Another simple-effect analysis revealed a greater likelihood of fixating competitor objects during both-difference than color-contrast critical referring expressions when CPA was present (both: M = -0.59, SD = 0.76; color: M = -0.95, SD = 0.76; t = 4.49, p < .001) than when it was absent (both: M = -0.75, SD = 0.84; color: M = -0.89, SD = 0.69; t < 1), indicating that CPA contributed to incorrect contrastive interpretation of non-contrastive critical referring expressions. Together, these results indicate that beat gesture and CPA serve as cues to contrast during online reference resolution in spoken discourse. Further, the absence of any significant Gesture x Accent interactions indicates that the effects of these cues are additive rather than interactive.

Discussion

Consistent with our predictions, the results indicate that the effects of beat gesture and CPA vary by contrast type during online reference resolution in spoken discourse. Specifically, beat gesture encouraged fixations on target objects during resolution of color-contrast critical referring expressions, confirming that beat gesture can convey contrast effectively. Moreover, CPA encouraged fixations on competitor objects during resolution of both-contrast critical referring expressions, indicating that it acted as a "garden path" resulting in an incorrect contrastive interpretation. Together, these results indicate that beat gesture and CPA each encourage contrastive resolution of referring expressions during online spoken discourse processing. By providing the

first evidence that beat gesture facilitates online resolution of contrastive referring expressions, the results of the current study build upon previous findings that beat gesture (Kushch & Prieto, 2016; Llanes-Coromina et al., 2018; Morett & Fraundorf, under review; Morett, Roche, Fraundorf, & McPartland, 2018) and CPA (Fraundorf et al., 2010; 2012; Lee & Fraundorf, 2016; Lee & Snedeker, 2016; Sanford, Sanford, Molle, & Emmott, 2006) enhance processing and memory of contrastive information in spoken discourse.

Considered in conjunction with the separate interactions with contrast discussed above, the lack of significant interactions between beat gesture and CPA indicates that these cues exert independent, additive effects on online contrastive reference resolution. This finding differs from work on discourse memory, which has shown interactive effects of beat gesture and CPA (Kushch & Prieto, 2016; Llanes-Coromina et al., 2018; Morett & Fraundorf, under review). Although the reasons for this difference are not entirely clear, one possibility is that separate effects of these cues on contrastive information processing in spoken discourse interact during storage or retrieval, leading to the interactive effects observed in studies of offline processing. Another possibility is that effects of these cues that appear separate in the short-term become interactive in the long-term. Future research should distinguish between these possibilities by introducing a delay during which recollection either is or is not required for discourses containing contrastive information in which these cues are varied.

It is worth noting that beat gesture and CPA affected target and competitor object fixations during the shape word but not the color word period, indicating that these cues affect resolution—but not anticipation—of referents. The timing of the effects of these cues is consistent with some previous work examining the effect of CPA on reference resolution (Ito & Speer, 2008), but is inconsistent with other work examining this same phenomenon (Kurumada et al., 2014; Watson, Tanenhaus, & Gunlogson, 2008) as well as work examining the effect of representational gesture on reference resolution (L. B. Silverman et al., 2010). While the reasons for the absence of effects of beat gesture and CPA on reference anticipation in the current study are not entirely clear, one possibility is that these cues may have elicited a processing cost, increasing reference resolution latency. This possibility is consistent with pupillometry data from the current study (Morett, Roche, Fraundorf, & McPartland, 2018), which indicates that the combination of beat gesture and CPA increases cognitive load during reference resolution. Alternatively, fixations to the video may have persisted during color word processing, reducing fixations to target and competitor objects. This possibility is consistent with the results of an analysis of target fixations during the color word period in which the video was included as an interest area, in which the significant main effect of contrast observed during this interest period in the model excluding the video interest area was absent. Thus, both cognitive load and persistence of fixations on the video may have contributed to the timing of the effects of beat gesture and CPA on online reference resolution in the current study.

In conclusion, the results of the current study indicate that beat gesture and CPA exert independent, additive effects that facilitate online contrastive reference resolution during spoken discourse processing. As such, they provide the first evidence that beat gesture is interpreted as a cue to contrast during online spoken discourse comprehension.

A Mechanistic Account of Constraints on Control-Dependent Processing: Shared Representation, Conflict and Persistence

Sebastian Musslick[1,*], **and Jonathan D. Cohen**[1]

Abstract

One of the most fundamental and striking limitations of human cognitive function is the constraint on the number of control-dependent processes that can be executed simultaneously. However, the sources of this capacity constraint remain largely unexplored. Previous work has attributed the constraints on control-dependent processing to the sharing of representations between tasks in neural systems. Here, we examine how shared representations interact with two other factors in producing constraints on control-dependent processing. We first demonstrate that the detrimental effects of shared representations on multitasking performance are contingent on the amount of conflict that is induced by the tasks that share representations. We then examine how the persistence of shared representations between tasks affects processing interference during serial task execution. Finally, we discuss how this set of mechanisms can account for various phenomena in neural architectures, including the psychological refractory period, task switch costs, as well as constraints on cognitive control.

Keywords: cognitive control; capacity constraint; dual-tasking; psychological refractory period; neural networks

Introduction

Despite the powerful abilities that cognitive control affords, and its ubiquitous engagement in daily life (e.g., mentally planning a grocery list, or navigating a new route to work), the capacity for controlled processing appears to be strikingly limited (e.g., the inability to plan and navigate at once). This limitation has been literally paradigmatic in defining cognitive control: it has been used to distinguish it from automatic processing (Posner & Snyder, 1975; Shiffrin & Schneider, 1977), and is used universally to operationalize it in the laboratory (i.e., diagnose it experimentally) in the form of dual task interference (Meyer & Kieras, 1997a; Welford, 1952).

A widely accepted view is that constraints in the capacity for control-dependent processing arise from structural limitations inherent to the control system itself. One of the earliest, and still most influential views, is that cognitive control relies on a centralized, limited capacity mechanism that imposes a seriality constraint on processing (Posner & Snyder, 1975; Shiffrin & Schneider, 1977). However, alternative ("multiple-resource") accounts (Allport, 1980; Meyer & Kieras, 1997a; Navon & Gopher, 1979; Salvucci & Taatgen, 2008) have suggested that the capacity constraints reflect properties of the processes that are being controlled. This proposes that control-demanding tasks, like any others, rely on a constellation of "local" resources; that is, task-specific representations, and that the inability to perform more than one task at a time may reflect the conflict that arises when the tasks involved demand that the same set of representations be used for different purposes, rather than reliance on a single centralized control mechanism. From this perspective, the very purpose of cognitive control is to prevent interference by limiting the number of task processes that make use of shared representations (Cohen, Dunbar, & McClelland, 1990; Botvinick, Braver, Barch, Carter, & Cohen, 2001).

One may argue that the constraints that shared representations between tasks impose on multitasking are negligibly small in a processing system as large as the human brain. However, simulation studies (Feng, Schwemmer, Gershman, & Cohen, 2014), followed by analytic work (Musslick et al., 2016) have studied the multitasking capability of two-layer neural networks as a function of the sharing of representations among tasks and found that the multitasking capability of a network drops precipitously with an increase in shared representations, and is virtually invariant to network size. Moreover, neural architectures appear subject to a tradeoff between learning efficiency and generalization that is promoted through the use of shared task representations, on the one hand, and processing efficiency and multitasking capability that is achieved through the separation of task representations, on the other hand (Musslick et al., 2017). This suggests that limitations in multitasking may reflect a preference of the neural system to learn tasks more quickly (Musslick et al., 2017; Sagiv, Musslick, Niv, & Cohen, 2018).

The studies above were based on the assumption that shared representations between tasks always cause interference. However, the amount of processing interference received by a single task has been shown to depend on the processing strength (automaticity) of the interfering task (Cohen et al., 1990; MacLeod & Dunbar, 1988). Another assumption made by these neural network studies is that multitasking can only be achieved by processing tasks concurrently. However, this assumption does not capture processing interference observed in the sequential execution of multiple tasks (Pashler, 1984; Welford, 1952), task switching effects (Alport, Styles, & Hsieh, 1994), nor multitasking behavior along a continuum from pure parallelism, through rapid task switching, to pure sequential processing (Salvucci, Taatgen, & Borst, 2009) .

In this work, we examine the interactive effect of (a) shared representations between tasks, (b) the conflict induced by

shared representations and (c) the persistence of representations on the constraints on control-dependent processing in two-layered, feed-forward, non-linear networks. Our findings suggest that the detrimental effect of shared representations on multitasking interference is only present if the tasks that share representations induce a sufficient amount of conflict between each other, and that persistence of those representations can lead to delays in the serial execution of two tasks. Finally, we discuss how this set of mechanisms may provide a unifying account of various cognitive phenomena in neural architectures, including the psychological refractory period, task switch costs, as well as constraints on cognitive control.

Neural Network Model

For the simulations described in the paper we focus on a network architecture that has been used to simulate a wide array of empirical findings concerning human performance (e.g. Cohen et al., 1990; Gilbert & Shallice, 2002), including limitations in multitasking (Musslick et al., 2016). In this section we lay out the architecture of this network, its processing, as well as the task environments used to train it.

Network Architecture and Processing

The network consisted of the following layers (Figure 1): an input layer with two partitions, one of which represented the current stimulus (nine units) and projected to an associative layer, and another that encoded the current task (five units) and projected to both the associative and output layers; an associative layer (100 units) that projected to the output layer; and an output layer (nine units) that represented the network's response. Input units were grouped by the stimulus dimensions relevant to performing each task (three units per dimension), and used a one-hot encoding (i.e., a single unit in a stimulus dimension was used to represent the current stimulus feature; the current stimulus feature was clamped to 1 and all others were clamped to 0). The task input units used a similar one-hot encoding, with one unit used to represent each task. Output units were grouped by response dimensions, and trained (see below) using a one-hot encoding for each response within a dimension. Each response dimension of the output layer projected to a leaky competitive accumulator (LCA, Usher & McClelland, 2001) layer (described below), which determined the response for that dimension.

The network was instructed to perform a given task by specifying the current stimulus and task to be performed in the input layer. These stimulus and task input values were multiplied by a matrix of connection weights from each partition of the input layer to a shared associative layer, and then passed through a logistic function to determine the pattern of activity over the units in the associative layer. This pattern was then used (together with the set of direct projections from the task layer) to determine the pattern of activity over the output layer.

The final response within a given response dimension of the network was determined by an LCA (Usher & McClelland, 2001) layer, implementing the assumption that the network could only provide one response per dimension (e.g. the network cannot say RED and GREEN at the same time). One LCA layer was assigned to each response dimension k, which was comprised of a set of units r_i that received as their input the activity of corresponding units in that response dimension. The winning response was determined by the accumulation of activity by each LCA unit, and the competition among them, the dynamics of which were given by

$$dr_i = [y_o - \lambda r_i + \alpha f(r_i) - \beta \sum_{j \neq i} f(r_j)] \frac{dt}{\tau} + \xi_i \sqrt{\frac{dt}{\tau}} \qquad (1)$$

where y_o is the activity of the corresponding response unit in response dimension k, λ is the decay rate of r_i, α is the recurrent excitation weight of r_i, β is the inhibition weight between LCA units, τ is the rate constant, and ξ is noise sampled from a Gaussian distribution with zero mean and standard deviation σ. The activity of each LCA response unit was lower bounded by zero via a threshold such that $f(r_i) = r_i$ for $r_i \geq 0$ and $f(r_i) = 0$ for $r < 0$. The response for response dimension k was determined by the unit within the corresponding LCA layer, the activity $f(r_i)$ of which first reached threshold z. The accuracy for each response dimension k corresponded to the probability of generating the correct response for that dimension $P(\text{correct})_k$ across 100 simulations of the LCA, and the reaction time (RT) for that dimension was the average number of time steps required for the response to reach threshold, scaled by a factor of 0.1. The following parameter values were used for all reported simulations: $\lambda = 0.4$, $\alpha = 0.2$, $\beta = 0.2$, $\sigma = 0.1$, and z for each LCA layer was chosen as the threshold that maximizes reward rate ($P(\text{correct})_k / (\text{ITI} + \text{RT}_k)$) for that dimension, where ITI corresponds to an inter-trial interval of 1s.

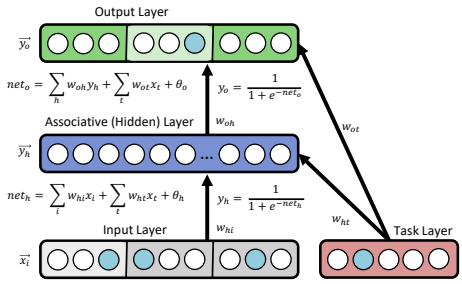

Figure 1: Feedforward neural network used in simulations. The input layer is composed of stimulus vector $\overrightarrow{x_i}$ and task vector $\overrightarrow{x_t}$. The activity of each element in the associative layer $y_h \in \overrightarrow{y_h}$ is determined by all elements x_i and x_t, and their respective weights w_{hi} and w_{ht} to y_h. Similarly, the activity of each output unit $y_o \in \overrightarrow{y_o}$ is determined by all elements y_h and x_t, and their respective weights w_{oh} and w_{ot} to y_o. A bias of $\theta = -2$ is added to the net input of all units y_h and y_o. Blue shades in the input and output units (circles) correspond to unit values of 1 and illustrate an example input pattern with its respective output pattern: The second task requires the network to map the vector of values in the first three feature units to one out of three output units (white shade).

Task Environment

Stimulus input units are structured according to stimulus dimensions (subvectors of the stimulus pattern), each of which was comprised of three feature units with only one feature unit activated per dimension. A task was defined as a mapping from the three stimulus features of a task-relevant stimulus dimension to three output units of a task-specific response dimension, so that only one of the three relevant output units was permitted to be active (see Fig. 1). For each simulation we considered the tasks A-E shown in Figure 2. Tasks A, B and C each map a different stimulus dimension to a different response dimension. Task D shares a stimulus dimension with Task A and shares a response dimension with Task B. Conversely, Task E shares a stimulus dimension with Task B and shares a response dimension with Task A.

Networks were initialized with a set of small random weights and then trained using the backpropagation algorithm (Rumelhart, Hinton, & Williams, 1986) to produce the task-specified response for each stimulus in each task, while suppressing all other responses (both within the task-relevant output dimension, and all task-irrelevant output dimensions). The network was trained in epochs, with each epoch containing all training patterns in random order. The error term used for training was the mean squared error (MSE) of the pattern of activities in the output layer with respect to the correct (task-determined) output pattern. The weights of the network were adjusted with a learning rate of 0.3 after presenting each training pattern within an epoch (online training) until the network reached an MSE of 0.001.

Shared Representation and Conflict

Multitasking limitations have been attributed to shared representations between tasks as they engender interference. However, the amount of interference introduced by shared representation is known to depend on how much conflict they transmit (Cohen et al., 1990; MacLeod & Dunbar, 1988). To illustrate this, consider the simultaneous execution of Tasks A and B depicted in Figure 2. The network can execute a task by limiting processing to the representations involved for that task. For instance, the network can execute Task A by allocating control to the representation that encodes the task-relevant stimulus features for Task A in the associative layer and to the task-relevant response units for Task A in the output layer. Executing Tasks A & B simultaneously would require allocating control to the representations for both tasks in both layers. However, allocating control to Task A would engage Task D if the two tasks share a representation at the associative layer. Once Task D is engaged, it interferes with Task B at the output layer. Similarly, allocating control to a shared associative representation between Tasks B and E would introduce interference with Task A. Shared representations between Tasks A and D, as well as between Tasks B and E therefore introduce a functional dependence between Tasks A and B (Figure 2; Musslick et al., 2016). In contrast, no such interference is expected when the network performs Tasks A & C at the same time.

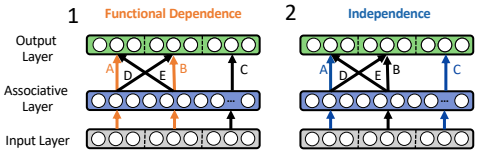

Figure 2: Illustration of dependencies between tasks. (1) Tasks A & B are considered functionally dependent due to shared representations with Tasks D and E, whereas (2) Tasks A & C are considered independent (see text).

In the example above, the amount of conflict introduced by Tasks D and E should decrease if the processing strength of both tasks is weak compared to the processing strength of Tasks A and B. Previous studies have demonstrated that extensive training on a task increases its processing strength which can induce greater conflict with other tasks (Cohen et al., 1990; MacLeod & Dunbar, 1988). This suggests a dilemma: While training on Tasks D and E should improve performance for each individual task, it should also lead to greater interference when dual-tasking seemingly unrelated Tasks A & B. However, dual-tasking performance for the two independent Tasks A & C should be unaffected. Here, we investigated the tradeoff between improvements in single task performance for Tasks D and E, on the one hand, and impairments in dual-task performance for Tasks A & B, as well as Tasks A & C, on the other hand, by varying the amount of training that a network receives for Tasks D and E. We were particularly interested in the amount of training that is required to cause impairments in dual-tasking performance.

We started by initializing 20 networks per training condition. In each condition, we sampled 100 patterns for each of the three Tasks A, B and C per training epoch. However, we varied the number of sampled training patterns for Tasks D and E from 0 (0% task strength) to 150 (150% task strength) across conditions. We then trained every network until it reached performance criterion for Tasks A, B and C. After training, we evaluated whether the network learned shared representations between Tasks A and D, and Tasks B and E in the associative layer of the network. In order to assess the similarity of learned task representations we focus our analysis on the weights from the task units to the associative layer, insofar as these reflect the computations carried out by the network required to perform each task. For a given pair of tasks we compute the learned representational similarity between them as the Pearson correlation of their weight vectors to the associative layer. Finally, we assessed the multitasking accuracy for performing Tasks A & B and the multitasking accuracy for performing Tasks A & C, as well as the single task accuracies of Task D and Task E.

Figure 3.1 shows the correlation between learned task representations in the associative layer of the network, averaged across all networks. As expected, Task A developed a shared representation with Task D in the associative layer since both tasks rely on the same set of stimulus features, as is the case

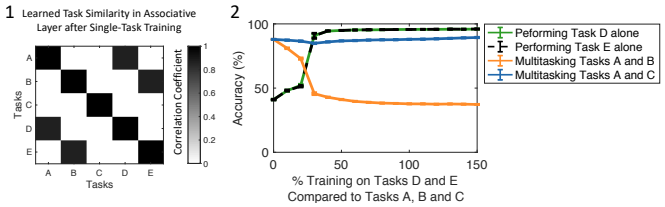

Figure 3: Effects of shared representation and conflict. (1) Average correlations between learned task representations in the associative layer. (2) Multitasking performance for Tasks A & B and Tasks A & C as a function of training on Tasks D and E. Error bars show the standard error of the mean across 20 simulated networks.

for Tasks B and E. Critically, dual-tasking performance for Tasks A & B decreased with the amount of training on Task D and Task E while dual-tasking performance for Tasks A & C was virtually unaffected by the training condition. Even small amounts of training on Tasks D & E (30%) improve performance on these tasks at the expense of impaired multitasking performance of Tasks A & B. Altogether, these results suggest that shared representations alone do not impose constraints on control-dependent processing, but they do so in combination with conflict.

Shared Representation and Persistence

In the network model described above, limitations in multitasking can be circumvented by executing the individual tasks in series. However, a large body of evidence suggests that humans are subject to dual-task interference, even if they execute two tasks one after another (Welford, 1952). To illustrate this, consider the serial execution of two tasks in the psychological response period (PRP) paradigm (Figure 4). A trial in this paradigm begins with the presentation of a stimulus relevant to the first task, followed by a stimulus for the second task. The time between the onset of the first and second stimuli is referred to as stimulus onset asynchrony (SOA) and serves as an independent variable. Participants tend to respond slower to the second stimulus when the SOA is reduced (Welford, 1952). The additional amount of time that it takes to respond to the second task in the presence of a short SOA is referred to as the PRP and serves as the dependent variable.

Symbolic architectures explain the PRP effect in terms of processing bottlenecks that delay execution of the second task while the first task is still being executed (Meyer & Kieras, 1997a; Navon & Gopher, 1979; Salvucci & Taatgen, 2008; Pashler, 1994). While some accounts, such as the EPIC model (Meyer & Kieras, 1997a, 1997b) or the ACT-R/PM model (Byrne & Anderson, 2001) attribute the PRP partly to structural limitations in perceptual processing or motor execution, other accounts claim that the bottleneck is located at a "central" processing stage for response selection (Pashler, 1994) that is preceded by sensory processes and followed by processes for motor execution. However, to date, there is no account of this effect in neural network architectures. For instance, in the feed-forward model considered above, tasks can either be executed concurrently, with the risk of multitasking interference, or in serial, without any risk of interference.

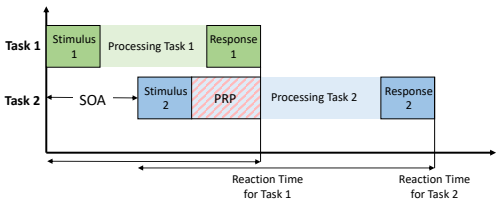

Figure 4: Psychological refractory period paradigm.

A crucial computational feature of neural systems is the integration of information over time, through persisting patterns of activity. Persistence characteristics can account for sequential processing of stimuli (Elman, 1990), working memory (Miyake & Shah, 1999), reconfiguration costs associated with switching tasks (Gilbert & Shallice, 2002) and many other cognitive phenomena. Persistence may also provide a mechanism for how the detrimental effects of shared representation on dual-task interference extend to the sequential execution of two tasks: the more a shared representation of a previously executed task persists in time, the more it may interfere with a subsequent task.

Here, we examine how shared representations interact with the persistence of activity in producing the PRP effect. To examine the PRP effect as a function of both, we first trained 10 networks on Tasks A-E until each network reached the performance criterion across all tasks. After training, we introduced persistence[1] in the computation of the net input of a unit i in the associative and output layers,

$$\overline{net}_i^T = (1-p)\cdot net_i^T + p\cdot \overline{net}_i^{T-1}, \qquad (2)$$

where $\overline{net}_i^{T-1}$ corresponds to the time averaged net input from the previous time step, net_i^T corresponds to the instantaneous net input and p determines how much the time averaged net input of the current time step $\overline{net}_i^T$ depends on the time averaged net input from the previous time step. Thus, the higher p, the longer activity persists over time. For each network, we considered different values for $p \in \{0, 0.5, 0.8, 0.9\}$.

We then simulated the PRP paradigm for two pairs of tasks, A & B, as well as A & C. As demonstrated in the previous section, Tasks A & B are functionally dependent and interfere with each other when executed simultaneously whereas Tasks A & C are independent and interfere less. In both cases, the network was instructed to perform Task A second. Thus, we first presented the network with a feature from the stimulus dimension relevant to Task B or Task C, by activating the corresponding unit in the input layer and by keeping all other input units inactivated. After a number of time steps (determined by the SOA), we presented the network with a feature from the stimulus dimension relevant to the second task (Task A), by activating a unit in the input dimension relevant to that task while the stimulus feature for the first task

[1]Note that persistence in neural networks is typically implemented in the form of recurrent connections between the processing units. Here, we chose, for simplicity, to implement persistence by explicitly integrating processed information over time.

(Task B or Task C) was still present. PRP studies commonly instruct participants to give priority to the first task (Koch, Poljac, Müller, & Kiesel, 2018). We therefore activated the task layer unit for the first task at the beginning of each trial[2] and then determined the optimal onset of the task layer unit for the second task such that the joint reward rate for both tasks is maximized,

$$\text{Reward Rate} = \frac{P(\text{correct})_{\text{first task}} P(\text{correct})_{\text{second task}}}{(\text{ITI} + \text{RT}_{total})} \quad (3)$$

where $P(\text{correct})_{\text{first task}}, P(\text{correct})_{\text{second task}}$ correspond to the accuracies of the first and the second task, respectively, ITI corresponds to an inter-trial interval of 1s , and RT_{total} is the reaction time of the last executed task, measured from the onset of the trial. We then assessed RTs for the first (Task B or Task C) and the second task (Task A) as a function of SOA, by varying the SOA from 1s to 8s in steps of 1s. Finally, we repeated the same analysis for 10 networks that were trained, within each epoch, on 100 patterns of dual-tasking Tasks A & B, as well as 100 patterns for dual-tasking Tasks A & C, in addition to being trained to perform all single tasks as described above. As in the previous section, we also assessed learned representational similarity between tasks as the Pearson correlation of their weight vectors to the associative layer.

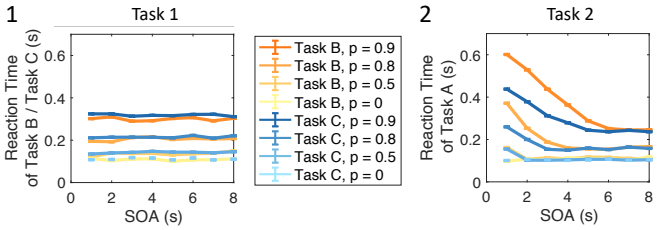

Figure 5: RTs of (1) the first and (2) the second task in the PRP paradigm as a function of persistence p and task. Error bars show the standard error of the mean across 10 simulated networks trained only on single tasks.

Simulation results indicate that higher persistence prolongs the reaction time for both the first and the second task (Figure 5). Moreover, the model replicates the PRP effect, showing a delay of the second task as a function of SOA (Figure 5.2). The delay in RT is overall higher after executing Task B compared to Task C, indicating that Task B interferes more with the subsequently executed Task A. This observation matches simulation results from the previous section, indicating that shared representations between Tasks A & D, as well as Tasks B & E lead to processing interference. However, shorter SOAs still affected RTs for Task A after executing Task C, indicating that there is processing interference between Tasks A & C that is not captured by shared representations in the associative layer alone. Interestingly, higher persistence amplifies the RT difference between Task A followed by a functionally dependent task and Task A followed by an independent task. In line with prior observations (Marill, 1957; Pashler, 1994), the RT of the first task remained unaffected by the SOA, irrespective of whether the first task was functionally dependent or independent of the second task. This observation reflects the embedded strategy of the model to first execute the task associated with the first stimulus. Finally, we observed that dual-task training reduces the amount of shared representation between tasks that rely on a common stimulus dimension (Tasks A and D, as well as Tasks B and E; see Figure 6.1), compared to training the network on single tasks only (cf. Figure 3.1). In addition, training on both dual-task conditions yielded significant reductions in the PRP effect despite high levels of persistence (Figure 6.2). For intermediate levels of persistence ($p \leq 0.5$), dual-task training eliminated the PRP entirely. Such "virtually perfect time sharing" has been observed by Schumacher et al. (2001) after training participants extensively on dual-tasking.

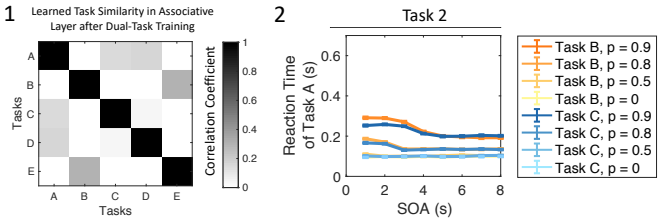

Figure 6: Effects of dual-task training. (1) Average correlations between learned task representations in the associative layer. (2) RT of the second task in the PRP paradigm as a function of persistence p and task. Error bars show the standard error of the mean across 10 simulated networks.

General Discussion and Conclusion

One of the most fundamental limitations of human cognitive behavior is the constraint on the number of control-dependent processes that can be executed simultaneously (Posner & Snyder, 1975; Shiffrin & Schneider, 1977). The multiple-resource hypothesis explains such limitations in terms of shared representations that prevent the interference-free execution of multiple control-demanding tasks (Allport, 1980; Navon & Gopher, 1979). While recent neural network studies provided computational and analytic arguments for the detrimental effects of shared representations on the capacity for control-dependent processing, they were either based on the assumption that shared representations always induce conflict or that tasks can only be executed concurrently (Alon et al., 2017; Feng et al., 2014; Musslick et al., 2016).

In this work, we examined the interactive effect of shared representations and two other factors on limitations associated with control-dependent processing. We first demonstrated that the detrimental effect of shared representations on multitasking interference is present only if the tasks that share representations induce a sufficient amount of conflict. This observation extends previous work, showing that performance of single tasks decreases with the amount of conflict induced by a competing task (Cohen et al., 1990; MacLeod & Dunbar, 1988). In both cases, the conflict induced by the competing task scales with the amount of training on that

[2]We assumed that the task layer unit for the first task becomes deactivated as soon as the model responded to the first stimulus.

task. This suggests that training on a task can improve its performance but may come at the cost of inducing interference with another task that shares a representation.

We also demonstrated that the limitations induced by shared representations can extend to situations in which tasks are executed sequentially. The detrimental effect of shared representation scales with the amount of persistence in the network: the more the representation of a task persists in time, the longer it interferes with other tasks. These observations provide a mechanistic interpretation of the psychological refractory period in neural systems. Symbolic architectures explain this effect in terms of a shared resource that can only be accessed by one task at a time (Anderson, 2013; Navon & Gopher, 1979; Meyer & Kieras, 1997a; Salvucci & Taatgen, 2008). In contrast, the neural network model suggests that tasks may always be processed in parallel but that the outcome of a task process may be strategically delayed to prevent interference from persisting representations of previously executed tasks, yielding a PRP.

The neural network model may also have virtue in explaining findings that central processing bottleneck models struggled to explain. For instance, the second task in the PRP paradigm can be prolonged (relative to single task execution) even if the stimulus for the second task was presented after the participant already responded to the first task (Welford, 1952; Marill, 1957). A central processing bottleneck alone cannot account for a delayed execution of the second task in this situation because a bottleneck should no longer be occupied after executing the first task (Pashler, 1994). The neural network model, however, shows that processing interference induced by shared representation with a previously executed task can persist, irrespective of whether a response for that task has already been generated. Furthermore, modality-specific PRP effects have challenged the notion of a domain-general (amodal) central processing bottleneck: Pairs of tasks with compatible stimulus-response mappings (e.g. a visual-manual task paired with an auditory-vocal task) show greater dual-task interference than two tasks with incompatible stimulus-response mappings (a visual-vocal task paired with an auditory-manual task), lending support to cross-talk models that explain dual-task interference in terms of representational overlap between tasks (Liepelt, Fischer, Frensch, & Schubert, 2011; Hazeltine, Ruthruff, & Remington, 2006). Similarly, our simulation results suggest that functional dependence between tasks induced by representational overlap can lead to higher dual-task interference. Finally, empirical work demonstrated that the PRP can be eliminated with dual-tasking practice, suggesting absence of a central processing bottleneck. (Schumacher et al., 2001). The simulation results presented here suggest that dual-task training may promote the learning of separated, task-dedicated representations that promote interference-free processing.

One of the most robust findings in the cognitive literature is the performance cost associated with the sequential execution of different tasks (Alport et al., 1994). One prominent account of such switch costs is task-set inertia, according to which the task-set of the previously executed task carries over to the next (Alport et al., 1994). Similarly, the findings described here suggest that persistence of task representations lead to a carry over of task interference. The successful sequential execution of two dependent tasks would then afford a temporal switch cost in order to minimize interference-based costs in dual-tasking accuracy. From this perspective, the dependence between tasks induced by shared representation, the amount of conflict, as well as persistence of task representations may all contribute to the performance costs associated with task switches. This suggests that the PRP effect and the costs associated with task switching may originate from the same set of mechanisms in neural systems.

While shared representations may account for limitations in the *number* of control-demanding tasks that can be executed at a time, they do not directly explain limitations in the *amount* of control that can be allocated to a single task (Shenhav et al., 2017). That is, once a commitment has been made to perform a given task (i.e., allocate cognitive control to it), and that precludes the performance of others, then the opportunity cost has already been paid, so why not allocate control maximally to the selected task? Musslick, Jang Jun, Shvartsman, Shenhav, and Cohen (2018) explored the hypothesis that constraints on control intensity (i.e., encoded as cost) reflect, at least in part, an optimal solution to the stability-flexibility dilemma: Allocating more control to a task results in greater activation of its neural representation but also in greater persistence of this activity upon switching to a new task, yielding switch costs. By considering the problem in terms of the parameterization of a nonlinear dynamical system, in which control signals are represented as attractors, Musslick et al. (2018) showed that constraints on the amount of cognitive control allocated to a task can promote cognitive flexibility at the expense of cognitive stability. While this dilemma provides a rationale for why humans should limit the amount of control allocated to a single task it is based on the implicit assumptions that tasks cannot be executed in parallel due to constraints in multitasking capacity and that task representations persist in time. This suggests that both the number of control-demanding tasks that can be executed simultaneously, and the amount of control that can be allocated to a single task may be subject to constraints that arise from (a) the shared use of representation between tasks, (b) the conflict induced by shared representations and (c) persistence of task representations in time.

The effect of stimulus presentation time on bias: A diffusion-model based analysis

Abstract

There are two main types of bias in simple decision tasks, response bias and stimulus bias. Response bias is a starting level of evidence in favor of a biased response, whereas stimulus bias is the evaluation of stimuli in favor of a biased response. Previous research typically dissociates between these two types of bias. Some studies suggest that it can be difficult to induce response bias without stimulus bias (Ratcliff & McKoon, 2008; van Ravenzwaaij, Mulder, Tuerlinckx, & Wagenmakers, 2012). We used a two-alternative forced-choice brightness discrimination task in which we manipulated the presentation length of the stimuli. We analyzed the data with a hierarchical diffusion model. The results show an overall response bias, as well as stimulus bias that increases as stimulus presentation time decreases. We argue that the results suggest a need to revise how stimulus bias is conceptualized through the drift rate parameter of the diffusion model.

Keywords: diffusion model; response bias; stimulus bias; prior bias; dynamic bias; drift criterion

Introduction

Decision bias is an important area of research because it reveals information about the underlying processes that drive decision making, highlighting how different contexts and goals can influence decision-making behaviour in different ways (White & Poldrack, 2014). Simple decision tasks, where individuals are asked multiple choice questions with only two possible responses, are fairly common in the field of decision making. Research has suggested that there are two distinct types of bias in simple decision tasks: response bias and stimulus bias, also known as prior and dynamic bias, respectively (van Ravenzwaaij et al., 2012; White & Poldrack, 2014). Response bias is a preparedness to make a certain response, whereas stimulus bias is an asymmetry in how two stimuli of equal value/magnitude but opposing valences are processed as evidence for their respective responses.

Decision making can be thought of as sampling information from your environment to build support for a response over time. There have been a number of response time models that have been proposed to formalize this concept. One popular model is the diffusion model (Ratcliff, 1978; Ratcliff & Rouder, 1998; Ratcliff, 2002). To exemplify this model, suppose an observer is tasked with categorizing the stimulus presented in Figure 1a as dark or bright, depending on whether it contains more black or white circles. The diffusion model keeps track of a single quantity of evidence, which reflects the relative amount of accumulated evidence for one choice over the other. This means that in this example, evidence for a 'dark' response counts as evidence against a 'bright' response, illustrated in Figure 1b. Once evidence for one response reaches a boundary, a decision is made.

The basic diffusion model is defined by 4 main parameters that are attributed to different cognitive components that make up the speed and accuracy involved in decision making. These parameters consist of the drift rate, starting point of evidence accumulation, response boundaries, and non-decision time parameters. The non-decision time represents the time taken to perform the processes not directly associated with the evidence accumulation process e.g. motor response to press a button associated with a response. The boundary refers to the amount of evidence required to make a response, and is often characterized as the level of caution the observer has chosen. The starting point of evidence accumulation and drift rate are the two parameters associated with response and stimulus bias respectively.

The starting point parameter is used to represent a baseline level of evidence towards a specific response before stimulus information is accumulated as evidence. Response bias is essentially a shift in the start point parameter, meaning less evidence is required to reach one response boundary compared to the other, as illustrated in Figure 1c. A start point halfway between the two response boundaries indicates no response bias. The drift rate describes the average rate at which evidence is accumulated in favour of one response over the other. Stimulus bias is when one type of stimulus elicits a stronger or weaker drift rate compared to the other type of stimulus. Stimulus bias is illustrated in Figure 1d.

Response bias and stimulus bias both play a large role in decision making, however they are typically presented as independent of each other and dissociable i.e., the preparedness to make a response does not affect the evidence accumulation process. The characterization of these processes as independent confers two main advantages. Firstly, it makes the model more parsimonious. Secondly, it gives a way to account for the different effects that different manipulations have on response times and accuracies.

A number of studies have contributed to this dissociation of response bias and stimulus bias and their associated parameters. The start point can be influenced by the relative frequencies of the presented stimuli and the relative reward rates associated with the stimuli, with limited effects on other parameters (Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006; Diederich & Busemeyer, 2006; Ratcliff & McKoon, 2008; White & Poldrack, 2014).

On the other hand, studies have illustrated that the drift rate is influenced by the quality and discriminability of information presented during a trial (Palmer, Huk, & Shadlen, 2005; Ratcliff & McKoon, 2008; Voss, Rothermund, & Voss, 2004). The standard interpretation for a bias in the drift rate parame-

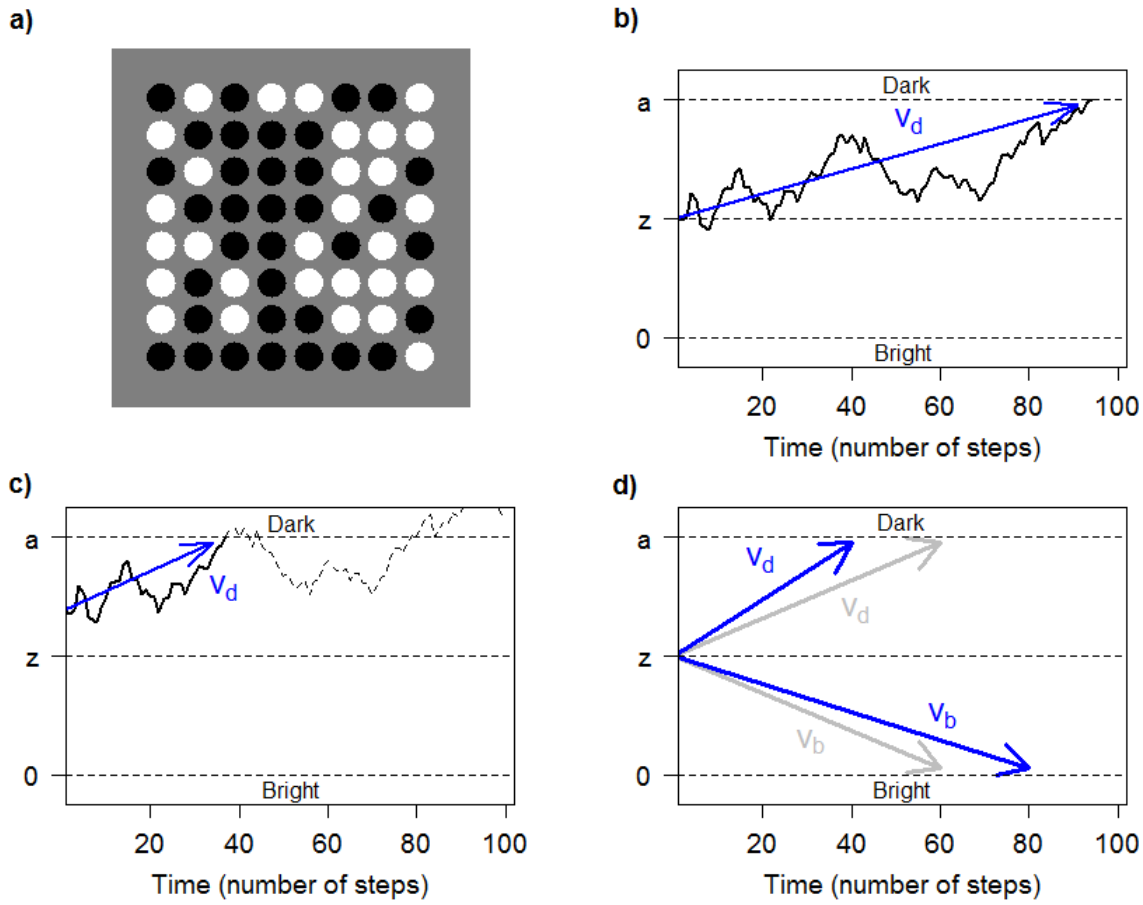

Figure 1: (a) Example of a stimulus where the participant had to decide the stimulus was dark or bright based on the proportions of black and white circles. (b) Diagram of the basic diffusion process. For this example, the top boundary represents the threshold for a 'dark' response, and the bottom boundary is the threshold for a 'bright' response. (c) Effect of a start point bias towards 'dark' responses. There is a shift in the starting point of evidence accumulation such that, given the same course of evidence accumulation observed in Figure 1b, the dark threshold is reached earlier. The dotted line represents the further evidence accumulation if the threshold was not reached. (d) Example of stimulus bias, with V_d and V_b representing drift rates for 'dark' and 'bright' stimuli respectively. Evidence is collected more quickly for the 'dark' response than it is for the 'bright' response. The grey arrows represent drift rates where there is no stimulus bias.

ter is one of criterion setting (Mulder, Wagenmakers, Ratcliff, Boekel, & Forstmann, 2012; Ratcliff, 1985; van Ravenzwaaij et al., 2012). The information observed from a stimulus is compared to a criterion, and the difference between the stimulus information and the criterion yields the evidence value that is to be accumulated in the model. Changing the criterion to permit more evidence for a particular response produces a bias. White, Mumford and Poldrack (2012) demonstrates this in a size discrimination task by showing participants a standard against which upcoming lines should be compared in order to determine what constitutes a 'long' or 'short' response. Their manipulation of this standard selectively influenced a drift criterion parameter in a diffusion model.

There have been studies that used the diffusion model to focus on specifically dissociating these two types of bias. Leite and Ratcliff (2011) examined the effects of stimulus frequency, response payoff, and decision criterion manipulations on start points and drift criterion parameters through a numerosity discrimination task where participants had to decide whether volume of asterisks contained within a 10 by 10 grid could be categorised as a 'low' amount or a 'high' amount, based on some given criteria. They found that changes in the start point parameter alone were able to account for changes in the RT and accuracy data when they manipulated stimulus frequency and payoff. When they manipulated the decision criterion for what was considered 'low' and 'high', they found the data was best fit by shifts in the drift criterion parameter. Similarly, White and Poldrack (2014) used a perceptual discrimination task and a recognition memory task and found that response bias and stimulus bias can be inde-

pendently induced in the diffusion model through the use of stimulus frequency and decision criterion manipulations respectively.

Other research in this field however, has proposed that these biases and the underlying parameters may not be necessarily be independently manipulated. Ratcliff and McKoon (2008) examined the effect of relative frequency and stimulus difficulty manipulations on model parameters using a motion discrimination paradigm. When stimulus difficulty was manipulated, they found that only drift rate varied, however when relative frequency of the stimuli varied, they found a bias in the start point as well as a modest effect on the drift criterion.

Additionally, van Ravenzwaaij et al. (2012) proposed that, theoretically, response bias is sufficient to account for optimal performance in a variable or fixed difficulty task when relative frequency of stimuli is manipulated, but only under certain conditions (cf. Moran, 2015). However, they found that the model fits of empirical data from individuals performing a motion discrimination task show that the relative frequency manipulations had effects on start points and drift criterion in both fixed and variable difficulty tasks.

Rather than being independent of each other, it is possible that base rate information plays a role in moderating how individuals evaluate information under certain circumstances. This provides a potential explanation for why both response bias and stimulus bias were found in studies which manipulated relative frequencies of stimuli. The current experiment aimed to test how response bias and stimulus bias may be expressed under conditions of limited information and differing stimulus frequencies. In doing so, we wanted to observe if this dissociation of these biases and their related parameters holds true. Our experiment empirically evaluated the effect of the relative frequency of stimuli and the duration of stimulus presentation on the parameters of the diffusion model through the use of a hierarchical Bayesian version of the simple diffusion model.

Method

Design

The stimuli used were various combinations of 64 black and white circles in a 8 by 8 grid. In each stimulus, there were 35 circles of one color, and 29 of the other. Participants were instructed to make 'black' or 'white' responses for each stimulus they were presented, indicating which color circle of which there were more. For clarity, stimuli with more black circles will be referred to as 'dark' stimuli and the associated response will be 'dark' responses. Similarly, stimuli with more white circles will be referred to as 'bright' stimuli and the associated response will be 'bright'. An example of a dark stimulus is shown in Figure 1a.

The independent variables manipulated were relative frequencies of stimuli and the presentation length of the stimuli. Relative frequencies of stimuli were manipulated across blocks. This manipulation had three levels, dark biased (two thirds of block were dark stimuli), bright biased (two thirds of block were bright stimuli), and unbiased (even proportions of dark and bright stimuli). There were 13 presentation lengths of stimuli, ranging from 0ms (where no stimulus is shown) to 200ms in 16.7ms (1 frame on a 60 Hz monitor) intervals. The presentation length varied from trial to trial within each block. The experiment consisted of 9 blocks of 80 trials each.

Procedure

At the start of the experiment, participants received instructions on the aim of the task and what they should expect to see on each trial. It was stated that the presentation time of the stimuli will vary within each block. Participants were also told the relative frequencies of each type of stimulus (dark and bright) will differ across blocks and received information about the proportions of dark and bright stimuli at the start of each block. At the end of each block, participants are given an opportunity to take a self-paced break before continuing onto the next block.

At the start of each trial, participants were required to press and hold the spacebar with the index finger of their dominant hand. Once spacebar was held, a fixation cross was presented for 500ms, followed by a mask presented for 100ms, followed by the stimulus. The stimulus is presented for a random duration from 0-200ms, followed by a backward mask of 100ms. There was 16.7ms before the disappearance of the mask and the appearance of the stimulus. Once they were prompted for a response, they had to release the spacebar and indicate a response using the 'F' or 'J' key to indicate whether they thought stimulus was 'dark' or 'bright' using the same finger the held down spacebar with. If they released their finger too early, they received a warning and the experiment would progress to the next trial. These instructions were given to discourage preemptive responses.

After each trial, participants received feedback on screen based on the accuracy of their response. For the 0ms trials where there is no 'correct' response, the feedback for their response was probabilistically determined based on the bias condition for the current block. 'CORRECT' was presented in green if their response was accurate and 'INCORRECT' was presented in red if their response was inaccurate. This feedback was on screen for 750ms before they were allowed to continue to the next trial.

Before the task began, participants were given 12 practice trials consisting of equal numbers of dark and bright stimuli. Each of the presentation lengths, excluding the 0ms presentation length, were used for one of the practice trials.

Model specification

Data were fit using a hierarchical Bayesian version of the simple diffusion model (for more information on hierarchical diffusion models see Vandekerckhove, Tuerlinckx, & Lee, 2011). MCMC estimation was performed through the JAGS Wiener module (Wabersich & Vandekerckhove, 2014) to estimate the parameters by running 3 chains with 5000 iterations each.

Individual-participant level parameters of the diffusion model were assumed to come from Gaussian distributions at the population level. For example, a drift rate for participant i in condition j was modelled as $v_{ij} \sim N(\mu^{v_j}, \lambda^j)$, where μ^{v_j} is the population-level mean drift rate parameter for condition j, and λ^j is the precision of the population-level drift rate parameter for condition j. The priors for the population-level mean parameters were set to be vague and relatively uninformative. For non-decision time, we used a normal distribution of mean 0 and a precision of 100, truncated to be above zero. For the boundary parameter, we used a normal distribution with mean of 3 and a precision of 2, truncated to be above zero. For start-point parameters, we used a uniform distribution from 0 to 1. For drift rate, we used a normal distribution with mean 0 and precision of 1. For the population-level precision parameters, λ, we used gamma distributions with shape and rate parameters of 0.001.

The distance between the boundaries (a), the mean distance of the starting point (z), the average rate of evidence accumulation (v), and the non-decision time parameter (T) were estimated for each individual while also estimated on a population level. The results discussed are the population level parameters estimated by the model. For the purpose of model fitting, dark responses were made when evidence passed the boundary at a and bright responses were made when evidence passed the boundary at 0. This means that higher start points and positive drift rates represent more starting evidence and evidence accumulation for dark responses and lower start points and negative drift rates represent more starting evidence and evidence accumulation for bright responses.

We allowed start points and drift rates to vary freely across all conditions in the experiment, but constrained boundaries and non-decision times to be equal across the three levels of relative frequencies of stimuli conditions. This results in the estimation of 13 boundary parameters and 13 non-decision time parameters (for the each of the trial types), 39 start point parameters (for each trial type across the 3 levels of relative frequencies of stimuli) and 78 drift rate parameters (same as the start point parameters, but estimated separately for the dark stimuli and the bright stimuli). This results in a total of 143 population level parameters. In the following section, we discuss the posterior distributions of the population-level mean parameters.

Results

Figure 2 illustrates posterior distributions of population level start point parameters for each presentation time. A start point closer to 1 and 0 indicates higher starting evidence for dark and bright responses, respectively. When no bias is expected in the start points, a start point of 0.5 is expected. This is what we observed for the unbiased blocks - start points for the unbiased stimulus frequency blocks are distributed around 0.5 across all presentation time conditions, as shown in the green violin plots in Figure 2. From the results of previous experiments that manipulated relative frequencies of stimuli, we expect a bias in the start point in both the dark and bright biased conditions (Leite & Ratcliff, 2011; Ratcliff & McKoon, 2008; van Ravenzwaaij et al., 2012; White & Poldrack, 2014). In the dark biased conditions, we expect start points to be above 0.5 and in bright biased conditions, start points are expected to be below 0.5. Our results are in line with this expectation and are fairly consistent across the different presentation times.

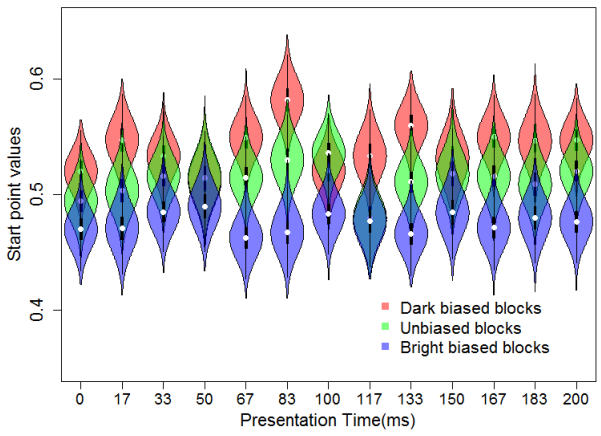

Figure 2: Violin plots of posterior distributions of population level start point parameters for each presentation time.

Regarding the estimates of the drift rate parameters, Since bright and dark stimuli carry the same amount of information (i.e. same proportion of dominant-color circles) we expect the drift rates to have the same magnitude, but in opposite directions. Stimulus bias is calculated as the average drift rate across dark and bright stimuli for a presentation time in a type of block. Since the drift rates for dark and bright stimuli should be equal but with opposite valences, if there is no bias, we expect the average drift rate to be 0.

For the unbiased blocks, the longer a stimulus was presented, the higher the drift rate in the direction of the response associated with that stimulus, with drift rates for short presentation times being distributed around 0, as shown in Figure 3a. This matches our expectations of a higher drift rate when more information (longer presentation time of stimuli) is presented, resulting in limited observed stimulus bias (as shown in the green plots in Figure 3d). For the biased blocks, we observe an overall shift in the drift rates for both bright and dark stimuli, away from 0 and towards the response for the biased stimuli. This is particularly prevalent for the shorter presentation time conditions i.e., for the bright biased blocks, drift rates are in the direction of a bright response when the stimulus is presented for a limited amount of time (0-67ms), regardless of what stimulus was presented (illustrated in Figure 3b). A similar effect is present for the dark biased blocks, illustrated in Figure 3c. Consequently, we found that the stimulus bias observed in the shorter presentation time conditions

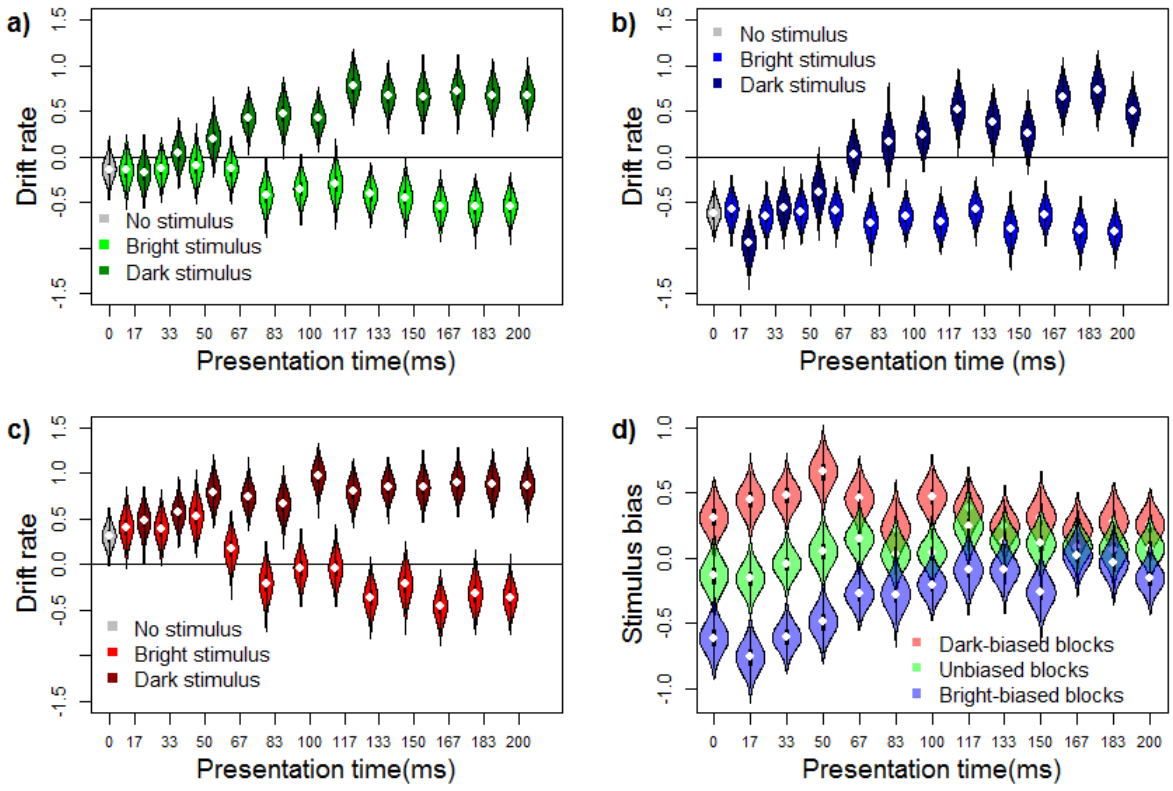

Figure 3: Violin plots of posterior distributions of drift rates for dark and bright stimuli across presentation times for the (a) unbiased, (b) dark biased and (c) bright biased blocks. (d) Average of the dark and bright stimulus drift rates for each presentation time for each block bias type.

was in favor of the biased stimuli for the biased blocks. This also changed as a function of presentation time; we observed a clear trend of stimulus bias decreasing as presentation time increased, summarized in Figure 3d.

Discussion

There are two main findings to take away from the experiment. Firstly, it replicated the response bias effect produced by relative frequencies of stimuli manipulations demonstrated in previous research (Bogacz et al., 2006; van Ravenzwaaij et al., 2012; White & Poldrack, 2014). Secondly, the results from the experiment suggest that stimulus bias has an inverse relationship with presentation time in relative stimulus frequency manipulations. The second finding is particularly interesting because does not coincide with typical interpretations of drift rate and drift rate bias in the diffusion model. If the drift rate reflects the accumulation of information, as stimulus information approaches 0, so too should the drift rate. The results of our current experiment contradict this, continuing to show modest drift rates towards the biased response when there is limited stimulus information.

One possible deviation from this perspective that could explain these results is a model which allows the drift rate to vary across the length of a trial. Its possible that initially, drift rate is driven by biases or sequential effects but is updated as the information from a presented stimulus becomes apparent. Diederich and Busemeyer (2006) discuss a similar concept of a two stage processing model for data from a perceptual discrimination task in which payoffs and deadlines were manipulated. They proposed a model that suggests there are two stages within a trial in which different aspects of the task inform the drift rate. This model suggests that during the first stage, payoff information determined the drift rate but after some period of time, stimulus information takes over. They found that this model was best able to account for the data when compared to two other models, one that allowed boundaries to vary over time, and another that allowed drift rates to vary across time.

On the other hand, a study by Ratcliff and Rouder (2000) manipulated stimulus presentation time in order to examine the concept of non-stationary drift rate in a two choice identification task. They found that a model with a non-stationary drift rate, where the drift rate rose during the onset of a stimulus and then fell to 0 once it was masked, was unable to satisfactorily explain the data. However, a model that used a constant drift rate over time fit the data well, suggesting that there is a constant accumulation of evidence over time even when the stimuli are shown then masked during a trial. In

light of their findings, Ratcliff and Rouder clarify that these findings may not necessarily extend to other domains such as perceptual stimuli (such as the one used in the current experiment) because a cognitive representation may not necessarily be the output of perceptual processing as it is in a letter identification task. Where previous studies focused on purely the onset of a stimulus, none have addressed how response bias may interact with stimulus onset asynchrony.

Another possible explanation is that expectancies or subjective values of responses, more typically reflected in the start point parameter, may moderate how the drift rate is set. The distinction between stimulus and response biases in the diffusion model is analogous to the Bayesian distinction between prior and likelihood. Bogacz, Brown, Moehlis, Holmes and Cohen (2006) argued that the diffusion model is a special case of Wald's (1945) sequential probability ratio test, which is an optimal procedure for deciding between two hypotheses (Wald & Wolfowitz, 1948). Under this equivalence, the start point of evidence accumulation corresponds to the prior probability of the two competing hypotheses (responses). The transformation of information into evidence is carried out by a likelihood function. The posterior probability of the hypotheses are then used as prior probabilities as the next piece of information is to be evaluated. Once the posterior probability of any one hypothesis is large enough, then a response is triggered.

Under the Bayesian framework, a drift rate bias is an adaptation of the likelihood function that is used to transform information from the stimulus into the evidence for competing responses. Our results suggest that the typical interpretation of drift rate bias, the concept of a drift criterion, may not be the whole story. Rather, it seems that the drift rate bias may be also based on what the participant knows about the environment. Usually, such environmental information is assumed to either adjust the prior probability of the different responses, or modify the lens through which stimuli are evaluated. Our data suggest that environmental information may also be accumulated as evidence, at least when the stimulus information is lacking.

Furthermore, some studies have examined how information can be weighted differently in their integration in their response based on their reliability. There has been previous research which show that individuals are able to integrate information from multiple sources, weighing them based on their reliability. (Ernst & Banks, 2002; Fetsch, Pouget, DeAngelis, & Angelaki, 2012; Ohshiro, Angelaki, & DeAngelis, 2011). This has been supported using a modified version of the diffusion model in order to account for the time course of the process (Turner, Gao, Koenig, Palfy, & McClelland, 2017). This further supports the possibility that individuals may be integrating both stimulus information and environmental information when accumulating evidence. When the stimulus is uninformative, individuals may give greater weight to the environmental information which results in the diffusion model showing stimulus bias in the parameter estimates.

When discussing these findings in the context of a diffusion model, it is important to keep in mind that the current set of analyses is a redescription of the observed data through the diffusion model and may not represent the 'true' underlying model. Some alternative models that may be able to account for the results of the current experiment are the leaky, competing accumulator (LCA) model proposed by Usher and McClelland (2001), and Kvam's (2019) theory of bias based on split attention and racing diffusion processes. Usher and McClelland's (2001) LCA model suggests that the observed stimulus bias may be caused by a lateral inhibition between accumulators for the two alternative choices. On the other hand, Kvam (2019) puts forward a model based on a continuous orientation judgement paradigm which suggests that stimulus information and predecision information (such as base rates) compete with each other as separate accumulators and cues can also moderate attention given to a stimulus. Although these models are outside of the scope of this paper, further research in this area should consider these models.

The results of the current experiment highlight that limited information can induce stimulus bias in blocks with uneven stimulus frequencies. Potential avenues for future research include investigating whether this stimulus bias can be induced by other manipulations such as stimulus difficulty or stimulus ambiguity, as well as using other modelling approaches, which may provide alternative explanations for the observed stimulus bias effects. This may help to shed light on the underlying mechanism through which information is processed and how it can result in stimulus bias. Investigating the source of these effects have important implications for understanding how individuals make decisions with different levels of information and may give some deeper insight into the roles of different types of information in decision making.

Abstract

The concept of Nash equilibrium has played a profound role in economics, and is widely accepted as a normative stance for how people should choose their strategies in competitive environments. However, extensive empirical evidence shows that people often systematically deviate from Nash equilibrium. In this work, we present the first resource-rational mechanistic approach to one-shot, non-cooperative games (ONG), showing that a variant of normative expected-utility maximization acknowledging cognitive limitations can account for important deviations from the prescriptions of Nash equilibrium in ONGs. Concretely, we show that Nobandegani et al.'s (2018) metacognitively-rational model, *sample-based expected utility*, can account for purportedly irrational cooperation rates observed in one-shot, non-cooperative Prisoner's Dilemma, and can accurately explain how cooperation rate varies depending on the parameterization of the game. Additionally, our work provides a resource-rational explanation of why people with higher general intelligence tend to cooperate less in OPDs, and serves as the first (Bayesian) rational, process-level explanation of a well-known violation of the law of total probability in OPDs, documented by Shafir and Tversky (1992), which has resisted explanation by a model governed by classical probability theory for nearly three decades. Surprisingly, our work demonstrates that cooperation can arise from purely selfish, expected-utility maximization subject to cognitive limitations.

Keywords: One-shot non-cooperative games; Nash equilibrium; resource-rational process models; expected utility theory; behavioral game theory; Prisoner's Dilemma; cooperation

1 Introduction

In his seminal work, Nash (1950) introduced a foundational concept of equilibrium, now called "Nash equilibrium," and mathematically proved that any one-shot, non-cooperative, n-player game enjoys (at least) one such equilibrium. In simple terms, Nash equilibrium (NE) is a set of strategies, one for each of the n players of the game, which has the desirable property that each player's strategy is her best response to the strategies adopted by the $n-1$ other players.

Importantly, NE satisfies a number of notable conditions which make it appealing from a normative standpoint. For example, NE passes the key announcement test (Holt & Roth, 2004): If all players publicly announce their strategies, no player would want to reconsider. Furthermore, when the goal is to advise players of a game about which strategies to follow, NE stands out as a rational choice: Any advice that is not an NE would have the unsettling property that there would always be some player(s) who would be better off by deviating from what they are advised (Holt & Roth, 2004). Finally, NE is a self-reinforcing agreement (Holt & Roth, 2004): Once reached by the players, NE does not need any external means of enforcement to endure.

Despite its firm rational grounds, NE has repeatedly failed to provide a descriptively adequate account of human behavior in a variety of important game-theoretic settings (e.g., Mailath, 1998; Goeree & Holt, 2001). By now, extensive empirical evidence shows that people often systematically deviate from Nash equilibrium, thus calling for alternative accounts (e.g., Fehr & Gächter, 2000; Keser & van Winden, 2000; Brandts & Schram, 2001). A prominent example of such violations of NE is the robust empirical finding that people typically cooperate in 2-player, one-shot, non-cooperative, Prisoner's Dilemma (2ONPD) games. Not only does NE prescribe against cooperation in 2ONPD (more precisely, every 2ONPD has only a single NE, and that is for both players to defect), but, more importantly, cooperation is not even *rationalizable* in 2ONPD (Bernheim, 1984; Pearce, 1984) because cooperation is not a best response to any strategy adopted by the other player.

From a purely computational perspective, people's apparent failure to follow the prescriptions of NE is not surprising: Recent theoretical work in computational complexity formally showed that evaluating NE is computationally intractable in general (Daskalakis et al., 2009), and, hence, is generally beyond the capacity of a cognitive system with limited computational power and resources (Simon, 1957).

In this work, we present the first resource-rational mechanistic approach to one-shot, non-cooperative games (ONGs), investigating the extent to which violations of NE could be seen as an optimal response subject to computational and cognitive limitations (Griffiths, Lieder, & Goodman, 2015; Nobandegani, 2017). Concretely, we ask whether these violations can be seen as an optimal behavior with the mind acting as a cognitive miser. To do this, we begin by presenting a general framework allowing us to conceptualize any ONG as a set of risky gambles, thereby reducing the problem of strategy selection in ONGs to a problem of choosing between a set of risky gambles.

To show the efficacy of our framework, we investigate the robust, yet puzzling, experimental finding that people typically cooperate in 2ONPD (e.g., Fehr & Gächter, 2000; Keser & van Winden, 2000; Brandts & Schram, 2001). As we demonstrate, Nobandegani, da Silva Castanheira, Otto, and Shultz's (2018) metacognitively-rational model,

sample-based expected utility (SbEU), not only can provide a resource-rational mechanistic explanation of cooperation behavior in 2ONPD, but also can provide a remarkably accurate quantitative account of how cooperation rate varies depending on the parameterization of 2ONPD (i.e., specific payoffs of the game).

Our paper is organized as follows. After providing a brief overview of SbEU, we present a general framework permitting us to reduce the problem of strategy selection in ONGs to the problem of decision-making under risk. We then turn to modeling cooperation in 2ONPD. Finally, we conclude by discussing the implications of our work for the debate on human rationality.

2 Sample-based Expected Utility Model

Extending the decision-making model of Lieder, Griffiths, and Hsu (2018) to the realm of metacognition, SbEU is a metacognitively-rational process model of risky choice, positing that an agent rationally adapts their strategies depending on the amount of time available for decision-making (Nobandegani et al., 2018). Concretely, SbEU assumes that an agent estimates expected utility

$$\mathbb{E}[u(o)] = \int p(o)u(o)do, \tag{1}$$

using self-normalized importance sampling (Hammersley & Handscomb, 1964; Geweke, 1989), with its importance distribution q^* aiming to optimally minimize mean-squared error (MSE):

$$\hat{E} = \frac{1}{\sum_{j=1}^{s} w_j} \sum_{i=1}^{s} w_i u(o_i), \quad \forall i:\ o_i \sim q^*,\ w_i = \frac{p(o_i)}{q^*(o_i)}, \tag{2}$$

$$q^*(o) \propto p(o)|u(o)|\sqrt{\frac{1+|u(o)|\sqrt{s}}{|u(o)|\sqrt{s}}}. \tag{3}$$

MSE is a standard normative measure of the quality of an estimator, and is widely adopted in machine learning and mathematical statistics (Poor, 2013). In Eqs. (1-3), o denotes an outcome of a risky gamble, $p(o)$ the objective probability of outcome o, $u(o)$ the subjective utility of outcome o, $\hat{E}$ the importance-sampling estimate of expected utility given in Eq. (1), q^* the importance-sampling distribution, o_i an outcome randomly sampled from q^*, and s the number of samples drawn from q^*.

SbEU posits that, when choosing between a pair of risky gambles A, B, people make their choice depending on whether the expected value of the utility difference $\Delta u(o)$ is negative or positive (w.p. stands for "with probability"):

$$A = \begin{cases} o_A & \text{w.p. } P_A \\ 0 & \text{w.p. } 1-P_A \end{cases} \tag{4}$$

$$B = \begin{cases} o_B & \text{w.p. } P_B \\ 0 & \text{w.p. } 1-P_B \end{cases} \tag{5}$$

$$\Delta u(o) = \begin{cases} u(o_A)-u(o_B) & \text{w.p. } P_A P_B \\ u(o_A)-u(0) & \text{w.p. } P_A(1-P_B) \\ u(0)-u(o_B) & \text{w.p. } (1-P_A)P_B \\ 0 & \text{w.p. } (1-P_A)(1-P_B) \end{cases} \tag{6}$$

In Eq. (6), $u(\cdot)$ denotes the subjective utility function of a decision-maker. Following Nobandegani et al. (2018), and consistent with prospect theory (Kahneman & Tversky, 1979; Tversky & Kahneman, 1992), in this paper we assume a standard S-shaped utility function $u(x)$ given by:

$$u(x) = \begin{cases} x^{0.85} & \text{if } x \geq 0, \\ -|x|^{0.95} & \text{if } x < 0. \end{cases} \tag{7}$$

Nobandegani et al. (2018) recently revealed that SbEU provides an account of the availability bias, the tendency to overestimate the probability of events that easily come to mind (Tversky & Kahneman, 1973), and can accurately simulate the well-known fourfold pattern of risk preferences in outcome probability (Tversky & Kahneman, 1992) and in outcome magnitude (Markovitz, 1952; Scholten & Read, 2014). Notably, SbEU is the first rational process model to score near-perfectly in optimality, economical use of limited cognitive resources, and robustness, all at the same time (see Nobandegani et al., 2018; Nobandegani et al., 2019a).

3 From One-shot, Non-cooperative Games to Multi-alternative Risky Choice

In this section, we present a general framework allowing us to conceptualize any ONG as a set of risky gambles $\mathcal{S}$. Importantly, this framework permits us to reduce the problem of strategy selection in ONGs to the problem of risky decision-making. By re-framing the problem this way, the strategy selected by an agent in an ONG corresponds to the risky gamble that the agent would choose among the set of available gambles $\mathcal{S}$.[1]

Without loss of generality, and for ease of exposition, we consider the case of a 2-player, one-shot, non-cooperative game (2ONG) here. Extending the results to the general case of an n-player, one-shot, non-cooperative game is straightforward.

Consider a generic 2ONG whose payoff matrix is given in Fig. 1. The game has two players: Player 1 (Row Player) and Player 2 (Column Player). Player 1 has two pure strategies to choose between: the strategy corresponding to choosing the top row (Top Strategy) and the strategy corresponding to choosing the bottom row (Bottom Strategy). Similarly, Player 2 has two pure strategies to choose from: the strategy corresponding to choosing the left column (Left Strategy) and the strategy corresponding to choosing the right column (Right Strategy). From the perspective of Player 1, Player 2 selects the Left Strategy with probability P_l, and the

[1] We should note that our framework naturally handles "mixed strategies" wherein the agent probabilistically chooses among the set of possible "pure strategies." The validity of this claim follows from the key understanding that the choice between the set of available gambles $\mathcal{S}$ would be also made probabilistically.

		Player 2 (Column Player)	
		Left	Right
Player 1 (Row Player)	Top	a, x	b, v
	Bottom	c, y	d, w

Figure 1: Payoff matrix for a generic 2-player, one-shot, non-cooperative game (2ONG). For example, if Player 1 (Row Player) selects the Top Strategy and Player 2 (Column Player) selects the Left Strategy, Player 1 and Player 2 receive payoffs a and x, respectively.

Right Strategy with probability $P_r = 1 - P_l$. Likewise, from the perspective of Player 2, Player 1 selects the Top Strategy with probability P_t, and the Bottom Strategy with probability $P_b = 1 - P_t$. As such, Player 1 is essentially choosing between the two gambles T and B:

$$T = \begin{cases} a & \text{w.p. } P_l \\ b & \text{w.p. } 1 - P_l \end{cases} \tag{8}$$

$$B = \begin{cases} c & \text{w.p. } P_l \\ d & \text{w.p. } 1 - P_l \end{cases} \tag{9}$$

with gambles T, B corresponding to choosing the Top Strategy and the Bottom Strategy, respectively, and Player 2 is essentially choosing between the two gambles L and R:

$$L = \begin{cases} x & \text{w.p. } P_t \\ y & \text{w.p. } 1 - P_t \end{cases} \tag{10}$$

$$R = \begin{cases} v & \text{w.p. } P_t \\ w & \text{w.p. } 1 - P_t \end{cases} \tag{11}$$

with gambles L, R corresponding to choosing the Left Strategy and the Right Strategy, respectively.

The line of reasoning presented above shows that the problem of strategy selection for a player in 2ONGs can be formally reduced to the problem of deciding between two risky gambles (T, B for Row Player and L, R for Column Player). By the same logic, more generally, the problem of strategy selection for a player in an n-player ONG (with each player having n pure strategies to choose from) can be formally reduced the problem of deciding between n risky gambles.

As evidenced by Eqs. (8-9) depending on the parameter P_l, Player 1's choice between T and B explicitly depends on Player 1's conception of the probability with which Player 2 would select the Left Strategy (i.e., P_l). Likewise, as evidenced by Eqs. (10-11), Player 2's choice between L and R explicitly depends on Player 2's conception of the probability with which Player 1 would select the Top Strategy (i.e., P_t).

As a case-study, in the next section we turn our attention to Prisoner's Dilemma, and we show that, together with the general way of reducing ONGs to risky decision-making discussed above, SbEU can accurately explain cooperation in 2ONPDs, thereby providing a process-level, rational basis for cooperation in 2ONPDs.

4 Cooperation in One-shot, Non-cooperative Prisoner's Dilemma

A wealth of real-life scenarios are modeled as an instance of Prisoner's Dilemma, e.g., conflict of two prisoners independently questioned by the police (Kaminski, 2003), cartel problems (Osborne, 1976), the conflict of two superpowers who engage in a nuclear arms race (Wiesner & York, 1964), doping in sports (Savulescu, Foddy, & Clayton, 2004; Haugen, 2004), and global warming (Milinski et al., 2008).

Although, normatively, one should never cooperate in one-shot, non-cooperative Prisoner's Dilemma games, substantial experimental evidence shows that people typically cooperate in 2ONPDs (e.g., Dawes & Thaler, 1988; Fehr & Gächter, 2000; Keser & van Winden, 2000; Brandts & Schram, 2001).

In a 2ONPD, each player has two strategies to choose from: either to cooperate or to defect. The payoff matrix of a generic 2ONPD is shown in Fig. 2.

		Player 2 (Column Player)	
		Cooperate	Defect
Player 1 (Row Player)	Cooperate	r, r	v, t
	Defect	t, v	p, p

Figure 2: Payoff matrix of a generic 2-player, one-shot, non-cooperative Prisoner's Dilemma (2ONPD), where $t > r > p > v$. For 2ONPDs, the constraint $r > p$ ensures that mutual cooperation is superior to mutual defection, while the constraints $t > r$ and $p > v$ grant that defection is the dominant strategy for both players. Players can either cooperate or defect.

According to the general framework presented in the previous section, assuming that (from the perspective of a player) the other player would cooperate with probability P_c, a player is essentially choosing from the following two risky choices:

$$\text{Cooperate} = \begin{cases} r & \text{w.p. } P_c \\ v & \text{w.p. } 1 - P_c \end{cases}$$

$$\text{Defect} = \begin{cases} t & \text{w.p. } P_c \\ p & \text{w.p. } 1 - P_c \end{cases}$$

According to the normative principle of least-informative priors (i.e., those prior distributions attaining highest entropy), having no priori knowledge of, or any opportunity to learn through interactions about, her opponent—due to the one-shot, non-cooperative nature of the game—it is rationally

justified for a player to assume that $P_c = 0.5$. Accordingly, throughout this paper we make the assumption that $P_c = 0.5$.

Recent work has provided mounting evidence suggesting that people often use very few samples in probabilistic judgments and reasoning (e.g., Vul et al., 2014; Battaglia et al. 2013; Lake et al., 2017; Gershman, Horvitz, & Tenenbaum, 2015; Hertwig & Pleskac, 2010; Griffiths et al., 2012; Gershman, Vul, & Tenenbaum, 2012; Bonawitz et al., 2014; Nobandegani et al., 2018; Lieder, Griffiths, Huys, & Goodman, 2018). Consistent with this finding, throughout this paper we assume that a player draws very few samples ($s = 1$; see Eqs. (2-3)) when deciding between cooperation and defection in 2ONPDs—except for Sec. 4.3 in which we directly investigate the effect of number of samples s on cooperation.

Under these justified assumptions (i.e, $s = 1$ and $P_c = 0.5$), in the following two subsections we show that Nobandegani et al.'s (2018) metacognitively-rational model, SbEU, accurately explains how cooperation rate varies depending on the parameterization of a 2ONPD.

4.1 Manipulation of Cooperation Index

Introduced by Rapoport and Chammah (1965), *cooperation index* (CI) is a concrete measure of cooperativeness in 2ONPDs; CI is a property of the experimental task. For a 2ONPD with a generic payoff matrix shown in Fig. 2, CI is given by (Rapoport & Chammah, 1965):

$$\text{CI} = \frac{r-p}{t-v}. \tag{12}$$

As for any 2ONPD holds $t > r > p > v$ (see Fig. 2), it follows that $0 < \text{CI} < 1$. (The latter result follows from having $t - v > r - p > 0$.)

Rapoport and Chammah (1965) experimentally demonstrated a linear relationship between CI and cooperation rate, with people tending to cooperate more as CI increases. Several studies have replicated this finding (e.g., Steele & Tedeschi, 1967; Vlaev & Chater, 2006).

Next, we show that SbEU can remarkably accurately account for this finding. To test how the cooperation rate predicted by SbEU changes as CI increases, we use nine representative 2ONPD games from Vlaev and Chater (2006, Table 1) which allow us to systematically vary CI equidistantly between 0.1 and 0.9. Recall that $0 < \text{CI} < 1$. We simulate $N = 100,000$ participants, with $s = 1$ and $P_c = 0.5$.

As Fig. 3 demonstrates, there is a significant positive, linear relationship between CI and the cooperation rate predicted by SbEU (Pearson's $r = .9998$, Kendall's $\tau = 1$, Spearman's $\rho = 1$, Ps $< 10^{-5}$).

In the next subsection, we directly compare the cooperation rate predicted by SbEU and human data.

4.2 Manipulation of Defection Payoff p

In a recent experiment investigating the effect of manipulation of defection payoff (i.e., parameter p; see Fig. 2) on cooperation, Engel and Zhurakhovska (2016) presented participants with eleven 2ONPDs; across these stimuli, they systematically varied parameter p while keeping the other parameters fixed (for experimental stimuli see Engel and Zhurakhovska, 2016, Sec. 3).

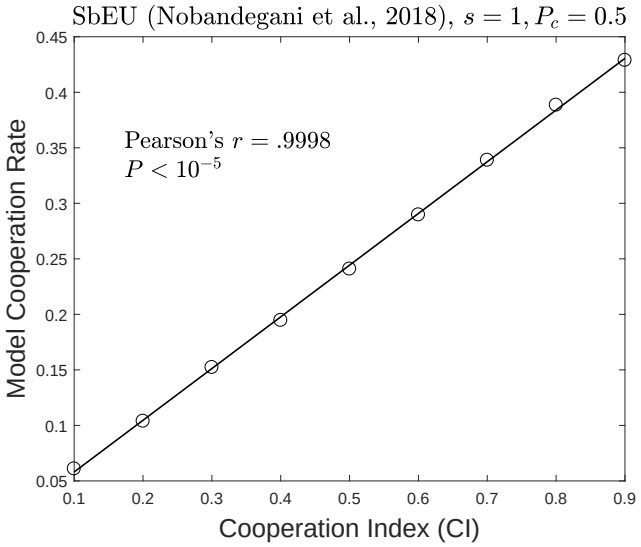

Figure 3: SbEU (Nobandegani et al., 2018) can accurately simulate the linear relationship between CI and cooperation rate, experimentally demonstrated by Rapoport and Chammah (1965).

Fig. 4 shows that SbEU can remarkably accurately account for Engel and Zhurakhovska's (2016) observed cooperation rates, explaining 98% of the variance in the experimental data (Pearson's $r = .9906$, Kendall's $\tau = .9909$, Spearman's $\rho = .9977$, Ps $< .001$). In Fig. 4, we simulate $N = 100,000$ participants, with $s = 1$ and $P_c = 0.5$.

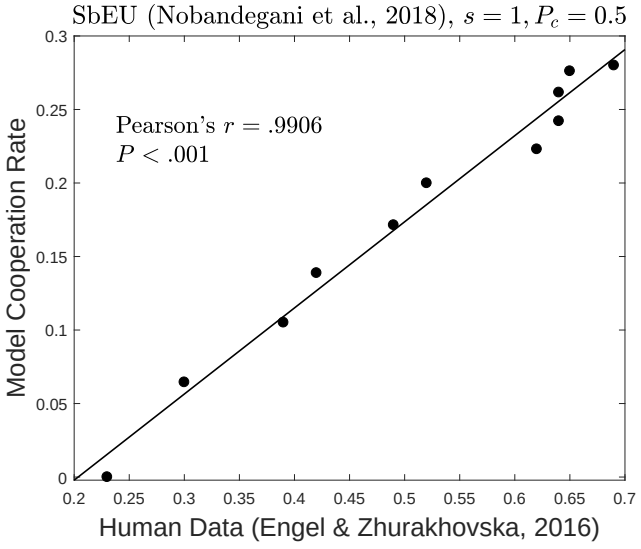

Figure 4: SbEU (Nobandegani et al., 2018) simulates Engel and Zhurakhovska's (2016) experimental data on the effect of manipulation of defection payoff (i.e., parameter p) on cooperation in 2ONPDs.

4.3 The Predictive Relationship between Number of Samples s and Cooperation

In a recent study, Kanazawa and Fontaine (2013) experimentally investigated the effect of general intelligence (measured by a Raven's-type nonverbal test of general intelligence) on cooperation in 2ONPDs, showing that individuals with higher general intelligence are less likely to cooperate.

In this section we investigate the predictive relationship between the number of samples s and cooperation rate in 2ONPDs. In the context of SbEU, we operationalize the well-supported assumption that people with higher general intelligence typically enjoy more cognitive resources, e.g. working memory (e.g., Colom, Jung, & Haier, 2007; Colom et al., 2008, Burgess, Gray, Conway, & Braver, 2011) by positing that these individuals tend to draw more samples.

Consistent with Kanazawa and Fontaine's (2013) finding, SbEU predicts that cooperation rate should decrease as the number of samples s increases; see Fig. 5. In Fig. 5, we adopt the Kanazawa and Fontaine's (2013) specific PD problem given to the subjects (a 2ONPD with $r = 3, v = 0, t = 5, p = 1$), and simulate $N = 100,000$ participants with $P_c = 0.5$.

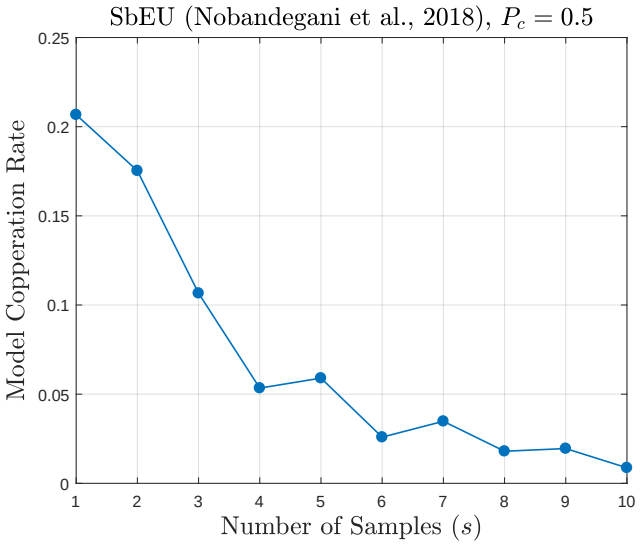

Figure 5: SbEU (Nobandegani et al., 2018) predicts that cooperation rate should decrease as the number of samples s increases, consistent with the experimental findings of Kanazawa and Fontaine (2013).

Importantly, SbEU's prediction depicted in Fig. 5 is supported by substantial evidence revealing that, in the context of 2ONPDs, deliberation (which can be readily operationalized in terms of drawing more samples) leads to increased defection rate, thus bringing behavior closer to the prescriptions of the normative standards of game theory (e.g., Rand, 2016).

4.4 Manipulation of P_c

Shafir and Tversky (1992) examined cooperation rates in a well-known variant of 2ONPD: In some trials, participants were told what the other player was doing. Unsurprisingly, when participants were told that the other person decided to defect, then their probability to cooperate was 0.03; and when they were told that the other person decided to cooperate, then their probability to cooperate was 0.16. However, in trials (within participants design) when participants were not told what the other person did, the probability to cooperate raised to 0.37. This pattern of responding has been independently replicated several times (e.g., Busemeyer, Matthew, & Wang, 2006; Croson, 1999; Li & Taplin, 2002), and has thus far remained a puzzle for optimal decision theorists to explain.

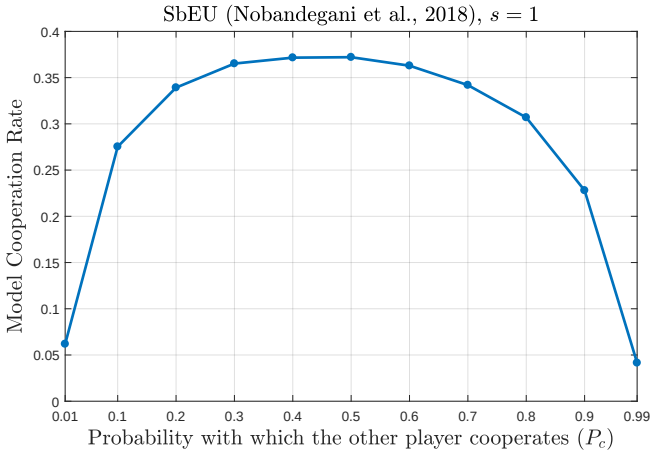

Figure 6: SbEU (Nobandegani et al., 2018) provides a resource-rational, process-level explanation of the puzzling finding of Shafir and Tversky (1992). This finding thus far has defied any (Bayesian) rational explanation. We simulate $N = 100,000$ participants, with $s = 1$. We use a representative 2ONPD game from Shafir and Tversky (1992, Fig. 28.2) with the following parameters: $r = 75, v = 25, t = 85, p = 30$.

The present study offers one, and thus far the only, (Bayesian) rational process-level explanation of this puzzle. As Fig. 6 shows, SbEU predicts that a participant should have only a minuscule tendency to cooperate when the other player is known to either fully cooperate or defect. However, consistent with Shafir and Tversky's (1992) finding, SbEU predicts that participants should have a substantially greater tendency to cooperate when they are maximally uncertain about what the other player would do. As such, SbEU provides a rational explanation of a clear violation of the *law of total probability* in 2ONPDs, as demonstrated by Shafir and Tversky (1992). According to the law of total probability (Durrett, 2010), the cooperation rate under the condition that the opponent's choice is unknown must fall between the cooperation rates observed under the two extreme conditions: full cooperation and full defection.

5 General Discussion

Despite its solid normative ground, NE has failed to provide a satisfying descriptive account of human behavior in many game-theoretic settings. In this work, we focus on a well-

documented, yet puzzling, deviation from NE: cooperation in 2-player, one-shot, non-cooperative, Prisoner's Dilemma games (2ONPDs). By way of introducing a general framework allowing us to conceptualize strategy selection in one-shot, non-cooperative games (ONGs) as the classical problem of decision-making under risk, we investigate whether (seemingly irrational) cooperation in 2ONPDs could be understood as an optimal behavior with the mind acting as a miser.

To our knowledge, our work provides the first (but, admittedly, preliminary) demonstration of how cooperation can arise from *purely selfish*, expected-utility maximization under cognitive limitations. Our findings challenge the widespread view that observed cooperation in 2ONPD games is primarily due to "cooperation bias" in humans, and are supported by recent experimental findings revealing little evidence for such cooperation bias (Pothos et al., 2011). As such, our work refutes the (very intuitive) widely-accepted conclusion that "If players are egoists, cooperation will not be observed in one-shot PD games" (Cooper et al., 1996).

Concretely, in this work we show that the Nobandegani et al.'s (2018) metacognitively-rational process model, SbEU, provides a resource-rational mechanistic explanation of cooperation in 2ONPDs, and offers an accurate quantitative account of how cooperation rate varies depending on the parameterization of a 2ONPD. Furthermore, by operationalizing higher intelligence in terms of drawing a larger number of samples in the available time, our work predicts that more intelligent individuals should tend to cooperate less, fully consistent with recent experimental findings (Kanazawa & Fontaine, 2013).

Shafir and Tversky's (1992) paradoxical finding on the violation of the law of total probability in 2ONPDs has resisted explanation by a model governed by classical probability theory (CPT) for nearly three decades. Interestingly, this paradoxical finding has been recently taken as strong evidence for quantum-probability models of cognition (e.g., Pothos & Busemeyer, 2009; Pothos & Busemeyer, 2013). Our work offers the first, and thus far the only, CPT-based explanation of Shafir and Tversky's (1992) paradoxical finding. As such, our work corroborates the view that decision-making behaviors that appear to be inconsistent with CPT, might after all be reconcilable with CPT when analyzed from an algorithmic perspective acknowledging cognitive limitations.

Being primarily inspired by the experimental finding that deliberation leads to a marked increase in defection rate in 2ONPDs (e.g., Rand, 2016), and applying a dual-process lens to cooperation in 2ONPDs, some researchers have recently argued that intuition favors cooperation while deliberation promotes selfishness (e.g., Rand, Greene, & Nowak, 2012; Rubinstein, 2007; Rand, 2016). Our work offers a completely new way of understanding this experimental finding—both qualitatively and quantitatively.

On the quantitative front, in sharp contrast to a dual-process perspective, our work presents the first, and thus far the only, *single-process* model of cooperation in 2ONPDs, providing a resource-rational mechanistic explanation of why deliberation leads to increased defection. According to our work, it is the optimal use of limited cognitive resources that underlies deliberation promoting selfishness in 2ONPDs. Relatedly, our recent work on modeling fairness in the Ultimatum Game (UG) also supports this view (Nobandegani, Destais, & Shultz, in prep).

On the qualitative side, our work offers a radically different interpretation of cooperation in 2ONPDs than the one provided by the classical dual-process account. From a dual-process perspective, intuition (moderated by System 1) is good and cooperative while deliberation (moderated by System 2) is evil and uncooperative. However, according to our singe-process model (SbEU; Nobandegani et al., 2018), a boundedly-rational agent that selfishly maximizes its expected utility while optimally using its limited cognitive resources should show the highest cooperation rate as an intuitive response, with cooperation rate declining with deliberation. As such, according to our work, humans' intuitive response being to cooperate in 2ONPDs, is still, quite counterintuitively, the effect of selfishly maximizing expected utility while optimally using limited cognitive resources.

Our work contributes to an emerging line of work attempting to explain human cognition as an optimal use of limited cognitive resources (*rational minimalist program*, Nobandegani, 2017; Griffiths, Lieder, & Goodman, 2015), thereby demonstrating that a wide range of human behaviors are rational, provided that the computational and cognitive limitations of the mind are taken into consideration (Simon, 1957).

By demonstrating that SbEU, a recently proposed metacognitively-rational process model of risky choice (Nobandegani et al., 2018), can quantitatively account for ostensibly irrational cooperation rates in 2ONPDs, our work bridges between two related, but distinct, areas of research: game-theoretic decision-making and risky decision-making. As such, the work presented here brings us a step closer to developing a unified, mechanistic account of human decision-making.

Recent work has shown that SbEU can account for the St. Petersburg paradox, a centuries-old paradox in human decision-making (Nobandegani, da Silva Castanheira, Shultz, & Otto, 2019b), and has experimentally confirmed a counterintuitive prediction of SbEU: Deliberation leads people to move from one well-known bias, framing effect, to another well-known bias, the fourfold pattern of risk preferences (da Silva Castanheira; Nobandegani, & Otto, 2019). An important line of future work would be to investigate whether SbEU could also serve as a resource-rational process-level account of contextual effects in multi-attribute decision-making (e.g., the attraction, similarity, and compromise effects), thus bringing us another step closer to developing this unified account of decision-making.

Abstract

The St. Petersburg paradox is a centuries-old philosophical puzzle concerning a lottery with infinite expected payoff, on which people are, nevertheless, willing to place only a small bid. Despite many attempts and several proposals, no generally-accepted resolution is yet at hand. In this work, we present the first resource-rational process-level explanation of this paradox, demonstrating that it can be accounted for by a variant of normative expected-utility-maximization which acknowledges cognitive limitations. Specifically, we show that Nobandegani et al.'s (2018) metacognitively-rational model, *sample-based expected utility* (SbEU), can account for major experimental findings on this paradox. Crucially, our resolution is consistent with two empirically well-supported assumptions: (1) people use only a few samples in probabilistic judgments and decision-making, and (2) people tend to overestimate the probability of extreme events in their judgment.

Keywords: St. Petersburg Paradox; bounded rationality; resource-rational process models; expected utility theory; inference by sampling

1 Introduction

Originally proposed in 1738 by Daniel Bernoulli, the St. Petersburg paradox is a famous economic and philosophical puzzle concerning a risky gamble on which people are asked to place a bid. The gamble goes as follows: The house offers to flip a coin until it comes up heads; the house pays \$1 if heads appears on the first trial (aka initial seed); otherwise the payoff doubles each time tails appears, with this compounding stopping and payment being given at the first heads. The St. Petersburg gamble is outlined in Table 1.

Trial	1	2	3	...	n	...
Event	H	TH	TTH	...	$\underbrace{\text{TT...TH}}_{(n-1)\ \textbf{tails}}$	...
Payoff	\$1	\$2	\$4	...	$\$2^{(n-1)}$	...

Table 1: The St. Petersburg gamble. A fair coin is flipped until the first heads appears. On the n^{th} trial of the gamble, corresponding to the event of having the first heads appear on the n^{th} coin flip, the house pays $\$2^{(n-1)}$ to the bidder and the game ends. The expected value (EV) of this gamble is infinite: EV = $\$1 \times (\frac{1}{2}) + \$2 \times (\frac{1}{4}) + \$4 \times (\frac{1}{8}) + \$8 \times (\frac{1}{16}) + \$16 \times (\frac{1}{32}) + \ldots = \$\frac{1}{2} + \$\frac{1}{2} + \$\frac{1}{2} + \$\frac{1}{2} + \$\frac{1}{2} + \ldots = +\infty$.

Despite the expected value (EV) of the St. Petersburg gamble being infinite (see Table 1), people are typically willing to place only small bids on this gamble (e.g., Bottom, Bontempo, & Holtgrave, 1989; Rivero, Holtgrave, Bontempo, & Bottom, 1990; Kroll & Vogt, 2009; Cox, Sadiraj, & Vogt, 2009; Hayden & Platt, 2009). Under the normative stance that people should prefer gambles with higher EVs, this paradox calls into question human rationality: The EV of the gamble being infinite, people, therefore, should be willing to place *arbitrarily* large bids on this gamble, but this is far from what experimental evidence suggests.

In spite of its innocent appearance, the St. Petersburg paradox occupied the minds of many over the past two centuries, eliciting a variety of reflections and explanations from several notable thinkers, including Daniel and Niklaus Bernoulli, Cramer, de Morgan, Condorcet, Euler, Poisson, and Gibbon, Marschack, Cournot, Arrow, Keynes, Stigler, Samuelson, von Mises, Ramsey and Aumann (see Arrow, 1951; Aumann, 1977; Dutka, 1988; Keynes, 1921; Samuelson, 1960). Nonetheless, no widely accepted explanation of this paradox exists to date.

In this work, we ask whether people's bids on the St. Petersburg paradox could be understood as an optimal behavior with the mind acting as a cognitive miser. Answering this question in the affirmative, we show that the St. Petersburg paradox can be accounted for by a variant of normative expected-utility-maximization which acknowledges computational and cognitive limitations. Specifically, we demonstrate that Nobandegani, da Silva Castanheira, Otto, and Shultz's (2018) metacognitively-rational model, *sample-based expected utility* (SbEU), can account for major experimental findings on the St. Petersburg paradox.

In the present study, our efforts are simultaneously guided by two well-supported observations about human judgment and decision-making under risk: (1) mounting evidence suggests that people often use very few samples in probabilistic judgments and reasoning (e.g., Vul et al., 2014; Battaglia et al. 2013; Lake et al., 2017; Gershman, Horvitz, & Tenenbaum, 2015; Hertwig & Pleskac, 2010; Griffiths et al., 2012; Gershman, Vul, & Tenenbaum, 2012; Bonawitz et al., 2014; Nobandegani et al., 2018; Lieder, Griffiths, Huys, & Goodman, 2018), and (2) people overestimate the probability of extreme events in their judgments (e.g., Tversky & Kahneman, 1972; Ungemach, Chater, & Stewart, 2009; Burns, Chiu, & Wu, 2010; Barberis, 2013; Lieder et al., 2018). As we discuss in the next section, previous explanations of the St. Petersburg paradox fail to respect at least one of these observations.

Our paper is organized as follows. We begin by present-

ing a brief historical overview of major explanations of the St. Petersburg paradox. After providing a brief overview of SbEU, we turn to modeling four major experimental findings on the St. Petersburg paradox. We conclude by discussing the implications of our work for the debate on human rationality.

2 A Brief Historical Overview of the Paradox

In this section, we present a brief overview of major resolutions of the St. Petersburg paradox, followed by notable critiques of them.

It is worth noting that most of the work on the St. Petersburg paradox thus far has been theoretical or philosophical. Comparatively little effort has been directed at providing empirical data on the bids people would be willing to place on the gamble and/or how people's bids would be affected by changing focal characteristics of the gamble, e.g. by varying the initial seed or limiting the number of coin flips in the gamble (e.g., Bottom, Bontempo, and Holtgrave, 1989; Rivero, Holtgrave, Bontempo, and Bottom, 1990; Kroll and Vogt, 2009; Cox, Sadiraj, and Vogt, 2011; Hayden & Platt, 2009; Neugebauer, 2010).

Diminishing marginal utility. Initially presented by Daniel Bernoulli (1738), the diminishing marginal utility explanation of the St. Petersburg paradox argues that, instead of evaluating the expected value (EV) of the gamble (which is infinite, see Table 1), people evaluate the expected utility of the gamble, with the utility function having a concave form (aka diminishing marginal utility).

As this explanation fails to account for super-St. Petersburg paradoxes in which the gamble's payoff increases super-exponentially with every coin flip, recent discussions of this explanation have to make the further assumption that the utility function is bounded from above (e.g., Aumann, 1977; Martin, 2008; Menger, 1934; Samuelson, 1977; Vickrey, 1960).

The diminishing marginal utility explanation has been discredited several times, mainly because it over-predicts bids (Lopes, 1981; Martin, 2008; Menger, 1934; Moritz, 1923; Samuelson, 1960, 1977). (This is not to say that marginal utility does not diminish, just that this factor is insufficient to explain the paradox.) Also, the diminishing marginal utility explanation completely neglects the well-supported observation that people overestimate the probability of extreme events in their judgment (e.g., Tversky & Kahneman, 1972; Ungemach, Chater, & Stewart, 2009; Burns, Chiu, & Wu, 2010; Barberis, 2013; Lieder et al., 2018), mistakenly assuming that the subjective probability of a low-probability extreme event in the St. Petersburg gamble (e.g., to win $\$2^{100}$ with probability $\frac{1}{2^{101}}$) is equal to its objective probability (e.g., $\frac{1}{2^{101}}$). Replacing expected utility with more modern variants which respect the latter observation, e.g. cumulative prospect theory (CPT), does not help either, as empirically fit values strongly over-predict bids in the St. Petersburg paradox (Blavatskyy, 2005; Rieger & Wang, 2006; Camerer, 2005).

Finitude of resources. Another classic explanation is that since the amount of money in the world is finite, the gambler must be skeptical about the ability of the house to pay the large outcomes of the gamble. Relatedly, it has been argued that time is finite, and the gambler, knowing he or she cannot continue playing the game forever, bids less than the expected value of the gamble. This argument has been expressed, in various forms, by several scholars (see Savage, 1954; Tversky & Bar-Hillel, 1983; Vickrey, 1960; Dutka, 1988).

Weaknesses of these arguments have been explicated by several critics. Bertrand argues that, even if the house cannot afford to pay the money, unites of currency can be reasonably replaced by more plentiful stuff, such as grains of sand, inches, or molecules of hydrogen, and the risk aversion still remains (Dutka, 1988). By the same logic, the payment may even be hypothetical or psychological (Martin, 2008; Aumann, 1977).

Ignoring low probabilities. This explanation argues that people consider events whose probability falls below some threshold to be impossible, i.e. they never happen. For example, D'Alembert posited a $1/10,000$ threshold, while Niklaus Bernoulli set the cutoff at a more conservative $1/100,000$ (Dutka, 1988).

However, there is a serious flaw with this argument: According to the well-known availability bias (Tversky & Kahneman, 1972), people over-represent extreme events, i.e., events whose utility is large (Lieder et al., 2018; Nobandegani et al., 2018). As low-probability events have (exponentially) larger payoffs in the St. Petersburg gamble, people should overestimate those low-probability events, putting more weights on those low-probability events in their valuation of the gamble.

A key contribution of our work is to provide a resource-rational process-level explanation of why people are willing to place only a small bid on the gamble *despite* over-representing extreme events in their judgment and decision-making (see Sec. 3). Particularly, past work has shown that SbEU can account for availability bias (Nobandegani et al., 2018).

Computing the median instead of the mean. Recently, Hayde and Platt (2009) proposed that people report the median (and not the mean) of the distribution associated with the St. Petersburg gamble as their bid. The median of the distribution associated with the St. Petersburg gamble is between \$1 and \$2, and is set by convention at \$1.50 (Weissstein, 2008).

The median explanation of Hayde and Platt (2009) is currently the only model which can simultaneously account for all the major experimental findings on the St. Petersburg gamble. We investigate all these major experimental findings in the present study in Sec. 4.

Nevertheless, despite its quantitative coverage, the median explanation remains too limited to explain the St. Petersburg paradox, markedly detached from the extensive literature on human judgment and decision-making. Similar to the diminishing marginal utility explanation, the median explanation completely neglects the well-supported observation that peo-

ple overestimate the probability of extreme events in their judgment (e.g., Tversky & Kahneman, 1972; Lieder et al., 2018), mistakenly assuming that the subjective probability of a low-probability extreme event in the St. Petersburg gamble is equal to its objective probability.

In this work, we seek to provide a resource-rational process model of the St. Petersburg paradox that can additionally account for several well-known effects in decision-making under risk; SbEU meets this criterion (see Sec. 3). As such, we seek to understand the St. Petersburg gamble as a particular risky gamble whose process-level explanation should be consistent with a broader process-level model of decision-making under risk.

3 Sample-based Expected Utility Model

Extending the cognitively-rational decision-making model of Lieder, Griffiths, and Hsu (2018) to the realm of metacognition (Cary & Reder, 2002), SbEU is a metacognitively-rational process model of risky choice that posits that agents rationally adapt their strategies depending on the amount of time available for decision-making (Nobandegani et al., 2018). Concretely, SbEU assumes that an agent estimates expected utility

$$\mathbb{E}[u(o)] = \int p(o)u(o)do, \tag{1}$$

using self-normalized importance sampling (Hammersley & Handscomb, 1964; Geweke, 1989), with its importance distribution q^* aiming to optimally minimize mean-squared error (MSE):

$$\hat{E} = \frac{1}{\sum_{j=1}^{s} w_j} \sum_{i=1}^{s} w_i u(o_i), \quad \forall i:\ o_i \sim q^*,\ w_i = \frac{p(o_i)}{q^*(o_i)}, \tag{2}$$

$$q^*(o) \propto p(o)|u(o)| \sqrt{\frac{1+|u(o)|\sqrt{s}}{|u(o)|\sqrt{s}}}. \tag{3}$$

MSE is a standard normative measure of the quality of an estimator, and is widely adopted in machine learning and mathematical statistics (Poor, 2013). In Eqs. (1-3), o denotes an outcome of a risky gamble, $p(o)$ the objective probability of outcome o, $u(o)$ the subjective utility of outcome o, $\hat{E}$ the importance-sampling estimate of expected utility given in Eq. (1), q^* the importance-sampling distribution, o_i an outcome randomly sampled from q^*, and s the number of samples drawn from q^*.

Recently, Nobandegani et al. (2018) showed that SbEU can account for availability bias, the tendency to overestimate the probability of events that easily come to mind (Tversky & Kahneman, 1972), and can accurately simulate the well-known fourfold pattern of risk preferences in outcome probability (Tversky & Kahneman, 1992) and in outcome magnitude (Markovitz, 1952; Scholten & Read, 2014). Notably, SbEU is the first rational process model to score near-perfectly in optimality, economical use of limited cognitive resources, and robustness, all at the same time (Nobandegani et al., 2018; Nobandegani et al., 2019a).

4 Simulation Results

In this section, we show that SbEU can quantitatively account for four major experimental findings on the St. Petersburg paradox: (1) Bids are only weakly affected by truncating the game (e.g., Cox et al. 2007; Neugebauer, 2010; Hayden & Platt, 2009), (2) Bids are strongly increased by repeating the game (Neugebauer, 2010; Hayden & Platt, 2009), (3) Bids are typically lower than twice the smallest payoff (Hayden & Platt, 2009), and (4) Bids depend linearly on the initial seed of the game (Hayden & Platt, 2009).

Recent work has provided mounting evidence suggesting that people often use very few samples in probabilistic judgments and reasoning (e.g., Vul et al., 2014; Battaglia et al. 2013; Lake et al., 2017; Gershman, Horvitz, & Tenenbaum, 2015; Hertwig & Pleskac, 2010; Griffiths et al., 2012; Gershman, Vul, & Tenenbaum, 2012; Bonawitz et al., 2014; Nobandegani et al., 2018; Lieder, Griffiths, Huys, & Goodman, 2018). Consistent with this finding, in the present study we assume that bidders draw only one sample ($s = 1$; see Eqs. 2-3) when evaluating their (subject) expected utility of the St. Petersburg gamble.

Concretely, we use the Metropolis–Hastings Markov chain Monte Carlo (MCMC) method—a well-known rational process model for sampling from a probability distribution of interest—to generate a single sample ($s = 1$) from the importance distribution q^* given in Eq. 3. MCMC methods have been successful in simulating important aspects of a wide range of cognitive phenomena, e.g., temporal dynamics of multistable perception (Gershman et al., 2012; Moreno-Bote et al., 2011), developmental changes in cognition (Bonawitz, Denison, Griffths, & Gopnik, 2014), category learning (Sanborn et al., 2010), and accounting for many cognitive biases (Nobandegani et al., 2018; Dasgupta et al., 2016).

Also, consistent with prospect theory (Kahneman & Tversky, 1979) and cumulative prospect theory (Kahneman & Tversky, 1992), in this paper we assume a standard S-shaped utility function $u(x)$ given by:

$$u(x) = \begin{cases} x^{0.35} & \text{if } x \geq 0, \\ -|x|^{0.45} & \text{if } x < 0. \end{cases} \tag{4}$$

4.1 Bids are weakly affected by truncating the game

In the original St. Petersburg gamble, there is no a priori upper-bound on number of coin flips; theoretically it can continue indefinitely. In a truncated variant of the St. Petersburg gamble, some a priori upper-bound is placed on the number of coin flips. Several experimental studies have shown that bids that people are willing to offer to play the St. Petersburg gamble are only weakly affected by truncating the game (Cox et eal., 2007; Cox et al., 2008, 2009; Hayden & Platt, 2009). This finding is generally taken as evidence for people ignoring small-probability events in the game (Neugebauer, 2010).

Recently, Hayden and Platt (2009) investigated bids for the St. Petersburg gamble truncated at 3 flips (maximum payoff: \$8, EV: \$2.50), 5 flips (maximum payoff: \$32, EV: \$3.50),

Figure 1: Hayden and Platt's (2009) experimental data on the effect of truncation on bids for the St. Petersburg gamble. Adapted from Hayden and Platt (2009).

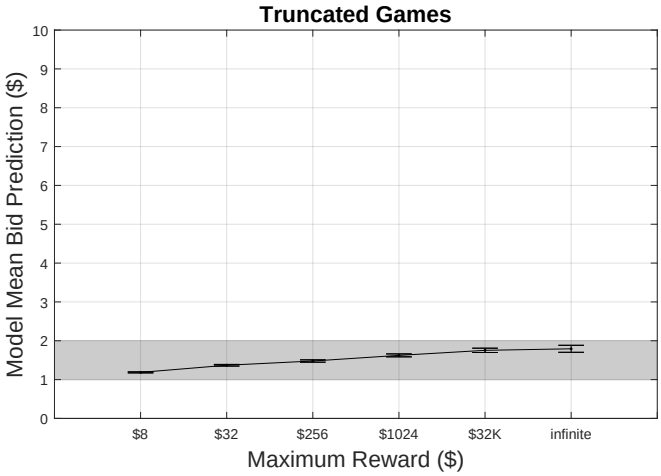

Figure 2: SbEU (Nobandegani et al., 2018) can accurately simulate the experimental data of Hayden and Platt (2009) on the effect of truncation on bids for the St. Petersburg gamble. Error bars indicate $\pm$ 1 SEM.

8 flips (maximum payoff: \$256, EV: \$5), 10 flips (maximum payoff: \$1024, EV: \$6) and 15 flips (maximum payoff: \$32,768, EV: \$8.50); their experimental data are shown in Fig. 1.

Fig. 2 shows that SbEU can account for the experimental data of Hayden and Platt (2009). In Fig. 2, we simulate $N = 1000$ participants, with $s = 1$.

4.2 Bids rise with repetitions of the game

Recently, Hayden and Platt (2009) experimentally showed that bids to play the (un-truncated) St. Petersburg gamble are strongly affected by repeating the game, with people willing to place higher bids with a larger number of game repetitions.

Fig. 3 shows that SbEU can qualitatively simulate people's tendency to place higher bids for a larger number of game repetitions, as experimentally shown by Hayden and Platt (2009). In Fig. 3, we simulate $N = 1000$ participants, with $s = 1$.

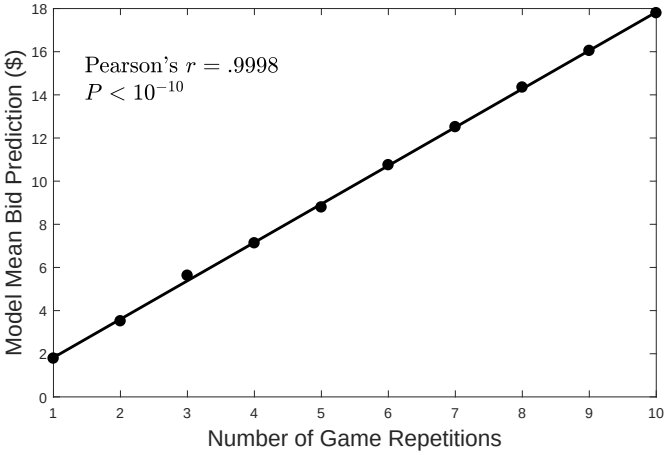

Figure 3: SbEU (Nobandegani et al., 2018) can account for the experimental finding of Hayden and Platt (2009) showing that people willing to place higher bids for a larger number of game repetitions (Pearson's $r = .9998$, Kendall's $\tau = 1$, Spearman's $\rho = 1$, $Ps < .001$).

4.3 Bids are typically lower than twice the smallest payoff

In their recent work, Hayden and Platt (2009) showed that bids to play the (un-truncated) St. Petersburg gamble are typically lower than twice the smallest payoff of the game.

Fig. 4 shows that SbEU can account for this experimental finding of Hayden and Platt (2009). In Fig. 4, we simulate $N = 1000$ participants, with $s = 1$.

4.4 Bids depend linearly on the initial seed

Interestingly, Hayden and Platt (2009) showed that bids to play the (un-truncated) St. Petersburg gamble depend linearly on the initial seed of the game, thus providing a quantitatively well-characterized criterion for evaluating a computational account.

Fig. 5 shows that SbEU can accurately account for this experimental finding of Hayden and Platt (2009) (Pearson's $r = .9758$, Kendall's $\tau = 0.9556$, Spearman's $\rho = .9879$, $Ps < .001$). In Fig. 5, we simulate $N = 1000$ participants, with $s = 1$.

5 General Discussion

The St. Petersburg paradox (Bernoulli, 1738) stands among the oldest philosophical puzzles of human decision-making, and has played a pivotal role in the emergence of the concept of the subjective utility curve, a central concept in economics

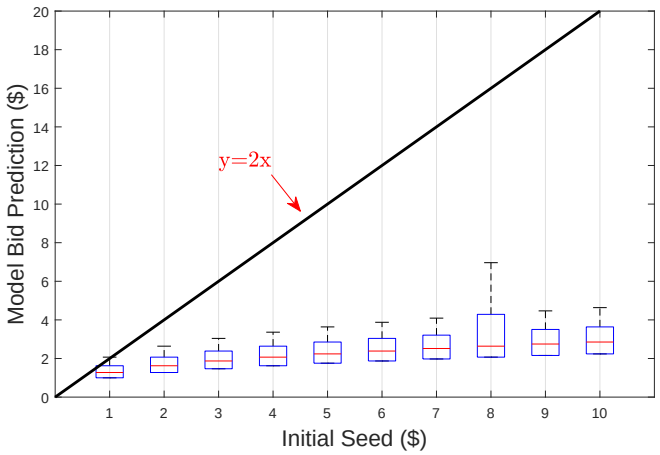

Figure 4: Boxplots of the model's bids. SbEU can account for the experimental finding of Hayden and Platt (2009) showing that people's bids are typically lower than twice the smallest payoff (i.e. initial seed) in the St. Petersburg gamble. On each box, the central red mark indicates the median, and the bottom and top edges of the box indicate the 25$^{\text{th}}$ (denoted by q_1) and 75$^{\text{th}}$ (denoted by q_3) percentiles of the data, respectively. On each box, the whisker extends to the most extreme data points not considered outliers. Outliers are data points that lie outside the interval $[q_1 - 1.5 \times (q_3 - q_1), q_3 + 1.5 \times (q_3 - q_1)]$), and are not shown in this plot. The boldfaced black solid line depicts $y = 2x$.

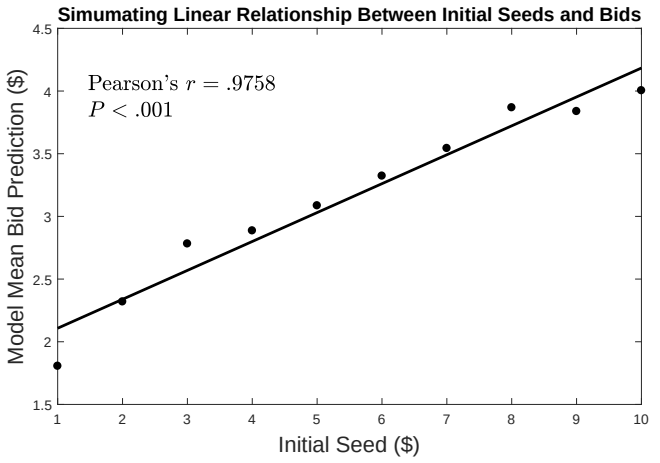

Figure 5: SbEU (Nobandegani et al., 2018) can account for the experimental finding of Hayden and Platt (2009) showing that bids depend linearly on the initial seed of the St. Petersburg gamble (Pearson's $r = .9758$, Kendall's $\tau = 0.9556$, Spearman's $\rho = .9879$, $Ps < .001$).

(Dutka, 1988). Despite occupying the minds of many important thinkers, eliciting many attempts and several proposals, no generally-accepted resolution is yet at hand.

In this work, we provide an algorithmic-level account of major experimental findings on the St. Petersburg paradox. Specifically, we show that a single parameterization of Nobandegani et al.'s (2018) metacognitively-rational model, SbEU, provides a unified, resource-rational, process-level explanation of (1) why bids are only weakly affected by truncating the game, (2) why people are willing to place higher bids for a larger number of game repetitions, (3) why bids are typically lower that twice the smallest payoff of the game (aka initial seed), and (4) why bids depend linearly on the initial seed of the game. As such, Items (1-4) can be understood as optimal behavior subject to cognitive limitations.

As opposed to the competing median explanation of Hayden and Platt (2009) that is too specific to the St. Petersburg paradox, our work provides a resource-rational process model of the St. Petersburg paradox that can additionally account for several well-known effects in decision-making under risk (Nobandegani et al., 2018), and is fully in line with the much broader process-level understanding of human probabilistic judgment and reasoning based on sampling (e.g., Stewart, Chater, & Brown, 2006; Sanborn & Chater, 2016).

Recent work has shown that SbEU provides a resource-rational mechanistic account of (ostensibly irrational) cooperation in one-shot Prisoner's Dilemma games, thus successfully bridging between game-theoretic decision-making and risky decision-making (Nobandegani, da Silva Castanheira, Shultz, & Otto, 2019b). There is also experimental confirmation of a counterintuitive prediction of SbEU: Deliberation leads people to move from one well-known bias, framing effect, to another well-known bias, the fourfold pattern of risk preferences (da Silva Castanheira; Nobandegani, & Otto, 2019).

Crucially, our explanation retains the well-supported assumption that people overestimate the probability of extreme events in their judgment and decision-making (Tversky & Kahneman, 1972; Lieder et al., 2018; Nobandegani et al., 2018), and is fully in line with mounting evidence suggesting that people use only a few samples in probabilistic judgments and reasoning (e.g., Vul et al., 2014; Battaglia et al. 2013; Lake et al., 2017; Gershman, Horvitz, & Tenenbaum, 2015; Hertwig & Pleskac, 2010; Griffiths et al., 2012; Gershman, Vul, & Tenenbaum, 2012; Bonawitz et al., 2014; Nobandegani et al., 2018; Lieder, Griffiths, Huys, & Goodman, 2018).

Recently, Blavatskyy (2005) showed that conventional parameterizations of cumulative prospect theory (CPT; Kahneman & Tversky, 1992) do not explain the St. Petersburg paradox. As we demonstrate in this work, assuming a standard S-shaped utility function, as advocated by CPT, suffices for explaining the St. Petersburg paradox with SbEU (see Eq. 4).

There have been several recent studies (see Lieder & Griffiths, 2018, for a review) attempting to show that many well-known (purportedly irrational) behavioral effects and cognitive biases can be understood as optimal behavior subject to computational and cognitive limitations (*rational minimalist program*, Nobandegani, 2017; Griffiths, Lieder, & Goodman, 2015). The present study contributes to this line of work by providing a resource-rational process-level account of a

centuries-old puzzle concerning human decision-making.

Future work should investigate whether other long-standing paradoxes of human judgment and decision-making, e.g., the Ellsburg paradox (Ellsberg, 1961), could be also understood as optimal behavior subject to cognitive limitations. We see our work as a step in this direction.

Abstract

Heuristics are simple, effective cognitive processes that deliberately ignore parts of information relevant to decision-making. Ecological rationality, as an essential part of the Adaptive Toolbox research program on heuristics, investigates the environmental conditions under which simple heuristics would outperform complex models of decision-making, thereby providing support for the surprising less-is-more effect. In this work, we present a new research program, dubbed formal science of heuristics (FSH), that nicely complements the ecological rationality research, developing it into a much richer research program. Concretely, FSH sets to (i) mathematically delineate the broadest class of environmental conditions under which a heuristic is fully optimal, and (ii) formally investigate how deviations from those conditions would lead to degradation of performance, thereby allowing for a mathematically rigorous characterization of their robustness. As an instantiation of the FSH research program, we present several analytical results aiming to delineate the mildest conditions granting the optimality of a well-known heuristic: Take The Best. We conclude by discussing the implications that pursuit of FSH could have on the science of heuristics.

Keywords: Ecological rationality; one-reason heuristics; formal science of heuristics; Take The Best heuristic

1 Introduction

Heuristics—simple, effective cognitive processes that deliberately ignore parts of information relevant to decision-making—are assumed to underpin much of human judgment and decision-making (e.g., Gigerenzer & Selten, 2001; Mousavi, Gigerenzer, & Kheirandish, 2016), and are widely considered to be sub-optimal, attaining higher speed at the expense of lower accuracy (e.g., Payne et al., 1993; Shah & Oppenheimer, 2008; Evans and Over, 2010).

Challenging the latter mindset, the influential *ecological rationality* research program (as part of the Adaptive Toolbox theory) maintains that heuristic are well-matched to the environment they are adopted in (Todd & Gigerenzer, 2007), and seeks to investigates the environmental conditions under which heuristics would outperform complex models of decision-making, giving rise to the surprising less-is-more effect: when less information or computation leads to more accurate judgments than more information or computation (Gigerenzer & Gaissmaier, 2011).

Despite great successes, ecological rationality work has predominantly focused on simulation-based demonstrations of simple heuristics outperforming complex strategies (e.g., Gigerenzer et al., 2008, Gigerenzer & Todd, 1999, Todd & Gigerenzer, 2000, Hoffrage & Reimer, 2004; Gigerenzer & Goldstein, 1996), directing comparatively little effort (but see, e.g., Martignon & Hoffrage, 2002, Hogarth & Karelaia, 2006) toward establishing a mathematically-rigorous characterization of the environmental conditions underpinning the less-is-more effect — Todd and Gigerenzer (2007) explicitly call for developing such deep theoretical accounts.

In this work, we present a new research program, dubbed formal science of heuristics (FSH), that nicely complements the ecological rationality research, developing it into a richer research program, and, additionally, permitting mathematicians and computer scientists to make important contributions to the science of heuristics.

Concretely, FSH pursues the following two objectives. (1) FSH seeks to mathematically delineate the *broadest* class of environmental conditions under which a heuristic is fully optimal (i.e., using the standard terminology of computer science, the environmental conditions under which a heuristic serves as a correct algorithm w.r.t. the objective of interest, or, equivalently, an approximation algorithm with an approximation ratio of one). (2) FSH aims to formally investigate how deviations from optimality conditions would lead to degradation of performance, thereby allowing for a mathematically rigorous characterization of a heuristic's robustness. As such, to provide strongest theoretical support for the robustness of a heuristic, FSH aims to analytically provide the *mildest* technical conditions granting the optimality of a heuristic. According to the Adaptive Toolbox theory, robustness is predominantly responsible for the less-is-more effect, and plays a central role in the success of fast-and-frugal heuristics in everyday life decisions (e.g., Gigerenzer & Todd, 1999; Gigerenzer & Gaissmaier, 2011).

With regard to objective (2) mentioned above, one of the mildest technical conditions worth considering is *distribution-free* performance guarantees, widely studied in statistical learning theory and machine learning (e.g., Valiant, 1984; Kearns, Vazirani, & Vazirani, 1994). As is often the case, a decision-maker lacks (at least partially) the knowledge of the regularities of their environment, and, therefore, is not fully informed as to how information relevant to a decision-making task of interest is distributed. Distribution-free results, as the term suggests, establish performance guarantees that hold true *regardless* of the probability distribution governing a decision-making task (e.g., the distribution of attributes in a multi-alternative decision-making task). As such, distribution-free results provide strong robustness guarantees while demanding *minimal* environmental knowledge on the

part of the decision-maker, thus playing an integral role in the FSH research program.

We should note that establishing distribution-free performance guarantees for a heuristic does *not* imply that: (1) the decision-maker is inattentive to their environment, nor that (2) the decision-maker is not trying to select a heuristic well-matched to the environment — experimental evidence clearly suggests otherwise (e.g., Rieskamp & Otto, 2006; Hoffart, Rieskamp, & Dutilh, 2018; Payne, Bettman, & Johnson, 1988; Bröder, 2003; Pachur, Todd, Gigerenzer, Schooler, & Goldstein, 2011). On the contrary, establishing distribution-free performance guarantees on a heuristic ensures that that heuristic is well-matched to the environment, even when the decision-maker's knowledge of the environment is *imperfect*—a psychologically plausible assumption.

This work is organized as follows. We begin by presenting an overview of a well-known heuristic: Take The Best (TTB). As an instantiation of FSH, we then establish several analytical results, including strong distribution-free performance guarantees, for TTB. Finally, we conclude by discussing the implications that pursuit of FSH could have on the science of heuristics.

2 Take The Best: An Overview

Take The Best (TTB; Tversky, 1969, Gigerenzer, Hoffrage, & Kleinbölting, 1991) belongs to the class of one-reason decision-making heuristics which base decisions on only one attribute value. In its classic form, TTB is concerned with the task of predicting which of two objects, each possessing several binary-valued attributes, has a higher value on a given criterion, e.g., which of two cities has a higher population, or, which of two cookies would be more delicious.

The machinery of TTB is quite simple: Starting with the attribute having the highest validity, make pairwise-comparisons between the attribute values of the two objects; as soon as the first discriminating attribute is encountered (i.e., the attribute on which the two objects differ), announce the object attaining the highest attribute value on the discriminating attribute to be the winning object. TTB visits attributes in a descending order of their validities. If no discriminating attribute is ever encountered, TTB selects the winning object uniformly at random.[1] In TTB, the validity v_i of the i^{th} attribute is given by (Gigerenzer et al., 2008):

$$v_i :\triangleq \frac{R_i}{R_i + W_i},$$

where R_i, W_i are the number of correct and incorrect inferences based on the i^{th} attribute alone, respectively.

The efficacy of TTB receives strong empirical support from a wide range of economic, demographic, environmental, and other prediction tasks (e.g., Gigerenzer et al., 2008; Czerlinski, Gigerenzer, & Goldstein, 1999; Chater, Oaksford, Nakisa, & Redington, 2003). For example, on the task of predicting which of two cities has a higher homeless rate, TTB achieves better prediction accuracy than several competitors, including multiple regression model (Gigerenzer et al., 2008). More strikingly, Czerlinski, Gigerenzer, and Goldstein (1999) empirically showed that, across 20 real-world prediction problems, on average TTB obtains the best prediction accuracy when competing with several prominent alternatives, including multiple regression and tallying heuristic. Relatedly, on the same 20 real-world prediction problems, Gigerenzer et al. (2008) empirically show that the predictive accuracy of TTB came, on average, within three percentage points of a complex Bayesian network model. More broadly, when environments are moderately unpredictable and learning samples are small, as with many social and economic situations, TTB tends to make inferences as accurately as or better than multiple regression and neural networks (Chater, Oaksford, Nakisa, & Redington, 2003).

To provide direct experimental evidence for TTB as a psychological model, Bröder and his colleagues (Bröder 2000; Bröder and Schiffer 2003) conducted 20 studies, concluding that TTB is used under a number of conditions such as when information is costly and the variability of the validity of the attributes is high. Furthermore, Bröder and Gaissmaier (2007) and Nosofsky and Bergert (2007) showed that TTB predicts response times better than weighted additive and exemplar models.

Previous work assessing the prediction accuracy of TTB has mainly focused on computer simulations, with some work establishing analytical results formally supporting the efficacy of TTB (e.g., Martignon & Hoffrage, 2002; Hogarth & Karelaia, 2005, 2006; Baucells, Carrasco, & Hogarth, 2008).

Pursuing the research program proposed by FSH, and contrary to past analytical work, in this work we consider a much broader class of problems involving nonlinear objective functions (Definitions 1-4) with interactions between attributes being also accounted for (Definition 2). For the broad class of problems discussed above, we formally establish conditions granting the optimality of TTB when dealing with both non-binary, discrete attribute values (Propositions 3, 5, and 6) and continuous attribute values (Proposition 4). We also analytically investigate a broad class of prediction problems—involving both structured (Definition 3) and unstructured noise (Definition 4)—for which only *probabilistic* guarantees can be provided. Additionally, and in sharp contrast to past analytical work, we provide strong distribution-free guarantees on TTB for several classes of prediction problems (Propositions 5, 6, and 8).

3 Instantiating FSH: The Case of TTB

As an instantiation of FSH, in this section we establish several analytical results, including strong distribution-free performance guarantees, for TTB.

Before we proceed further, let us formally delineate an objective function which characterizes a broad class of decision-

[1] Without loss of generality, we assume that the decision-maker initially recognizes all the objects which s/he has to choose from. Accordingly, the use of recognition heuristic (Gigerenzer et al., 2008), as the first step of TTB, is implicitly considered in our work.

making problems.

Definition 1. (Objective function) Let $O_1, O_2, \ldots, O_N$ denote the set of N objects a decision-maker should choose from. Let also $O_{ij} \in \{0,1\}$ denote the value of the j^{th} attribute of object O_i where $1 \leq j \leq M$, and w_k denote the weight corresponding to the k^{th} attribute, A_k. Finally, let $\psi(\cdot)$ be an *arbitrary* monotonically-increasing function (i.e., $\forall x\colon \frac{d}{dx}\psi(x) > 0$). Then, the winning object $O_{i^\star}$ is the one whose index $i^\star$ satisfies the following objective function:

$$i^\star :\triangleq \arg\max_i \psi(\sum_{j=1}^{M} w_j O_{ij}). \tag{1}$$

Therefore, in the case of having only two objects O_1, O_2 to choose from, the optimal decision rule is given by:

$$\psi(\sum_{j=1}^{M} w_j O_{1j}) \underset{O_1}{\overset{O_2}{\lessgtr}} \psi(\sum_{j=1}^{M} w_j O_{2j}), \tag{2}$$

where $A \underset{O_1}{\overset{O_2}{\lessgtr}} B$ denotes the following: choose O_1 if $A > B$; choose O_2 if $A < B$; and choose uniformly at random between O_1, O_2 if $A = B$. ■

It is worth noting that in Eqs. (1-2), ψ can be *any* monotonically-increasing function, e.g., $\psi(x) = e^x, \psi(x) = 2^x + \log(x)$.

Proposition 1. (Sufficient condition for optimality) *If there exists a $k \in \mathbb{N}$ such that $\forall p < k$, $\forall i, j \in \{1, \ldots, N\}$ $O_{ip} = O_{jp}$ and $w_k > \sum_{i>k} w_i$, then the following holds true:*

$$\exists j \in \{1, \ldots, N\}\ \forall i \neq j\ O_{jk} > O_{ik} \Rightarrow O_{i^\star} := O_j. \tag{3}$$

Importantly, Proposition 1 establishes a condition granting basing decision on only one attribute while preserving optimality with respect to the objective given in (1). As such, Proposition 1 provides a firm rational basis for the *possibility* of one-reason decision-making for the broad class of decision-making problems characterized in Definition 1.

Next, Proposition 2 establishes a condition granting the optimality of TTB (when choosing between an *arbitrary* number of objects) with respect to the objective given in (1).

Proposition 2. (Generalizing TTB to N-object prediction tasks) *Let $O_1, O_2, \ldots, O_N$ denote the set of N objects a decision-maker is to choose from. Let also w_k denote the weight corresponding to the k^{th} attribute (see Definition 1), and v_k denote the validity of the k^{th} attribute. If $\forall k\ w_k = v_k$ and $\exists r \in \mathbb{R}^{>2}$ s.t. $\forall k\ v_k \leq (\frac{1}{r})v_{k-1}$, then TTB is an optimal strategy for the class of decision-making problems characterized in Definition 1.* ■

In the N-object setting (as in Proposition 2), TTB works as follows: Starting with the attribute having the highest validity, compare attribute values across the N objects; as soon as the first discriminating attribute is encountered (i.e., the attribute on which at least two objects differ), exclude from consideration those objects faring worse on the discriminating attribute; announce the object surviving this elimination process to be the winning object. TTB visits attributes in a descending order of their validities. If no discriminating attribute is ever encountered, TTB selects the winning object uniformly at random.

Proposition 3. (Multi-level attribute values) *Let $O_1, O_2, \ldots, O_N$ denote the set of N objects a decision-maker is to choose from, with each object having M attributes. Let also $O_{ij} \in \{0, 1, \cdots, \theta\}$ denote the value of the j^{th} attribute of object O_i where $1 \leq j \leq M$. Finally, let w_k denote the weight corresponding to the k^{th} attribute (see Definition 1), and v_k denote the validity of the k^{th} attribute. If $\forall k\ w_k = v_k$, and $\exists r > 1 + \theta$ s.t. $\forall k\ v_k \leq (\frac{1}{r})v_{k-1}$, then TTB is an optimal strategy for the class of decision-making problems characterized in Definition 1.* ■

In simple terms, Proposition 3 analytically establishes a conditions granting the optimality of TTB (when generalized to the setting of N objects, each with discrete, multi-level attribute values) with respect to the objective given in (1).

Proposition 4. (Continuous attribute values) *Let $\forall i \in \{0,1\}$, O_i denote the two objects a decision-maker should choose from, with each object having M attributes. Let also $O_{ij} \in \mathbb{R}$ denote the value of the j^{th} attribute of object O_i. Finally, let w_k denote the weight corresponding to the k^{th} attribute (see Definition 1), and v_k denote the validity of the k^{th} attribute. Assuming that k^* denotes the index of the discriminating attribute on which TTB halts, and $|O_{1k^*} - O_{2k^*}| \leq \delta$, the following statement holds true: If $\forall k\ w_k = v_k$, and $\forall i, j \in \{1, \ldots, M\}$ $O_{ij} \leq U$, and $\exists r > 1 + \frac{U}{\delta}$ s.t. $\forall k\ v_k \leq (\frac{1}{r})v_{k-1}$, then TTB is an optimal strategy for the class of decision-making problems characterized in Definition 1.*

Proposition 4 analytically establishes a conditions granting the optimality of TTB (when choosing between two objects, each with continuous attribute values) with respect to the objective given in (1).

Following the line of research proposed by FSH, next we present our first distribution-free guarantee for TTB.

Proposition 5. (Distribution-free guarantee) *Let $O_1, O_2, \ldots, O_N$ denote the set of N objects a decision-maker is to choose from, with each object having M attributes. Let also $O_{ij} \in \{0, 1, \cdots, \theta\}$ denote the value of the j^{th} attribute of object O_i, where $\{O_{ij}\}_{i,j} \overset{d}{\backsim} P$ with P denoting a joint probability distributions over the set of all attribute values $\{O_{ij}\}_{i,j}$. Finally, let w_k denote the weight corresponding to the k^{th} attribute (see Definition 1), and v_k denote the validity of the k^{th} attribute. Then, for* any *joint probability distribution P the following statement holds true: If $\forall k\ w_k = v_k$, and $\exists r > 1 + \theta$ s.t. $\forall k\ v_k \leq (\frac{1}{r})v_{k-1}$, then TTB is an optimal strategy for the class of decision-making problems characterized in Definition 1.* ■

Proposition 5 analytically establishes a condition ensuring the optimality of TTB (when generalized to the setting of N objects, each with discrete, multi-level attribute values) with respect to the objective given in (1), in a strong distribution-

free manner. It is crucial to note that the optimality guarantee given in Proposition 5 holds true for *any* joint distribution P on the set of all attribute values.

Next, in Definition 2, we formally characterize a broad class of prediction problems wherein interactions between attribute values are also accounted for.

Definition 2. (Objective function) Let $O_1, O_2, \ldots, O_N$ denote the set of N objects a decision-maker should choose from, and $O_{ij} \in \{0, 1, \cdots, \theta\}$ denote the value of the j^{th} attribute of object O_i where $1 \leq j \leq M$. Additionally, let w_k denote the weight corresponding to the k^{th} attribute, and r_{pq} denote the weight quantifying the amount of interaction between the p^{th} and the q^{th} attributes. Finally, let $\chi(\cdot)$ be an *arbitrary* monotonically-increasing function (i.e., $\forall x\colon \frac{d}{dx}\chi(x) > 0$). Then, the winning object $O_{i^\star}$ is the one whose index $i^\star$ satisfies the following objective function:

$$i^\star :\triangleq \arg\max_i \chi\Big(\sum_{j=1}^{M} w_j O_{ij} + \sum_{\substack{p,q \\ p\neq q}} r_{pq} O_{ip} O_{iq}\Big). \tag{4}$$

Proposition 6. (Distribution-free guarantee) *Consider the class of prediction problems formally characterized in Definition 2. Let also P denote a joint probability distributions over the set of all attribute values $\{O_{ij}\}_{i,j}$, i.e., $\{O_{ij}\}_{i,j} \overset{d}{\backsim} P$. Then, for* any *joint probability distribution P the following statement holds true: If $\forall k\ w_k = v_k$, and $\exists R \in \mathbb{R}$ s.t. $\forall p, q \in \{1, \cdots, M\}\ r_{pq} < R$, and $\exists r > 1 + \theta$ s.t. $\forall k\ \frac{r-1}{r-(\theta+1)}\binom{M}{2}\theta^2 R \leq v_k \leq (\frac{1}{r})v_{k-1}$, then TTB is an optimal strategy for the class of decision-making problems characterized in Definition 2.* ■

In simple terms, Proposition 6 formally establishes a distribution-free result granting the optimality of TTB (when generalized to the N-object setting, each with discrete, multi-level attribute values) with respect to the broad class of prediction problems characterized in Definition 2 (with interactions between attributes also accounted for).

Next, Definition 3 formally characterizes a broad class of predictions problems under the *noisy-world* setting wherein the noise component contaminating the prediction problem has a particular structured form: Gaussian distribution.

Definition 3. (Objective function) Let $\forall i \in \{0, 1\}$, O_i denote the two objects a decision-maker should choose from, and $O_{ij} \in \{0, 1\}$ denote the value of the j^{th} attribute of object O_i where $1 \leq j \leq M$. Additionally, let w_k denote the weight corresponding to the k^{th} attribute, and C_i denote the score the object O_i attains on the criterion of interest to the prediction task (e.g., the population of a city, if the prediction task is to predict which of two cities has a higher population). Finally, let $\chi(\cdot)$ be an *arbitrary* monotonically-increasing function (i.e., $\forall x\colon \frac{d}{dx}\chi(x) > 0$). Then, consider the class of prediction problems satisfying the following:

$$C_i :\triangleq \chi\Big(\sum_{j=1}^{M} w_j O_{ij}\Big) + \varepsilon, \quad \varepsilon \overset{d}{\sim} \mathcal{N}(0, \sigma^2). \tag{5}$$

Proposition 7. (Noise-level-independent probabilistic guarantee) *Consider the class of prediction problems formally characterized in Definition 3. Then, for any noise variance $\sigma^2 > 0$, the following statement holds true: If $\forall k\ w_k = v_k$, and $\exists r \in \mathbb{R}^{>2}$ s.t. $\forall k\ v_k \leq (\frac{1}{r})v_{k-1}$, then the probability with which TTB correctly selects the superior object is ≥ 0.5.*

Proposition 7 formally establishes the following important result for the inherently-noisy world characterized in Definition 4: For *any* noise level σ^2, TTB dominates the *selection-purely-by-chance* strategy which select the winning object uniformly at random. This result importantly demonstrates that, independent of noise level σ^2, the adoption of TTB (instead of the selection-purely-by-chance strategy) is rationally justified for the inherently-noisy, class of prediction problems formally characterized in Definition 3.

Definition 4 below formally characterizes a broad class of predictions problems, once again, under the noisy-world setting; this time, however, the noise component contaminating the prediction problem has an *un*structured form.

Definition 4. (Probabilistic guarantee) Let $\forall i \in \{0, 1\}$, O_i denote the two objects a decision-maker should choose from. Let also $O_{ij} \in \{0, 1\}$ denote the value of the j^{th} attribute of object O_i, w_k denote the weight corresponding to the k^{th} attribute, and C_i denote the score the object O_i attains on the criterion of interest to the prediction task (e.g., the population of a city, if the prediction task is to predict which of two cities has a higher population). Finally, let $\phi(\cdot)$ be a monotonically-increasing function (i.e., $\forall x\colon \frac{d}{dx}\phi(x) > 0$). Then, consider the class of prediction problems satisfying the following:

$$\mathbb{P}(C_1 > C_2 | \phi(\sum_{j=1}^{M} w_j O_{1j}) > \phi(\sum_{j=1}^{M} w_j O_{2j}) \geq 1 - \eta, \quad 0 < \eta \ll 1.$$

Proposition 8. (Distribution-free guarantee) *Consider the class of prediction problems formally characterized in Definition 4. Let also P denote a joint probability distributions over the set of all attribute values $\{O_{ij}\}_{i,j}$, i.e., $\{O_{ij}\}_{i,j} \overset{d}{\backsim} P$. Then, for* any *joint probability distribution P the following statement holds true: If $\forall k\ w_k = v_k$, and $\exists r \in \mathbb{R}^{>2}$ s.t. $\forall k\ v_k \leq (\frac{1}{r})v_{k-1}$, then the probability with which TTB mistakenly selects the inferior object is less than η, where $0 < \eta \ll 1$.* ■

Proposition 8 establishes a distribution-free condition sufficient to grant that the probability of TTB erring in a prediction task belonging to the class of problems characterized in Definition 4 is minuscule.

4 General Discussion

In this work, we presented a research program, dubbed formal science of heuristics (FSH), that nicely complements the influential ecological rationality research program (Todd & Gigerenzer, 2007), developing it into a much analytically-richer scientific endeavor. By pursuing its two stated goals (see Introduction section), FSH seeks to (i) mathematically

delineate the key premise ecological rationality rests on—that heuristics are well-matched to the environments in which they are adopted (Todd & Gigerenzer, 2007)—and (ii) establish the strongest analytical results supporting this premise. After all, to rigorously and thoroughly answer whether a heuristic is well-matched to its environment, we need to formally characterize the *broadest* class of environments for which that heuristic performs (near) optimally, and experimentally investigate how often people use that heuristic in such environments.

Instantiating FSH with the well-known Take The Best (TTB) heuristic, and contrary to past analytical work, in this work we considered a much broader class of prediction problems involving nonlinear objective functions (Definitions 1-4) with interactions between attributes also being accounted for (Definition 2). For the classes discussed above, we formally established conditions granting the optimality of TTB when dealing with both non-binary, discrete attribute values (Propositions 3, 5, and 6) and continuous attribute values (Proposition 4). We also analytically investigated a broad class of prediction problems—involving both structured (Definition 3) and unstructured noise (Definition 4)—for which only *probabilistic* guarantees can be provided. Additionally, and in sharp contrast to past analytical work, we also provided distribution-free guarantees on TTB for several classes of prediction problems (Propositions 5–6, and 8).

Our work also serves as a potential template for how FSH could be pursued: For a given heuristic, formally characterize the class of decision-making problems with respect to which the performance of the heuristic is to be analytically investigated, followed by analytical results rigorously delineating the extent to which that heuristic is performing (near) optimally for that class. A generic approach would be to start with a narrow class (containing a set of restricted problems) for which a heuristic is performing (near) optimally; and then gradually expand that class into a larger one and see if previously established performance guarantees still hold (or to establish new performance guarantees, in case they fail to hold). A similar approach has been widely and productively used in theoretical computer science and computational complexity theory, e.g., through formally introducing many complexity classes, with one class serving as a relaxation of another.

Our particular focus on TTB in this work was only meant to showcase how the mindset advocated by FSH could be pursued in the case of a given heuristic—in our case, the Take The Best (TTB) heuristic. Ultimately, a serious investigation of FSH should lead to having mathematically rigorous answers to the two stated goals of FSH for *every* experimentally well-documented heuristic that people use, e.g., the Tallying heuristic (Gigerenzer & Gaissmaier, 2011), the Priority heuristic (Katsikopoulos & Gigerenzer, 2008), the Recognition heuristic (Gigerenzer & Gaissmaier, 2011), and the Minimalist heuristic (Gigerenzer et al., 2008). By now, a large number of heuristics are documented in the literature, many of which still lack an adequate characterization of the environmental conditions under which they are (near) optimal and/or how deviations from those conditions would lead to performance degradation. Thus, future work following FSH should address this analytical shortcoming.

Rieskamp and Otto (2006) show that people are sensitive to the distribution of cues in an environment, appropriately applying either TTB or a weighted additive mechanism, depending on which will be more accurate. However, how people are able to determine which type of environment they are in has largely remained an open question. Establishing distribution-free guarantees, as advocated by FSH, sheds new light on this open question, by formally demonstrating that a heuristic may well yield adequate performance despite the decision-maker's possibly incomplete (or, in the worst case, erroneous) assumptions about her environmental conditions, thereby liberating her from having a thorough understanding of her environment—a more psychologically plausible assumption. For example, Proposition 5 establishes a condition granting the optimality of TTB (with respect to the class of problems characterized in Definition 1) that holds true for *any* joint probability distribution $\mathbb{P}$ on the set of attribute values. This result has an important implication: Even if the decision-maker makes wrong assumptions about the true underlying distribution $\mathbb{P}$ governing the set of attribute values, adopting TTB still remains to be the optimal strategy (for the class of problems characterized in Definition 1). Crucially, the latter statement remains valid regardless of how wrong the decision-maker's assumptions about $\mathbb{P}$ are.

We must note, however, that the present work (and pursuit of FSH, in general) does not address the recent conundrum raised by Otworowska et al. (2018) regarding the computational intractability of the Adaptive Toolbox theory. As Otworowska et al. (2018) analytically demonstrate, there exists no efficient (i.e., polynomial-time) process that can adapt toolboxes to be ecologically rational for *all* possible environments. A resolution of this complexity-theoretic conundrum might be attained by restricting the class of environments under consideration, based on the psychologically plausible assumption that the range of environments humans have to deal with is undoubtedly vast, but *not* arbitrary.

Pursuit of FSH would have important implications for experimental wok on heuristics: Every analytical result (however general it may be) is established under a particular set of assumptions the validity of which needs to be experimentally confirmed. Experimental work should therefore investigate the empirical validity of such assumptions. Likewise, an empirical disconfirmation of an assumption on which an analytical result rests should call for the development of new empirically-grounded formal results. Accordingly, pursuit of FSH yields new experimental work, and, conversely, those experimental findings guide the development of new analytical results—a synergetic scientific endeavor.

Finally, pursuit of FSH allows mathematicians and theoretical computer scientists to make important contributions to the science of heuristics by developing a mathematically-

rigorous foundation for the effectiveness of heuristics in everyday life decisions. As such, we hope that FSH paves the way for having a highly interdisciplinary research program on heuristics wherein analytical and experimental studies, hand in hand, deepen our understanding of the effectiveness of the heuristics we live by. We see our work as a step toward that.

Investigations into human judgment and decision-making have led to the discovery of a multitude of cognitive biases and fallacies, with new ones continually emerging, leading to a state of affairs which can be characterized as the cognitive fallacy zoo! Recently, we have formally presented a principled way to bring order to this zoo (Nobandegani, Campoli, & Shultz, 2019). The work presented here, together with recent formal advances on bringing systematic order to the cognitive fallacy zoo (Nobandegani, Campoli, & Shultz, 2019), suggest a fresh formal approach to pursuing the heuristics-and-biases research program: an approach which aims to lay the formal foundations of the "unreasonable" effectiveness of the heuristics we live by, and to bring mathematically-rigorous systematic order to the cognitive biases ensued by those heuristics.

Abstract

How does cooperation arise in an evolutionary context? We approach this problem using a collective search paradigm where interactions are dynamic and there is competition for rewards. Using evolutionary simulations, we find that the unconditional sharing of information can be an evolutionary advantageous strategy without the need for conditional strategies or explicit reciprocation. Shared information acts as a recruitment signal and facilitates the formation of a self-organized group. Thus, the improved search efficiency of the collective bestows byproduct benefits onto the original sharer. A key mechanism is a visibility radius, where individuals have unconditional access to information about neighbors within a limited distance. Our results show that for a variety of initial conditions—including populations initially devoid of prosocial individuals—and across both static and dynamic fitness landscapes, we find strong selection pressure to evolve unconditional sharing.

Keywords: Collective search; cooperation; evolutionary simulations; pseudo-reciprocity; prosociality; swarm intelligence

Introduction

Social behavior is structured by the dynamics of the environment and how we interact with one another. Strategies that thrive in one context may be poorly suited to others. How do social behaviors arise in an evolutionary context? And can the dynamics of social interactions support the emergence of cooperation without appealing to conditional strategies?

Evolution is often summarized as "survival of the fittest", evoking a notion of fierce competition between individuals. Where is there room for prosociality and cooperation in the midst of evolutionary competition? One of the early challenges for Darwin's theory of evolution (1859) was to explain the origin of prosocial adaptations that improve the welfare of others or one's group as a whole, but at a potential cost to the individual. Darwin's explanation appealed to the notion of *group selection*, where the costs of altruism are ultimately justified by increased fitness for the group (Darwin, 1871). Thus, groups with more prosocial members may outcompete rival groups. Although group selection offers a potential pathway for the emergence of cooperation, it often requires strong assumptions, such as stable group structures and strong competition between groups (Janssen & Goldstone, 2006). Without these assumptions, selection at the individual level can undermine group selection. Thus, a comprehensive understanding of prosociality requires a theory of individual selection (Wilson & Wilson, 2007).

Theories of Cooperation

One traditional explanation for individual selection of prosociality is through the mechanism of *kin selection* (also known as inclusive fitness), where recipients of altruistic acts tend to be genetically related to the donor (Nowak, 2006). Hamilton's law (1964) states that the costs of prosociality C must be justified relative to the benefits of the recipient B by accounting for the relatedness of individuals r such that $\frac{C}{B} < r$. While kin selection explains prosociality between genetically similar individuals, Hamilton's law alone fails to account for all the social behaviors we see in human society (Rand & Nowak, 2013; Fehr & Fischbacher, 2003) and in animals (e.g., Spottiswoode, Begg, & Begg, 2016; Brown, Brown, & Shaffer, 1991). Many mechanisms have been proposed in order to justify the evolution of cooperation towards non-relatives, typically requiring an initial investment of a donor towards a non-related individual with expectations of reciprocity or benefits.

Conditional Cooperation. Theories of conditional cooperation operate on expectations of future reciprocity, where seemingly prosocial behavior is ultimately grounded in self-interest. Often described as impure altruism (Andreoni, 1989), both direct and indirect reciprocity appeal to conditional strategies (e.g., tit for tat; Nowak & Sigmund, 1992), where individuals conditionally cooperate with each other, so long as future reciprocation is expected. Direct reciprocity depends on multiple interactions with the same individual, while indirect reciprocity typically relies on reputation systems, where cooperative behavior is used as a social signal to third-parties (Nowak & Roch, 2007). Conditional cooperation has been widely studied in the context of game theory, yet simple mechanisms of social or spatial dynamics can also explain the origins of cooperation (Nowak & May, 1992).

Unconditional Cooperation. Theories of unconditional cooperation explain the origin of prosocial behavior through changes in the interaction structure for the donor (Perc, Gómez-Gardeñes, Szolnoki, Floría, & Moreno, 2013). Thus, behaving prosocially can make it more likely to interact with other prosocial individuals. *Network reciprocity* operates on similar principles as kin selection, but where the cost-benefit ratio is defined relative to interaction partners (Nowak, 2006). This approach has shown that by situating agents on a network (Ohtsuki, Hauert, Lieberman, & Nowak, 2006) or in a

spatial landscape (Nowak & May, 1992), prosocial individuals tend to interact more with similar partners, thus creating self-organized regions where prosociality proliferates (Perc et al., 2013). It is also possible to replace spatial similarity or network connectivity with some arbitrary feature or tag (Riolo, Cohen, & Axelrod, 2001), such that individuals with similar features are more likely to interact with one another. This provides a useful bridge between individual and group level mechanisms, because it describes how groups can form based on spatial, network, or feature similarity.

Two key assumption are made by these theories. The first is that the initial population already includes multiple prosocial individuals (Nowak & May, 1992; Ohtsuki et al., 2006). Yet this doesn't answer the crucial question of how cooperation emerges *ex nihilo*. Secondly, the interaction structures are more or less static: agents are either embedded in some spatial location (Nowak & May, 1992), as a fixed node in a network (Ohtsuki et al., 2006; Barkoczi, Analytis, & Wu, 2016), or given a fixed feature tag (Riolo et al., 2001). While groups can still emerge through the dynamics of evolution, interaction partners remain relatively stationary (but see Janssen & Goldstone, 2006) and individual dynamics (e.g., search behavior) are largely unaccounted for.

Pseudo-reciprocity is a related theory of unconditional cooperation, where the key difference from network reciprocity is that the fitness of the donor does not depend on the phenotype of the recipient. Thus, prosocial behavior can be beneficial without depending on the presence of other prosocial individuals in a group. Prosociality can alter the social environment for the donor (e.g., by sharing information about resources), such that the donor gains byproduct benefits through self-interested behavior of the recipients (Connor, 1986; Brown et al., 1991). For example, Cliff Swallows (*Hirundo pyrrhonota*) share information about the location of insect swarms through a unique vocal signal (i.e., a food call), which attracts other peers. While it is difficult to track the insect swarms individually, the collective recruited by the information sharer tracks the swarm more efficiently. Hence, even without expectations of reciprocity (i.e., future vocal signals from peers), each individual benefits by behaving prosocially and sharing information (Brown et al., 1991). Thus, pseudo-reciprocity offers a mechanism where individuals can be unconditionally prosocial towards all the members of the group, rather than towards a restricted set of cooperative partners.

Goals and Scope

Here, we analyze the emergence of cooperation through sharing information. We use evolutionary simulations to study how individual selection pressure can give rise to sharing, even from initial populations void of prosocial individuals. We simulate agents searching for rewards on a high dimensional fitness landscape, where the flow of information is dynamically and spatially defined. Agents have a binary phenotype that defines whether or not they share information unconditionally to the rest of the population. We show that this global sharing signal acts as a recruitment mechanism

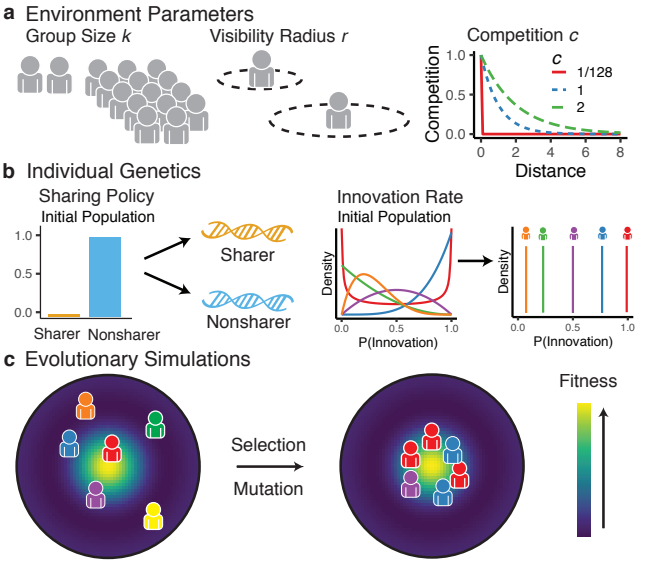

Figure 1: Evolutionary Simulations. **a**) We vary three main environmental parameters: group size, the visibility radius, and competition level. Group size k specifies the number of agents interacting together. Visibility radius r defines the maximum Chebyshev distance between two agents where information can be passively observed. Competition level c defines the decay rate of an exponential competition function that determines how agents split rewards (higher values of c result in splitting over larger distances. **b**) Each agent is defined by a sharing policy (either sharer or non-sharer) and an innovation rate (between 0 and 1). **c**) We use evolutionary simulations over 200 generations to see which individual genes emerge through selection pressure and mutation.

that facilitates the self-organization of dynamic groups. Because groups are more effective at finding rewards than lone individuals, we find that sharing emerges and dominates our evolved populations across a large range of initial conditions and in both static and dynamic fitness landscapes.

Collective Search Simulations

We use a multi-agent framework based on Bouhlel, Wu, Hanaki, and Goldstone (2018), who found that sharing information can be beneficial to the donor, even in competitive contexts and without expectations of reciprocity. The costs of sharing information (through resources lost to competition) can be outweighed by the byproduct benefits of cooperation. A simple coordination mechanism of a local visibility radius (i.e., nearby agents have access to each others' rewards) facilitates the formation of a self-organized collective. Thus, sharing information acts as a recruitment signal, attracting others to the donor, and increasing the likelihood of future social interactions (via the visibility radius). These future interactions are the source of byproducts benefits for the sharer. Here, we use evolutionary simulations and more extreme levels of competition (compared to Bouhlel et al., 2018) in order to study how sharing interacts with innovation, and under which initial conditions there exists individual selection pressure for unconditional sharing, leading to group-level cooperation (Goldstone & Janssen, 2005). Code for reproducing these results is publicly available at https://github.com/alantump/adaptiveSharingEvolution.

Methods

Adopted from Bouhlel et al. (2018), we simulate groups of k agents searching for rewards on a 10-dimensional[1] fitness landscape over $T = 50$ trials. On each trial t, agents can use either individual or social information (see below) to search for rewards on the fitness landscape. Payoffs are proportional to the inverse Manhattan distance of agent i from a global optimum Ω:

$$f(\mathbf{x}_{ti}) = \frac{1}{1 + \|\mathbf{x}_{ti} - \Omega\|_1} \tag{1}$$

where $\mathbf{x}_{ti}$ contains the coordinates for each dimension $m = 1, ..., 10$ of the current location of agent i at trial t. The coordinates of the global optimum Ω are sampled from a uniform distribution $\mathcal{U}(1, 10)$ for each dimension.

Competition. The payoffs $f(\mathbf{x}_{ti})$ are subject to competition, which we implement by having agents split rewards when occupying nearby spaces in the environment. Specifically, we use a competition parameter c that defines an exponentially decaying competition metric $C(\mathbf{x}_{ti}, \mathbf{x}_{tj})$ between each pair of agents i and j:

$$C(\mathbf{x}_{ti}, \mathbf{x}_{tj}) = \exp(-\frac{\left\|\mathbf{x}_{ti} - \mathbf{x}_{tj}\right\|_1}{c}); \tag{2}$$

Larger values of c induce higher competition over larger distances (see Fig. 1a), while in the limit of $c \to 0$, competition only occurs when agents occupy the exact same solution (as in Bouhlel et al., 2018). Splitting of rewards is proportional to the sum of competition values for all other agents. Hence, for location $\mathbf{x}_{ti}$, the acquired reward is:

$$R(\mathbf{x}_{ti}) = \frac{f(\mathbf{x}_{ti})}{1 + \sum_{j \neq i} C(\mathbf{x}_{ti}, \mathbf{x}_{tj})} \tag{3}$$

Individual search. Each agent begins at a random starting location, where each dimension is sampled from a uniform distribution $\mathcal{U}(1, 10)$. On every trial, each agent i stores the location $\mathbf{x}_{tj}$ and reward value $R(\mathbf{x}_{ti})$ of both individually and socially acquired information (see information sharing and visibility radius). We use a local search strategy, where the agent selects the location with the largest observed reward value $\mathbf{x}^*_{ti}$ up until time t, and then has an opportunity to innovate on it by modifying each value in $\mathbf{x}^*_{ti}$ by a discrete value in $\{-1, 0, 1\}$.

We define the *Innovation rate* as the probability that an agent innovates, where otherwise $\mathbf{x}^*_{ti}$ is copied verbatim. If the agent innovates, we modify each dimension of $\mathbf{x}^*_{ti}$ by drawing from a Binomial distribution centered on zero $\sim \mathrm{B}\left(2, \frac{1}{2}\right) - 1$. Intuitively, half of the time there is no change along that dimension, while changes of both -1 or $+1$ are equally likely, each with a probability of 25%.

[1] Bouhlel et al. (2018) studied environments of different dimensionality, while here we use 10-dimensional environments as a prototypical example.

Social information. Depending on their sharing policy, agents are deterministically either sharers or non-sharers. Sharers will unconditionally share information about both reward location $\mathbf{x}_{ti}$ and value $R(\mathbf{x}_{ti})$ to all other agents, while non-sharers will withhold it. Sharing information is associated with an increased cost due to splitting rewards with imitators, but can also confer byproduct benefits by broadcasting high quality solutions, which are subsequently modified by group members and improved upon, before being transmitted back via the visibility radius or by other sharers.

In addition to the global sharing signal, we use a visibility radius as a feature of the environment. At each trial t, agents passively provide information about reward locations and magnitudes to other agents that are within visibility radius r. For any two agents $i \neq j$, agent j is visible to agent i if the maximal distance between the two agents on any dimension (i.e., the Chebyshev distance) is not greater than the visibility radius r:

$$D_{Chebyshev}(\mathbf{x}_{ti}, \mathbf{x}_{tj}) = \max_m |d^t_{mi} - d^t_{mi}| \leq r \tag{4}$$

The visibility radius is a coordination mechanism that allows for localized transmission of information. Whereas the sharing signal is a global mechanism operating at all distances, the local visibility radius allows for dynamic interaction structures to emerge and facilitates the spontaneous formation of spatially coherent groups. Crucially, given the high dimensionality and size of the search space, it is unlikely for any two agents to fall within the same visibility radius without explicit information sharing. For example, there is 0.1% probability of two agent being visible to one another at initialization for a radius of 2.

Evolutionary Simulations

Inspired by biological evolution, we embed the simulation framework in an evolutionary algorithm, which uses selection pressure and mutations over multiple generations to discover which sets of behavioral parameters evolve. The evolutionary algorithm is well suited for our research question because fitness-maximizing behavior (e.g., willingness to share information) depends on the behavior of others in a game theoretical context.

Initial conditions. Beginning with a population of 300 agents, each agent carries genes determining innovation rate and sharing policy (i.e., sharer or non-sharer). We start with an initial population consisting of only non-sharers to address the question of how cooperative behavior can emerge *ex nihilo* through individual selection. We vary the initial mean innovation rate in the populations to ensure that the results of the evolutionary algorithm are not dependent on the starting conditions. The initial values for innovation rate were sampled from a Beta distribution, with the mean of the distribution sampled from a uniform distribution $\mathcal{U}(0, 1)$.

For each generation, we repeatedly sample k agents from the whole population. We simulate these agents performing

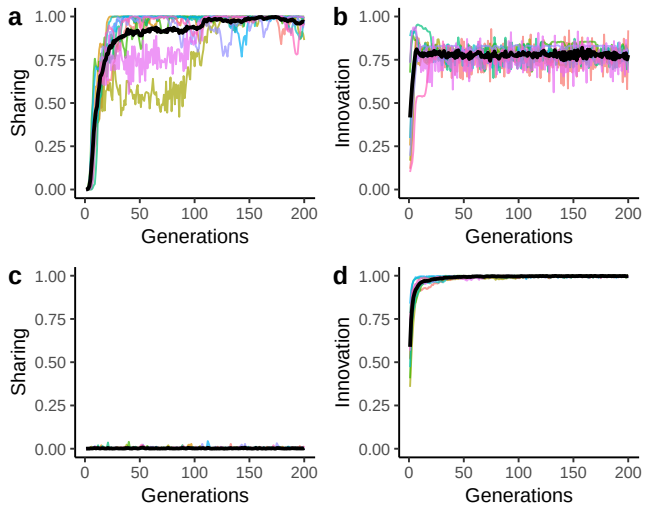

Figure 2: Evolution of sharing and innovation over 200 generations. **a**-**b**) An example where populations evolve high sharing and innovation rates, with group size $k = 6$, visibility radius $r = 4$ and competition level $c = 1/128$. **c**-**d**) An example where individuals adopted high innovation rates but did not evolve sharing, based on group size $k = 6$, visibility radius $r = 0$ and competition level $c = 2$. Each colored line represents the average parameter value within a population, while the black line indicates the average across populations.

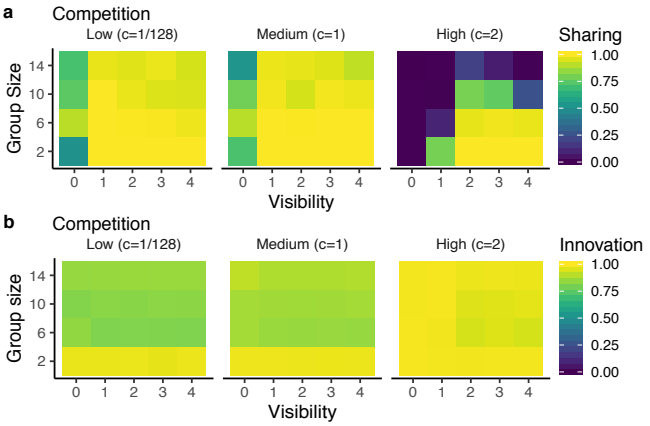

Figure 3: Equilibrium results for different combinations of environmental parameters. **a**) Agents evolved high sharing rates in low and medium competitive environments, although sharing was found in more restricted contexts under high competition (requiring smaller groups and larger visibility radius values). **b**) Overall, we find high levels of innovation, although we also see the trend that larger groups evolve slightly lower innovation rates.

collective search, where behavior is determined by their genetic makeup (innovation rate and sharing policy). We repeat the simulation procedure over $\frac{300}{k} \times 5$ repetitions, resulting in approximately 5 simulations per agent in each generation.

Selection and mutation. We select the agents with the highest fitness to produce genetically similar offspring via tournament selection. In this selection procedure, we repeatedly sample 7 random individuals from the population, whereby the individual with the highest relative performance passes its genes onto the next generation. This selection process is repeated 300 times in order to produce a new generation of 300 agents. The genes of the new generation are exposed to weak mutation to consistently ensure gene variation, where each gene has a probability of mutation. The sharing gene mutates with $p = .002$, whereby a new sharing policy is drawn from a binomial distribution $\sim \mathrm{B}\left(1, \frac{1}{2}\right)$, with the new policy equally likely to be sharer or non-sharer. The innovation gene mutates with $p = .02$, whereby the previous innovation is modified by adding Gaussian noise $\sim \mathrm{N}(0, 0.2)$. The innovation rate was truncated between [0,1]. Note that we chose the mutation probabilities and strengths to be high enough to ensured constant variation in the gen pool.

The genetic algorithm repeats the process of fitness evaluation, selection, and then reproduction with mutation for 200 generations to ensure the population converges to a stable outcome. We ran 10 replications of this procedure and report the average evolved parameters of the last 10 generations (i.e., generations 190 to 200) over each of the 10 replications. We systematically varied group size ($k \in [2, ...14]$), visibility radius ($r \in [0, 1, 2, 3, 4]$), and competition level (low $= \frac{1}{128}$; medium = 1; high = 2) to investigate how the structure of the environment influences the selection of individual characteristics (sharing and innovation).

Results

When exposed to selection pressure via the evolutionary algorithm, the populations evolved different sharing and innovation rates depending on the environmental parameters (see Fig. 2 for examples). Figure 3 shows the proportion of sharers and the innovation rate at equilibrium for different parameter combinations, where yellow tiles indicate high levels of either sharing or innovation.

Sharing evolves ex nihilo. Starting from initial conditions of no sharers in the population, we find that sharing emerges in the overwhelming majority of our simulation parameters, and that sharing often dominates the population at close to ceiling levels (Fig. 3a). However, we also discover the limits of sharing as an adaptive strategy as we increase the level of competition for rewards. Under high levels of competition, only smaller groups with larger visibility radius are able to support sharing.

Sharing and innovation co-evolve. We find that over the entire parameter space, all populations evolved high innovation rates (Fig. 3b), although not at ceiling level (i.e., yellow tiles) compared to sharing behavior. Looking more closely, we find relatively higher innovation rates in small groups compared to large groups, with this effect most pronounced under low or medium levels of competition. Yet, how are sharing and innovation behaviors related to each other?

To further understand the interaction between strategies, we ran additional simulations with innovation rate fixed at low (25%), medium (50%) or high (100%) values. The results are shown in Figure 4, where we replicate the main findings of the previous simulation for high innovation rate (top row). However, we find that sharing becomes substantially

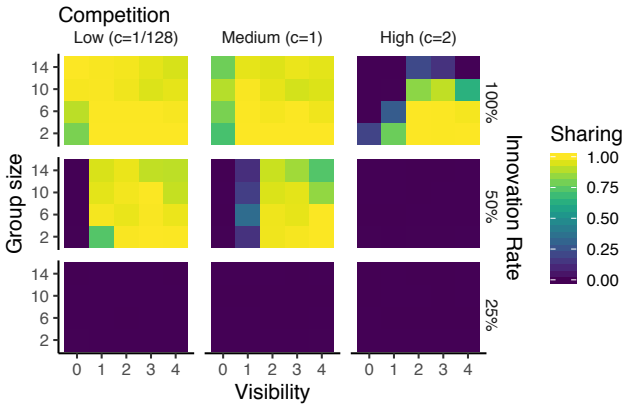

Figure 4: Equilibrium results of sharing for fixed innovation rates (rows) at various parameter combinations. When the innovation rate is fixed at 100%, we largely replicate the results in Figure 3. However, when innovation is fixed at 50%, we find that sharing evolves in a more restricted set of parameters and exclusively with a visibility radius of 1 or larger. When there is an innovation rate of 25%, we find virtually no emergence of sharing.

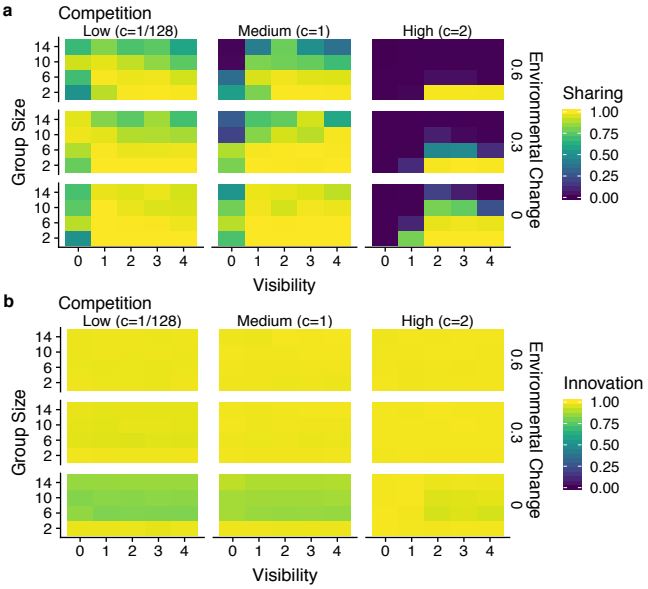

Figure 5: Equilibrium results in a dynamic environment. **a**) Again we find high sharing rates in low and medium competitive environments, but now higher rates of environmental change reduced the levels of sharing in the population. We also see stronger indications of an interaction between group size and visibility radius, where a larger visibility radius is required to coordinate larger groups and support a larger sharing population. **b**) Across all parameters, we find high levels of innovation emerge, although lower competition and larger groups reduces the extent of innovation.

less adaptive for populations with innovation fixed at low or medium levels. Thus, innovation is an essential ingredient for prosocial traits to develop, as has been shown in previous work on cultural transmission through iterative cycles of imitation and innovation (Ehn & Laland, 2012; Wisdom & Goldstone, 2011; Derex, Feron, Godelle, & Raymond, 2015).

Interim conclusion

We show that sharing can evolve across a variety of different environments and in mixed groups with different proportions of sharers and non-sharers. The selection pressure for sharing can lead to it becoming a dominant trait prevalent in the vast majority of the population. The spatial dynamics of this simulation framework facilitated by a visibility radius lead to a setting where selection pressure does not prioritize free-riding and the group does not succumb to a tragedy of the commons.

Dynamic Simulations

We now extend the framework to account for a changing environment, implemented by a wandering global optima. We define the global optima Ω^t and modify it on each time t with a probability determined by the environmental change rate p_e. With probability p_e, the environment's global optima changes, otherwise it stays the same ($\Omega^{t+1} = \Omega^t$). When the environment changes, each coordinate of the global optima $d^t_m \in \Omega^t$ has a 50% probability of being modified by +1 or -1, and a 50% probability of remaining the same. This is the same as the local search rule used by individual agents.

In order to account for the decreasing validity of past observations in a changing environment, we introduce a temporal discount rate γ. Thus, the history of past observations maintained by each agent decays as a function of the elapsed time:

$$\hat{R}(x_{ti}) = \gamma^{\tau} R(x_{ti}) \quad (5)$$

where $\hat{R}(x_{ti})$ is the discounted reward and τ is the elapsed time between the observation and the current time. Thus, agents locally search around the reward location that has the largest discounted reward $\hat{R}(x_{ti})$. Both individually and socially acquired information follow the same decay rate. In our simulations we fixed the Discount rate $\gamma = .99$, which approximately corresponds to a 10% discount after 10 trials.

Dynamic Results

Figure 5 shows the equilibrium results of our dynamic simulations. Again, we find that sharing is a beneficial strategy under many environmental conditions (Fig. 5a). Similar to the static case, there are limits to the conditions under which sharing emerges, particularly in highly competitive environments. The relationship between the visibility radius and group size becomes increasingly important, where a larger radius allows sharing to emerge in larger groups. We also observe that the evolved proportion of sharers decreases in more volatile environments (higher change rates) and in larger groups. This interaction is not observed in the static environment, but may be partially due to the increased difficulty of coordination and because out-of-date information can harm instead of help others (Boyd & Richerson, 1988; Henrich & Boyd, 1998). Additionally, we find that environmental change increases the evolved innovation rates (Fig. 5b). The intermediate levels of innovation found in the static simulations are eclipsed by even higher rates under environmental change.

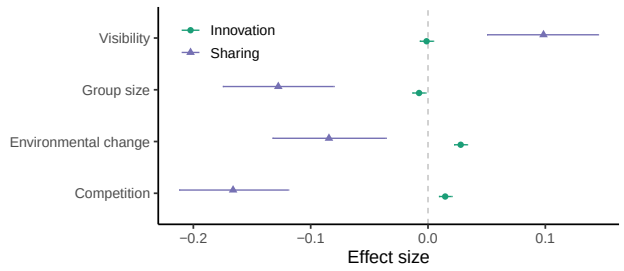

Figure 6: Regression results. The estimated effect sizes of environmental parameters on innovation rate (green) and sharing (purple). Error bars show 95% CI.

General Discussion

We use evolutionary simulations to show that for a variety of initial conditions and across both static and dynamic fitness landscapes, there exists individual selection pressure for the unconditional sharing of information. To summarize the effects of each environmental parameter on the equilibrium characteristics of innovation and sharing, we fit a linear model on the dynamic simulation results (Fig. 6). The size of the visibility radius contributes positively to the rate of sharers in the evolved population, while group size, environmental change, and competition all reduce the rate of sharers. Thus, the evolution of cooperation in the absence of reciprocity operates at a fine balance between coordination (via the visibility radius) and discord (through competition and the communication of out-of-date information).

In comparison, the environmental effects on innovation are relatively small. We find relatively high levels of innovation in all simulations. Environmental change had the strongest influence on innovation, while higher competition also increased innovation. Rather, the more interesting result of our simulations involves the interaction between innovation and sharing, which co-evolve and are dependent on one another for producing the emergent behavior of collective search.

How do the dynamics of cooperation work? To get a deeper understanding of how sharing improves the welfare of the donor, we present a vignette of an agent who is either a sharer or a non-sharer in a population of non-sharers (Fig. 7). The sharer transmits a global signal that recruits peers and gathers them within visible range (Fig. 7a, orange line). This means that a sharer will have access to more social information compared to a non-sharer by being closer to others (Fig. 7a, blue line). Since we find high rates of innovation in all simulations, any imitated information is also tweaked and modified. Some of these modifications will improve upon the originally copied solution. This creates a feedback cycle of solutions that are consistently improved over time, which can benefit the original sharer through local transmissions within the visibility radius (Fig. 7b). Compared to a group of non-sharers (blue line), the sharer is able to explore the reward landscape better and achieve higher rewards despite the stronger local competition (Fig. 7c, orange line).

In summary, as is the case with the Cliff Swallows (Brown et al., 1991), sharers recruit peers within their visibility radius and reap the byproduct benefits of passively acquired modifications to the original solution. Intuitively, larger visibility increases the ability of a group to stay connected with one another. However, the global sharing signal is an essential recruitment device that facilitates the formation of a group in the first place. Group coherency facilitated by the visibility radius provides byproduct benefits to the originator of the sharing signal, creating a feedback loop of imitation with innovation.

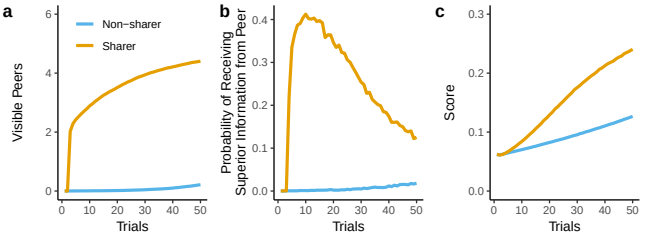

Figure 7: How sharing leads to cooperation. These results are the mean performance over 10,000 replications with a group size of $k = 6$, a visibility radius of $r = 2$, a innovation rate of 1 and a competition level $c = 1$. **a**) The sharer (orange line) attracts other individuals within their visibility radius through the sharing signal, leading to richer informational exchanges than compared to a non-sharer (blue line). **b**) Individuals who imitate the shared information also innovate, and thus passively provide improved information to the sharer through the visibility radius. **c**) As a result, the sharer benefits from passively gained information and acquires an overall higher pay-off compared to individuals in a non-sharing group.

Conclusion

Through the lens of evolution, we show how individual selection pressure can give rise to the unconditional sharing of information. The sharing signal does not require expectations of reciprocity in order to be beneficial, but rather directly benefits the sharer through the byproducts of cooperation. Shared information about a high reward acts as a recruitment signal, which leads to the emergence of a self-organized collective centered on the original donor. A key ingredient is a visibility radius, which allows individuals to observe the rewards of neighbors within a fixed spatial distance. This visibility radius provides a simple yet effective coordination mechanism that is grounded in simple spatial and social dynamics, creating complex patterns of emergent behavior.

More broadly, our results indicate that prosocial behaviour can evolve from initial conditions devoid of other prosocial individuals. While theories explaining the evolution of conditional reciprocity have been very influential (Nowak & May, 1992; Ohtsuki et al., 2006), our results provide an explanation for the initial emergence of prosocial individuals, which is an essential requirement for both conditional cooperation and group selection. Future implementation of conditional strategies in our framework could provide further insight into how various strategies co-evolve.

Abstract

We experimentally investigate, by means of a novel gesture-elicitation paradigm, the spontaneous spatial frames of reference (FoRs) used by bilingual individuals who speak Japanese (which has been labeled as a "relative" language) and one of the endangered Ryukyuan languages (Miyako or Shiraho) whose speakers have been reported to routinely use absolute FoRs. How would these last elderly bilingual speakers spontaneously resolve the clashing FoRs the two languages they speak bring forth? We find that despite the fact that Japanese and these Ryukyuan languages have full corresponding grammatical and lexical resources for expressing both, relative and absolute FoR, Ryukyuan speakers tend to markedly prefer the latter gesturally. Methodologically, the results, which are consistent with data obtained with standard FoRs methods, corroborate the reliability of the novel gesture elicitation task, which adds to the battery of techniques for studying FoRs a method that assesses effortless spontaneous real-time cognition with high ecologically validity.

Keywords: spatial construals; gesture; absolute frames of reference; linguistic relativity hypothesis, bilingual; endangered languages; Miyako, Shiraho, Japanese, Japonic languages; Ryukyu islands; elderly participants

Introduction

The study of spatial frames of reference (FoRs) (Levinson, 2003) has received significant attention in the last 20 years. While speakers of some languages have been found to prefer relative FoRs (i.e., egocentric; e.g. 'left' and 'right') to describe or reason about spatial relations among tabletop objects, speakers of others prefer absolute FoRs (i.e., allocentric; e.g. 'north', 'south') (Gumperz & Levinson, 1996; Levinson and Wilkins, 2006). A common interpretation of these results has been that it is language that plays a significant role in structuring the cognition of fundamental domains like space (Majid, Bowerman, Kita, Haun, and Levinson, 2004) —the core of the linguistic relativity hypothesis (Gumperz and Levinson, 1991; Lucy, 1992). This proposal, however, is largely based on the implicit assumption that the human mind is fundamentally monolingual, an assumption that doesn't seem to hold as bi- and multi-linguism have been ubiquitous throughout the history of humanity (Evans, 2011; Pavlenko, 2014). In fact, scholars investigating the linguistic relativity hypothesis have explicitly asked themselves "What are the cognitive consequences of being a bilingual in languages that rely on different frames of reference?" (Majid et al., 2004, p. 113), but no clear answer has been proposed so far, and no significant efforts seem to have been spent in order to address the question properly. Indeed, following the linguistic relativity hypothesis, bilingual individuals who fluently speak languages from the same linguistic family, and which are equipped with exactly the same relevant linguistic resources should not exhibit any marked preference in using relative or absolute FoRs. Here we ask, do fully bilingual individuals who speak such languages spontaneously exhibit any preferences when the linguistic practices of these languages elicit clashing absolute-relative frames of reference?

The last bilingual speakers of endangered languages spoken in the Ryukyus (the chain of islands stretching between Taiwan to Kyushu, Japan) provide a particularly interesting population for addressing this question. The Ryukyuan languages Miyako and Shiraho, are, for instance structurally equivalent to Japanese with respect to lexical spatial encodings. The three languages —all members of the Japonic family— have precise words for left and right, front and back, north and south, etc. (see Table 1), often even sharing cognate words (i.e., sharing the same original root, like "left" and "right" from proto-Japonic **pidari* and **migiri*, respectively). However, while speakers of Japanese have been reported to clearly prefer relative FoRs (Pederson, Danziger, Wilkins, Levinson, Kita, and Senft, 1998), ethnographic descriptions (Suzuki, 1978) as well as empirical psycho-linguistic studies (Celik, Takubo, and Núñez, 2019) have reported that speakers of Ryukyuan languages commonly rely on absolute FoRs. Interestingly, the preference of absolute FoRs of these individuals takes place despite being themselves fluent Japanese-bilinguals, and having been schooled and enculturated into the

mainland Japanese culture for most, if not all of their long lives (Japanese elementary school has been implemented in the Ryukyu islands since the end of 19th century, and there has been an overwhelming presence of mainland Japanese culture in TV and radio for decades).

Table 1: Spatial terms in Japanese, Miyako, and Shiraho

FoR	Translation	Japanese	Miyako	Shiraho
Absolute	east	higashi	agaɪ	anta

	left	hidari	pɪdaɪ	pitare
Intrinsic/ Relative	side	yoko	juku	jagata/aza
	front	mae	mavkjaa	menta
	behind/back	ushiro	tɕibi, kusɪ	ʃinta
	straight	massugu	massɪgu	meŋga
Intrinsic	be aligned	narab-	narab-	narab-

In this study, we experimentally investigate the spatial FoRs used spontaneously by bilingual Ryukyuan speakers (Miyako-Japanese or Shiraho-Japanese) and by monolingual speakers of standard Japanese from Tokyo. Endangered languages such as the Ryukyuan languages, however, are primarily spoken by elderly people, who are often challenged by problem-solving, reasoning, and memory tasks (Brinley, Jovick, and McLaughlin, 1974) such as the ones used in standard FoRs studies (e.g., "Animals-in-a-row" task (Pederson et al., 1998) or complex arrays of toys (Haun, Rapold, Janzen, and Levinson, 2011)). For this reason, we focus here on spontaneous cognition by means of a novel gesture elicitation paradigm that, while being ecologically valid, adequately assesses effortless spontaneous cognition (McNeill, 1992; Bates and Dick, 2002; Kendon, 2004; Goldin-Meadow, 2005) and can readily be implemented in cross-cultural field studies (Núñez and Sweetser, 2006; Le Guen, 2011; Núñez and Cornejo, 2012; Núñez, Cooperrider, Doan, and Wassmann, 2012; Cooperrider, Slotta, and Núñez, 2018).

Method

Fieldwork locations

The fieldwork took place in the southern part of the Ryukyu islands, where the languages we investigate in this study (Miyako and Shiraho) are spoken. The southern Ryukyus are approximately 1,900 kms southwest from Tokyo, located on the western end of nowadays Okinawa prefecture, Japan. Two sites were involved. The Miyako site was primarily situated in the main island of the Miyako archipelago (total population 54,863 in 2005, Miyakojima shishi hensan iinkai, 2012), which are composed of 7 inhabited islands: Ikema, Irabu, Miyako, Ogami, Kurima, grouped into the city of Miyako, and Tarama, Minna, grouped into the village of Tarama. The Shiraho site was located in the village of Shiraho (population 1,602 in 2010, Ishigakishi kikaku-bu kikaku seisaku-ka, 2013), along the southwestern shores of the Ishigaki island, one of the many islands belonging to the Yaeyama archipelago. This village is the only place where the Shiraho language is spoken. Both Miyako and Yaeyama islands got integrated into the Ryukyu kingdom at the beginning of the 16th century and were ruled and administered by the Ryukyu Kingdom until the Meiji era (1868-1912), before becoming part of Okinawa prefecture (Miyagi, 1968). Both fieldwork sites are located in rural areas that have agriculture (e.g. sugar cane), and, more recently, tourism as main economic activities.

Languages

Ryukyuan languages are traditionally spoken in the Ryukyuan islands and stand in sister relationship with Japanese, with which they form the Japonic family. They all share a common ancestor —proto-Japonic— thought to have been spoken before the 7th century (Pellard, 2015). They are divided into two branches, Northern Ryukyuan spoken in Amami and Okinawa islands, and Southern Ryukyuan, spoken in Miyako and Yaeyama islands. While not mutually intelligible as a consequence of the independent development of each language, both Miyako and Shiraho belong to the Southern Ryukyuan branch. The Ryukyuan languages are virtually entirely unintelligible to speakers of standard Japanese from the mainland, a fact that has been attested empirically (Yamada et al., in press). Ryukyuan speakers, on the other hand, are completely fluent in Japanese due to the fact their entire scholastic, administrative and civic lives are conducted in Japanese. As in the rest of the Ryukyus, there is an on-going language shift to Japanese, resulting in the elderly generations being bilingual in the traditional language and Japanese, and the younger generations monolingual in Japanese, with almost no knowledge of the local language. Miyako and Shiraho are thus reported to be definitely, and severely endangered, respectively (Moseley, 2010). The exact number of fluent speakers is difficult to assess due to the complex sociolinguistic situation induced by the language shift, but coarse estimates have given the figure of 12,000 to 22,000 speakers for Miyako (Jarosz 2015), and only 147 for Shiraho (Nakagawa, Lau, and Takubo, 2016). Miyako, Shiraho and modern Standard Japanese share many broad morpho-syntactic features. Among others, they are characterized by an agglutinative morphology, a SOV word order, the use of postpositions and suffixes, and a nominative/accusative case system.

Participants

Thirty-eight individuals participated in the study, 15 Miyako inhabitants-speakers (5 men, 10 women) tested in the Miyako islands, 8 Shiraho inhabitants-speakers (3 men, 5 women) tested in Shiraho, Ishigaki island, and 15 monolingual speakers of Standard Japanese (8 men, 7

women) all born and raised in Tokyo as the control group, tested in Tokyo. Given that Miyako and Shiraho are endangered languages (like all other Ryukyuan languages), the population of speakers is essentially constituted by senior citizens. As a result, the Ryukyuan samples in this study, as well as the matching control group, were formed by elderly men and women (mean age of the Miyako group was 83.2 and SD 8.13; for Shiraho was 83.63 years and SD 2.62; for the Japanese group was 73.47 years, SD 4.49). Miyako and Tokyo participants were recruited through elderly and rehabilitation centers. Shiraho speakers, being considerably less in number and living in a relatively small village, were recruited through the network of one of the authors (NN). As compensation Ryukyu participants received a small gift, and Tokyo controls a small amount of money. Three Miyako speakers and four Japanese speakers were excluded from the analysis because they failed to produce directional gestures with a clear trajectory in two or more of the four trials. One female Miyako participant was excluded because during the experiment she spoke in Japanese (not in Miyako, as instructed). In total, the data from 30 participants (11, 8, and 11, from the Miyako, Shiraho, and Japanese groups, respectively) were included in the analysis.

Materials

The set of stimuli consisted of eight simple live dynamic events made up of a combination of tabletop objects. These objects were: two ping-pong balls (one white, one black), two book-size boards (one white, one black), and one transparent small box used as a support for reclining the boards. In four of the eight events the experimenter releases a black/white ball to roll down a contrasting reclined white/black board and on the other four events s/he releases the ball (with corresponding color schemes) to bounce down the reclined board (see Figure 1).

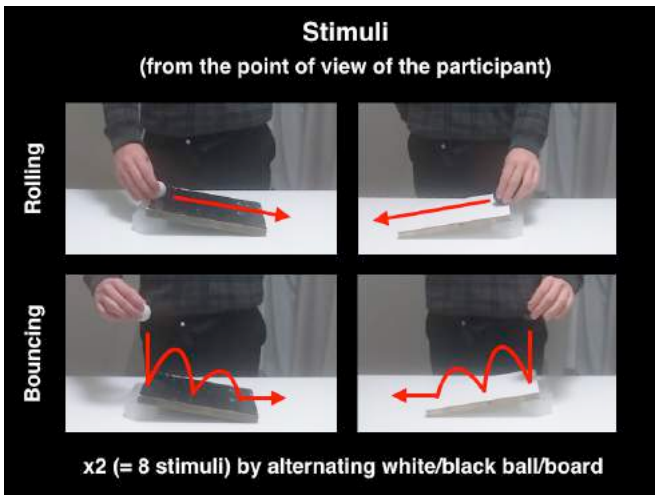

Figure 1: Gesture elicitation stimuli.

From these, four events had the action unfolding towards the left of the participant and four towards the right of him/her. Figure 1 shows four of the eight stimuli (the other four stimuli correspond to the ones shown but with alternated black/white colors of the ball/board).

Procedure

The experimental procedure consisted of four trials, in which participants were tested individually. In each trial the participant was placed in front of a table facing either north or south (the direction was selected randomly).

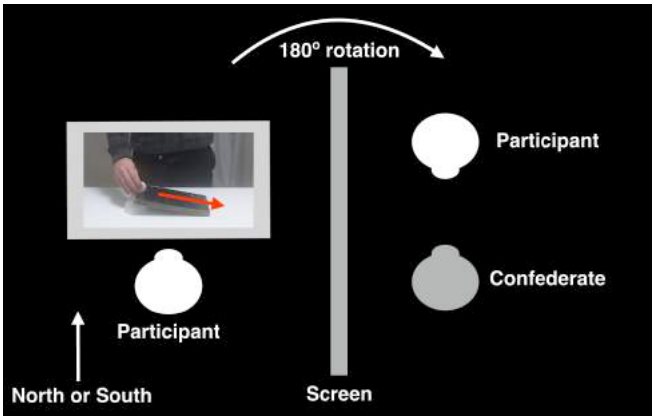

Figure 2: Schema of the gesture elicitation procedure.

Across the table there was an experimenter, who enacted for the participant one of the eight dynamic stimuli (events) described in the "Materials" section. The mode of movement (rolling/bouncing ball) and direction of the movement (eastward/westward) implemented in each of the four trials were selected randomly so that each participant experienced in the 4 trials all possible combinations of mode and direction of movement, namely ball rolling east, ball rolling west, ball bouncing east and ball bouncing west (the color scheme for each trial in the sequence was fixed, alternating the black ball over the white board with the white ball over the black board, beginning with the former configuration[1]). When the brief presentation of the event ended (with the experimenter catching the ball), the participant was invited to go to a section of the room located a few meters away on the other side of a screen that blocked the view of the table where the stimulus had been shown (see Figure 2), and was instructed to sit on an armrest-less chair that placed him/her with a 180° rotation with respect to his/her original orientation (i.e., if s/he observed the dynamic stimulus facing north, s/he was then sat facing south). At this point, sitting in front of the participant there

[1] Since the Ryukyuan languages are endangered, the number of (elderly) speakers available is reduced (especially in Shiraho). This made a full counterbalanced design (manner of movement, direction of movement, and color scheme) not viable.

was a confederate fluent in the participant's language[2] and who, being on this side of the screen, had not observed the dynamic stimulus. The participant was then invited to describe (in the relevant language: Miyako, Shiraho, or Standard Japanese) to the confederate sitting in front of him/her the scene that had been shown to him/her on the table on the other side of the screen. The presence of the confederate was meant to ensure that the participant would have a genuine real-world interlocutor who de facto had not observed the stimulus. The confederate's participation was primarily limited to listening to the descriptions given by the participant (and, occasionally, to nodding to signal comprehension of the participant utterances). Once the description was completed, the participant was invited to go back to the original table on the other side of the screen in order to begin the next trial. There was no mention of the possibility or necessity of gesturing during the instructions. All participants' descriptions were video-recorded.

Results

The directionality of the gestures was easily assessed as they primarily exhibited transversal hand (and sometimes head) movements indexing ball trajectories (often co-produced with utterances that referred to the motion of the ball itself: e.g. "it rolled away", or with vocalizations that characterized the manner of the ball's motion: e.g., "bom, bom, bom" for the bouncing ball). Only gestures that unambiguously unfolded either to the left or to the right of the participant while describing the trajectory of the ball were considered for analysis[3].

Figure 3: Example of a gesture produced by a Miyako speaker exhibiting an absolute frame of reference

Figure 3 shows an example of a Miyako participant describing the trajectory of a westward bouncing ball, which she had observed facing south on the other side of the white screen (i.e., as the ball moved to her right). Her description, as she now faces north, involves a right-handed swiping gesture towards her left (i.e., westwards) reflecting an absolute FoR.

[2] A native speaker for the cases of Miyako and the Standard Japanese controls. For Shiraho, the confederate was the third author (NN), who has done extensive fieldwork on the language.

[3] In this report we ignore gestures co-produced with non-targeted descriptions such as the size of the table or the texture of its surface.

Based on these gestural properties, the gestures depicting the trajectory of the dynamic stimuli of each of the four trials was classified as either "relative" or "absolute", depending on whether it followed an egocentric or an allocentric pattern, respectively[4]. The classification yielded a mean percentage of absolute gestures per participant.

In average both Ryukyuan groups produced a much higher percentage of absolute gestures (Miyako mean = 71.09%, SD = 23.7%; Shiraho mean 81.25%, SD = 34.72%) than the Japanese-only group (Mean = 40.9%, SD = 30.15%). Individual data show that only 1 of the 11 Miyako participants (9.1%), and 1 of the 8 Shiraho participants (12.5%) manifested absolute FoRs in less than 50% of the trials. In contrast, nearly half of the Japanese-only speakers did so (5 of the 11 participants; 45.5%). Besides, more than half of the Miyako participants (6 out of 11; 54.5%), and almost all Shiraho participants (7 out of 8; 87.5%) exhibited absolute FoRs at least in 75% of the trials. In contrast, only 2 of the 11 Japanese speakers (18.2%) did so. A One-Way ANOVA reveals that the difference between the three groups is statistically significant ($F(2,27) = 5.10$, $p = 0.013$), exhibiting a large effect size ($\eta^2 = 0.27$) (see Figure 4). Post-hoc Bonferroni and Holm simultaneous comparisons of the Ryukyu groups versus the Japanese controls yield statistically significant differences for both, Miyako (Bonferroni and Holm T-statistic = 2.42; Bonferroni p-value = 0.045; Holms p-value = 0.023) and Shiraho (Bonferroni and Holm T-statistic = 2.97; Bonferroni p-value = 0.013; Holms p-value = 0.013).

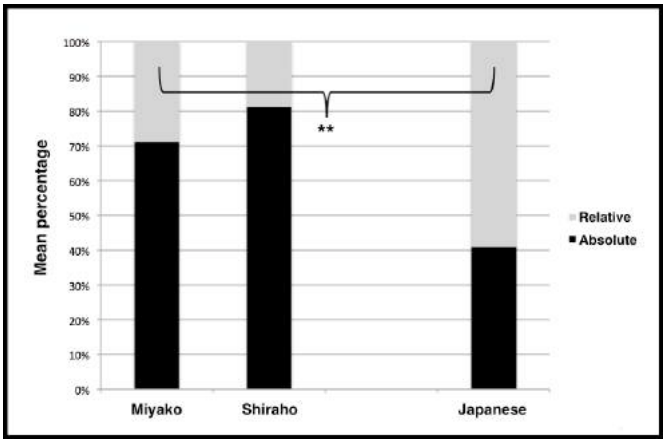

Figure 4: Mean percentage of absolute gestures (black) per participant.

Discussion

The study of FoRs has been an important area for the investigation of the linguistic relativity hypothesis (Gumperz & Levinson, 1996; Li & Gleitman, 2002; Majid et al., 2004; Haun et al. 2011). However, with rare

[4] For the analysis presented here we do not analyze the details and extension of participants' verbal production.

exceptions (e.g., Marghetis, McComsey, and Cooperrider, 2014; Meakins, Jones, and Algy, 2016), many of these studies have focused on monolingual populations. When bilinguism has been present, which is the case of many colonized regions around the world where individuals speak the indigenous language as well as that of the colonizer, more often than not the emphasis has been put only on one of the languages spoken (usually the indigenous one). This situation has left open questions involving the status of the linguistic relativity hypothesis when bilingual (or multilingual) cognition is concerned— an underestimated but ubiquitous condition in human history (Evans, 2011; Pavlenko, 2014). The linguistic relativity hypothesis makes clear predictions of FoRs preferences when the languages under investigation are not structurally equivalent, like when comparing those that do not have terms for "left" and "right" with languages that do, such as Mesoamerican Tzletal and Dutch, respectively (e.g., Brown and Levinson, 1993; Levinson, 2003; Majid et al., 2004). Usually these predictions are about comparisons of speakers of languages that, differing substantially in the deployment of relative vs. absolute FoRs, belong to completely unrelated and radically different linguistic families, such as the one just mentioned (Tzeltal belongs to the Mayan family and Dutch to the Indo-European family) or ≠Akhoe Hai||om form the savannah of Northern Namibia (Central Khoisan language family) and Dutch (Indo-European family) (Haun et al, 2011).

Some studies with bilingual speakers of indigenous/Indo-European languages that exhibit clashing absolute-relative encoding have investigated extra-linguistic factors that appear to delimit the role of language in shaping thought (e.g., Spanish (Indo-European)-Juchitán Zapotec (Otomanguean family) from Oaxaca, Mexico (Marghetis, McComsey, and Cooperrider, 2014); English (Indo-European)-Gurindji (Pama-Nyungan family) from Northern Australia (Meakins, Jones, and Algy, 2016). These studies suggest that environmental and sociocultural factors such as schooling and writing practices affect the choice of FoRs in fundamental ways that are not strictly speaking linguistic.

To help evaluating the precise role that language might play in shaping thought —the essence of the linguistic relativity hypothesis— and further delineate the contribution of extra-linguistic factors, an important step is to investigate cases of bilingual populations of people that speak languages that: (1) in practice tend to elicit clashing FoRs (e.g., absolute vs. relative), (2) that belong to the *same* linguistic family (hopefully sharing cognate words), and, importantly, (3) that are structurally equivalent with respect to the relevant lexicon and grammatical resources. In this study we have done so by investigating the preference of FoRs of Japanese-bilingual speakers of two endangered Ryukyuan languages that belong to the same Japonic linguistic family as Japanese, and that, while being mutually unintelligible, share an important number of grammatical features and cognate words (e.g. Hattori (1959) reports 59% of shared cognates for Miyako and Tokyo Japanese). Importantly, while Japanese has been reported to preferentially elicit the use of relative FoRs for characterizing small-scale spatial relations (Pederson et al., 1998; Kita, 2006) the Ryukyuan languages have been reported to do so primarily via absolute FoRs (Suzuki, 1978; Celik, Takubo, and Núñez, 2019).

The use of FoRs by (elderly) Miyako speakers had been previously studied experimentally via a referential communication task (Celik, Takubo, and Núñez, 2019) adapted from the standard "Man-and-tree" task (Pederson et al. 1998). In this task —of a director-matcher type (e.g., Le Guen, 2011)— speakers are asked to describe to a partner sitting on the other side of a screen simple scenes containing two toy animals that the latter could not see (Cooperrider, Slotta, and Núñez, 2017). The study on Miyako confirmed, as predicted, that (elderly) monolingual Japanese-speaker controls almost exclusively relied on relative terms to describe the stimuli to their partners. In stark contrast, Miyako speakers, when speaking in Miyako, exhibited a marked tendency to describe the spatial configurations of the figurines using absolute terms, such as 'west' and 'east', and this despite being fully bilingual in Japanese and having been massively exposed to mainland Japanese culture for decades. Surprisingly, in addition, speakers from the same Miyako bilingual population when doing the same task in Japanese relied extensively on relative terms, showing no significant difference from Standard Japanese speakers. These results suggest that, beyond the grammatical and lexical resources of languages, the referential communicative practices and conventions brought forth when a speaker is immersed in speaking a particular language may be an important factor influencing thought (and spatial construals, in this case). In order to test whether these results were triggered by the goal-oriented, performance-driven, explicit cooperation dimension that is demanded in this communicative task, in this study we investigated the spatial construals that would be spontaneously enacted gesturally in real-time without the demands of goal-oriented cooperation and performance that are present in the referential communication director-matcher task. Moreover, to gain a richer insight into the Ryukyuan mind, we extended this approach to investigate another Ryukyuan language— Shiraho, from the Ishikagi island.

This study shows that the investigation of spatial construals and FoRs preference can be enriched with the addition of observations of speech-gesture co-production. Spontaneous gesture production is largely effortless, which is an important factor when evaluating elderly speakers, and it is universal, so it is expected to be observed in all human groups (McNeill, 1992). Since, in general, spontaneous gesture production is less monitored than speech, it largely unfolds below the level of awareness, and therefore provides a remarkable backdoor to real-time cognition (McNeill, 1992). And being effortless and largely unconscious, gesture production does not provide the intimidating effect that challenging reasoning and memory tasks might bring for some individuals. This is especially relevant when

studying elderly speakers of endangered languages who often are unschooled (or poorly schooled) and are less exposed to testing and scholastic practices. Importantly, gesture production often provides content that is not observable through speech alone (Kendon, 2004) allowing for the observation of construals that are not accessible via purely linguistic means (Le Guen, 2011; Núñez et al., 2012). Finally, gestures are often co-produced with abstract analogical and metaphorical thinking that reveal important features of the underlying conceptual mappings and inferential affordances (McNeill, 1992), which often rely on spatial construals (e.g., see Núñez and Sweetser (2006) for spatial construals of time).

The novel gesture elicitation paradigm used in this study builds on these important properties of gesture-speech co-production. The results confirm, via a different, but complementary approach into cognition, the preference of absolute FoRs observed in Miyako speakers with a more traditional method such as that of referential communication director-matcher tasks (Celik, Takubo, and Núñez, 2019). These results help establish the reliability of this novel gesture elicitation method for investigating tabletop spatial construals. Morever, the results of this study extend the findings to speakers of another Ryukyuan language — Shiraho— which being consistent with those obtained with Miyako speakers, confirm some of the socio-geographic observations (Suzuki, 1978) that Ryukyuan people exhibit a marked tendency to use absolute FoRs.

The fact that the elderly Ryukyuan individuals exhibit preference for absolute FoRs despite being fluent Japanese-bilinguals and being fully immersed in mainland Japanese culture for most of their extended lives is quite remarkable. In fact, other groups, such as the Gurindji people of Northern Australia who traditionally relied on absolute FoRs, have been shown to have shifted to relative patterns due to exposure to English and the associated cultural and literary practices that go with it (Meakins, Jones, and Algy, 2016). Similary. regarding spatial construals of time, Mandarin-English bilinguals have been reported to exhibit chronic inter-language influences on patterns in thought, and this already by the time they are young adults (Lai and Boroditsky, 2013). But in stark contrast to these cases, the last speakers of the Ryukyuan languages we have studied, despite a life-long immersion in the dominant Japanese culture and language, manifest a preference for an absolute FoR that appears to be robust and long-lasting. How pervasive is this pattern among speakers of other languages of the Ryukyu islands? Why is it so resilient? We don't know. More research is needed for answering this and many other open questions. We are, however, running out of time, as the last speakers of these endangered languages may leave us taking with them their rich cultural heritage along with the precious answers.

Acknowledgments

We thank Yukinori Takubo for comments and insights regarding the Japonic languages and for facilitating access to the fieldwork locations. We also thank Hamakawa Keiko for helping with data collection in Miyako. This research was supported by grants from the Japan Society for the Promotion of Science (17H02333, 25284078, 18K12360).

Designing good deception: Recursive theory of mind in lying and lie detection

Abstract

The human ability to deceive others and detect deception has long been tied to theory of mind. We make a stronger argument: in order to be adept liars – to balance gain (i.e. maximizing their own reward) and plausibility (i.e. maintaining a realistic lie) – humans calibrate their lies under the assumption that their partner is a rational, utility-maximizing agent. We develop an adversarial recursive Bayesian model that aims to formalize the behaviors of liars and lie detectors. We compare this model to (1) a model that does not perform theory of mind computations and (2) a model that has perfect knowledge of the opponent's behavior. To test these models, we introduce a novel dyadic, stochastic game, allowing for quantitative measures of lies and lie detection. In a second experiment, we vary the ground truth probability. We find that our rational models qualitatively predict human lying and lie detecting behavior better than the non-rational model. Our findings suggest that humans control for the extremeness of their lies in a manner reflective of rational social inference. These findings provide a new paradigm and formal framework for nuanced quantitative analysis of the role of rationality and theory of mind in lying and lie detecting behavior.

Keywords: deception; Theory of Mind; Bayesian reasoning; non-cooperative games; computational modeling

Introduction

The frank truth is that humans lie frequently, and the abilities to lie and detect lies are practical, but cognitively demanding, tools we develop over time (Vrij, Fisher, Mann, & Leal, 2006). Although much of the research on lying focuses on physical cues that give away lying (like facial expressions), both liars and lie detectors must consider not only the execution of lies (e.g. Vrij, Granhag, & Porter, 2010; Ekman, Friesen, & O'Sullivan, 1988) but also the informational content of lies. In our current era of endemic fake news (Allcot & Gentzkow, 2017), it is ever more critical that we develop an understanding of what cognitive processes contribute to deception and its detection.

Lying *at all* requires believing that the recipient could have a belief different from your own, and thus lying has long been tied to theory of mind (ToM), or the understanding of others' mental states, such as beliefs. Children struggle with the ability to represent false beliefs and second-order beliefs conditioned on false beliefs (Wimmer & Perner, 1983; Talwar, Gordon, & Lee, 2007). This poor ToM in children should also make them terrible liars. Indeed, improvement in children's detection and production of lies appears to be directly related to the development of their ability to use ToM (Ding, Wellman, Wang, Fu, & Lee, 2015). To lie at all, we need to be able to entertain the possibility of a false belief in our interlocutor, however, successful deception requires a far more nuanced process of decision-making interacting with ToM inference.

We usually lie to benefit ourselves. For example, a male date-seeker may want to optimize his chances of attracting potential romantic interests by inflating his height on his online dating profile (Toma, Hancock, & Ellison, 2008). What height should he make up and report to accomplish this goal? A taller height might be more attractive in the eye of potential dates; so perhaps, he could choose the height of his favorite professional basketball player. However, being caught in a lie tends to be costly: he may jeopardize his trustworthiness. An overly tall height is likely to make his date more suspicious, so to decrease the chance of getting caught in a lie, he should not make the height too suspicious. How should he balance these competing pressures on his lie?

On the receiving end of a lie, it is advantageous for humans to be attuned to the detection of lies. Potential dates should want to detect the date-seeker's lie in order to discern whether he is a trustworthy human. But dates cannot haphazardly accuse others of lying, as a false accusation can also result in tarnishing the accuser's reputation. Both liars and lie detectors not only must navigate the constraints placed upon themselves, but they should also consider the other agent's perspective.

In the current study, we argue that good deception not only requires the use of ToM, but we make a stronger claim that good lie detectors evaluate, and good liars conjure, their lies under the assumption that their partner is a rational utility-maximizing agent. We formalize the role of rational and recursive social inference in the production and detection of deception. We argue that it is not only the ability to represent partners' false beliefs that distinguishes good liars from bad liars; rather, good liars balance maximizing reward with maintaining plausibility in their lies, such that liars can avoid having their lies detected by another agent. In order to maximize achievement of these goals, liars consider their partner's prior expectations, the likelihood of observations, and how these expectations shift in response to considering the other agent.

Traditionally psychological studies examining the role of ToM in deception are one-shot experiments. Examples of

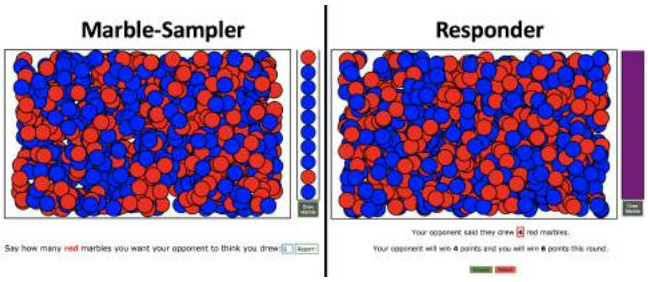

Figure 1: Lying game. In both the marble-sampler and responder roles, participants see the distribution of marbles. (Left) Marble-samplers sample 10 marbles, then either lie or tell the truth about the number of red marbles sampled. (Right) Responders accept or call BS.

such studies are those in which children are instructed to not peek at a toy while the experimenter temporarily leaves the room, and children choose to either lie or tell the truth about peeking (Lewis, Stanger, & Sullivan, 1989; Talwar & Lee, 2002). Alternatively studies of dishonesty in the behavioral economics literature use quantitative measures but emphasize the tendency of people to cheat at an individual level, independent of how other agents affect their deception (e.g. Mazar, Amir, & Ariely, 2008). Taking inspiration from both designs, we developed a novel repeated dyadic stochastic game allowing us to focus on the quantitative, socially-motivated production and evaluation of lies.

Using Bayesian game-theoretic computational modeling and experimental methods, we argue that a well-calibrated, Bayesian ToM supports the production of believable lies and the detection of poorly-formed lies, and introduce a novel ideal observer model of deception.

Lying Game

To study how humans actually behave in lying situations, we developed a novel lying game that rewarded participants for strategic detection and production of lies (Figure 1).

In each round of the game, both players are presented with a box containing red and blue marbles, with some proportion p of red marbles. Players alternate between playing as the marble-sampler or the responder. The marble-sampler randomly samples 10 marbles from the box, of which k are red. However, the sampled marbles are occluded from the responder, so the responder cannot see the true distribution of sampled marbles. The marble-sampler chooses a number k^* to report as the number of red marbles they want their opponent to *think* they sampled. The marble-sampler could choose to (a) tell the truth and report the true number of red marbles sampled, or (b) lie and report a false number of red marbles sampled. The responder then has the opportunity to either (A) accept the reported value or (B) reject it as a lie (i.e. call BS).

Both the marble-sampler's decision to (a) tell the truth or (b) lie about the number of red marbles sampled, and the responder's decision to (A) accept or (B) reject the reported value impact each player's payoff (Table 1). If the reported number of red marbles sampled k^* is accepted, the marble-sampler receives k^* points and the responder received $10-k^*$ points. If the responder rejects the reported number then the payoffs depend on whether or not it was a lie: if the reported number is the truth ($k = k^*$), the marble-sampler gets the k^* points, and the responder pays a penalty of $-k^*$; if the reported number is a lie ($k \neq k^*$) then the responder gains k^* points, while the marble-sampler pays a penalty of $-k^*$. Altogether, this game sets up a reward function that motivates marble-samplers to lie, but not be caught, and motivates the responder to call out egregious lies, but avoid false accusations.[1]

		Marble-Sampler	
		$k = k^*$	$k \neq k^*$
Responder	$BS = 0$	$2k^* - 10$ / $10 - 2k^*$	$2k^* - 10$ / $10 - 2k^*$
	$BS = 1$	$2k^*$ / $-2k^*$	$-2k^*$ / $2k^*$

Table 1: Players' payoff differential (player - opponent points). Utility is determined by reported k^* and whether BS was called. Values to the right of the diagonal in cells indicate points awarded to the marble-sampler, while values to the left are awarded to the responder.

Models

No-Theory-of-Mind Model

As a baseline, let's consider a model that has no model of the opponent, or believes that the opponent is effectively random. In deciding upon what number to report (k^*), such a model does not consider the behavior of the opponent, and would simply lie with probability $1-p$. Moreover, when it lies it would either sample uniformly from values larger than the truth (k), or it would simply pick the largest value (10 – as this is expected-value maximizing response under the assumption that the opponent calls BS at random). This is the best that an agent that has no model of their opponent could do. This no-theory-of-mind model makes a qualitative prediction about lying behavior, such that the expected value of k^* increases linearly as a function of k.

Likewise, a lie-detector that has no model of their opponent, and thus believes them to be random, would only consider the probability of k^* under the true world distribution of $P(k)$. Since this model does not consider the motives and payoffs for their opponent, it would amount to playing the game without knowing the opponent's payoff structure, e.g. whether they would receive points for red or blue marbles. If the marble-sampler were to say that they sampled one red marble when $p = 0.5$, the responder may call BS, simply because such a value is unlikely to occur by chance. This lie detector amounts to conducting a two-tailed hypothesis test. It computes what is statistically significant under a binomial test and calls BS on all k^* that have a p-value $< \alpha$. Regardless

[1] Code available at `github.com/la-oey/Bullshitter`

of α, this lie-detector would call BS on all reports of unlikely k^*, and would thus have a U-shaped lie-detection profile.

Oracle Model

Alternatively, suppose we have a theory-of-mind model that has a *perfect* model of its opponent (i.e. it has an oracle-like omniscience over its opponent's probability to lie and detect lies). This model does not require recursive social inference as a simple first-order inference will suffice, given that they have already perfectly adapted their model of the opponent. It is critical to understand how such a model would behave, as this exemplifies an ideal agent.

To accomplish this, we developed an inferential model of deception, which we term the oracle model, whose opposing agent lies and detects lies using the algorithms from the AI that participants competed against in our lying game in both experiments.

When detecting lies, the AI computes $P_D(BS \mid k^*)$ using the cumulative binomial probability of k^*, $P(X \leq k^*) = \sum_{x=0}^{k^*} Binomial(x \mid p, 10)$ centered at 0.5 when $k^* = 5$. To compute $P_L(k^* \mid k)$, the AI randomly samples a potential k^*, $\hat{k^*}$, from a binomial distribution. If $\hat{k^*}$ is greater than the true k, it lies and uses $\hat{k^*}$ as its reported k^*. Otherwise, it tells the truth by using the true k as its reported k^*.

As participants in our behavioral experiment iteratively competed against this very same non-inferential algorithm over several trials, it seems viable that participants may become perfectly calibrated to the algorithm that their opponent operated upon. In that case, human behavior would rationally match the predictions of the oracle model performing inference over the AI.

Recursive Theory-of-Mind Model

Finally, we consider a model of an ideal observer who does not know *a priori* the behavior of their opponent, but can estimate it from first principles, on the assumption that their opponent is as rational as they are, and is also trying to anticipate their opponent's behavior. This amounts to paired, adversarial ideal observers in which liars L and lie detectors D act as competing rational utility-maximizers. Our model builds on previous Bayesian frameworks of social cognition and communication (Baker, Saxe, & Tenenbaum, 2009; Frank & Goodman, 2012). Both agents perform inference over one another, i.e. L determines what number to report based on his prediction of D's tendency to call BS for different reported numbers, and vice versa. Both agents assume the other agent is acting rationally, namely the other agent is performing optimally given their goal to maximize their own utility. Furthermore, this process of performing inference over the other agent's actions is recursive. In other words, L decides upon his action based on what he believes D will do in light of what she believes L will do, etc. As infinite recursion is memory delimited, our model implements a decay function that breaks the chain of recursion with some degree of probability and implements a base case.

L is constrained by two competing goals: (1) gain (i.e. the agent wants to gain the highest reward possible given that they successfully deceive their partner), and (2) believability (i.e. the probability of having a lie go undetected, which is constrained by the extremeness of their lie). Meanwhile, the competing goals of D include to (1) successfully detect lies, while (2) avoiding falsely accusing their partner of lying when they are in fact telling the truth. The adversarial nature of the agents' goals is captured in the inverse relationship of the utility values for both L and D in our lying game.

Given some true state of the world k, L asserts to D that the state of the world is k^*. If k^* is not equal to k, L is telling a lie, otherwise L is telling the truth. D then sees the reported k^*, and responds by choosing whether to challenge the veracity of k^* by calling $BS = 1$, or accepting k^* as stated ($BS = 0$).

Our formalization of deception is represented as a zero-sum game. We assume that the probability of an action follows a Luce choice rule based on the expected utility of the action relative to alternative actions, with softmax parameter α (Luce, 1959):

$$P(A) = \underset{A}{softmax}(\mathrm{EV}[A]) = \frac{\exp(\alpha \mathrm{EV}[A])}{\sum_{A'} \exp(\alpha \mathrm{EV}[A'])} \quad (1)$$

D chooses to call BS following a Luce choice rule weighting of the expected value of the two options: calling BS, or accepting k^*:

$$P_D(BS \mid k^*) = \underset{BS}{softmax}(\mathrm{EV}_D[BS \mid k^*]) \quad (2)$$

The expected value of calling BS is obtained by marginalizing over the possibilities that $k^* = k$ (here abbreviated as $T = 1$), and $k^* \neq k$ ($T = 0$):

$$\mathrm{EV}_D[BS \mid k^*] = \sum_T \mathrm{u}_D(BS; k^*, T) P(T \mid k^*) \quad (3)$$

where $\mathrm{u}_D(BS; k^*, T)$ is the payoff for D associated with a particular BS response, given k^* and whether or not it corresponds to the true k (T).

The probability of a given k^* being true is given by

$$P(T \mid k^*) = P(k^* = k \mid k^*) = \frac{\sum_k P(k) P_L(k^* \mid k) P(k = k^* \mid k, k^*)}{\sum_k P(k) P_L(k^* \mid k)} \quad (4)$$

relying on the prior probability of k (here: $P(k) = Binomial(k \mid p, 10)$), and the probability that L would produce a given k^* in response to seeing a particular k, $P_L(k^* \mid k)$. Thus, calculating the expected value of calling BS, and choosing whether or not to call the lie requires an estimate of how L is likely to behave.

L, in turn chooses k^* based on a softmax weighting of the expected value of different responses,

$$P_L(k^* \mid k) = \underset{k^*}{softmax}(\mathrm{EV}_L[k^* \mid k]) \quad (5)$$

with the expected values given by:

$$\mathrm{EV}_L[k^* \mid k] = \sum_{BS} \mathrm{u}_L(k^* \mid BS, k^* = k) P_D(BS \mid k^*) \quad (6)$$

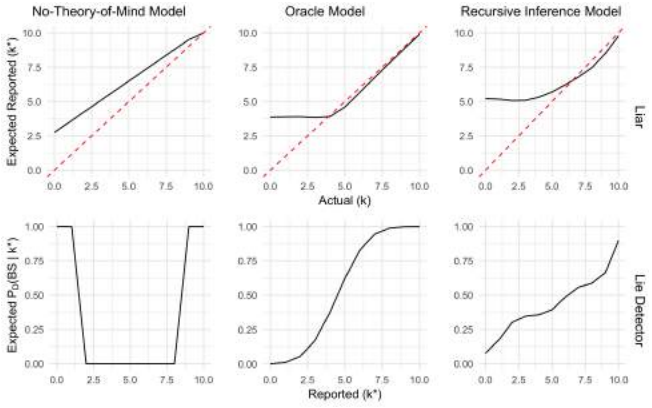

Figure 2: Computed predictions across all models (no-theory-of-mind, oracle, and recursive inference) when $p = 0.5$. Top row displays the liar's predicted performance: reported value as a function of the true value. The red dashed line indicates reported values that would be true. Bottom row displays the lie detector's predicted performance: conditional probability of calling BS by the reported value k^*.

where $u_L(k^* \mid BS, k^* = k)$ is the payoff for the L when reporting k^* given that BS was called, and whether that k^* was a lie. Calculating these expected values requires that L consider $P_D(BS \mid k^*)$ – the probability that D would call BS for a particular reported k^*.

Thus the expected values of various choices for L depends on his beliefs about D, and the expected values of calling BS for D, depends on her beliefs about L. This would yield infinite recursion, so in practice we assume that L's model of D has some probability λ of simply returning a constant $P_D(BS \mid k^*) = c$.

Model Predictions

In Figure 2, we computed predictions from each of the three models about the performance of liars' reported k^* given true k and lie detectors' $P(BS \mid k^*)$ given the reported k^*.

The oracle and recursive inference models make qualitatively similar predictions. For lying, above a certain k, reported values tend to fall on the identity line, indicating that beyond that value, lying is imprudent. For values of k below the average, it is better to lie with a false report of an average outcome (here, $\mathrm{E}[k^*] = 5$ for small values of k). This threshold value in the oracle model is lower than the one in the recursive inference model. This pattern of lying seems to reflect the liar's attempt to balance the gain of lies and the risk of detection from reporting improbable values. For lie detecting, both models predict a sigmoidal pattern, calling BS more often as k^* increases. The fact that both the oracle and recursive inference models appear similar along both the liar and lie detector behaviors indicates that the recursive inference model can emulate the same behavior as the oracle model, despite having no information about the specific behavioral policies of the opposing agent.

In contrast to the theory-of-mind (oracle and recursive inference) models, the no-theory-of-mind model only reduces lying on account of a ceiling effect; thus making k^* a linear function of k. As a lie detector, the no-theory-of-mind model does not consider the reward function of the liar, and thus predicts that both extremely high and extremely low reported values would be called out as lies.

We qualitatively tested these predictions from the theory-of-mind and non-theory-of-mind models in experiment 1. In experiment 2, we tested how manipulating the prior probability of sampling k by varying p would influence human lying and lie detecting behavior. Under the assumption that liars and lie detectors behave rationally, we would expect to see that their behavior would be robust to changes in the probability of the world.

Experiment 1

Participants

We recruited 193 UC San Diego undergraduate students to participate in an online study for course credit.

Procedure

There were a total of 40 trials, with the player acting as the marble-sampler in the initial trial, and then switching roles between each trial, resulting in 20 trials as the marble-sampler and 20 trials as the responder. Participants were instructed to "beat [their] opponent into the ground by winning by the highest point differential possible," in order to motivate participants to successfully lie and detect lies throughout the task. The distribution of marbles was uniform, such that there were 50% red and 50% blue marbles ($p = 0.5$)

Results

When in the marble sampler role, participants showed a non-linear pattern of drift from the truth with lower k values, as shown in the top of Figure 3. We find that this pattern of lying in a positive utility direction for the liar, i.e. above the red line, occurs at lower numbers up until the actual marbles sampled is equal to 5 (i.e. the expected mean).

When in the role of responder, participants' results showed a sigmoidal trend, as shown in the bottom of Figure 3. Both the liar and lie detector pattern of results provide evidence against the no-theory-of-mind model and instead support the oracle and recursive inference models.

It should be noted that due to the nature of binomial distributions, sampling a low number (or high number) of red marbles is rare. As the AI was set up in such a way that the computer tends to lie toward the mean value when the sampled number of marbles is low, this produced a low probability of the computer reporting a low number of red marbles sampled. As a result, there were only a small number of data points available to determine how people detect lies under those conditions. To help offset the wide variance resulting from low counts across k^*, we converted counts to proportion using $(n_{BS=1} + 1)/(n + 2)$ and for all figures, we included points in which there were greater than three observations for a given value along the x-axis.

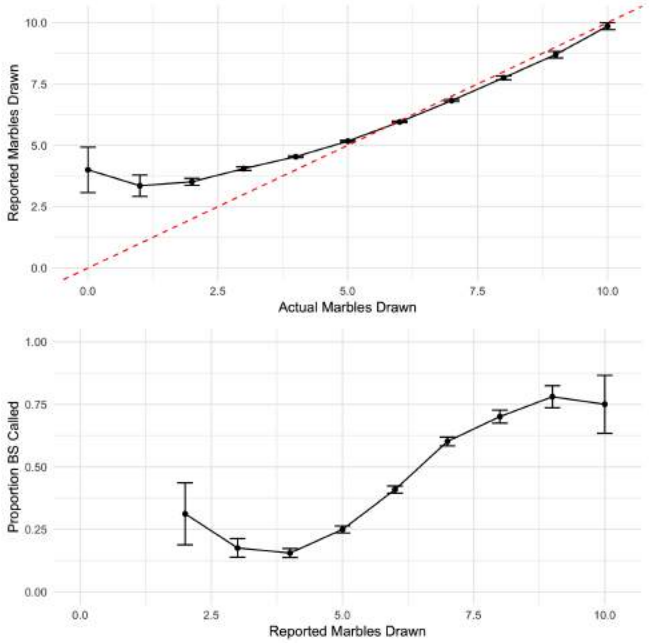

Figure 3: Results from experiment 1: (Top) Marble-sampler's reported number versus actual red marbles sampled. (Bottom) Responder's proportion of calling BS by the reported number of red marbles sampled.

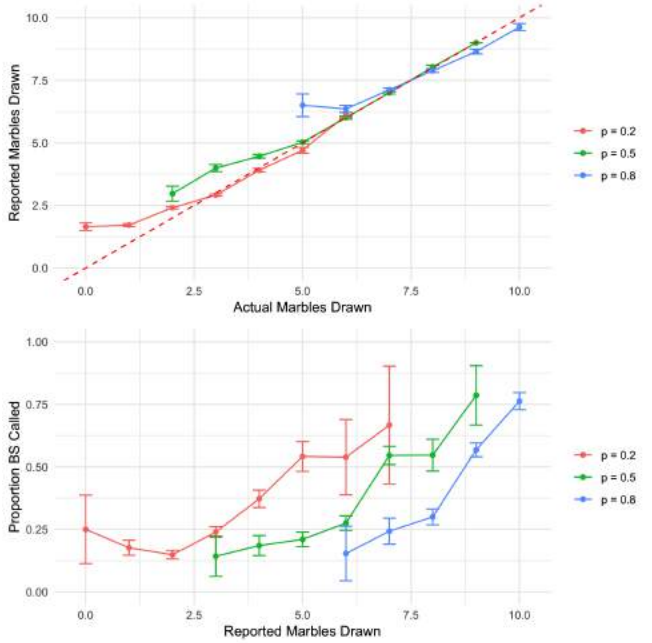

Figure 4: Results from experiment 2: (Top) Marble-sampler's reported versus actual number of red marbles sampled, by changes in the distribution of red-to-blue marbles (indicated by color). (Bottom) Responder's proportion of calling BS by the reported number of marbles sampled.

Experiment 2

We predicted that if people were making flexible, rational inferences, they would be able to flexibly take into account the distribution of marbles in the population, both in the lies they generated and in their detection of others' lies. In lying, we expect a shift in the point on k at which reported values drift from the truth. Similarly, in lie detecting, we expect a change in the tolerance for different k^* values, resulting in a horizontal shift of the BS calling function.

Experiment 2 used a similar design to experiment 1, except that crucially we manipulated the prior probability of k and removed feedback about the other agent's actions. By eliminating feedback, we hoped to distinguish between whether participants are simply adapting to the strategy of the other agent from this feedback, or if participants are performing inference on the other agent's decision process.

Participants

We recruited 86 UCSD undergraduates. Fifteen participants failed to meet the attention check criteria, which entailed accurately answering greater than 75% of the 12 comprehension questions disbursed throughout the experiment. This left 71 participants in our final pool.

Procedure

The procedure for experiment 2 was similar to experiment 1, except we varied between-subject the probability distribution from which the marbles were sampled. There were three conditions: the (red-to-blue) distribution of marbles was either 50-50 ($n = 20$), 20-80 ($n = 32$), or 80-20 ($n = 19$). Participants were not explicitly told about the distribution of marbles; rather they gathered the value of $P(k)$ via visual observation (i.e. the distribution of marbles in the box). In addition, the number of trials increased to 80 trials.

Participants also received no feedback about player decisions between each trial. Thus, the marble-sampler no longer received feedback about whether the responder called BS, and the responder no longer received about whether the marble-sampler lied or not. To ensure that participants understood the payoff structure, participants completed four pre-task practice trials with feedback, i.e. players' decisions, points earned a given trial, and cumulative score, after each trial. These practice trials were included to demonstrate to the participants that the other agent was generating lies or evaluating the participants' lies, and to establish the game's payoff matrix. After the practice trials, participants were told they would no longer receive feedback after each trial, instead only seeing the cumulative score every fifth trial.

Lastly, we used a new payoff structure, in order to contend with a puzzling characteristic of the payoff structure used in experiment 1. In particular in experiment 1, when $k^* \leq 2$, the responder received a lower relative payoff for successfully calling BS on a k^* lie than accepting k^*. Therefore, it would be in the responder's best interest to accept k^* even if they were to believe the marble-sampler was lying. In the $p = 0.2$ condition, the expected value of $k^* = 2$, suggesting that this condition may be affected by the unusual payoff at lower k^* values. To contend with this issue, experiment 2's new payoff structure resulted in a relative gain of 10 for the responder

(and a relative loss of 10 for the marble-sampler) whenever the responder successfully called BS on a lie. Meanwhile, falsely accusing the marble-sampler of lying resulted in a -5 penalty (deducted from the points they would have received had they accepted) for the responder.

Results

Overall we found that participants calibrate their lies, as well as their lie detection, based on the probability structure of the world. Firstly, when examining the lies given by the marble-sampler, we can see a drift in the reported k^* across all conditions, following the pattern of response seen in experiment 1. This point of drift shifts in accordance with the condition, such that the shift in condition $p = 0.2, 0.5, 0.8$ occurs around $k = 3, 5, 7$, respectively.

Secondly, in examining lie detecting behavior, we found that participants shift their judgments of which k^* values they called out as a lie, based on the probability distribution of marbles in the population. We used a mixed-effects logistic regression model to describe the probability that BS is called as a function of the reported number of red marbles sampled k^* and the marble distribution p dummy coded with $p = 0.5$ as the reference group. We found a significant main effect of both reported number of red marbles sampled ($\hat{\beta} = 0.723$, $z = 9.032$, $p < 0.0001$) and marble distribution in the $p = 0.2$ condition ($\hat{\beta} = 2.069$, $z = 3.081$, $p = 0.002$) and in the $p = 0.8$ condition ($\hat{\beta} = -5.823$, $z = -4,714$, $p < 0.0001$). These results not only suggest that people's detection of lies varies as a function of the reported value, but people also calibrate their BS calling depending on the probability of the world.

Using the estimated β values, we computed the number of marbles k^* at which lie detectors would call BS 50% of the time ($P_D(BS \mid k^*) = 0.5$). These thresholds varied systematically across the different marble distributions ($p = 0.2$: 5.236; $p = 0.5$: 7.327; $p = 0.8$: 8.762). The decision boundary shifts to higher k^* values as p increases. This result suggests that lie detectors change their BS calling behavior as a function of their prior expectations about the distribution of the world.

Discussion

In this paper, we report evidence that people lie, and detect lies, in ways that are well-captured by an adversarial recursive Bayesian model. We argue that good liars not only require an ability to represent the idea that others might have mental states different from their own, but they make inferences about the beliefs and actions of their interlocutor to successfully evade detection. In determining what utterances to call out as lies, good lie detectors must rationally consider the goals and utilities of their interlocutor and statistical information about the probability structure of the world.

We introduced the oracle model, in which the model has perfect information about how its opponent behaves. We compared the oracle model to an ideal observer model that does not know the opponent's exact behavioral policies – as is the case in real-world lying – but must instead deduce the opponent's behavior from first principles. This ideal observer assumes that the opponent is rational, and thus, estimates the opponent's behavioral policies by performing recursive social inference. We found that both the oracle and recursive inferential models make qualitatively similar predictions about both lying (i.e. non-linear lies as a function of the true value) and lie detecting (i.e. logistic pattern of calling BS as a function of the lie). This lack of distinguishing predictions across these two models suggests that even though the recursive inferential model lacks the omniscience of the oracle model, it can reproduce qualitatively the same behavior with a far sparser explicit representation of the other agent.

The oracle and recursive theory of mind models are contrasted with an agent that has *no model* of the opposing agent. This agent lies by only considering rewards (and not the opponents' reaction), and detect lies by only considering what is improbable (and not what lies would favor the opponent). This agent makes qualitatively different predictions about both lying and lie detecting behavior. We then tested these model predictions by examining human behavior in a novel lying game. The empirical results suggest that the recursive inferential model of deception capture how human liars choose which lie to tell: they tend to choose lies that are not too implausible. Likewise, we find that lie detecting behavior is consistent with recursive ToM and is calibrated to the probability of the sample under the prior distribution of the world.

To better determine how recursion in these rational models maps onto human behavior, one natural future direction would be to have participants compete against each other in this game. Is it truly the case that liars assume lie detectors are reasoning rationally about the liar, and lie detectors assume liars are reasoning rationally about the lie detector?

In the current experiments, people played against a computer opponent with fixed, non-adaptive behavior. Perhaps over the iterative trials, participants perfectly adapted their model of the other agent, such that they knew how it would behave as a liar and lie detector–essentially acting like the oracle model, with no need for any more than first-order ToM, or ToM over an agent who does not assume rationality about the other agent. Do participants typically perform recursion, or do people only perform first-order ToM? Our first pass at providing evidence against this alternative hypothesis is shown in our second experiment in which the lack of feedback about the opponent's behavior requires players to generate a model of the agent without actual knowledge about the agent's behaviors. Given this lack of feedback, it would be far more difficult to develop an accurate non-inferential generative model of the other agent.

In summary, in the study we present here, we propose and contribute empirical evidence that liars and lie detectors act as rational utility-maximizing agents. Liars and lie detectors choose how to lie and when to call out lies under the assumption that the other agent is also behaving rationally. These findings provide a stepping stone for novel quantitative approaches to studying deception.

Imagining the good: An offline tendency to simulate good options even when no decision has to be made

Abstract

Even when we are not faced with any decision, we sometimes engage in offline cognition where we simulate various possible actions we can take. In these instances, which options do we tend to simulate? Computational models have suggested that it is better to focus our limited cognitive resources towards simulating and refining our representations of options that appear, at first blush, to have higher values. Two experimental studies explore whether we use this strategy. Participants went through an 'offline' thinking phase, and an 'online' decision-making phase. Participants first freely viewed various options, which they had to simulate to determine their actual values. They were later asked to decide between good or bad options. Offline simulation produced faster online response times for the options that appeared to have higher values, indicating a pre-computation benefit for these items. These results suggest that people focus their offline cognition on the apparently good.

Keywords: Sampling; simulation; decision-making; mental rotation

Introduction

When people are trying to make decisions, they sometimes proceed by simulating possible options and asking what the outcome would be for each. Existing research has explored the various ways people use such simulations not just in making inferences about the world in general (e.g. Battaglia, Hamrick, & Tenenbaum, 2013; Callaway, Hamrick, & Griffiths, 2017; Gerstenberg, Goodman, Lagnado, & Tenenbaum, 2014), but also in the specific context of decision-making (e.g. Barron, Dolan, & Behrens, 2013; Hamrick, Smith, Griffiths, & Vul, 2015; Hamrick et al., 2016; Lieder, Griffiths, & Hsu, 2018; Wimmer & Shohamy, 2012). Because of the limited time and capacity during online processing, a central question is how to efficiently allocate computational resources. Previous work has investigated how people determine which simulations and how many to run at the moment when they have to make a decision (e.g. Callaway, Gul, Krueger, Griffiths, & Lieder, 2018; Hamrick & Griffiths, 2014; Srivastava, Mller-Trede, Schrater, & Vul, 2016; Vul, Goodman, Griffiths, & Tenenbaum, 2014).

Importantly, however, people are also capable of simulating different possible options offline, i.e., considering possible options when they are not faced with any immediate decision (see, e.g. Gershman, Markman, & Otto, 2014). For example, even when you are not out with someone on a dinner date, you may find yourself simulating various possible ways you might introduce yourself to a (perhaps hypothetical) person. This offline simulation may then prove helpful when you later face an actual online decision-making problem.

Though our capacity for running simulations offline is not quite as limited as our capacity for running simulations online, we still cannot simulate all possible options. Thus, if you are thinking offline about how to introduce yourself on a date, you would inevitably simulate some options (e.g., talking about your background and interests) but not others (e.g., talking in detail about how loudly you snore). This raises the question—which options do people tend to simulate when thinking offline?

What *should* we think about offline?

One way in to this problem is to begin by asking which options it would actually be rational to simulate. Suppose our aim is to select the best action during a subsequent episode of online decision-making. Given this aim, which options would it be best to simulate offline?

Of course, one possible answer would be that it does not matter which specific options we end up simulating. Simulating different possible options for hypothetical situations might simply be helpful in a broad way, for learning the general features of good versus bad options, without having to specifically compute which option is better than another. In other words, running simulations may be a good way of discovering various heuristics about different options that we can then use later, during online decision-making.

An alternative possibility, however, is that simulating offline is not just good for learning various decision-making heuristics, but can also help us get better value estimates for specific options. When we simulate an option, we can improve our representation of the value of that option. This 'pre-computed' value can come in handy when we have to make decisions in the pressure of the moment, when we do not have much time to think.

The problem can then be formulated as follows. At any given point, we have a representation of the value of each option. Some options are represented with high values (i.e. as good options), others with low values (i.e. as bad options), and others as having an intermediate level of value. At first blush, all of these representations will be at least somewhat inaccurate. We may have a sense of what is good or bad, but generally need to think more about which of these is actually the best or the worst. In simulating a specific option, we can then improve our representation of its value. However, we cannot run simulations for all options. Thus, we have to

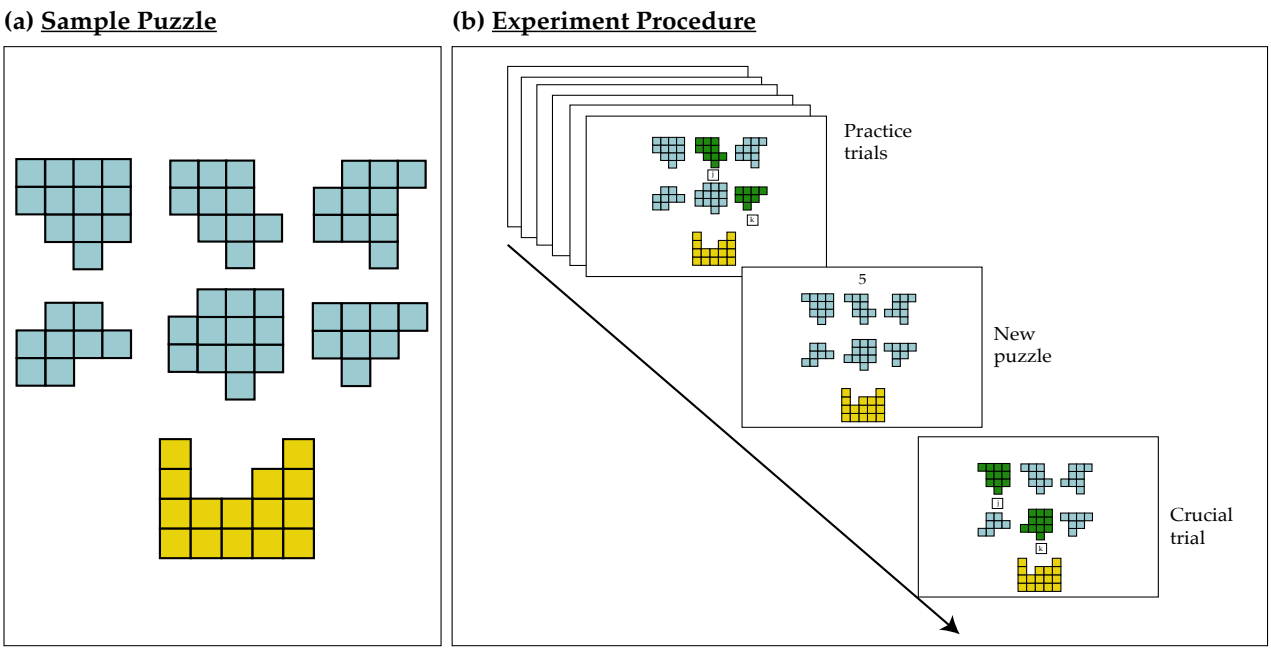

Figure 1: (a) A sample puzzle of the sort used in the experiments. The yellow blocks constitute the puzzle, the blue blocks constitute the pieces. While looking at the puzzle, readers may simulate which pieces would fit or not fit. (b) A caricatured depiction of a sample experimental procedure without the instructions. Participants first go through a series of practice trials, are given a unique puzzle, and are then asked to decide between two options.

decide which of our representations we want to have a more accurate value estimate of, while allowing others to remain inaccurate.

One intriguing finding from existing research is that, other things being equal, it is generally a good idea to run offline simulations of options that we initially think have high values (e.g. Gelly & Silver, 2011; Icard, Cushman, & Knobe, 2018). In other words, if we can only improve our representation of some options, it is better to improve our value estimates of the options we initially represent to have high value than to improve our value estimates of the options we now represent to have low value.

Existing computational work has explored this point within the framework of reinforcement learning (e.g. Icard et al., 2018), but the core intuition is easy to grasp even independently of any formal framework. Suppose that there are now two different inaccuracies in your representations: (a) the option that you mistakenly represent as second-best is actually the best, and (b) the option that you mistakenly represent as second-worst is actually the worst. Now suppose that you are only able to correct one of these inaccuracies, which would you focus on?

The key point is that when you later use these representations in online decision-making, you would ideally want to choose the best option. Thus, it is important to be highly accurate about which of the good options truly is the best, but it is not nearly as important to be accurate about which of the bad options truly is the worst. You should therefore devote your limited offline cognition to the options that you initially think to have high value, and then improve your representations from there.

A question now arises as to whether human cognition actually works in this way. When people only have a limited amount of time to devote to offline cognition, do they tend to run simulations of the options they regard as having high value, even when they do not have to (as there are infinite possibilities one can simulate offline, and there is no immediate specific decision that has to be made)?

The present studies

To address these questions, we conducted two studies in which participants had an opportunity to go through an 'offline' thinking phase before a subsequent 'online' decision-making phase. In the offline phase, participants were given an array of options to freely think about. Crucially, they had to simulate these different options to determine their actual values. In the online phase, participants were asked to decide between two options. The key question was which options would participants think about during the offline phase, when they were not told what decisions they eventually would have to make. To tap into participants' tendencies during offline simulation, we used their response times during the online decision-making phase. We reasoned that if participants were refining their values about specific options and

computing which ones were better than others during the offline phase, then they should respond faster when choosing between those same options during the online phase.

In a novel paradigm, we used incomplete block-puzzles (that look like Tetris) with arrays of different puzzle pieces that would either fit the puzzle or not. In this design, determining whether the puzzle pieces fit would require participants to manipulate these pieces in their minds, akin to classic mental simulation and rotation studies (e.g. Cooper, 1975; Shepard & Metzler, 1971). Moreover, this block-puzzle design allowed us to also specify a 'surface' or apparent value (what people initially think the value of a piece to be) and an actual value (the value of the piece after being simulated) for each puzzle piece, where value could be defined by both the number of blocks the piece had, and whether the piece would actually fit the puzzle.

The idea behind this particular design was that, at first glance, one should be able to immediately 'see' the surface values of the different puzzle pieces, such that some pieces would clearly have higher values (as indicated by the brute number of blocks) than others. From this surface value, one can either simulate the apparently good or the apparently bad. Crucially, it is only by mentally rotating and simulating how these pieces would fit the incomplete block-puzzle that one can get a better sense of the actual values of these pieces. However, one cannot simulate all pieces during the limited window of the offline phase. This time limit allowed us to check which pieces people would simulate over others.

In Experiment 1, we looked at whether people systematically responded faster during online decision-making to some options over others as a function of offline simulation. In Experiment 2, we investigated the mechanism by which offline simulation may lead to benefits in online decision-making, as a function of developing broad heuristics about what options are good and bad in general versus actually precomputing and refining the value of specific options. These experiments altogether explore the principles governing online and offline thinking, and suggest that these may in fact be more closely related than we previously thought: people systematically and actively imagine the good not only when there is an immediate judgement or decision to be made, but also offline, even when they do not have to.

Experiment 1

Participants were given an array of six rotated puzzle pieces per incomplete puzzle during the offline phase. Each piece had a specific value, defined by how many blocks would end up above the puzzle, once the piece fit. In general, the more blocks a piece had, the better. However, to determine the precise value of the piece, participants had to simulate the different pieces. In Figure 1a, the upper leftmost piece would fit the puzzle when rotated counter-clockwise, and would have 7 blocks above the completed puzzle. If participants selected this piece, they would get 7 points. In contrast, the lower middle piece has the same number of blocks, but would not fit the puzzle. If participants chose this piece, they would get 0 points. Thus, we wanted to see whether people would consider the pieces that have a high surface value (like 7) during the offline thinking phase. If participants consider some pieces more than others, they might respond faster when they have to decide between these specific pieces.

Method

All methods and analyses were pre-registered (`http://aspredicted.org/blind.php?x=rd2bd2`). Data and code for all experiments reported here are available on `https://osf.io/npwdq/?view_only=a808e1dd2d594b7992892bfa32fb7e8c`.

Participants. Sixty subjects from the Yale University Library participated (with candy as compensation). The sample size was determined before data collection began.

Apparatus. Stimuli were presented using custom software written in Python with the PsychoPy libraries (Peirce, 2007) and were displayed on a monitor with a 60Hz refresh rate. Participants completed the study on a 13-inch MacBook Air with a 1440 x 900 resolution.

Stimuli. Puzzles were generated randomly through PsychoPy. Puzzles were made of 20 yellow blocks (0.5° black border) stacked in 4 rows of 5 blocks each. Each block was 2° in size. In each puzzle, a number—three or four—of the blocks in the top two rows would be missing. This created an incomplete section at the top of the puzzle.

The puzzle pieces were also generated randomly. Pieces comprised of the specific arrangement of blocks that were determined to be missing, along with additional blocks that made up the value the piece was assigned (e.g. a value of 7 meant that there were 7 blocks on top of the piece). Additional blocks were stacked on top of the piece randomly, for as long as they were always connected to a block in the piece. When the blocks were stacked, the piece was checked on all sides to make sure that only one side would fit in the puzzle. If the piece was not supposed to fit (i.e. have a value of 0), the bottom-most part of the piece was shifted to the left or to the right, in order to ensure that the piece would not fit the puzzle. Puzzle pieces were made out of 2° grey blocks (0.5° black border).

Procedure and design. Throughout the experiment, on the top-left of the screen, there was 'Total Points:' counter. All the text in this experiment was drawn in black Monaco font (0.6° in height). In a single-trial experiment, participants first went through the instructions for the task. They were told that their goal was to earn as many points as they could. They were given sample incomplete block-puzzles and arrays of possible options. They were told that they would be asked questions about these different options afterwards, and would get a number of points corresponding to the particular option they would be asked about. They were told that the value of each piece was defined by the number of blocks

that would end up above the completed puzzle once the piece fit, and that pieces would also be rotated but never flipped. They were also told that speed in responding will be important so the participants would go through a practice section first before the actual trial. After these instructions, participants would then be shown the puzzle, which subtended from 1° above to -3° below the center.

In the offline phase, participants were told that six pieces would now appear above the puzzle, in two rows of 3 pieces each. Participants were told that they did not have to do anything but just look and study the pieces. The six pieces comprised of three pairs with surface values of 3, 5, and 7. In each pair, each piece would have a different actual value: one would fit, and the other was made to not fit the puzzle. During this time, a countdown timer (6° below the center) would start from 5 and decrease per each passing second.

After the offline phase, the online decision-making phase began, where participants now had to decide which of two pieces was the better piece. The blocks of two of the pieces would turn from grey to green to indicate which pieces the participants would have to choose from, and each of these pieces was assigned either a letter j or k. Participants were simply asked, "Which piece is better?", and indicated which piece they preferred by keying in the letter of the piece. In the practice section, participants responded to a total of six practice trials. Throughout the practice trials, if participants responded correctly, the total points counter would increase by the value of the piece they chose (if the piece fit, then this value was determined by the number of blocks above the completed puzzle; if the piece did not fit, the participants would automatically get 0 points).

After participants completed the practice section, they were told that they would be shown a different puzzle and a new set of pieces. Participants were again told that they could be asked about any of these pieces afterwards. To facilitate the pressure of having to decide in the moment, participants were now encouraged to respond as fast as possible, and were told that they would get bonus points for responding quickly. Participants first went through the offline phase, where they were again presented a new puzzle with six puzzle pieces. The countdown timer appeared again. After five seconds, participants began the online decision-making phase, responded to two pieces from the array of six options. In the Good Options condition, participants decided between the two pieces with a value of 7. In the Bad Options condition, participants decided between the two pieces with a value of 3. Participants were randomly assigned to decide either between the good options or the bad options.

Results and discussion

Three participants were excluded because their mean performance in the practice section was 2 standard deviations below the grand population mean (M=29.08 out of 34 total points that could be earned in the practice section; the cut-off was at 18.63). These subjects were replaced, until a total of 60 participants was reached (30 decided between the good options, and 30 decided between the bad options). Response accuracy and response times for the single trial were recorded for each observer. Only response times where participants responded correctly were included in the analysis.

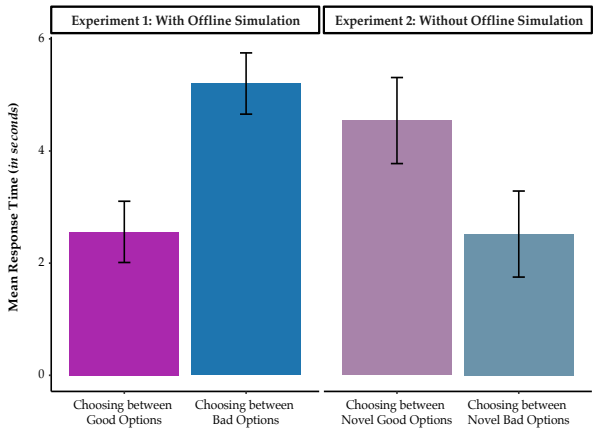

Figure 2: Results from Experiments 1 and 2. The left bar graph presents the mean response times per decision type in Experiment 1, while the right bar graph presents the mean response times per decision type in Experiment 2. The vertical axis represents the mean response time in seconds. The horizontal axis represents the key comparisons in both experiments. The error bars reflect 95% confidence intervals within experiments.

Initial inspection of the left bar graph in Figure 2 shows a lower mean response time for good options than for the bad options. This initial impression was confirmed with statistical tests. Mean reaction time for good options (M=2.56s, MSD=1.77s) was significantly faster than for bad options (M=5.20s, SD=3.82s), $t(25.31)=2.87$, $p=.008$, $d=0.93$. Because the response time distributions violated the normality assumption, we conducted a t-test on the log transformations of the distributions (which now meet the normality assumption), $t(43.37)=3.65$, $p<.001$, $d=1.06$. (We also note that including the incorrect answers did not yield any different results, $t(55.41)=3.51$, $p<.001$, $d=0.91$). There was no significant difference between the percentage of people who responded accurately when choosing between good options (86.67%) vs. bad options (66.67%) (Fisher's exact, $p=.125$).

These results suggest a pre-computation 'imagination' benefit for the good options. In other words, it appears that when given the opportunity to freely think about an array of various options offline, people tend to simulate the options they initially think have a higher value rather than those they initially think to have lower values, even when they do not know what specific decisions they will have to make later on. In simulating the good options, people can determine offline what the actual values of these good options are, such that when it comes to having to make a decision, they re-

spond faster to the good options they had already simulated, computed, and compared beforehand.

Experiment 2

The results from the initial experiment were promising because they suggested that when given an opportunity to think, participants think about and simulate the good options more than the bad options, resulting in a response time benefit at the time of decision-making. But is this a benefit from simulating specific options and refining our representations of their values, and not just from being exposed to and learning what the good or bad options are (for instance, participants could simply have been learning throughout the practice section that the bigger pieces, regardless of their specific configurations, have higher values)? To explore the mechanism underlying the response time benefit observed in Experiment 1, we used the same block-puzzle design. We asked participants to again look at a puzzle and an array of six options. This time, during decision-making, unbeknownst to the participants, instead of presenting them with pieces that were originally in the array of six options, we presented them with a novel pair of good or bad options. Thus, none of their offline thinking strategies should have changed, since they were not told that they would be shown novel pieces. If offline simulation were simply a way of discovering heuristics about which options are good or bad, then participants should still respond faster to the good options than the bad options. However, if offline simulation involves the precomputation of the values of specific pieces, then the precomputation benefit observed in Experiment 1 should disappear when participants are presented with a novel pair.

Method

This experiment was identical to Experiment 1, except as noted. Sixty new participants participated, with this sample size chosen to match Experiment 1. During the decision-making phase, a new pair of pieces with the value of either 7 (i.e. Novel Good Options condition) or 3 (i.e. Novel Bad Options condition) were generated and presented to the participants. All methods and analyses were pre-registered ((`http://aspredicted.org/blind.php?x=bw5n59`).

Results and discussion

One participant was excluded because their mean performance in the practice section was 2 standard deviations below the grand population mean (M=29.08 out of 34 total points that could be earned in the practice section; the cutoff was at 20.65). This subject was replaced, until a total of 60 participants was reached (30 decided between the good options, and 30 decided between the bad options). Response accuracy and response times for the single trial were recorded for each observer. Only response times where participants responded correctly were included in the analysis.

Initial inspection of the right bar graph in Figure 2 shows a lower mean response time for bad options than for the good options. Mean reaction time for good options (M=4.54s, SD=2.51s) was significantly slower than for the bad options (M=2.52s, SD=1.12s), $t(30.52)=3.53$, $p=.001$, $d=1.04$. Again, because the response time distributions violated the normality assumption, we conducted a t-test on the log transformations of the distributions, $t(44.51)=3.45$, $p=.001$, $d=0.99$. (We also note that including the incorrect answers again did not yield any different results, $t(58.22)=2.36$, $p=.021$, $d=0.60$). There was no significant difference between the percentage of people who responded accurately when choosing between good options (76.67%) vs. bad options (76.67%) (Fisher's exact, $p=1$).

To compare these results with those of Experiment 1, we ran a 2 (offline vs. no offline phase) x 2 (good options vs. bad options) ANOVA. There was no main effect of offline thinking, $F(1, 88)=0.12$, $p=.728$, $\eta^2=.002$, or of decision type, $F(1, 88)=0.33$, $p=.570$, $\eta^2=.004$. Crucially, there was a significant interaction, $F(1, 88)=20.99$, $p<.001$, $\eta^2=.193$.

In short, these results show a reversal of the pattern observed in Experiment 1. Since the task is constructed in such a way that the higher value pieces contain more blocks, one might expect at baseline that participants would show longer reaction times for the higher value pieces. In Experiment 1, where participants had an opportunity to engage in offline simulation, we instead found shorter reaction times for the higher value pieces. By contrast, in the present study, we find the expected baseline result: when participants do not have an opportunity to engage in offline simulation, they show longer reaction times for the higher value pieces (perhaps because they had more blocks in general).

General Discussion

There are many instances when we imagine different options without having to immediately make a decision, as when we daydream about which restaurant to go to for dinner or what to say when we are on a date or in an important meeting. In these instances of offline simulation, what do we tend to think about, and why? The present experiments explored this question in terms of the mental simulation of visual stimuli, and asked whether people tend to simulate the apparently good options over the apparently bad options.

The key takeaway from these experiments is simple to summarize: people choosing between two good options responded faster at the point of decision-making than people choosing between two bad options, suggesting that people were thinking more about the good options during the offline thinking phase, when they did not actually have to (and we note, interestingly, even when the good options were more difficult to think about and took longer to process at baseline). Moreover, this does not seem to be just a matter of general practice and exposure to deciding between good versus bad options. When presented a novel pair of good or bad options, participants no longer show this pre-computation benefit, and in fact, perform in the opposite way (responding slower to good options than the bad options). This suggests that thinking in the general does not suffice to produce the

benefit at decision-making. Rather it is thinking and mentally simulating specific possible options offline that proves particularly adaptive when eventually having to choose between these same options.

This result adds to the existing body of work that has explored what people should think about given limited computational resources (e.g. Callaway et al., 2018; Srivastava et al., 2016; Vul et al., 2014). In online decision-making, it generally makes sense to be actively sampling the options with the highest values in order to make the best decision. Our results demonstrate that simulating the best possible options also occurs in offline cognition, when people are allowed to freely think about any option, and do not have to make any decision at all. The tendency to imagine the good options may reflect a more general principle of cognition that is at play while running both online and offline simulations.

This tendency might be interestingly related to recent work on mind-wandering and on memory replay. Research on mind-wandering finds that people tend to spend a good amount of their waking hours just thinking offline (e.g. Mason et al., 2007). Such research indicates that peoples minds are in general more likely to wander to pleasant topics than unpleasant topics (e.g. Killingsworth & Gilbert, 2010). A separate strand of literature, mostly focused on nonhuman animals, has explored the 'replay' of memories. Intriguingly, this literature indicates a similar tendency: animals tend to replay particular memories in proportion to potential gain, and that this process may support future decision-making (see Mattar & Daw, 2018). Future work should explore the potential connection between these two strands of research and the patterns of offline simulation observed here.

These results are also relevant to previous work on people's judgements in moral situations. Existing research suggests that moral judgments can impact people's intuitions about causation, intentional action, and a variety of other apparently non-moral issues (Knobe, 2010). One hypothesis about these effects is that they are explained by a tendency to simulate counterfactuals in which agents perform actions that are morally good, and not to simulate counterfactuals in which agents perform actions that are morally bad (e.g. Icard, Kominsky, & Knobe, 2017; Phillips, Luguri, & Knobe, 2015). Future research could ask whether this tendency is best understood as just another manifestation of the same basic pattern observed in the present studies.

The principal contribution of the present studies is its suggestion that our cognition is particularly attuned to the best possible options, regardless of whether there is an immediate decision that has to be made. One possibility is that our minds are simply wired to default to simulating the good possibilities during offline cognition and that people will therefore show this tendency even when they do not want to be thinking of the good (as when they do not want to get their hopes up), or even when it may not even be beneficial to the task to be thinking of the good (as when they need to be looking out for potential worst-case scenarios).

But another possibility is that our offline tendencies are more flexible depending on the context. Here we explored cases where people can choose which option they want, making it rational to identify the best possible ones. Yet, critical life events are often out of our control, and we can do nothing but prepare for what may come. In cases like these, we may hope for the best and prepare for the worst, making it rational to switch our offline tendencies to focus on bad outcomes to decide what to do in response. We are curious about whether people will show this same tendency when they have less control over which options they end up with, or when there is greater uncertainty about the bad outcomes. Future work can explore the boundaries of this offline tendency to imagine the good.

Risk is Preferred at Lower Causal Depth

Jeffrey Parker
University of Illinois at Chicago, Chicago, Illinois, United States

Abstract

Risk and uncertainty are inherent in life, and how people perceive, respond to, and manage both are topics of great academic interest. One critical insight is that people distinguish between types of uncertainty (see, e.g., Fox & lkmen, 2011) and, consequently, may respond to objectively equally probabilistic events differently (e.g., with more polarized predictions of those events outcomes). The current work identifies another way in which risk (a specific form of uncertainty) is differentiated: on the basis of causal depth (Sloman, Love, & Ahn, 1998). Specifically, in contexts where an uncertain outcome (e.g., win/lose) is determined by a causal chain, people tend to prefer for the uncertainty to arise at lower causal depth within the chain (i.e., at later causal stages). This occurs even though the causal depth at which the uncertainty arises makes no difference in the overall probability that the causal chain will generate one outcome or another.

The interactions of rational, pragmatic agents lead to efficient language structure and use

Abstract

Despite their diversity, languages around the world share a consistent set of properties and distributional regularities. For example, the distribution of word frequencies, the distribution of syntactic dependency lengths, and the presence of ambiguity are all remarkably consistent across languages. We discuss a framework for studying how these system-level properties emerge from local, in-the-moment interactions of rational, pragmatic speakers and listeners. To do so, we derive a novel objective function for measuring the communicative efficiency of linguistic systems in terms of the interactions of speakers and listeners. We examine the behavior of this objective in a series of simulations focusing on the communicative function of ambiguity in language. These simulations suggest that rational pragmatic agents will produce communicatively efficient systems and that interactions between such agents provide a framework for examining efficient properties of language structure and use more broadly.

Keywords: Communicative efficiency, Rational Speech Act theory, computational modeling, information theory, agent-based simulation

Introduction

Why do languages look the way they do? Zipf (1949) proposed that distributional properties found in natural language were evidence of speaker-listener effort minimization. In his own words, "we are arguing that people do in fact act with a maximum economy of effort, and that therefore in the process of speaking-listening they will automatically minimize the expenditure of effort." Evidence for this claim has been largely derived at the level of the lexicon. Zipf argued that the particular relationship between a word's frequency and its rank, length, and denotation size could be explained as an emergent property of speaker-listener effort minimization.

Zipf articulated what is now considered a *functionalist* approach to language science – analyzing language structure and use in terms of efficiency. Such an approach might reframe our opening question as follows: how does having property x make using language ℓ more or less useful for communication? This efficiency-based framing has produced a rich set of theoretical and empirical targets exploring semantic typology (Regier, Kemp, & Kay, 2015), properties such as ambiguity (Piantadosi, Tily, & Gibson, 2011) and compositionality (Kirby, Griffiths, & Smith, 2014), and the efficient use of reduction and redundancy in production (Genzel & Charniak, 2002; Levy & Jaeger, 2007).

The approaches above typically posit efficiency measures that are motivated by information-theoretic principles, but they typically do not ground out in language use by interacting agents. In this work, we derive a novel objective function from first principles of *rational language use* and show how optimizing this objective can lead to communicatively efficient systems. We also demonstrate that assumptions about interlocutors impact whether language properties are used efficiently. In this way, we integrate questions of language design and language use in a single framework.

Functionalist theories commonly frame language efficiency in terms of a fundamental effort-asymmetry underlying everyday communication: what is "hard" for a speaker is likely different than what is "hard" for a listener. Zipf described this as follows: purely from the standpoint of speaker effort, an optimal language $\ell^*_{speaker}$ would tend toward a vocabulary of a single, low-cost word. Given such a language, the full set of potential meanings would be conveyed using only that word, i.e. $\ell^*_{speaker}$ would be fully ambiguous and all possible meanings would need to be disambiguated by a listener. From the standpoint of listener effort, an optimal language $\ell^*_{listener}$ would map all possible meanings to distinct words, removing a listener's need to disambiguate. In this example, speaker effort is related to *production cost* and listener effort to *understanding or disambiguation cost*. Clearly, natural languages fall between the two extremes of $\ell^*_{speaker}$ and $\ell^*_{listener}$. Zipf proposed that the particular lexicon-level properties he observed were a result of optimization based on these competing forces – the pressure to jointly minimize speaker and listener effort.

But how does this optimization take place? The example given by Zipf (1949) describes local, communicative interactions in terms of a *reference game*. Speakers intend to refer to some object in the world m. They choose some utterance u to transmit this intended meaning, $u \rightarrow m$. The listener attempts to reconstruct this intended meaning given the transmitted utterance, $m \rightarrow u$. Other projects have assumed this basic reference game setting (Piantadosi et al., 2011; Regier et al., 2015) and this simplification of the communicative act has proven productive in theoretical (Ferrer-i-Cancho, 2018), simulation-based (Kirby et al., 2014) and empirical explorations (Hawkins, Franke, Smith, & Goodman, 2018) of efficient language structure and use.

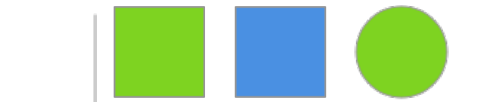
Adopting reference games as a basic unit of analysis suggests that optimization may take place at the level of conversation. Importantly, Zipf's conception of speaker and listener

effort should be connected to how language is used; in particular, whether interlocutors engage in pragmatic reasoning during conversation. Under a Gricean treatment of pragmatics, speakers and listeners follow a set of conversational maxims in which they cooperate to transfer information (Grice, 1975). These maxims appear to emerge from efficiency concerns, however (Horn, 1984). We formalize this connection – showing how system-level efficiencies can emerge from local interaction behavior of pragmatic agents. Our claim is that to understand an "efficient" property of a system it is essential that we consider how that property is *used* efficiently.

We provide a case study for this approach, in which functionalist regularities emerge from the dynamics of pragmatic communication. We choose a property of languages that could, in principle, vary freely, but shows strong regularities across languages. The explanandum is why this regularity holds. We examine ambiguity as our property, extending ideas by Piantadosi et al. (2011). We define a novel measure of efficiency that depends on the interactional behavior of speaker and listener agents. We adopt the reference game as our primary unit of interaction and model language users with the Rational Speech Act (RSA) framework – a computational model of language use, which is supported by experimental data on interaction. Using these ingredients, we show that the property of interest (ambiguity) is prevalent in languages that optimize our measure of efficiency (Simulation 1). Further, we show how ambiguity is used efficiently during local, in-the-moment interactions (Simulation 2). Put differently, these simulations examine efficiency from two angles – in the first we vary languages, fixing agents, and search for efficient language designs. In the second we vary agents, fixing language, and examine efficient use.

The contributions of this work are twofold – we derive a novel measure of linguistic efficiency and also show how the reference game framework, in combination with formal models of communication, can be used to connect ideas about system-level efficiencies to in-the-moment language use.

Exploring efficient language design and use in rational pragmatic agents



square	1	1	0
circle	0	0	1
green	1	0	1
blue	0	1	0

Figure 1: An example reference game with associated literal semantics (in our terminology a "language").

Reference games Zipf's example of optimal speaker- and listener-languages took the form of a reference game. We adopt that formulation here, assuming these communication games as our basic unit of analysis. In this framework, speakers and listeners are aware of a set of objects M (*meanings*) and are knowledgeable about the set of possible signals U (*utterances*) that can be used to refer to a given meaning (see Figure 1). Utterances may have different relative costs, operationalized via a prior over utterances $P(U)$. Similarly, meanings differ in the relative degree to which they need to be talked about, operationalized as a prior over meanings $P(M)$[1]. We consider a set of contexts C with an associated prior $P(C)$. Each context $c \in C$ describes a different distribution over meanings e.g. $p(M|C = c_i) \neq p(M|C = c_j)$. Finally, we consider a set of communicative events $e \in E$ where $< u, m, c >= e$ is an utterance-meaning-context triple.

Languages A language ℓ defines the set of semantic mappings between utterances and meanings. For example, Figure 1 contains four utterances $U = \{$"blue","green","square","circle"$\}$ and three meanings $M = \{\text{green-square}, \text{blue-square}, \text{green-circle}\}$. The boolean matrix describes the literal semantics of the language. We define a language as "ambiguous" if there is some utterance $u \in U$ which can apply to multiple meanings (i.e. $|[[u_i]]| > 1$)[2]. In Figure 1 both the words "square" and "green" are ambiguous so we would say that ℓ contains ambiguity.

Speakers and listeners The Rational Speech Act framework (RSA) is a computational-level theory of pragmatic language use, which has produced good fit to human communication behavior across a range of language phenomena (Frank & Goodman, 2012; Goodman & Frank, 2016). RSA is a formalization of essential Gricean pragmatic principles – agents reason about one another and their shared context (Grice, 1975). We adopt RSA as our representational framework to model Gricean (rational and pragmatic) speakers and listeners in the reference game setting (see SI).

An RSA *speaker agent* defines a conditional distribution over utterances, mapping from intended meanings M to utterances U using ℓ in a given context c. That is, a speaker defines $P_{speaker}(u|m,c;\ell)$. We will use $S(u|m,c;\ell)$ as short-hand throughout. A *listener agent* defines a conditional distribution over meanings, mapping from utterances U to meanings M using ℓ in a given context c (i.e. $L(m|u,c;\ell)$). Speakers and listeners can induce joint distributions over utterance-meaning pairs, although, these distributions may differ:

$$P_{speaker}(u,m|c;\ell) = S(u|m,c;\ell)p(m|c)$$

$$P_{listener}(u,m|c;\ell) = L(m|u,c;\ell)p(u|c)$$

Zipfian objective for linguistic system efficiency

Zipf (1949) proposed that the particular distributional properties found in natural language emerge from competing

[1]The prior over meanings is equivalent to the *need probabilities* assumed in previous work (Regier, Kemp & Kay (2015)).

[2]We use double brackets $[[\ldots]]$ to represent denotation.

speaker and listener pressures. We operationalize this objective in equation (1) – the efficiency of a linguistic system ℓ being used by speaker and listener agents S and L is the sum of the expected speaker and listener effort to communicate over all possible communicative events $e \in E$.

$$\begin{aligned}\text{Efficiency}(S,L,\ell) = \mathbb{E}_{e\sim P(E)}[\text{speaker effort}] \\ +\mathbb{E}_{e\sim P(E)}[\text{listener effort}]\end{aligned} \quad (1)$$

We assume that speaker effort is related to the surprisal of an utterance in a particular context[3] – intuitively, the number of bits needed to encode the utterance u. This particular formalization of speaker-cost is general enough to accommodate a range of cost instantiations, such as production difficulty via articulation effort, cognitive effort related to lexical access, or others (Bennett & Goodman, 2018).

$$\text{speaker effort} = -log_2(p(u|c))$$

We assume listener effort is the semantic surprisal of a meaning given an utterance. This operationalization of listener effort is intuitively related to existing work in sentence processing in which word comprehension difficulty is proportional to surprisal (Hale, 2001; Levy, 2008).

$$\text{listener effort} = -log_2(L(m|u,c;\ell))$$

Importantly, we assume that events $e =< u,m,c >$ are sampled according to the following generative model – some context occurs in the world with probability $P(C = c)$. Within this context, an object m occurs with probability $p(m|c)$. The speaker attempts to refer to that object by sampling from her conditional distribution $S(u|m,c;\ell)$ (i.e. $e \sim p(c)p(m|c)S(u|m,c;\ell)$). From these ingredients it is possible to derive the following objective between the speaker and listener distributions (see SI 2.1 for complete derivation).

$$= \mathbb{E}_{c\sim P(C)}[H_{cross}(P_{speaker}, P_{listener}|c;\ell)] \quad (2)$$

From an information-theoretic perspective this objective is intuitive: H_{cross} denotes the Cross-Entropy (CE), a measure of dissimilarity between two distributions – the average number of bits required to communicate under one distribution, given that the "true" distribution differs. In our case, we have an expectation over this term – the expected difference between the distributions assumed by the speaker $P_{speaker}$ and listener $P_{listener}$ given a set of contexts C[4]. In other words, an "efficient" language ℓ minimizes the distance between what speakers and listeners think.

[3]In the current set of simulations we consider utterance costs as independent from context (i.e.. $p(u|c)p(c) = p(u)p(c)$).

[4]Note that in the single context case $|C| = 1$ this objective is simply the speaker-listener Cross-Entropy.

Simulating the communicative function of ambiguity

The task of understanding language is marked by a frequent need to handle various forms of ambiguity: lexical, syntactic, among others (Wasow, Perfors, & Beaver, 2005). The ubiquity of this property, however, has been argued to provide evidence that languages have not been optimized for communication (Chomsky, 2002).

Piantadosi et al. (2011) argue just the opposite, claiming that ambiguity is an efficient property of any communication system in which *communication is contextualized*. Simply put, it is useful to have a language that re-uses low-cost material (has ambiguity) so long as the cost of disambiguating the material is low. In particular, context (or common ground) can provide useful information for disambiguation.

As an example, say we have two objects (m_1 and m_2), two utterances (u_1 and u_2), differing in cost, and two languages (ℓ_1 and ℓ_2), describing different utterance-meaning mappings. In language ℓ_1, the low-cost u_1 can be used to refer to both m_1 and m_2 ($[[u_1]]_{\ell_1} = \{m_1, m_2\}$), but the high-cost u_2 cannot be used at all ($[[u_2]]_{\ell_1} = \emptyset$). By contrast, in language ℓ_2, u_1 can only refer to m_1 and u_2 can only refer to m_2 ($[[u_1]]_{\ell_2} = \{m_1\}$ and $[[u_2]]_{\ell_2} = \{m_2\}$). While it is cheaper for a speaker to use ℓ_1 (because speaking it is always lower cost), it is more difficult for a listener (because u_1 is ambiguous). Crucially, if context is disambiguating then the speaker can use u_1 to refer to either m_1 or m_2 and ℓ_1 should be preferred to ℓ_2.

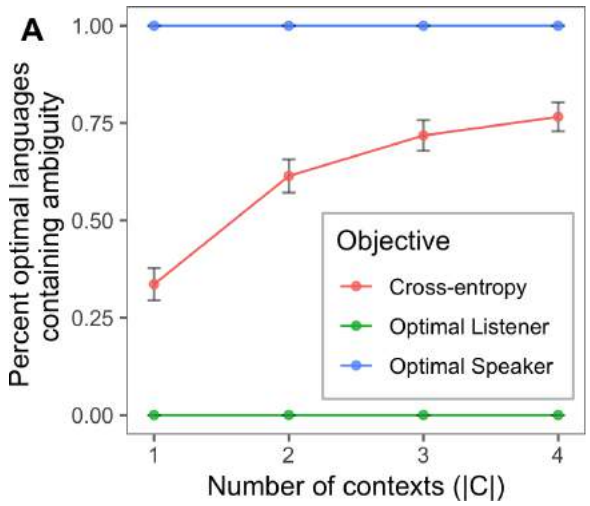
In the following simulations we explore two aspects of Piantadosi's et al.'s claim. In Simulation 1, we examine the efficient language *structure* aspect of their claim, exploring when the optimal linguistic system ℓ^* is most likely to contain ambiguous expressions. In Simulation 2, we explore an efficient language *use* aspect of the claim – under what assumptions will agents use ambiguity efficiently in a conversation?

Simulation 1: Optimal languages contain ambiguity when context is informative

We show that ambiguity is an efficient property under our CE objective in the reference game setting. We proceed by generating languages with different amounts of contextual support (varying the size of $|C|$). We search the space of languages, examining whether ones which minimize our objective contain ambiguity. If context leads to more efficient communication, then optimal languages should be more likely to be ambiguous as the amount of context increases.

Simulation set-up

We conduct $N = 2000$ simulations. For each simulation we enumerate the set of *valid* languages in which $|U| = |M| = 4$ (U is our set of utterances and M our set of meanings). Recall that languages are boolean matrices and a language $\ell \in L$ is "valid" so long as each possible meaning $m \in M$ can be referred to by at least one form $u \in U$ (every column of ℓ has some non-zero assignment) and each form maps to at least one meaning (every row has some non-zero assignment).



B

	m_1	m_2	m_3	m_4
u_1	0	0	**1**	0
u_2	0	**1**	0	0
u_3	**1**	0	0	**1**
u_4	**1**	0	0	0

C

	m_1	m_2	m_3	m_4
u_1	0	0	0	**1**
u_2	0	**1**	0	0
u_3	0	0	**1**	0
u_4	**1**	0	0	0

Figure 2: Panel (A) Vertical axis shows the proportion of optimal languages containing ambiguity. Horizontal axis shows the context-size (1-4) in each condition. Optimal language under CE objective (red). Speaker-optimal (blue). Listener-optimal (green). Error bars represent 95 percent confidence intervals. Panel (B), example CE-optimal language (ambiguous) from a four-context simulation. Panel (C), example CE-optimal language (unambiguous) from a single-context simulation.

For a given simulation, the goal is to find the language ℓ^* which minimizes our objective and then check to see if that language contains ambiguity.

We define language efficiency as a function of the particular semantic mappings induced by that language, the speaker and listener agents (S and L), as well as the utterance ($P(U)$), meaning ($P(M)$), and context priors ($P(C)$). Rather than assume particular structure, for each simulation we generate $P(U) \sim \text{Dir}(1,|U|)$, $P(M|C=c) \sim \text{Dir}(1,|M|)$ (a separate conditional distribution over meanings for each context c), and $P(C) \sim \text{Dir}(1,|C|)$, where $\text{Dir}(1,k)$ specifies the uniform Dirichlet distribution over a k-dimensional probability vector.

Context We want to assess the impact of *context* on the presence of ambiguity in optimal languages. To do so we consider four conditions with $n = 500$ simulations each (that is, 500 unique sets of $\{P(U),P(M|C),P(C)\}$. Our first is a *one-context* condition ($|C| = 1$) – only a single distribution over meanings $P(M)$. In our *two-context* condition ($|C| = 2$), we consider efficiency under both $P(M|C = c_1)$ as well as $P(M|C = c_2)$. *Three-* and *four-context* conditions corresponding accordingly.

Baselines For comparison, we examine properties of optimal languages under two additional objectives. Zipf (1949) proposed that the speaker-optimal language $\ell^*_{speaker}$ would minimize speaker effort and the listener-optimal language $\ell^*_{listener}$ would minimize listener effort. We define these objectives using the first and second half of equation 1 (see SI 2.2.).

Results and Discussion

In Simulation 1 we explored the degree to which ambiguity is an efficient property of languages when communication is contextualized. Figure 2, panel (A) plots the proportion of optimal languages under each objective as a function of number of contexts. The red line shows that as the number of contexts increases, so does the probability that an optimal language ℓ^*_{cross} contains ambiguity (at least one utterance maps to two meanings) under our CE objective. For comparison we also plot the proportion of speaker-optimal $\ell^*_{speaker}$ (blue line) and listener-optimal $\ell^*_{listener}$ (green line) languages that contain ambiguity. In line with Zipf's predictions, if languages are designed only to minimize speaker effort then optimal languages always contain ambiguity. If languages are designed to minimize listener effort then ambiguity is always avoided.

While our results indicate that ambiguity is an efficient property of contextualized language use, these simulations assumed that agents had perfect knowledge of the relevant conditional distributions ($P(M|C)$). This assumption may be too strong for describing much of day-to-day communication – we seldom interact with others with perfect knowledge of the current context (or topic) at the start of a conversation. To explore how ambiguity may be *used* efficiently in our framework, we next examine a case in which the listener has imperfect knowledge of context at the start of the conversation, but may infer it from the discourse history.

Simulation 2: Rational, pragmatic speakers use ambiguity efficiently

In Simulation 1 we showed that efficiency defined in terms of pragmatic agents leads to a preference for languages that contain ambiguity. In Simulation 2 we assume a single fixed language ℓ, which contains ambiguity, and instead vary the types of agents using ℓ. We will show that efficient *use* of ambiguity depends on an agent's ability to use context for disambiguation. More generally, Simulation 2 is intended to

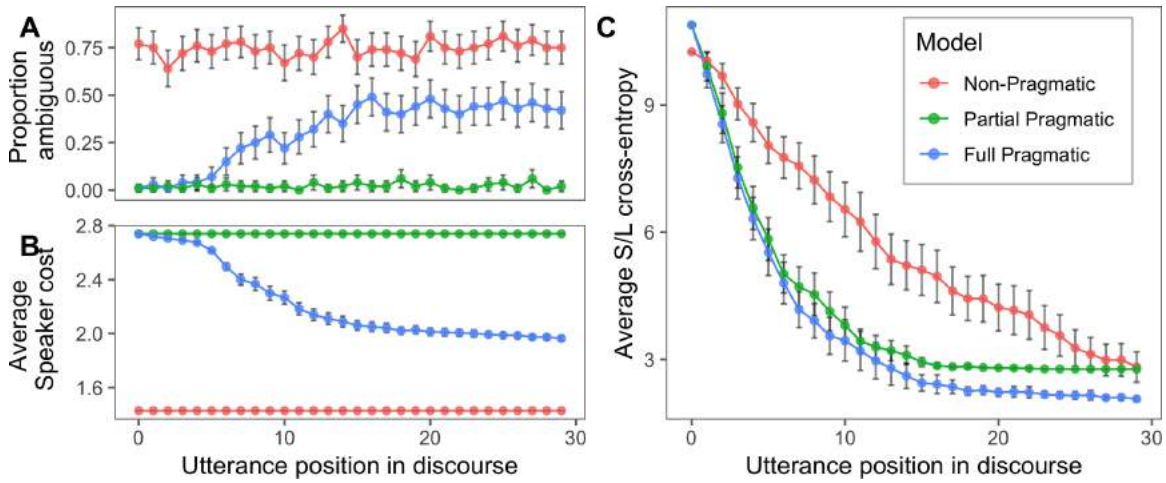


Figure 3: (A) shows the empirical probability that our speaker used an ambiguous utterance as a function of discourse position. (B) shows speaker effort across the three models. (C) shows the Cross-Entropy objective under our three speaker models. Error bars represent 95 percent confidence intervals.

demonstrate how we can assess both questions of efficient use (current simulation) as well as design (previous simulation) in the same framework.

Imagine a scenario in which a reader is beginning a news article. While they may have some knowledge about the article's topic (perhaps from the title), they may not have complete knowledge of its contents, including the persons or events involved. In this setting, using a low-cost, but ambiguous referring expression (say a pronoun like "he") early may lead to misunderstanding if context is not informative. But, if by a later position enough contextual information has accumulated, it may be efficient to use the ambiguous expression. We pursue this general framework in Simulation 2 – examining when in a discourse using ambiguity is efficient. We will consider "context" as analogous to a "topic" of conversation.

Simulation set-up

We consider a single language ℓ, which contains both ambiguous and unambiguous utterances. We assume ambiguous utterances are lower cost. Crucially, we do not assume that the listener knows the particular topic ($c_{current}$) of the conversation *a priori*. Rather, that the listener has knowledge of the set of possible topics $C = \{c_1, \ldots, c_k\}$, but does not know which one is currently being used by the speaker. Formally, this means the listener does not have access to the correct conditional distribution over meanings $P(M|C = c_{current})$ at the start of the discourse.

Over the course of a discourse D, the listener tries to infer both the current topic, $c_{current}$, as well as the particular meaning m of a given utterance u. That is, we consider agents who can track the history of previous utterances D. Importantly, an agent can attempt to infer the current topic of conversation $c_{current}$ using the discourse history D.

We conduct $N = 600$ simulations, generating discourses of length $|D| = 30$ utterances, comparing three speaker models ($n = 200$ each). We consider a single language ℓ[5] with $|U| = 6$ and $|M| = 4$ in which two of the utterances are ambiguous and lower cost than the unambiguous utterances. (Note that use of this particular language is not essential – the results are broadly generalizable to languages that contain ambiguity, but exploring this space is computationally expensive.)

Speaker agents

We vary the degree to which agents can use context for disambiguation. We consider three types of speaker models. Our *Full pragmatics* agent, models a speaker who reasons about her listener and also has complete recall of the set of utterances in the discourse D. This speaker believes that the listener may not know the current topic $c_{current}$ at the start of the discourse, but can infer it over the discourse. We compare two baseline models. The first, a *Partial pragmatics* baseline describes a speaker who reasons about a listener, but assumes they have no access to the discourse history. The second, a *No pragmatics* baseline speaker does not consider a listener at all, but produces utterances according to the underlying language semantics (ℓ) and topic probabilities ($p(M|C = c_{current})$ (see SI 3).

Hypotheses

We are interested in how each speaker-model uses ambiguity over the discourse. A speaker strategy that is mutually efficient for both agents should avoid ambiguity until sufficient contextual information has accumulated. We should expect this to be reflected in our *Full pragmatics* model who reasons about the listener and discourse history. By contrast, a speaker-optimal model who does not consider the listener should greedily use ambiguous utterances (*No pragmatics* model), while a listener-optimal model should avoid ambiguity entirely (*Partial pragmatics* model).

[5] See SI for the matrix notation of this language.

Results and Discussion

Figure 3, panel (A) shows the empirical probability a speaker uses an ambiguous utterance as a function of discourse position. The *No pragmatics* baseline uses ambiguous utterances frequently and at a constant rate over the discourse. The *Partial pragmatics* baseline avoids ambiguous utterances entirely. But, the *Full pragmatics* model avoids ambiguous material only at the start of the discourse, employing it increasingly as the discourse proceeds. Panel (C) tracks our CE objective for each model over the discourse. Note that the objective decreases for all three models, primarily driven by the listeners updating their beliefs about the actual topic ($P(C = c_{current}|D)$). However, the objective declines more quickly under the *Full* and *Partial pragmatics* speakers as listener agents are better able to infer the correct context. Additionally, the difference in CE between the *Full-* and *Partial pragmatics* models at the end of the discourse is driven by the reduction in speaker costs. Panel (B) tracks speaker effort, which remains constant in both *No pragmatics* and *Partial pragmatics* baselines. But, effort declines in the *Full pragmatics* model as speakers increasingly rely on ambiguous material later in the discourse.

General Discussion

How do the competing pressures imposed by speakers and listeners give rise to the distributional regularities found in natural language? Zipf (1949) proposed that the asymmetry between speaker and listener costs gives rise to a range of properties at the level of the lexicon. We explored the interactions of rational pragmatic agents as a framework for understanding efficient language structure and use. We focused on an argument on the communicative function of ambiguity (Piantadosi et al., 2011), deriving a novel speaker-listener Cross-Entropy objective for measuring the efficiency of linguistic systems from first principles of efficient language use. In Simulation 1 we showed that optimal languages are more likely to contain ambiguous material when context is informative. In Simulation 2 we showed how rational pragmatic agents use ambiguous material efficiently in conversation.

A limitation of the current work is an analysis of exactly how the CE objective compares to existing measures. For example, previous work has described competing speaker-listener pressures in terms of a trade-off of simplicity and informativeness (Kemp & Regier, 2012) or expressivity and compressibility (Smith, Tamariz, & Kirby, 2013) to explain linguistic regularities. Future work should assess the degree to which we can derive the same properties as previous studies using our current framework. More generally, we hope that this framework can serve as a domain general tool to assess the range of functionalist theories examining efficient language-structure and use.

Why do echo chambers form? The role of trust, population heterogeneity, and objective truth

Abstract

Many real-world situations involve learning entirely or mostly based on the information provided by other people, which creates a thorny epistemological problem: how does one determine which of those people to trust? Previous work has shown that even populations of rational Bayesian agents, faced with this problem, polarise into "echo chambers" characterised by different beliefs and low levels of between-group trust. In this study we show that this general result holds even when the reasoners have a more complex meaning space and can communicate about their beliefs in a more nuanced way. However, even a tiny amount of exposure to a mutually trusted "ground truth" is sufficient to eliminate polarisation. Societal and psychological implications are discussed.

Keywords: Bayesian reasoning; echo chambers; polarisation; social inference; trust; epistemology

Introduction

The real world is full of situations where the vast majority of what we learn comes from other people. In some, like language learning, the "ground truth" of the matter simply *is* whatever people agree that it is. However, many other situations pose a much more challenging epistemological problem: the ground truth is (at least mostly) inaccessible, and the only way to learn about it is to rely on other people. Regardless of why the truth is often inaccessible – due to spatial or temporal distance, or difficulties in interpreting ambiguous data – people are often faced with questions of this character. Did humans evolve or were we created by a superior being? Did Trump assist the Russians to influence the US 2016 elections? Did Bob have an affair with Mindy? In all of these cases, there *is* a truth of the matter, but it is not a truth that is directly accessible to most people. All of the data is mediated through other agents – scientists studying evolution, politicians receiving confidential documents, journalists deciding what to report on, Bob and Mindy – and few have the access or training necessary to make sense of the data on their own.

What is a rational learner to do in this difficult epistemological situation? One option would be to simply try to communicate fully with everybody and update one's beliefs accordingly. When this happens, groups of Bayesian learners will converge to a shared belief system equivalent to the population prior, at least when organised as chains (Griffiths & Kalish, 2007) or fully interconnected (Whalen & Griffiths, 2017). When data are additionally generated from an external ground truth, the convergent distribution is also shaped by that world (Perfors & Navarro, 2014). However, these results only hold when agents cannot select who to talk to and when all share the same prior. When people have heterogeneous priors, the beliefs of the population are systematically distorted towards the beliefs of the most extreme individuals (Navarro, Perfors, Kary, Brown, & Donkin, 2018).

This amplification of extreme priors is concerning because it suggests that the process of information transmission itself can distort belief – and that this occurs even if all agents are fully rational and can share information fully. But our situation in real world is even more difficult. Limited by temporal and cognitive constraints, people cannot exchange information with everyone else. Moreover, the real world includes people who you might not want to learn from – not just because they have different or more extreme priors, but because they might be completely wrong or actively deceptive.

Intuitively, one solution to this dilemma would be for agents to learn who *not* to trust: to lower the weight given to the data from people who are inaccurate or miscalibrated. This is an appealing idea, but raises an important question: in the absence of any direct access to the ground truth, how should a rational learner determine who is to be trusted? One possibility is that agents might favour those who seem to make sense: those who make claims that are consistent with one's own beliefs. Indeed, there is evidence that people do adopt this strategy (Collins, Hahn, & von Gerber, 2018). Unfortunately, trusting people with similar beliefs more often leads to polarisation (e.g., Axelrod, 1997; Hegselmann & Krause, 2002; Olsson, 2013; Ngampruetikorn & Stephens, 2016; O'Connor & Weatherall, 2018; Madsen, Bailey, & Pilditch, 2018). Instead of converging on a shared set of beliefs, populations split into echo chambers: sub-groups characterised by high trust and shared beliefs within groups, but low trust and shared beliefs between groups.

Although this general result is robust and has been shown in a variety of modelling paradigms, in many cases the reasoners in such paradigms are not meant to be optimal (e.g., Axelrod, 1997; Hegselmann & Krause, 2002; Ngampruetikorn & Stephens, 2016). Some studies that *do* use Bayesian agents have established that polarisation arises even when all of the agents reason rationally (Olsson, 2013; O'Connor & Weatherall, 2018; Madsen et al., 2018); however, these studies generally involve fairly impoverished one-dimensional meaning spaces and agents who can only communicate about those spaces in a limited way. For instance, the agents in Olsson (2013) may believe in a proposition to only some degree (e.g., 70%) but are only capable of communicating binary ("yes" or "no") beliefs about the proposition.

The agents in Madsen et al. (2018) are permitted more nuance, being able to communicate their beliefs about the mean of a one-dimensional Gaussian, but have no way to communicate their level of certainty. Would polarisation still arise in groups of Bayesian agents with a richer space belief and the ability to communicate those beliefs in a more nuanced way? We explore this question here.

In Study 1 we present a new modelling paradigm in which agents must learn and communicate about a two-dimensional meaning space by sampling items from their current beliefs, while simultaneously making inferences about which of the other agents are trustworthy. We show that, as long as the distribution of prior beliefs in the population is sufficiently heterogeneous, echo chambers form even in this circumstance. Study 2 investigates whether polarisation can be eliminated and trust built by selectively communicating about only some topics (dimensions). We find that this is not a solution: doing so does build trust but at the cost of never coming into agreement. In Study 3 we explore another potential solution: access to a mutually trusted ground truth. Reassuringly, when agents have access to such a truth – even if it makes up only a tiny fraction of all of the data – polarisation is eliminated.

Study 1: Baseline

Method

Our simulations involve populations of n optimal Bayesian agents who each learn a hypothesis by receiving data from other agents (we vary $n = 6$ or $n = 18$). Agents perform inference over which other agents are trustworthy t at the same time as inferring which hypothesis h best describes the data x seen so far by calculating the joint posterior $P(t,h|x)$. Performing joint inference over trust and beliefs is somewhat different from the typical approach, in which agents directly prefer others who have similar beliefs (Olsson, 2013; Madsen et al., 2018; O'Connor & Weatherall, 2018). We opted for this approach for two reasons. First, people appear to make inferences about trust at the same time that they evaluate beliefs, and use their perceptions of trust to decide whose data to rely on (Petty & Briñol, 2008; Shafto, Eaves, Navarro, & Perfors, 2012; Perfors, Navarro, & Shafto, 2018). More importantly for our purposes, explicitly differentiating inferences about trust from beliefs allows us to explore what happens if agents can change their communication style (but not their beliefs) in order to build trust, as in Study 2.

Trust is a real value between 0.0 (no trust) to 1.0 (perfect trust) while beliefs consist of 2D Gaussians parameterised by an unknown mean μ and a known symmetric covariance Σ_0, as described in more detail below.

Initialisation. Each agent a is initialised with a different prior belief about the mean $\mu_a \sim N(0,\Sigma)$, where $\Sigma = 0.5\mathbf{I}$. All agents share the same prior about the covariance Σ_0. We manipulate population heterogeneity by changing the size of the prior covariance Σ_0 relative to the initial generating covariance Σ. Populations with high heterogeneity are initialised with means that are more "distant" in belief space relative to their beliefs about how wide the category is. There are three conditions, each defined by their covariance matrix Σ_0: HOMOGENEOUS ($\Sigma_0 = 0.25\mathbf{I}$), NEUTRAL ($\Sigma_0 = 0.15\mathbf{I}$), and HETEROGENEOUS $\Sigma_0 = 0.05\mathbf{I}$).

It would have been mathematically equivalent to manipulate heterogeneity by keeping the agents' covariance priors Σ_0 constant and varying the covariance of the generating distribution Σ; the important thing is the ratio of the two. (We chose to do it this way because one of our dependent variables is the average distance between agents in belief space, and this permits all conditions to be initialised with a similar average distance.) Smaller initial covariance matrices imply more heterogeneity because heterogeneous populations contain more individuals who are more likely to initially disagree (by inferring that the data provided by the other was unlikely). The same intuition is captured in other paradigms via the tendency to seek out those who are distant in belief space; agents with less of this tendency are more likely to polarise (Olsson, 2013; O'Connor & Weatherall, 2018; Madsen et al., 2018).

Agents are also initialised with trust vectors t with one cell for each other agent in the population, such that $t \sim \text{Beta}(1,1)$. This prior means that each agent may initially trust any other to any degree. Because the prior is weak, it is easily changed in response to data.

Iterations. During each iteration we loop through our population of n agents. At each iteration, agent i selects another agent j to learn from, proportional to the relative degree of trust i has in j. Upon being selected, agent j samples a single data point x at random from their hypothesis such that $x \sim N(\mu_j,\Sigma_0)$. Agent i then then updates their beliefs about $\mu_\mathbf{i}$ in the direction of x.[1] Thus, each iteration involves agents learning from others, in all cases revising their beliefs in the direction of the data provided, but weighting the data that was provided by trusted agents more.

At each iteration each agent i also updates their trust in all other agents j, based on the data $\mathbf{X_j}$ provided by each. The intuition is that agents will infer trustworthiness based on the extent that the other says sensible things: in this context, that means that agent j will be trusted proportional to the degree to which the data they provide to i is consistent with i's own beliefs. Agent i accomplishes this by computing the probability that they themselves would have generated that data $P(\mathbf{X}_j|N(\mu_i,\Sigma_0))$ and comparing it to the probability that it was generated by an uninformative and unhelpful other $P(\mathbf{X}_j|N(0,\Sigma_u))$.[2] Agents are thus more likely to trust those who provide data that is consistent with their own beliefs.

[1] Technically, agent i performs $n-1$ Metropolis-Hastings steps, one for each of the other agents j, in which the likelihood is calculated for all of the data points $\mathbf{X}_j$ shared by j, including the new data point x. Likelihood is weighted by trust in that agent, so that agents who are more trusted have more of an affect on belief revision.

[2] The reason for comparing against a baseline is that the raw probability of an agent providing any set of datapoints is low in absolute terms, and without the comparison all simulations tend for all agents to trust nobody. Results are qualitatively similar for a wide range of choices for the covariance of the uninformative baseline, as long as it is larger than Σ_0. All simulations here set $\Sigma_u = \mathbf{I}$.

Our approach is most similar to that of Madsen et al. (2018), but there are a few key differences in addition to those already discussed. First, their agents make inferences about both mean *and* variance, and communicate by providing the mean directly rather than sampling from their posterior. Polarisation occurs in their simulations at least in part because the learned variances approach size zero. This was probably facilitated by the fact that agents could not sample from their distributions when providing data and thus could only give point estimates, leading to a severe underestimation of the variance. Here we test whether polarisation still emerges even with agents with constant variance who can also provide more information about the extent of their distribution.

A second difference is that their agents can revise their beliefs *away* from the data they receive, whereas ours cannot. This sort of belief revision is not necessarily irrational (Jern, Chang, & Kemp, 2014), but it is difficult to determine to what extent it drives polarisation in Madsen et al. (2018). In order to explore whether polarisation arises even when the conditions for it are as unfavourable as possible, our agents disregard data they do not trust rather than move away from it.

Results

For each condition and population size, we ran 50 runs (differing only in the initial random distribution of agents in belief space) for 500 iterations each. All of our simulations were characterised by changes in the beliefs of the agents as well as their mutual trust. We consider each in turn.

Trust. We can visualise the distribution of trust across the population using pairwise mutual trust matrices T in which T_{ij} denotes the trust that agent i has toward j. We are specifically interested in the distribution of trust within the population: does it tend to be uniform, or are there clusters of agents who highly trust in each other but distrust anyone else? As the top right panel of Figure 1 shows, this clustering can be quantified using Gini mean difference (GiniMD): the mean absolute difference between all distinct elements in the pairwise trust matrices. A lower GiniMD indicates a higher shared trust, and GiniMD values over 0.3 correspond to highly polarised populations: the pairwise trust matrices show a "block" structure in which agents are in subgroups characterised by high within-group trust and low between-group trust.

As the top of Figure 1 shows, regardless of the population size, populations with HETEROGENEOUS agents were highly likely to become polarised. An ANOVA found a significant effect of condition on GiniMD ($F(2,296) = 29.34, p < 0.0001$) but not number of agents ($F(1,296) = 0.81, p = 0.369$). Initial random differences in beliefs between agents were exacerbated as they grew to trust those with similar beliefs and minimised data from those with dissimilar beliefs. Heterogeneity was the determining factor because it affected how much weight agent i put on data from j. In heterogeneous populations, more agents had initial beliefs that were far from the covariance of other agents; they were thus more apt to be distrusted. Once distrusted, they could not recover.

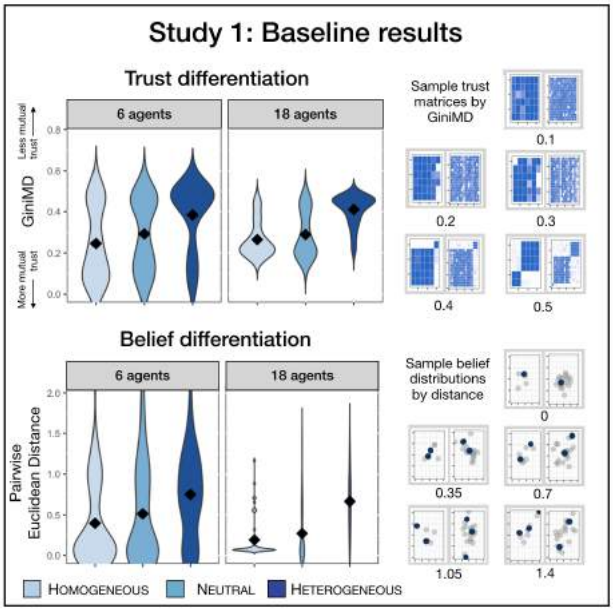

Figure 1: *Study 1: Emergence of polarisation.* Top: Polarisation is evident in the pairwise mutual trust matrices between agents, and quantified using GiniMD (right). Values above 0.3 indicate that agents have formed subgroups characterised by high within-group trust and low between-group trust. Populations of all size become polarised when they are HETEROGENEOUS (left), despite the fact that all agents are optimal Bayesian reasoners. Bottom: More HETEROGENEOUS agents also show a greater divergence in beliefs (left). Sample runs (right) showing the average pairwise Euclidean distance between agents in belief space (grey dots plot the locations of agents' initial hypotheses (μ) and dark blue dots plot the final ones) reveal that larger differences tend to correspond to more than one cluster in belief space.

The bottom of Figure 1 illustrates that these trust-based echo chambers correspond to greater average distance from each other in belief space; agents do not converge on a shared belief. As before, this effect was driven by population heterogeneity ($F(2,296) = 22.11, p < 0.0001$), although population size was also significant ($F(1,296) = 11.24, p = 0.001$). Even though agents in all conditions began the simulations at similar distances in belief space from each other, the HETEROGENEOUS agents tended to form widely-separated clusters while more HOMOGENEOUS agents were more likely to converge on the same belief. Distance in belief space and trust clustering thus both tell the same story: in sufficiently heterogeneous populations, polarisation is highly likely, even when all of the agents involved are optimal Bayesian reasoners. Consistent with this, there is a strong correlation between GiniMD and distance ($r = 0.81, t(298) = 23.7, p < 0.0001$).

How might we disrupt this tendency toward polarisation? Study 2 explores one idea: building trust by communicating tactically. Our agents are always constrained to be honest, but here we make it possible for them to refrain from communicating about topics on which disagreement is likely.

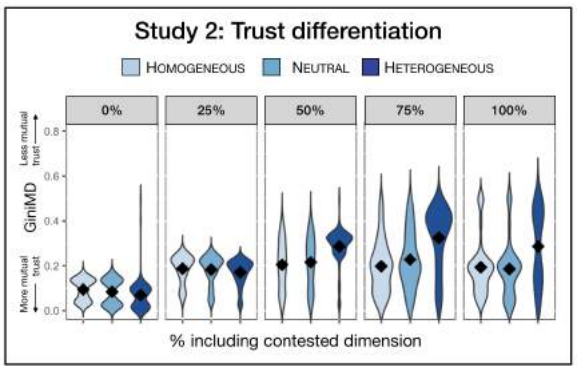

Figure 2: *Emergence of trust when agents can avoid contested subjects.* Average GiniMD as a function of the proportion of time agents included information about the contested dimension. As the dimension is included less, the agents show ever-higher levels of mutual trust. Trust is consistently unpolarised by the time the contested dimension is included 25% of the time, even in the HETEROGENEOUS condition.

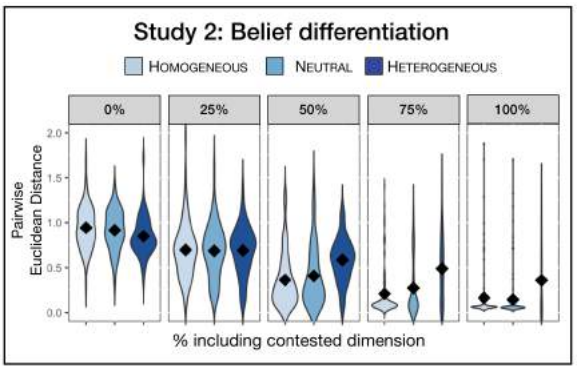

Figure 3: *Evolution of belief when agents can avoid contested subjects.* Average pairwise distance in belief space as a function of the proportion of time agents included information about the contested dimension. As the dimension is included less, the agents show more divergence in beliefs; as trust increases, the divergence in beliefs increases more. Thus, lower polarisation does not reflect more agreement.

Study 2: Tactical topic selection

Method

One of the simplifications we made in Study 1 was to assume that agents were required to communicate fully as well as honestly. In real life, however, people have discretion in what they choose to talk about. If you are visiting an uncle with whom you disagree politically, you might spend the majority of your time talking about something that you agree on, like football. This enables you to grow trust in each other and might give you the space to occasionally talk about politics.

Does adopting this strategy decrease the emergence of polarisation? Key to answering this question is realising that it is important to talk about contested issues at least some of the time: otherwise, you might trust each other, but still have irreconcileable beliefs about the facts of the matter. In these simulations we test whether there are any "sweet spots" in which agents can talk about contested beliefs just enough to come to agreement and maintain trust.

We tested this by initialising the agents differently. Where before the initial means for agents $\mu_{\mathbf{a}}$ were generated by sampling from a Gaussian with symmetric covariance matrix $0.5\mathbf{I}$, in Study 2 we sampled them from an asymmetric matrix with the same covariance as before along one dimension but four times tighter along the other. This meant that agents *a priori* only disagreed on one dimension, rather than two.

We then systematically varied the proportion of time that agents chose to include the contested dimension that they were more likely to disagree on. If an agent received a data point that did not include that dimension, they "filled it in" themselves by sampling it from their own prior. This was done in order to maximise the probability of eliminating polarisation; if it cannot be avoided even when agents are making the most charitable assumptions about what is going unstated, then it would be even harder to avoid if agents are making less charitable assumptions.

Results

The results suggest that enabling agents to only discuss one dimension and avoid contested dimensions *does* increase mutual trust, but the price of this is that agents no longer form a shared set of beliefs. As Figure 2 shows, communicating less about the contested dimension systematically increases trust ($F(4, 1495) = 117.5, p < 0.0001$). If the contested dimension is included only half of the time, GiniMD values are consistently below 0.4, and if it is included 25% of the time or less the level of polarisation is nearly nonexistent.[3]

However, as Figure 3 reveals, that lack of polarisation corresponds to situations where the average distance between beliefs has increased substantially ($F(4, 1495) = 137.7, p < 0.0001$). When the contested dimension is included half of the time, the average distance between beliefs is even higher than in the baseline HETEROGENEOUS case, even though the trust levels are still low. By the time polarisation has been eliminated in the trust matrices (when talking about the contested dimension 25% of the time or less), agents radically differ in their beliefs. What appears to be happening is that, unaffected by external data, evolution along that dimension proceeds in a random walk. Thus, although agents agree with each other on the non-contested dimension, they diverge ever more strongly on the contested one.

Thus, the higher levels of trust have not bought more agreement: they just reflect the fact that some topics are not discussed. Most importantly, we could find no "sweet spots" in our simulations where strategically communicating about contested beliefs only part of the time could allow trust to be maintained *and* beliefs to converge. This finding should be interpreted with caution because it depends to some extent on choices we made about values of Σ_0, Σ_u, and Σ. However, it is not reassuring that the divergence in belief occurs *before*

[3]For ease of presentation, we collapse across population size in the figures and analyses but the qualitative effect is identical whether there are 6 or 18 agents in the population.

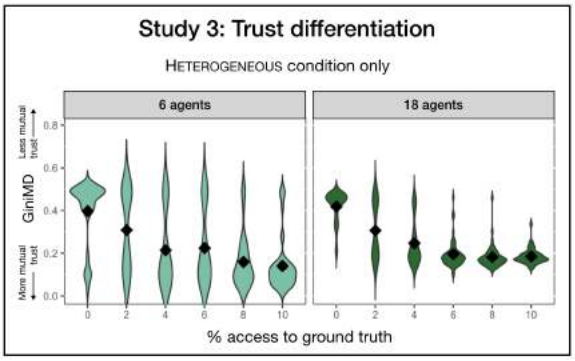

Figure 4: *Evolution of trust when agents have access to the ground truth.* It only takes a little bit of access to a ground truth source that everyone agrees is trustworthy to disrupt the formation of echo chambers, even in a HETEROGENEOUS population. Even 2% of all data points make a big difference, and by 4% or so everyone trusts everyone else.

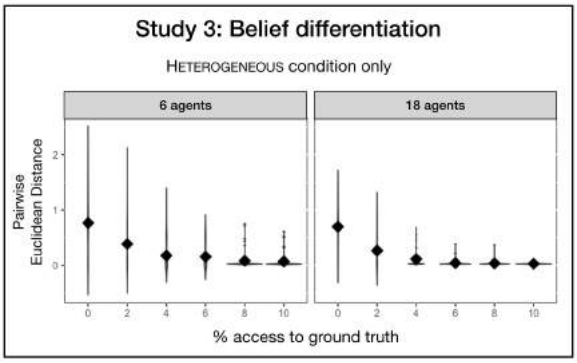

Figure 5: *Evolution of belief when agents have access to the ground truth.* It only takes a little bit of access to a ground truth source that everyone agrees is trustworthy to disrupt the formation of echo chambers, even in a HETEROGENEOUS population. Even 2% of all data points make a big difference, and by 4% or so there are no differences in beliefs.

the emergence of mutual trust, suggesting that even if such a sweet spot exists, it is tiny and highly dependent on a very specific set of parameter choices.

So far we have found that echo chambers persistently form in populations of rational agents, despite making as many charitable assumptions as possible: our agents do not revise beliefs away from those they disagree with and communicate about a rich meaning space in a way that includes their confidence (variance) about the mean rather than the mean alone. Even with these assumptions, as long as the initial beliefs are heterogeneous enough, agents cluster into echo chambers. Allowing them to build trust by communicating more often on less contentious topics does not solve this problem; communicating rarely enough to build trust means not communicating often enough to converge on a set of shared beliefs. Taken together, this appears to support the intuition we began with: this is a very difficult epistemological problem. How can one sensibly learn from others when you have no way to evaluate who to trust aside from the data they provide, and no way to evaluate that data against the state of the world?

These considerations suggest that echo chamber formation might be eliminated by simply giving agents access to some mutually-agreed upon ground truth of the matter. This might be data supplied by the external world directly or information provided by an objective observer; all that is necessary is that everyone has access to it and everyone trusts it. Does access to the ground truth disrupt the formation of echo chambers? If so, how little is required?

Earlier work has investigated these questions and found that access to the ground truth is not sufficient to disrupt echo chamber formation (O'Connor & Weatherall, 2018; Madsen et al., 2018). However, in O'Connor and Weatherall (2018) the agents sought out such evidence in a confirmatory way, testing their current hypothesis only. It is possible that receiving data relevant to all hypotheses might have led to a different result. Furthermore, agents in Madsen et al. (2018) often ended up ignoring the ground truth because it was outside of their inferred variance, which had shrunk to zero. In that sense it was not actually a "ground truth", because although it was available to all, very few people trusted it. In Study 3 we therefore provide a ground truth that all agents have access to and all trust equally.

Study 3: Ground truth

Method

Our method was exactly the same as in Study 1, except that sometimes the agents received a data point x_g sampled from the "ground truth" of the world, $x_g \sim N(0, \Sigma)$. Agents revised their belief based on this data exactly as they did on any other data; the only difference is that they did not perform inference over trust, instead assuming perfect trust in the source. We systematically vary how often agents have access to the ground truth. Because echo chambers only emerged in the HETEROGENEOUS condition in Study 1, we consider only that condition here. As in Study 2, for ease of presentation we combine the runs with 6 and 18 agents.

Results

As Figures 4 and 5 show, even a very small amount of access to ground truth data is sufficient to disrupt the formation of echo chambers. When only 2% of the data comes from the ground truth, a substantial proportion of runs result in high levels of mutual trust and shared beliefs. When 4% of the data is ground truth, polarisation is consistently eliminated: even initially HETEROGENEOUS agents converge on the same set of shared beliefs and trust everybody in the population.

Discussion

This paper is part of a growing literature investigating what happens to populations of rational agents when faced with a difficult epistemological puzzle: how to learn a set of beliefs from other people, without having access to external evidence about those beliefs or knowing *a priori* who to trust.

Consistent with that literature, we find that echo chambers consistently emerge, despite making every effort we could to eliminate them. Even though we provided agents with a richer meaning space and more nuanced communication abilities than other studies, polarisation was still highly likely as long as the population was sufficiently heterogeneous in their initial beliefs. One contribution of our work, therefore, is to further underline the robustness of this effect.

We make several larger contributions as well. First, we show that enabling agents to strategically talk less about topics that they disagree on did not solve the problem. Avoiding those topics did lead to improve trust, but at the expense of *increasing* the distance between beliefs; we found no "sweet spot" where both mutual trust and shared belief were possible. To our knowledge this is the first attempt to simulate the population-level effects that results from agents adopting different communicative tactics. Our framework is rich enough to investigate many other such tactics. What happens if people sample based not just on their own beliefs, but also on their inferences about the beliefs of others? What if people deliberately select more or less extreme beliefs, in an effort to shift the Overton window of acceptable discourse? How vulnerable are these strategies to deceptive or malicious agents?

Our work is also the first, to our knowledge, to show that having access to a trusted "ground truth" is an extremely powerful way to break the echo chamber effect. Previous work found that ground truth did not help that much (Madsen et al., 2018; O'Connor & Weatherall, 2018), but as discussed before, this was probably because of specific modelling choices that resulted in their "ground truth" being neither fully shared nor fully trusted. When it *is* shared and trusted, only a small proportion of data is necessary for even initially heterogeneous populations to develop high trust and converge on shared beliefs. The reason for this is that this common ground breaks the vicious cycle and creates a virtuous one: agents make inferences about their beliefs based in part on the ground truth data, thus trusting agents more who agree with it, and so forth. Our framework is flexible enough to enable further exploration of the robustness of this effect. How important is it that *everyone* have access to it? What if the ground truth is more accessible or less ambiguous to some? Is there any way for agents to identify those people that cannot be "gamed" by malicious agents seeking to mislead?

Our finding about the necessity of the ground truth may have important implications in light of the "post-truth" era that many believe we are now in (Lewandowsky, Ecker, & Cook, 2017). This era is characterised not only by attempts to delegitimise previously trusted sources but, more profoundly, a pervasive denial that a truth exists at all and a persistent belief that no sources are to be trusted (McCright & Dunlap, 2017). Indeed, one of the characteristics of fascism was a denial of the utility of external evidence (Varshizky, 2012), and conspiracy theories are associated with lower levels of trust in external sources (Einstein & Glick, 2015). Our simulations suggest why: shared access to the truth is one of the few things that might rescue agents from an otherwise inescapable epistemic trap. Agents who do not have access or belief in this truth are far easier to confuse, polarise, and manipulate.

Although our work further demonstrates that echo chamber formation is a robust and consistent effect even in populations of perfectly rational learners, it does suggest a key to disrupting them. Perhaps polarisation can be minimised and trust increased not by throwing more evidence toward mistaken beliefs, but by working to persuade people instead that objective truth exists and shoring up their (perceived) capacity to access and evaluate it.

Abstract

Previous research with typically developing (TD) children and adults show an advantage of active control for episodic memory as compared to conditions lacking this control. The present study attempts to replicate this effect in autistic children. Six- to 12-year-old autistic children (n = 30) were instructed to remember as many of 64 presented objects as possible. For half of the materials presented, participants could decide the order and pacing of study (Active condition). For the other half, they passively observed the study decisions of a previous participant (Yoked condition). We found that recognition memory was more accurate for objects studied in the active as compared to the yoked condition, even after a week-long delay. The magnitude of the effect was comparable to that obtained in previous studies with TD children and adults, suggesting a strong robustness for the benefits of active learning. We discuss how pedagogical approaches may be encouraged to utilize self-directed learning strategies to promote inclusive learning.

Keywords: active learning; Autism Spectrum Disorder; Enactment Effect; recognition memory; pedagogy

Introduction

The opportunity to exert active control over the learning experience, often referred to as active, or self-directed learning, has been shown to lead to improved outcomes as compared to more passive forms of instruction (see Bruner, Jolly, & Sylva, 1976; Gureckis & Markant, 2012; Montessori, 1912; Piaget, 1930). In particular, studies with adults show an advantage of active control for episodic memory of objects (Voss, Galvan & Gonsalves, 2011), faces (Liu, Ward, & Markall, 2007), and in spatial learning tasks (Plancher, Barra, Orriols, & Piolino, 2013; for a review see Markant, Ruggeri, Gureckis, & Xu, 2016), as compared to conditions lacking this control. A more recent study suggests that the benefits of active learning for episodic memory of objects might already emerge during early childhood, and become comparable to adults' by age 8 (Ruggeri, Markant, Gureckis, Bretzke, & Xu, 2019). Difficulties in active selection (and thus control) of the contents of learning may emerge in situations where exploratory behaviours are limited. In this paper we explore the effects of active control of learning on episodic memory in autistic children. The examination of atypically developing children might help to further understand the full spectrum of development (Graham & Madigan, 2016) and support the development of novel pedagogical approaches to promote inclusive learning.

Benefits of active control of study and enactment effect. To investigate the effects of active control for episodic memory, studies have typically employed *yoked* designs, which implicate a pair of learners: An active participant who controls the flow of information during learning (e.g., selecting what to study and for how long), and a yoked participant, who observes the experience generated by the active participant (Markant et al., 2016). By matching the content experienced during study across conditions, yoked designs isolate the effects of active decision making on learning and memory. For example, Ruggeri and colleagues (2019) presented 5- to 11-year-old children with a simple

memory game in which they were tasked to remember and later recognize a set of 64 objects. For half of the materials presented, participants could decide the order and pacing of study (Active condition). For the other half, they passively observed the study decisions of a previous participant (Yoked condition). The authors showed that recognition memory was more accurate for objects studied in the active as compared to the yoked condition, and that this memory advantage persists over a week-long delay. This advantage of active learning has been shown to be fairly robust across different types of tasks, developmental stages, and even populations of learners of different nationalities (Brandstatt & Voss, 2014; Ruggeri et al., 2019).

Self-performed tasks (SPT) (Cohen, 1981) present a similar design: Participants are presented with action phrases (for example, "Clap your hands") that they either have to read/perform (Active condition) or that are read/performed by somebody else (Verbal task/Experimenter performed task; Engelkamp & Zimmer, 1989). Participants are then usually tested through a recall or recognition memory task for the action phrases presented. Results from studies using the SPT have convergently indicated advantages for learning associated with the active condition (Engelkamp, 1998). For example, Baker-Ward and Colleagues (1990) found that children as young as six years old exhibited better recall for actions they performed compared to the observed actions of someone else. This effect, referred to as the e*nactment effect*, is extremely robust and is thought to improve memory mainly through motor actions (Engelkamp & Zimmer, 1998). Along these lines, Engelkamp and Zimmer (1994) found that participants, when they physically performed an action, remembered it better than when they just read a distractor phrase similar to the target action.

The ecological validity of self-performed tasks might be limited though, for instance, as SPTs use stimuli exclusively associated with specific actions. Yet, learning processes, particularly those based on recognition memory, involve interactions of different abilities, functions, semiotics, and experiences with a variety of stimuli. Furthermore, SPT paradigms make it difficult to isolate the sources of enactment effects as the content of the tasks differ across verbal, or experimenter performed conditions. As a participant remembers an action they performed more accurately it becomes challenging to separate motor involvement from other kinds of self-representation, for example. Aside from motor actions, there may be different factors influencing enactment effects like metacognition, attention, motivation, or agency. Further work incorporating different stimuli and target behaviors aimed at isolating motor involvement is needed to expand our knowledge on the function and implications of enactment effects in developmental and learning processes.

Learning strategies in autistic individuals. Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by persistent social communication difficulties as well as restricted interests, repetitive activities and sensory abnormalities (American Psychiatric Association, 2013). Autistic children seem to explore both space and objects less than others. In autistic children, restricted interaction with objects, or an insistence on exploring only a few features of an object may limit the possibilities for learning (Bjorne, 2007). As a consequence, autistic children might be at risk of missing important opportunities for learning, except for those things that lie within their interests, and this might have important consequences for their development (Pierce & Courchesne, 2001). Bondy and Frost (1994) indicate that 80% of autistic children, aged 5 years and younger, who enter special education are non-verbal, and 30% are minimally verbal at 9 years old (see also Anderson et al., 2007). Verbal tasks may thus not be the most methodologically appropriate to assess active learning in autistic children, considering their well-known communication and other general learning difficulties.

As memory enhancements from active learning paradigms seem to be extremely robust in typically developing individuals, research evidence suggests that the enactment effect may also be intact in autistic individuals (see; Grainger, Williams, & Lind, 2014a; Grainger, Williams, & Lind, 2017; Lind & Bowler, 2009; Summers & Craik, 1994; Williams & Happé, 2009). Summers and Craik (1994) found no significant differences in recognition memory for action-phrases between autistic and typically developing (TD) children from an SPT design. These results were confirmed in a study by Yamamoto and Masumoto (2018), who examined the enactment effect for recall and recognition memory in autistic adults and a TD comparison group through an SPT. They found that although overall recall performance was lower for autistic individuals than for the TD group, there were no differences in the enactment effect between groups. Overall, there seem to be no significant differences in the magnitudes of enactment effects for memory tests in autistic children compared to TD children (see Grainger et al., 2014a for a review), measured through research paradigms adopting self performed tasks.

The present study. The present study aimed to explore the benefits of active learning on episodic memory in autistic children by examining their recognition memory for objects studied in an active compared to a yoked learning condition. The design we have adopted is one step beyond the SPT paradigm used by previous studies to elicit the enactment effect, presenting several advantages: First, we used images of objects that are not explicitly associated with performing an intended action. Second, due to its yoked design, the content experienced during study was carefully matched across conditions, so that we could isolate the effects of active control of study on learning and memory. Third, participants were instructed to perform the same motor actions in both active and yoked conditions. In this way, we could also disentangle the effects of active control from the effects that, in SPTs, have often been attributed to motor engagement. Along these lines, a study by Williams and Happé (2009) designed a task in which autistic children were asked to self-perform an action and to perform the

same action on behalf of a doll that represented a separate agent. The authors found that memory was better for the actions that had been self-performed, suggesting that even the enactment effect cannot be exclusively attributed to motor engagement.

Finally, a number of studies have revealed diminished recall but intact recognition memory in autistic individuals (see Boucher, Mayes, & Bigham, 2012 for a review). For this reason, we thought testing recognition memory would be a sufficient task to isolate the effects of active control. Moreover, evidence has suggested that adopting interactive teaching strategies (i.e. visual-interactive materials paired with music) enhances active engagement and learning of autistic students (Carnahan, Musti-Rao & Bailey, 2009). In this sense, the use of a tablet device, with an interactive interface, to assess autistic children who might have communication impairments might be particularly suitable to deliver the paradigm. Past research has also shown that autistic children seem to be more attentive, and motivated resulting in better performance and enjoyment of intervention sessions implemented through tasks involving technological tools (Moore, & Calvert, 2000). This task can reveal the non-verbal learning strategies adopted by autistic children. Our results will add further information on visual object exploration strategies, and contribute to a broader picture of active learning. Based on the literature reviewed above, we expected that autistic children would show active learning benefits to memory similar to that found in TD children of the same age (Ruggeri et al., 2019). In particular, with this design we can explore whether and how the effects of active control of study depend on how participants explore the objects. These insights would bear relevant implications for future research directions and clinical practice.

Method

Participants

We recruited 30 6- to 12-year-old autistic children (4 female, M_{age} = 113.17 months; *SD* = 19.89 months) from the Neuropsychiatry and Neuroscience Unit, I.R.C.C.S. Bambino Gesù Pediatric Hospital (OPBG), Rome, Italy. Participants had been previously screened for a formal diagnosis of ASD using the Autism Diagnostic Observation Schedule (ADOS; Lord et al., 2000). To minimize differences between participants, we recruited individuals who had scored between 5 to 8 out of 10 on the ADOS (*M* = 6.13; *SD* = 1.04). Once we re-ran the ADOS test with the subjects recruited, we excluded one participant who scored below 5. Participants were also previously screened for IQ (*M* = 109.20; *SD* = 13.43) using the Raven's Coloured Progressive Matrices (Raven, Court, & Raven, 1990). The data from 5 additional autistic children were excluded for reasons due to behavioral issues, symptom severity, and technical difficulties.

Materials

As in Ruggeri and colleagues (2019), the stimuli set consisted of 200 line drawings of the most frequent objects mentioned by 2- to 5-year-old children in their everyday conversations with adults, as recorded by the CHILDES corpus (Child Language Data Exchange System; MacWhinney & Snow, 1985). Eight of the 200 drawings were used as training stimuli for the familiarization trials and 192 drawings were used as stimuli during the first and second experimental sessions. The experimental materials were presented on an Android touchscreen tablet using custom software.

Design and Procedure

The experimental procedure was identical to that implemented by Ruggeri and colleagues (2019). The stimuli were presented as a simple memory game whereby children were tasked with remembering as many of the presented objects as possible.

Familiarization phase. Participants were first presented with two familiarization trials aimed at introducing the goal of the game, the study procedures, and making children comfortable using the touchscreen. During each familiarization trial, children were presented with four objects arranged in a 2x2 grid. The objects were shown on the screen for two seconds before disappearing under occluders (same as for the main experimental session, see Figure 1, top). Participants were instructed that the goal of the game was to remember all the objects presented on the screen. The first familiarization trial introduced the study procedure of the active blocks. Participants were told that in some rounds they could decide which occluder button to touch in order to view the object hidden beneath. After a touch, a red frame appeared for 500 ms, followed by the removal of the occluder that would reveal the hidden object. Children were instructed that, before studying another object, they had to touch the object currently displayed once more to make it disappear behind the occluder. The experimenter modeled the touching actions while explaining the procedure. Children then had the opportunity to practice the active study procedure. If necessary, the experimenter provided feedback and repeated the instructions. Once children were familiar with the active study procedure, they moved on to the second familiarization trial, which introduced children to the study procedure of the yoked blocks. They were told that in other rounds the game would decide what objects they would see and for how long. Children were then presented with a randomly generated study sequence. As in the active blocks, a red frame preceded each object for 500 ms so that children had time to allocate their attention to the new study location before the object appeared. To keep engagement and attention level comparable to the active blocks, during yoked blocks children were asked to touch the objects as soon as they appeared, although this touch had no effect on the display.

There were no time constraints for the familiarization trials.

Study phase. The main experimental session consisted of two active and two yoked study blocks (four blocks total), presented in alternating order (i.e., active, yoked, active, yoked). The active block was always presented first, so that children's initial active study pattern would not be influenced by the study pattern observed in the yoked blocks. Each study block presented children with 16 objects arranged in a 4x4 grid. All 16 objects were visible on the screen for 2 seconds at the beginning of each study block, before disappearing under occluders (see Figure 1, top). Across the four blocks, children were asked to memorize 64 objects. In the active blocks, children had 90 seconds to select and study the objects in order to memorize them. In the yoked blocks, children were presented with the 90-second study sequence (i.e., same objects and pacing) of one of the previous participant's active learning blocks. In between blocks, there was a 20-second break in which children were briefly reminded of the study procedure for the next block.

Test phase. The study phase was immediately followed by a test phase consisting of 8 blocks. In each test block, 16 objects were again presented in a 4x4 grid (see see Figure 1, bottom). Across the 8 test blocks, 64 of the objects had appeared during the study phase (old objects) and 64 were objects that were not presented during study (new objects). The number of old objects in each block was randomly varied between 1 and 15. The number of old objects from active and yoked blocks randomly varied across test blocks (active: M = 4:23, SD = 2:16; yoked: M = 4:3, SD = 2:25).

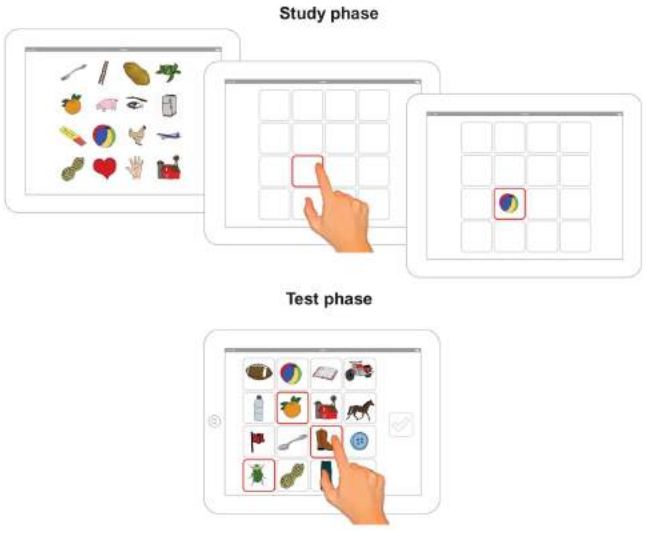

Figure 1. **Top:** Each study round began with all objects displayed for two seconds. After the objects disappeared, participants either selected a location to study (Active condition), causing a red frame to appear, followed by the object, or touched the location where the object appeared (Yoked condition), preceded by a red frame. **Bottom:** During each test block, participants selected the objects that they recognized from the study phase.

All objects were arranged in random locations on the grid. For each block, children were asked to indicate the objects they had studied earlier by touching them on the screen. Selected objects were framed in red to help participants keep track of the objects selected as recognized. Children could deselect any of the previously selected objects by touching them again on the screen and making the red frame disappear. After selecting all the objects they recognized from the study phase, children were prompted to touch a button to proceed to the next test block. Children were not given any feedback about their performance during or after the test phase.

About one week later (range 5 to 8 days; M = 7.04 days; SD = 0.58 days), children revisited the Hospital for a second session in which they were asked to complete 8 new test blocks. The 64 objects studied in the first session were randomly mixed with 64 new objects (i.e., objects that were not used during the first experimental session, neither as study nor as test objects).

Results

We analyzed (1) recognition accuracy (i.e., the number of objects recognized among the ones studied); (2) the correlations between study experience and performance, to test whether certain participants' exploration strategies and patterns lead to better recognition accuracy. In particular, we examined the correlation between the recognition accuracy for a certain object and the time spent studying it, as well as the number of times it had been visited during study. We also examined the correlation between participants' average recognition accuracy and the distance between subsequent study locations (that is, the average distance on the grid between the object currently visible and the one selected next), a basic measure of how systematically a child explored the grid.

Recognition accuracy. We examined recognition accuracy using an ANOVA with study condition (2 levels: active versus yoked) and session (2 levels: test versus one-week-later retest) as within-subject variables. We found a significant main effect of study condition, $F(1, 81) = 16.44$, $p = < .001$. Children recognized more objects studied in the active learning condition (M_{active} = 19.02; SD = 6.70) as compared to the objects studied in the yoked condition (M_{yoked} = 16.26; SD = 6.52), a 9% difference (see Figure 2). We also found a significant effect of session $F(1, 82) = 19.09$, $p = < .001$. Children recognized more objects studied in the first test session (M_{test} = 18.92; SD = 6.72) compared to approximately one week later in the retest session (M_{retest} = 16.22; SD = 6.51). There was no reliable interaction effect between study condition and session (p = .559).

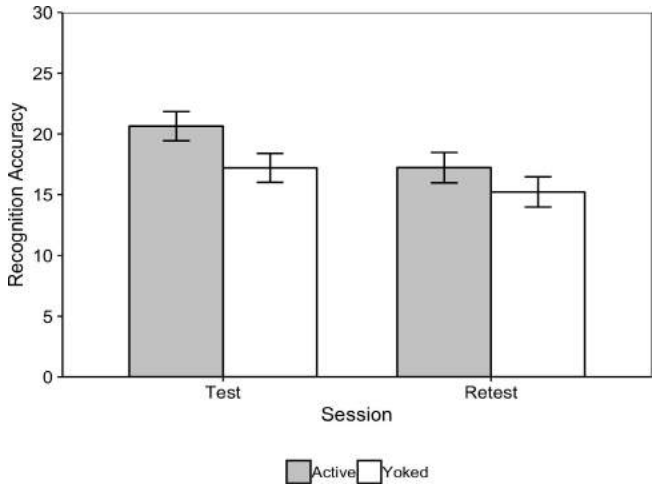

Figure 2: Number of objects correctly recognized in the test trials, displayed by study procedure (active vs. yoked) and session (test vs. retest). Error bars indicate 1 SEM.

Correlations between study experience and performance. Surprisingly, we found that object recognition accuracy was not correlated with the time spent studying an object, nor with the number of times the object had been visited in the active study condition, for both test and retest (see Table 1). However, we found a correlation between recognition memory for objects studied in the active blocks and the distance between the location in which the objects were presented on the study grid and their location on the test grid, $r = .577$, $p = < .01$.

Table 1: Correlations between study measures.

Active study condition				
	Correlations between tests			
Test	1	2	3	4
1. Accuracy in test				
2. Accuracy in retest	.810***			
3. Number of visits	-.093	.087		
4. Study duration	.099	.226	-.340	
7. Distance from study position	.577**	.363	-.242	-.184
Yoked study condition				
	Correlations between tests			
Test	1	2	3	4
1. Accuracy in test				
2. Accuracy in retest	.788***			
3. Number of visits	.067	-.088		
4. Study duration	.479*	.470	-.473*	
5. Distance from study position	-.067	-.356	.096	-.198

* Correlation is significant at the 0.05 level (2-tailed).
** Correlation is significant at the 0.01 level (2-tailed).
*** Correlation is significant at the 0.001 level (2-tailed).

Discussion

The present study investigated whether active control over a learning experience leads to benefits in episodic memory for 6- to 12-year old autistic children. As hypothesized, and similar to previous studies with TD adults and same-aged children, we found that participants' memory was more accurate for objects studied in the active learning compared to the yoked condition. Moreover, the strength of active control for memory encoding is strikingly comparable to the effect found with TD children from an identical recognition task (9% increase over the yoked condition; Ruggeri et al., 2019), and similar to that found in other studies examining the enactment effect in autistic individuals (see Grainger et al., 2014a for a summary). Thus, our results add to the universal robustness of active learning effects. Concurrently, this study complements and adds to the presence of the enactment effect in autistic individuals by employing an alternative paradigm to the commonly used SPTs. Considering our findings with respect to long-term memory, we found that memory improvement for objects studied by active control lasted for at least one week after testing. These findings lend support to established evidence suggesting improved long-term retention as a result of active control of learning (Ruggeri et al., 2019; Yamamoto, & Masumoto, 2018).

As mentioned in the introduction, bearing in mind possible mechanisms responsible for the active learning advantage, motor involvement has often been suggested to play an important role (Engelkamp, 1998; Markant et al., 2016). In experiments that implement SPTs, the participant enacts an action phrase like 'Wave Goodbye' in the active condition, and observes the experimenter performing a different action phrase in the passive condition. This idea (Engelkamp & Zimmer, 1989) supposes that performing an action involves motor components, which add rich contextual properties that help the encoding process of SPTs (Engelkamp, 1998). However, in our study participants are engaged in approximately the same motor actions in both active and yoked conditions. This result suggests that the process of physically performing an action is not necessary to scaffold memory performance.

Rather unexpectedly our results also seem to suggest, that episodic memory is not influenced by autistic children's study patterns, in both conditions. Objects studied for a longer time or visited more often were not recognized more accurately. This differs from all previous adults and children active learning studies that have used this paradigm (see Gureckis & Markant, 2012; Markant et al., 2014; Markant et al., 2016; Ruggeri et al., 2019). This might be related to the deficit in metamemory and metacognition demonstrated in autistic individuals (Grainger, Williams, & Lind, 2014b). That is, due to such deficits, autistic children may not have been strategically devoted to their study effort, allocating the same amount of time and visits to all object images. Therefore, we did not have enough variability to capture a correlational effect. It is extremely interesting to notice that the advantage of active learning for memory encoding does not seem to depend on the efficiency of children's study strategies and metacognitive decision making, and that it persists when such processes do not play a prominent role. Future studies should investigate more thoroughly the role

of metacognition and metamemory, as well as attention and motivation on the active learning benefit for memory encoding.

Again in contrast with results from prior research, we found that recognition accuracy for object studied in the active condition is correlated with the distance between the location in which the object was presented on the study grid and its location on the test grid. Having the objects presented in the same location on the grid across the study and test blocks did help children recognize them more accurately, but only in the active condition. These results might speak, though indirectly, in favor of an active learning advantage for spatial recall in autistic children. However, only a direct test of spatial memory would allow confirmation of this hypothesis.

The natural next step would be to extend this paradigm to include more real-world stimuli and tasks targeted to autistic children as well as other developmental disorders. For example, Ruggeri and colleagues (2019) designed a task to model real learning situations children encounter in school. Using a similar paradigm to our study, children were tasked to learn the French words for images of objects presented in a study space. The experimenters found that French words were remembered more accurately studied in an active as compared to a yoked condition. Based on this research, future studies might explore the role of active learning in learning new actions, words or behaviors. We are currently in the process of collecting a much larger sample, across different age groups and encompassing a wider range of symptom severity and cognitive maturity. On one hand, this would allow us to trace the emergence of the active learning advantage and compare the developmental trajectories of this effect in autistic and TD children. On the other hand, we are keen to explore whether and how general cognitive performance and symptom severity might impact the advantage of active learning and children's active study strategies, although previous research suggests that ASD traits do not impact memory for self-representations (Williams, Nicholson, & Grainger, 2018).

In conclusion, because autistic students often have difficulties participating in classroom activities (Sparapani, Morgan, Reinhardt, Schatschneider, & Wetherby, 2016), it is important to better understand how these children learn to improve and develop current and novel teaching methods. If active control over the learning experience can enhance episodic memory in ASD, then teachers and educators might think of supporting active learning approaches in pedagogical applications. Offering children with developmental disorders opportunities for concrete self-generated, active learning experiences could help promote greater learning outcomes (Haslam, Wagner, Wegener, & Malouf, 2017). Involving the student in their own learning can also be beneficial for reducing problematic behaviors, while at the same time improving skill acquisition (Toussaint, Kodak, & Vladescu, 2016). Alternative modes of teaching based on the use of images and pictures, rather than written words, are encouraging new therapeutic and instructional strategies for autistic children. Consequently, language and communication development devices (e.g. the Picture Exchange Communication System, PECS; Bondy & Frost, 1994) might aim to utilize active learning benefits to ameliorate memory.

Finally, this study tries to bridge atypical, developmental and cognitive research without relying on clinical variations to determine major differences between comparative groups. Rather, our results highlight that autistic individuals share the same memory advantage from active control of learning as TD individuals. This dimensional approach allows for researching *similarities* between typical and atypical groups, and while being as informative as revealing differences (Graham & Madigan, 2016), can support inclusive classrooms. Considering that active learning effects on memory are present in TD as well as autistic children, classrooms could adopt self-directed, active learning methods that would not only benefit both typical and atypical children, but also children who fall somewhere in between these categories.

Acknowledgements

We would like to thank all the children and families who kindly participated, as well as the staff at the Neuroscience and Neuropsychiatric Unit of the Bambino Gesù Pediatric Hospital in Rome for their helpful support in data collection.

Deception in evidential reasoning: Willful deceit or honest mistake?

Toby D. Pilditch[1,2], Alexander Fries[3], and David Lagnado[1]

Abstract

How does one deal with the possibility of deception? Extant literature has mostly focused on identifying deception via cue detection. However, how we reason about the possibility of deception remains under-explored. We use a novel formalism to expose the complexity of this reasoning problem (e.g. separating the uncertainty of an honest mistake, from willful deception), in the process highlighting several reasoning errors regarding deception. Notably, we show reasoners to make substantial errors when reasoning about a (possibly) deceptive source *in isolation* (including base rate neglect errors), but find that reasoning improves when further (independently sourced) corroborative or contradicting reports are introduced.

Keywords: deception; evidential reasoning; probabilistic reasoning; Bayesian Networks; belief updating

Introduction

The question of how to deal with the possibility of deception has long been of interest to police, military and intelligence investigation, among other domains. A potentially deceptive source, more so than a generally unreliable (e.g. incompetent) source, can be particularly deleterious to an investigation, via the wilful sowing of misinformation. Critically, however, investigators seldom have definitive proof of deception, and are therefore placed into the realm of reasoning under uncertainty. In the present paper, we demonstrate a novel Bayesian formalism for capturing the complex uncertainties surrounding (potentially) deceptive sources, such that optimal inferences regarding the likelihood of deception, as well as the hypothesis being informed upon, may be updated with minimised inaccuracy (Pettigrew, 2016). Moreover, we demonstrate that lay reasoners wildly diverge against such a normative expectation.

Deception in Psychology

Deception has typically been researched in terms of lie detection (see Vrij, 2008). Crucially, previous research has noted that individuals struggle with the uncertainties surrounding the possibility of deception (e.g. chance error vs deception) when explaining errors (Schul, Mayo, Burnstein, & Yahalom, 2007).

Research on perceived trustworthiness has shown that it influences attitudes (Cuddy, Glick, & Beninger, 2011; Fiske, Cuddy, & Glick, 2007), persuasive efficacy (Briñol & Petty, 2009), risk perception (Siegrist, Cvetkovich, & Roth, 2000; Earle, Siegrist, & Gutscher, 2010), and advice uptake (Schul & Peri, 2015). But relatively little research has been conducted in regards to not only how people *do reason* about the *possibility of deception*, but also how they *should*. Within evidential reasoning, one can consider deception to be a special case of (dis)trustworthiness. Dual process models in argumentation, like the Heuristic Systematic Model (HSM; Chaiken & Maheswaran, 1994) and Elaboration Likelihood Model (ELM; Petty & Cacioppo, 1984) have argued that cues to the trustworthiness of a source are only attended to in the absence of effortful engagement with the arguments made by that source.

More recently, coherence-based models, such as the Bayesian source credibility model (Hahn, Harris, & Corner, 2009; Harris, Hahn, Madsen, & Hsu, 2015) have provided a framework that moves beyond the directional predictions of earlier models. This has allowed for the integration of a source's trustworthiness (the willingness to impart accurate information) and orthogonally, expertise (the capacity to impart accurate information) into the support provided by a report from a source. Using these models as a normative backdrop, lay reasoners have been shown to take into account the impact of credibility on argument strength (Hahn et al, 2009), and even follow appropriate adjustments in estimations of argument strength and source reliability in light of (shared) compromising reliability information (Madsen, Hahn, & Pilditch, 2018).

Formalising Deception

Taking forward the notion of deception as a special form of (un)reliability, work using Bayesian networks representations to model legal cases has used an idiomatic approach for witness testimony (Fenton, Neil, & Lagnado, 2013). More precisely, when modelling the strength of a witness's testimony, one may consider two possible (non-exclusive) causes of it – the hypothesis being reported on (e.g. guilt of suspect), and the reliability of the witness.

In the same manner, we may model the representation of deception as a possible cause, along with the hypothesis being reported upon (Lagnado, Fenton & Neil, 2013). Fig. 1 below uses an example case of a target hypothesis – "Is the suspect under questioning in fact the mob's hitman?", and a number of informing sources in a police investigation. Two of these, a forensic scientist and an eyewitness (each retaining their own respective reliabilities), and two Inspectors, McGarret and Graham, who are typically accurate in their investigative reports. Critically, each source reports independently of the other, but there is reason to believe McGarret and Graham *may* in fact be in league with the mob, and thus the possibility of deception is introduced (left-most node in Fig. 1).

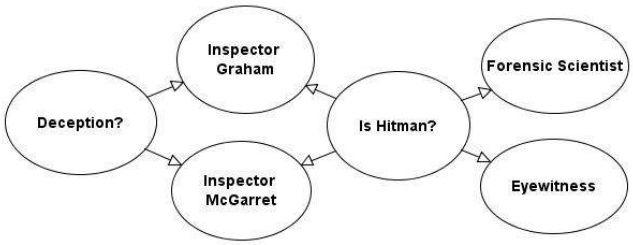

Figure 1. Graphical representation of deception scenario.

To tease apart the levels of uncertainty introduced by the possible deception cause, it is necessary to look at an example conditional probability table (CPT) that represents a (possibly) deceptive agent:

Table 1. Conditional probability table (CPT) representation of a potentially deceptive source, reporting on a hypothesis (Hyp) as either true (T) or false (F).

	Deception = False		Deception = True	
	Hyp = F	Hyp = T	Hyp = F	Hyp = T
Rep = Yes	α	β	γ	δ
Rep = No	(1 -α)	(1 - β)	(1 - γ)	(1 - δ)

In Table 1, α is the probability that the source reports that the suspect is a mob hitman (Rep = Yes) given that he *is honest (Deception = false)* and the suspect is not a mob hitman (Hyp = false). β is the probability that the source reports that the suspect is a mob hitman (Rep = Yes) given that he *is honest (Deception = false)* and the suspect is a mob hitman (Hyp = True). γ is the probability that the source reports that the suspect is a mob hitman (Rep = Yes) given that he *is dishonest (Deception = true)* and the suspect is not a mob hitman (Hyp = false). Finally, δ is the probability that the source reports that the suspect is a mob hitman (Rep = Yes) given that he *is dishonest (Deception = true)* and the suspect is a mob hitman (Hyp=true). δ and (1 - γ) may be due to an imperfect deception, or due to long-run motivations to keep the deception in place. For this initial proof of principle, we simplify the notion of deception by removing this possibility (δ = 0; γ = 1). Put another way, in the scenario we model (and present to participants), deceivers will a) have insider knowledge (i.e. know the true state of "Hyp"), and b) always lie.

Placing Table 1 within the context of the model (and scenario) outlined in Fig. 1, there are a number of important inferences of which to take note.

Firstly, the difference between the probability of a report due to honest error and due to wilful deception (α versus γ), plays a pivotal role in the potential diagnosticity of the report for both P(Deception) and P(Hyp), such that as γ – α increases, the report becomes more diagnostic of deception.

This in turn has a multiplicative effect when considering the second elements: the prior probability of deception (P(Deception)) and – critically – the prior probability of hypothesis being true (P(Hyp)). More precisely, if a report confirms a hypothesis that is *likely* (e.g. P(Hyp) > .5), then P(Deception) should *decrease*, whilst if the report confirms an *unlikely* hypothesis (e.g. P(Hyp) < .5), then P(Deception) should increase. These inferences can best be explained with consideration of how *surprising* a report would be from an honest agent. If unsurprising (e.g. they are saying something *expected*), then an alternative explanation of the report (e.g. deception) is less warranted, and vice versa.

Thirdly, subsequent testimony from independent witnesses will lead to intercausal inferences of P(Deception). For instance, if potentially deceptive agents have their reports *corroborated* by independent testimony, then the increasing probability of P(Hyp) *explains away* the possible deception explanation, lowering P(Deception). Conversely, if independent testimony contradicts the reports of the potentially deceptive sources, then P(Hyp) becomes a less likely explanation of their reports, and again via explaining away, P(Deception) becomes a more likely explanation.

Finally, we seek to provide reasoners with one further clue to deception inferences. The common-cause structure of the deception explanation (left-most node of Fig. 1) – where if deception is true, it explains *both* Inspector Graham and Inspector McGarret's reports, in conjunction with "always liars" (δ = 0; γ = 1) element of their CPTs, allows for an observation-based way of dismissing the possibility of deception. More precisely, given the above, it is not possible for P(Deception) to be true if the two Inspectors contradict each other.

In sum, we use the above formalism to test lay reasoners on 3 different elements of the uncertainty surrounding deception: the prior probabilities of deception (and reported hypothesis) as explanations, the conditional probabilities, and observation-based inference.

The Experiment We present lay reasoners with the above scenario of a police investigation looking into whether a suspect in custody is a mob hitman. The key element to this scenario is to assess how well lay reasoners can integrate the influence of the possibility of deception when integrating testimony from what may otherwise be considered reliable sources.

Of interest is whether reasoners are able to make the following key inferences as more evidence comes in from the available sources:

1. Will reasoners sufficiently account for the likelihood of an honest report when estimating the probability of deception? I.e. If the source is reporting the (a priori) more likely state of the world, then P(Deception) should in fact *decrease*?
2. Will reasoners sufficiently account for the common-cause element of this form of deception? Namely that if the two potentially deceptive sources contradict one another, then they cannot (both) be (all-knowing, perfect liar) deceivers.
3. Will reasoners sufficiently account for the impact of independent sources, when their reports either a) corroborate the deceptive agents (and thus P(Deception) should decrease) or b) contradict the

deceptive agents (and thus P(Deception) should increase)? However, reasoners are likely to get the qualitative direction of these latter inferences.

Method

Participants 180 UK participants were recruited and participated online through the Prolific Academic platform. Participants were native English speakers, with a median age of 28.5 (*SD* = 11.3), and 113 participants identified as female. All participants gave informed consent, and were paid 1.30GBP for their time (*Median* = 8.69 minutes, *SD* = 4.38).

Procedure & Design Participants are provided with a brief background to the scenario, in which they are investigating whether a suspect is in fact a hitman hired by the local mob. They are instructed that they have a number of sources to inform their investigation: two highly reliable inspectors, Graham and McGarret, a Forensic Expert, and an eyewitness – all of whom provide assessments independently of one another. Critically, along with being provided with a prior probability of the suspect being the hitman (P(Hitman) = .1), participants are told there are some logs that suggest the two investigators may be in league with the mob. It is explained to participants that although this is unlikely (P(Deception = .1), if true, the two inspectors will both know the truth (they know the identity of the hitman) and will be motivated to always lie (make sure the innocent suspect takes the fall, or prevent the guilty suspect from going to jail). All the necessary probabilities to populate the underlying model (e.g. error rates of each source) and structures (e.g. common-cause structure of P(Deception)) were provided to participants.[1]

Having had the background explained to them, participants then repeated back the prior probabilities for P(Hitman) and P(Deception):

P(Hitman): *"Until you receive the assessments of other professionals investigating whether the suspect is in fact the hitman, you can safely assume a fairly low (10%) chance of the suspect being the hitman. Please indicate you understood the initial (baseline) probability of the suspect being the hitman:"*

P(Deception): "*... there is only a 10% probability that the two criminal investigators are in fact compromised ...*

Please indicate you understood the initial (baseline) probability of the two criminal investigators being in league with the mob boss:"

Using the gRain package in R (Højsgaard, 2012), these elicited prior probabilities were used to outfit a Bayesian Network (BN) model (Fig. 1) for each participant, creating individually fitted BNs (hereafter termed Behaviorally Informed Bayesian Networks; BIBNs). The remaining structure and parameters were taken from the background information presented to all participants. Thus, a fitted normative comparison could be made for inferences on the participant level.

Following the elicitation of priors, participants then saw three stages of observations, with questions asked at each stage.

(T1) Firstly, participants heard from both the potentially deceptive agents ("DecAgents"). This was manipulated between-subjects, as: Both Report Hitman=True, Both Report Hitman=False, One Contradicts the other.

(T2) Participants then heard from the Forensic Expert, followed by the eyewitness (T3), in separate elicitation stages. These ("OtherAgent") reports were also manipulated between-subjects, as: Both Report Hitman=True, Both Report Hitman=False.

Across these 3 stages, participants were asked two sets of questions:

Probability Estimates (sliders from 0-100%, no default):

- **Hitman Hypothesis:** *"Based on the evidence so far, what do you believe is the current probability of the suspect being the hitman?"*
- **Deception Hypothesis:** "*Based on the evidence so far, what do you believe the current probability is that the criminal investigators are in league with the mob boss?*"

Qualitative Judgments (forced choice; response options: "Increased" / "Decreased" / "Same"; randomized presentation order.):

- **Hitman Hypothesis:** *"Based on the evidence so far, do you believe the probability of the suspect being the hitman has increased, decreased, or remained the same?"*
- **Deception Hypothesis:** "*Based on the evidence so far, do you believe the probability that the criminal investigators are in league with the mob boss has increased, decreased, or remained the same?*"

Thus, this 3 (DecAgents reports) x 2 (OtherAgents reports) x 3 (Elicitation stage) x 2 (Hypothesis) design allows for the testing of the influence of explanation priors, internal (within DecAgents) contradiction, and independent corroboration/contradiction, on estimates (both quantitative and qualitative) of the probability of the hypothesis, and the probability of deception.

Results

Bayesian statistics were employed throughout[2] using the JASP statistical software (JASP Team, 2018). For the sake of brevity, analyses are not reported exhaustively here.

[1] Using the notation of Table 1, participants were given values $\alpha = .05$ (honest false positive); $\beta = .95$ (honest true positive); and $\gamma = 1$, $\delta = 0$ (deception = always lie) for deceptive agents. For full details of the materials used, as well as the collected data, please see https://osf.io/4hvu6/.

[2] Bayes Factors (BF_{10}: likelihood ratio of data given hypothesis, over data given null), may be interpreted as: 1 – 3 = anecdotal support; 3-10 = substantial; 10-30 = strong; 30-100 = very strong; >100 = decisive (Jeffreys, 1961). Conversely, Bayes Factors < .33 can be considered substantial support for the *null* (Dienes, 2014). All analyses used an objective (uninformed) prior. Sample sizes for a given analysis (*N*), and Bayesian Credibility Intervals (95% CI) are indicated wherever appropriate.

Hypothesis 1: Priors and Deception (Base rate neglect)
To understand the impact of priors, we look at estimates and judgments relating to the introduction of the potentially deceptive agents reports (i.e. Baseline to T1), on both P(Hitman) and P(Deception) estimates and judgments, with greater errors predicted for the latter.

P(Hitman) estimates (black lines, Fig. 2). A repeated measures ANOVA was run using elicitation stage (Baseline, T1) and Observed vs Predicted (Data vs BIBN Model) as within-subject factors, and DecAgents condition (restricted to Hitman=True vs Hitman=False reports) as a between-subject factor. This found main effects of elicitation stage (positive trend), $BF_{Inclusion} > 10000$, Observed vs Predicted (data > model), $BF_{Inclusion} = 4.905$, DecAgents condition (Hitman=True > Hitman=False), $BF_{Inclusion} > 10000$, decisive deviations from expectation over time, $BF_{Inclusion} = 5.334$, and opposing trends based on DecAgents condition (increases with Hitman=True, decreases with Hitman=False), $BF_{Inclusion} > 10000$. Crucially, there was no evidence for an interaction of Observed vs Predicted with DecAgents condition, $BF_{Inclusion} = 1.112$, or in conjunction with elicitation stage, $BF_{Inclusion} = 2.178$, indicating no influence of reported base rates on the correctness of P(Hitman) estimates.[3]

P(Deception) estimates (grey lines, Fig. 2). Not only are the same background terms all decisive ($BF_{Inclusion}$'s all > 10000), but there are decisive interactions of Observed vs Predicted and DecAgents condition, $BF_{Inclusion} > 10000$, and the three-way including elicitation stage, $BF_{Inclusion} > 10000$. As can be seen in Fig. 2 by looking at grey solid (participant) vs grey dashed (BIBN model) lines in the middle row (DecAgents reports Hitman=False) vs bottom row (DecAgents reports Hitman=True), estimates *increase* when they should *decrease* in the former, and insufficiently increase in the latter.[4]

Qualitative judgments. Correct responding proportion for the change in P(Hitman) to P(Hitman|DecAgents) did not differ between the DecAgents reports Hitman=True (.39) and DecAgents reports Hitman=False (.25) conditions (N = 121), $BF_{10} = 0.852$. However, in line with probability estimate data, there was substantial evidence for correct responding proportions for the change in P(Deception) to P(Deception|DecAgents) being worse in the DecAgents reports Hitman=False (.1) than DecAgents reports Hitman=True (.28) conditions (N = 121), $BF_{10} = 3.99$.

This latter effect, in conjunction with the P(Deception) estimates, confirms the neglect of the report base rates when considering the possibility of deception, leading to substantial overestimation.

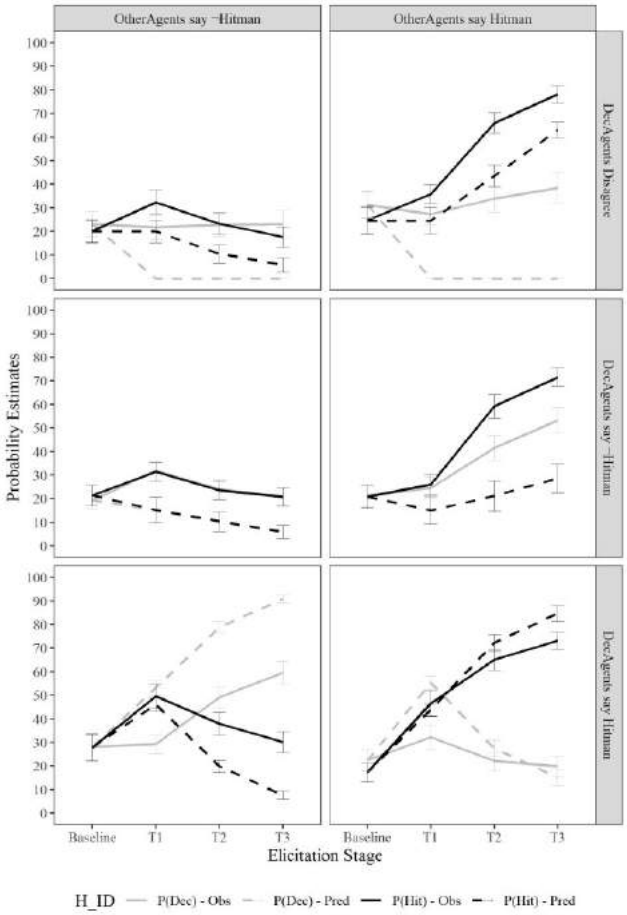

Figure 2. P(Deception) estimates (solid grey lines) and P(Hitman) estimates (solid black lines) across elicitation stages, split by condition. BIBN model predictions are also shown (dashed lines). Error bars reflect standard error.

Hypothesis 2: Common-cause, logic and Deception
To address hypothesis 2, we turn to the DecAgents disagree condition (top row, Fig. 2). Here we focus again on the change in P(Deception) estimates from baseline to T1, as well as the correctness of qualitative judgments. The logic of the structure and conditional probabilities dictate that disagreement between deceptive sources *disproves deception*. However, the repeated measures ANOVA found a decisive deviation from expectation in P(Deception) estimates when moving from baseline to T1, $BF_{Inclusion} > 10000$[5] – an effect corroborated by a t-test showing participants P(Deception) estimates at T1 to be decisively above 0 (N = 59, M = 24.61, SD = 25.44), $BF_{10} > 10000$, δ = 0.937 (95% CI: [0.657, 1.240]).

This error was further confirmed qualitatively, with correct responses (i.e. "Probability decreases") no different from chance level (0.33) responding (N = 59), $BF_{10} = 0.162$, δ = 0.309 (95% CI: [0.203, 0.432]) in a binomial test,

[3] The model with only the above significant terms yielded the best fit, $BF_M = 14.099$, and was significant overall, $BF_{10} = 1.160 * 10^{19}$.

[4] The model with all terms included yielded the best fit, $BF_M = 1.929 * 10^9$, and was significant overall, $BF_{10} = 3.098 * 10^{27}$.

[5] The model including this interaction term yielded the most significant fit, $BF_M = 733042.66$, and was significant overall, $BF_{10} = 3.958 * 10^{15}$.

further confirming an ignorance of the structure and logic based capacity to refute the possibility of deception.
Taken together, these results show that when reasoning about deception, inferences based on structural relations (and logic) alone are highly error prone, once more leading to substantial deception overestimation.

Hypothesis 3: Corroboration, contradiction, and Deception (Explaining Away)

To step through participant estimations of the impact of corroboration / contradiction of possibly deceptive agents, we look first at quantitative estimates (P(Hitman) and P(Deception)) across elicitation stages 1 to 3 – assessing deviation from normative expectation. Second, the correctness of qualitative judgments are assessed over these same stages. This is split by each 2x2 cell (Corroborating Hitman=True, corroborating Hitman=False, contradicting Hitman=True, contradicting Hitman=False).

Corroborating Hitman=True (bottom-right facet, Fig. 2). Repeated measures ANOVAs (elicitation stages T1-T3, and Observed vs Expected) reveal participants do not differ from normative expectation for P(Hitman) estimates, $BF_{Inclusion}$ = 1.777, and track this expectation across elicitation stages, $BF_{Inclusion}$ = 1.436. However, P(Deception) estimates are shown to decisively differ from normative expectation (underestimation), $BF_{Inclusion}$ > 10000, but this deviation decreases across stages, $BF_{Inclusion}$ > 10000.

Table 2 below reveals that whilst qualitative judgments at T1 (when only DecAgents have reported) are correct no better than chance, correct responding at T2 and T3 are greater than chance.

Table 2. Proportion of correct responding in corroborating Hitman=True group. N = 30.

Stage	Hypothesis	Proportion	$\neq .33$ (BF_{10})
T1	Hitman	0.433	0.443
	Deception	0.300	0.218
T2	Hitman	0.900	> 10000
	Deception	0.600	21.16
T3	Hitman	0.733	5313.25
	Deception	0.567	7.527

Corroborating Hitman=False (middle-left facet, Fig. 2). Repeated measures ANOVAs reveal participants decisively differ from normative expectation for P(Hitman) estimates (overestimation), $BF_{Inclusion}$ > 10000, but this deviation does not change across elicitation stages, $BF_{Inclusion}$ = 0.390. Similarly, P(Deception) estimates are shown to decisively differ from normative expectation (overestimation), $BF_{Inclusion}$ > 10000, and this does not change across stages, $BF_{Inclusion}$ = 0.45.

Table 3 below reveals that once again whilst qualitative judgments at T1 (when only DecAgents have reported) are correct no better than chance, correct responding at T2 and T3 are again greater than chance.

Table 3. Proportion of correct responding in corroborating Hitman=False group. N = 32.

Stage	Hypothesis	Proportion	$\neq .33$ (BF_{10})
T1	Hitman	0.25	0.306
	Deception	0.031	707.137†
T2	Hitman	0.781	> 10000
	Deception	0.563	8.124
T3	Hitman	0.656	248.427
	Deception	0.594	22.385

† = Decisively *worse* than chance level.

Contradicting Hitman=True (bottom-left facet, Fig. 2). Repeated measures ANOVAs reveal participants decisively overestimate P(Hitman), $BF_{Inclusion}$ > 10000, and there is strong evidence that this overestimation increases across elicitation stages, $BF_{Inclusion}$ = 17.66. However, participants decisively *underestimate* P(Deception), $BF_{Inclusion}$ > 10000, a trend that does not change across elicitation changes, $BF_{Inclusion}$ = 0.656. Table 4 below reveals that qualitative judgments at T1 (when only DecAgents have reported) are again correct no better than chance, whilst correct responding at T2 and T3 are decisively greater than chance.

Table 4. Proportion of correct responding in contradicting Hitman=True group. N = 31.

Stage	Hypothesis	Proportion	$\neq .33$ (BF_{10})
T1	Hitman	0.355	0.220
	Deception	0.258	0.282
T2	Hitman	0.677	499.34
	Deception	0.774	> 10000
T3	Hitman	0.774	> 10000
	Deception	0.677	499.34

Contradicting Hitman=False (bottom-left facet, Fig. 2). The final repeated measures ANOVAs reveal participants again decisively overestimate P(Hitman), $BF_{Inclusion}$ > 10000, and that this overestimation increases across elicitation stages, $BF_{Inclusion}$ = 334.9. Similarly, participants decisively overestimate P(Deception), $BF_{Inclusion}$ > 10000, but this does not change across elicitation changes, $BF_{Inclusion}$ = 1.965.

Finally, Table 5 below reveals that qualitative judgments at T1 (when only DecAgents have reported) are once again correct no better than chance, whilst correct responding at T2 and T3 are substantially greater than chance.

Table 5. Proportion of correct responding in contradicting Hitman=False group. N = 31.

Stage	Hypothesis	Proportion	$\neq .33$ (BF_{10})
T1	Hitman	0.25	0.307
	Deception	0.179	0.897
T2	Hitman	0.857	> 10000
	Deception	0.714	1164.74
T3	Hitman	0.821	> 10000
	Deception	0.607	20.143

Hypothesis 3 Summary. Taking these 4 sets of analyses together, it is clear that participants can qualitatively appreciate the influence of both corroboration and contradiction from independent sources on potentially deceptive sources, for both P(Hitman), via diagnostic inference, and P(Deception), via an explaining away inference. This is in stark comparison to the substantial qualitative error rates at T1, when only potentially deceptive agents have been observed (see Hypothesis 1). However, estimation data reveals participants consistently overestimate P(Hitman), irrespective of condition (with the exception of corroborating hitman=True). In line with Hypothesis 1, P(Deception) is overestimated when the potentially deceptive agents are reporting the a priori more likely hypothesis (Hitman=False), and underestimated when reporting the less likely hypothesis (Hitman=True). This again suggests a base rate neglect component to assessments of deception.

Conclusions

The issue of how to deal with the possibility of deception when reasoning under uncertainty is as complex as it is potentially deleterious. We present novel findings that lay reasoners are prone to several systematic errors when integrating the possibility of deception, often leading to substantial overestimation.

Using a Bayesian Network formalism, we disentangle the underlying components of deception, including the base rates of deception and the hypothesis the (potentially deceptive) source is reporting on (here, P(Hitman)), structural and logical components, as well as internal (potentially deceptive source reports) and external (corroborative / contradicting reports) observation.

Crucially, we show lay reasoners to be ignorant of the influence of base rates (leading to overestimation of deception, both qualitatively and quantitatively), and structural relations / logic-based negations (again, resulting in deception overestimation). Lay intuitions regarding the impact of corroborative / contradicting testimony on P(Deception) – via explaining away - are (although conservative) shown to qualitatively correspond to normative expectations.

Taken together, this shows erroneous inferences are highest when dealing with potentially deceptive reports alone (where base rates, conditional probabilities, and logical structure are the only active elements to integrate), but accuracy improves when a reference point (other reports / observations) comes into play. This suggests a note of caution for investigative domains in which deception is a possibility (e.g. intelligence analysis), where estimation errors are likely to be substantial until independent evidence (e.g. corroborating testimony) is gathered.

Further work is proposed to incorporate inaccurate / long-run deception motives (i.e. δ), something that we argue may be captured in the present formalism.

Zero-sum reasoning in information selection

Toby D. Pilditch[1,2], Alice Liefgreen[1], and David Lagnado[1]

[1]Department of Experimental Psychology, University College London, 26 Bedford Way, London, WC1H 0AP, UK
[2]University of Oxford, School of Geography and the Environment, South Parks Road, Oxford, OX1 3QY, UK

Abstract

Recent research (Pilditch, Fenton, & Lagnado, 2019) shows that people are susceptible to zero-sum thinking in evidence evaluation, where they dismiss or underweight the probative value of evidence that is equally predicted by multiple independent hypotheses. But such an assumption is only valid when explanations are mutually exclusive and exhaustive. The present work extends these findings by looking at the context of information selection, and the decisional consequences of the zero-sum fallacy. It uses an information metric to quantify the cost of the error in terms of overlooked information.

Keywords: zero-sum; evidential reasoning; probabilistic reasoning; Bayesian Networks; belief updating

Introduction

When reasoning under uncertainty, the search and selection of evidence is fundamental to accurate and efficient prediction and diagnosis. Whether in formal investigative domains such as medical diagnosis, forensics, or intelligence gathering, or in everyday reasoning, we often have to search out information to make inferences about a target hypothesis (e.g. which test to conduct? Which source to query? Etc.). To address these questions, reasoners must consider the prospective "value" or *information* provided by new evidence. These estimates are often fraught with biases and errors (e.g. Jones & Sugden, 2001; Nelson, McKenzie, Cottrell & Sejnowski, 2010; Slowiaczek, Klayman, Sherman & Skov, 1992) making accurate choice of what evidence to gather a non-trivial task for lay reasoners.

In the present work, we explore the question of evidence selection in the context of a novel evidential reasoning fallacy, the zero-sum error (Pilditch, Fenton, & Lagnado, 2019), where reasoners assume that evidence which is equally predicted by multiple alternative hypotheses is non-probative. We explore whether this error also drives similar errors in information choice, in particular whether it leads to people overlooking the most useful evidential tests. We explore the mechanisms that might underpin this reasoning fallacy. Furthermore, we highlight the methodological and theoretical value of incorporating information measures into our understanding of how reasoners navigate more complex reasoning structures.

The Zero-sum fallacy

When reasoning about evidence that is equally predicted by two independent explanations, lay reasoners tend to assume that this evidence offers no support to either hypothesis, because it does not discriminate between them (Pilditch, Fenton, & Lagnado, 2019). However, this assumption is only applicable when the explanations are both mutually exclusive and exhaustive (i.e. exactly one of the explanations is true). In fact, given positive evidence, *both* explanations become more probable. Across a number of experiments, reasoners judged such evidence irrelevant to a target hypothesis, even when the inappropriateness of applying the assumptions of exclusivity and exhaustiveness was highlighted.

The posited mechanism behind this error was a fallacy of considering evidential support between hypotheses to be a "zero-sum" situation: one hypothesis may only gain support (i.e. become more probable) at the detriment of another. To elucidate, reasoners were inclined to dismiss a medical test that could not distinguish between 2 diseases – failing to consider that the positive test result could in fact make the patient having *both* diseases more probable.

Work on the zero-sum fallacy has so far looked at qualitative judgments of support. In building on this work, via the incorporation of alternative evidence options and a measure of the amount of overlooked information given a preference, we seek to quantify the *cost* of this error, and further uncover the mechanism underpinning it.

A Bayesian Framework

To further elucidate the nature of the zero-sum fallacy, and outline the foundational formalism upon which information in the context of reasoning under uncertainty may be built, we briefly highlight the role of Bayesian Networks (BNs; Pearl, 1988; 2009) in evidential reasoning.

BNs are directed acyclic graphs (DAGs) that provide a computational framework for modelling the strength of inferential relationships when reasoning under uncertainty. A BN is made up of nodes that represent the variables of interest, and directed arrows capturing probabilistic dependency relations between variables, quantified by conditional probability tables. The probabilities of the unknown nodes are normatively updated given new evidence using Bayes rule (Pearl, 1988). Consequently, BNs are used as a normative comparison against which human reasoning can be compared (e.g. Pilditch, Fenton, & Lagnado, 2019).

To explain in the zero-sum case, two possible hypotheses, each with their own prior probabilities are represented by separate, *independent* nodes (see H1 and H2 in Fig. 1). This reflects the acknowledged assumptions that the two hypotheses are neither mutually exclusive (i.e. both could be true) nor exhaustive (i.e. both could be false), and there are no direct causal links between them. Critical to the fallacy,

however, is the conditional probability table (CPT) of the evidence that depends on both hypotheses (E1 in Fig. 1). Table 1 below provides an example of how likely the evidence is to be observed, given the possible states of the two hypotheses.

Table 1: Example conditional probability table for "common effect" evidence, given two possible causes, H1 and H2.

E	**¬H1, ¬H2**	**H1, ¬H2**	**¬H1, H2**	**H1, H2**
E = T	0.01	0.9	0.9	0.99
E = F	0.99	0.1	0.1	0.01

The two central columns of Table 1 represent the possibilities that participants making the zero-sum fallacy arguably focus on. More precisely, if one (falsely) assumes that only one of the two hypotheses is true (i.e. they are exclusive and exhaustive), then one is only considering two possibilities: the probability of E given H1 being true (P(E|H1,¬H2); center-left column) or given H2 being true (P(E|¬H1,H2); center-right column). Consequently, by adopting this narrow focus, the evidence appears to be *equally predicted* by each possibility (P(E|H1,¬H2) = P(E|¬H1,H2) = 0.9) suggests the evidence is non-probative.

Critically, this reasoning neglects two important possibilities: first, the fact that evidence *could* still occur when neither hypothesis is true (P(E|¬H1,¬H2) > 0) – i.e. the hypotheses are *not* exhaustive explanations of the evidence. Second, that not only is there the possibility that both hypotheses are true i.e. the hypotheses are not exclusive, but that when both *are in fact true*, this results in an even greater probability of observing the evidence (i.e. P(E|H1,H2) > (P(E|H1,¬H2) | P(E|¬H1,H2))). Thus, when making the diagnostic inference from observed evidence to probable hypotheses, *both* H1 and H2 become more probable, given E.

Information Search

In the real world people are habitually required to *actively* seek and acquire information in order to make a decision, causal inference or judgement, and do not merely act as passive observers of their surroundings. Within the psychological literature, measures have been proposed to quantify the informative value of a piece of evidence and the exploration of people's information search behaviour in a variety of contexts (for an overview, see Nelson, 2008). Here we adopt the Kullback-Liebler Divergence (KL-D; Kullback & Liebler, 1951) as a quantitative measure of the expected informative value of different pieces of evidence given a defined probabilistic environment. KL-D is a form of relative entropy and assigns high informative value to evidence that reduces uncertainty the most, entailing the largest divergence between prior and posterior probability distributions (Nelson, 2008). Formally, it quantifies the subjective expected usefulness of evidence before the state of the evidence is known as:

$$KL(E_i) = \sum_{H_j} P(H_j|a_i) \log \frac{P(H_j|a_i)}{P(H_j)}$$

Where E_i is an item of evidence within a set $\{E_1, E_{2...}E_i\}$, H is a set of hypotheses, $\{H_1, H_{2...}H_j\}$ and a_i is a set of possible states of the evidence, $\{a_1, a_2, a_i\}$. This quantification enables not only the evaluation of whether people have a preference for evidence with the highest information value, but also allows for a quantitative measure of the amount of *overlooked* information (as a consequence of sub-optimal search behaviour). This approach directly addresses how violations of normative measures of the value of information relate to known violations of normative models of evidence evaluation such as the zero-sum fallacy. Or more informally, puts an explicit value on the cost of the error.

Present Work

As mentioned above, the goal of the present work is to investigate the zero-sum fallacy further, via the inclusion of information search. To do this we expand the previous zero-sum fallacy model (two hypotheses, H1 and H2, with a single, shared piece of evidence, E1) to include an alternative evidence option (E2) – only explainable by the target hypothesis.

In this way, the reasoning probe shifts from an explicit evaluation of whether E1 provides any support for H1, to a decision-making preference between two evidence items: E1, which has an alternative explanation H2 (and thus invites the zero-sum error), and E2, with no alternative cause represented in the model. To explore the possible influence of zero-sum thinking, and to quantify overlooked information costs, the general structure illustrated in Fig. 1 required populating with several different sets of parameters.

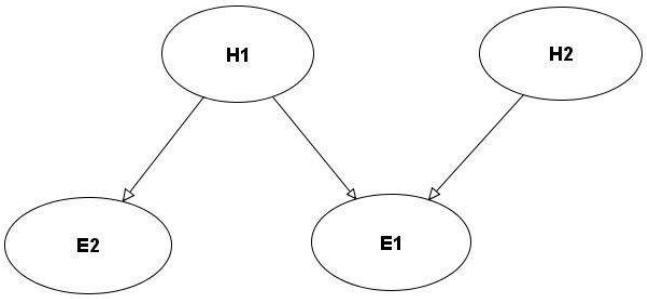

Figure 1. Graphical representation of BN Model.

Four sets of parameters were created (shown in Table 2), each incrementally differing from another, so as to determine the influence of various reasoning components. The prior probabilities of each hypothesis were manipulated as either both rare (P(H1) = P(H2) = .1), both common (P(H1) = P(H2) = .5), or unequal (P(H1) = .5, P(H2) = .1). In this way, the degree to which H2 is providing a "false positive" for E1 (i.e. another explanation for a positive, that is not the hypothesis of interest, H1) is manipulated. This is

of interest to determine whether the zero-sum fallacy is based on the integration of this "false positive" probability (i.e. when H2 is more probable, the zero-sum fallacy is more prevalent), or solely on the *presence* of a possible alternative explanation. Further, the manipulation of 50/50 (or "common") priors can be used to assess whether participants will be more inclined to apply the false assumptions of mutual exclusivity and exhaustiveness that underpin the zero-sum fallacy. Lastly, if the manipulation of unequal priors (P(H1) = .5, P(H2) = .1) resulted in a *reduction* of zero-sum fallacy errors, it would be suggestive of participants using the relative rarity of H2 to *discount it* as an explanation of E1.

In addition, across these three sets, the likelihoods of E1 and E2 were held as unequal, in that E1 was more diagnostic of H1 than E2 (P(E1|H1,¬H2) = .9, vs P(E2|H1) = .6). However, one final parameter set was added in which (along with rare priors) these values were equal across E1 and E2 (P(E1|H1,¬H2) = P(E2|H1) = .8). It should be noted that in all these parameter sets, this results in E1 being the more informative evidence for determining H1, and thus selecting E2 comes at a cost of overlooked information. However, by manipulating the false positive rate of E2 as either high (P(E2|¬H1) = .2/.4), or low (P(E2|¬H1) = .01), we can manipulate between subjects a condition in which E1 is superior (the former), or inferior (the latter), to further determine sensitivity to the parameters underlying the fallacy.

This leads to several predictions: Firstly, there will be a general aversion to selecting E1 (i.e. the decision analogue of a zero-sum fallacy). Secondly, participants will be sensitive to parameter manipulations, such that when E2 is manipulated as more diagnostic (e.g. P(E2|¬H1) = .01 condition), aversion to E1 / preference for E2 will (correctly in this instance) increase. Conversely, when parameter manipulations in fact favour E1 (e.g. equal likelihoods parameter set) participants will (falsely) remain aversive to it.

Method

Participants 180 US participants were recruited and participated online through the Amazon Mechanical Turk platform. Participants were native English speakers (leading to 2 exclusions), with a mean age of 35.88 (*SD* = 10.5), and 90 participants identified as female. All participants gave informed consent, and were paid $1.20 for their time (*Median* = 12.75 minutes, *SD* = 9.62).

Procedure & Design Participants were shown 4 scenarios in a randomized order. These scenarios all originated from the model structure of Fig. 1, to include a target hypothesis (H1), evidence that may inform on the hypothesis (E1), but may also be explainable by an alternative hypothesis (H2), and finally an alternative evidence item only dependent on H1, and not H2 (E2). The scenario contexts were an arson case (identifying an accelerant), a conservation case (tracking a target species), a medical diagnosis case (confirming a brain tumor), and a digital forensics case (identifying a cyberattack culprit).

Crucially, along with the structure of Fig. 1, contexts were also furnished within the text with sufficient parameter details to fully populate a Bayesian Network model of the scenario. These included the priors for each hypothesis (P(H1) and P(H2), the likelihoods for each evidence-hypothesis relationship (P(E1|H1,¬H2), P(E1|¬H1,H2), and P(E2|H1)), and false positives - P(E1|¬H1,¬H2) and P(E2|¬H1). The latter of these parameters (E2 false positive) was manipulated between subjects, as a method of shifting the balance of expected information between E1 and E2. The remaining parameters were deployed as 4 "sets" (see Table 1 below), each designed to test particular parameters trade-offs, and randomly allocated to scenario contexts.[1]

Table 2. Parameter sets, allocated across scenario contexts.

	Parameter Sets			
	RareP. EqL	RareP. UneqL	UneqP. UneqL	ComP. UneqL
P(H1)	.1	.1	.5	.5
P(H2)	.1	.1	.1	.5
P(E1|H1,¬H2)	.8	.9	.9	.9
P(E1|¬H1,H2)	.8	.9	.9	.9
P(E1|¬H1,¬H2)	.01	.01	.01	.01
P(E2|H1)	.8	.6	.6	.6
P(E2|¬H1)	.01 / .2	.01 / .4	.01 / .4	.01 / .4
Information				
KL(E1)*	0.12	0.135	0.27	0.06
KL(E2)	0.22/0.06	0.16/0.005	0.268/0.01	0.268/0.01
KL(E1 – E2)	-0.1/0.06	-0.026/0.13	0.002/0.25	-0.205/0.05

*Only takes into account H1

For each scenario, participants answered the following questions:

Priors: Participants were asked to provide the prior probabilities of H1 and H2 (i.e. *before* observing any evidence). Although participants had already been provided with prior probabilities for H1 and H2, by also eliciting these prior probabilities any participant-based assumptions could be incorporated into the models used for normative comparisons. More precisely, for each participant, elicited priors were used to outfit a Bayesian Network fitting the structure of Fig. 1 (and the remaining parameters drawn from the parameter set being tested), using the gRain package in R (Højsgaard, 2012). These individually fitted BNs (hereafter termed Behaviorally Informed Bayesian Networks; BIBNs) thus provided a fitted normative comparison for participant inferences on the participant by parameter set level. BIBNs were not only then used to generate predicted responses, but also to calculate the informative value (KL-D) of each item of evidence, given

[1] P(E|H1, H2), though not provided explicitly to participants, is based on an assumption of a noisyOR function (see Pearl, 1988), which is based on the reasonable assumption that causes H1 and H2 are independent.

that model – essential for calculating any forgone information.

Preference: Participants were then asked "Which test (evidence item) would you prefer, so as to best determine [H1]?" This qualitative judgment was forced choice [E1 / E2 / "They are the same."]

Confidence in preference: Following the qualitative evidence preference, participants were asked to provide a confidence in that preference ("How confident are you that your response is correct?" 0-100%).

Other DVs: Although posterior probability estimates for each evidence item ("Probability of [H1] ***only*** **given a positive [E1]**" 0 - 100%; "Probability of [H1] ***only*** **given a positive [E2]**" 0 - 100%), and open text reasoning responses were collected, for the sake of brevity, these results are not reported here.

Results

Using the JASP statistical software (JASP Team, 2018), Bayesian statistics were employed throughout[2].

Evidence Preferences

Overall, binomial tests comparing evidence preferences to chance (.33) found the evidence with a single possible cause (E2) to be preferred at a rate decisively greater than chance (.54, $N = 712$), $BF_{10} = 3.06 * 10^{26}$, whilst preferences for the evidence with two potential cause (E1) were no different than chance, (.35, $N = 712$), $BF_{10} = 0.083$, and preferences for "They are the same." occurred decisively less often than expected by chance (.11, $N = 712$), $BF_{10} = 4.59 * 10^{37}$. Further, a contingency table comparing observed to predicted preferences found decisive evidence for these preferences deviating from normative expectation ($N = 1424$), $BF_{10} = 1.196 * 10^{25}$. Importantly, there was a null influence of the potential confounds of scenario order ($N = 712$), $BF_{10} = 0.109$, or scenario context ($N = 712$), $BF_{10} = 5.087 * 10^{-5}$.

In line with expectations, when the false positive rate of E2 was low (.01), and thus sensitivity was higher, then E2 was preferred substantially more often (and E1 less often) than when the false positive of E2 was high (N = 712), $BF_{10} = 4.068$.

Turning next to parameter sets (rows of Fig. 2), we break down the analysis for each set to determine a) the dominant participant preference, and b) whether this deviates from the normative predictions for that set. This split by parameter set is motivated by the potential sensitivity of participants to particular combinations of parameters (e.g. equal likelihoods, or unequal priors).

[2]All analyses assumed an uninformed prior. Bayes Factors (BFs), are interpreted as: 1 – 3 = anecdotal support; 3-10 = substantial; 10-30 = strong; 30-100 = very strong; >100 = decisive (Jeffreys, 1961). Conversely, Bayes Factors < .33 are considered substantial support for the *null* (Dienes, 2014).

Rare Priors, Equal Likelihoods. When both H1 and H2 priors were rare, and evidence likelihoods were equal, participants chose E2 at levels decisively above chance (.612, N = 178), $BF_{10} = 6.729 * 10^{11}$, and E1 significantly less than chance (.23, N = 178), $BF_{10} = 5.565$. This runs contrary to model predictions, where E1 is preferred decisively above chance level (.674, N = 178), $BF_{10} = 1.035 * 10^{18}$, and E2 at no different than chance (.326, N = 178), $BF_{10} = 0.088$. This is further corroborated by a contingency table analysis which finds decisive evidence for a deviation of participant choices from normative expectation (N = 356), $BF_{10} = 6.729 * 10^{11}$.

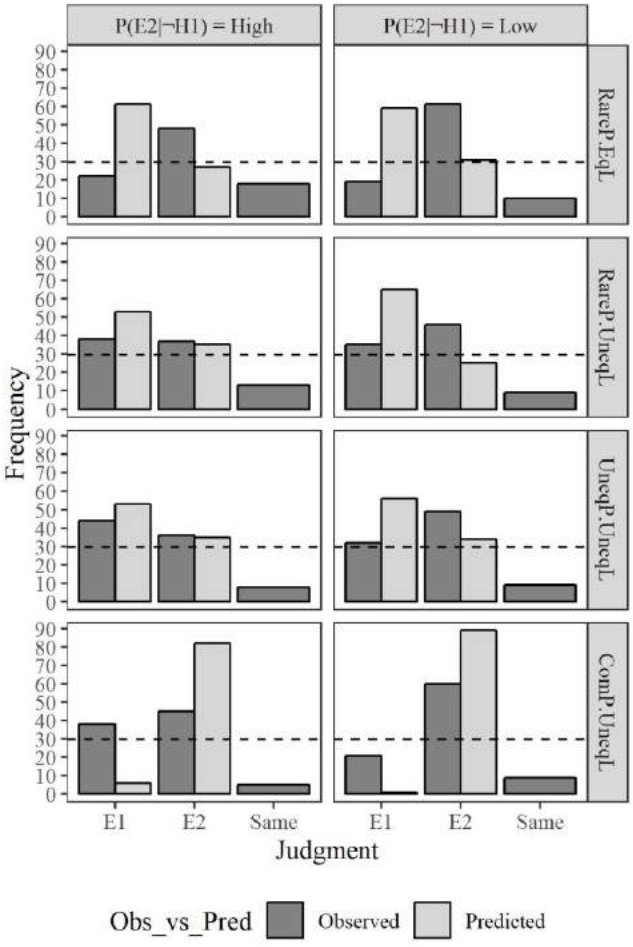

Figure 2. Evidence choice frequencies across parameter sets (rows) and condition (columns).

Rare Priors, Unequal Likelihoods. When priors are rare, and evidence likelihoods are unequal (E2 at .6, and E1 at .9), we again find the same pattern. Participants choose E2 at above chance levels (.466, N = 178), $BF_{10} = 111.88$, and E1 no different than chance (.41, N = 178), $BF_{10} = 1.115$. Once again, however, model predictions show the opposite pattern, with E1 choices above chance level (.663, N = 178), $BF_{10} = 6.223 * 10^{16}$, and E2 choices no different than chance, (.337, N = 178), $BF_{10} = 0.09$. This is again

corroborated by the decisive deviation between participants and their model predictions found by contingency table analysis (N = 356), $BF_{10} = 1.473 * 10^7$.

Unequal Priors, Unequal Likelihoods. When both priors (P(H1) = .5; P(H2) = .1) and likelihoods are unequal, we find the same general trend, albeit to a lesser degree. More precisely, although participant choices for E2 are again greater than chance (.478, N = 178), $BF_{10} = 368.73$, choices for E1 are also just above chance level (.427, N = 178), $BF_{10} = 3.499$. However, model predictions again show a decisive preference for E1 (.612, N = 178), $BF_{10} = 6.729 * 10^{11}$, whilst E2 should be preferred no more often than chance (.388, N = 178), $BF_{10} = 0.335$. This insufficiency of E1 choices is again captured by the decisive difference in judgment proportions when comparing participants and model predictions in a contingency table (N = 356), $BF_{10} = 15735.87$.

Common Priors, Unequal Likelihoods. Turning finally to when priors are both common (.5) and likelihoods are unequal, we see the same behavioral pattern of a preference for E2 above chance level (.59, N = 178), $BF_{10} = 7.748 * 10^9$, and E1 no different than chance (.331, N = 178), $BF_{10} = 0.088$. However, unlike the preceding parameter sets, E2 is also chosen above chance level by model predictions (.961, N = 178), $BF_{10} = 1.996 * 10^{69}$, whilst E1 is in fact chosen decisively less than chance (.039, N = 178), $BF_{10} = 7.246 * 10^{18}$. Further, participant choices for E2 are shown to be insufficient compared to model predictions (N = 356), $BF_{10} = 9.44 * 10^{14}$. This is likely due to the high E1 "false positive" due to marginalization over high H2 probability, making E1 comparatively less diagnostic of H1.

Confidence in evidence preferences. Confidence was generally high across all preferences (M = 66.00, SD = 23.96). Although a Bayesian repeated measures ANOVA revealed confidence to be unaffected by preference, $BF_{Inclusion} = 0.781$, or parameters, $BF_{Inclusion} = 1.064$, but there was strong evidence for confidence being higher in the E2 false positive rate = low condition (M = 68.98, SD = 23.39), rather than high (M = 62.95, SD = 24.18), $BF_{Inclusion} = 11.377$. This finding fits with an easier E2 preference when it is a more sensitive test.

Overlooked information

To elucidate the information cost of the above deviations from normative expectation, for each BIBN model (i.e. each participant-fitted model) the expected informative value (in KL-D) was calculated for E1 and E2. In this way, if a participant selected the evidence with the highest KL-D as predicted by their model, they had not overlooked any information, and thus scored 0. However, if participants selected the less informative evidence, then the overlooked information was the difference (in KL-D) between the optimal (i.e. most informative) evidence and their selected option.[3]

As Table 3 indicates, across all break-downs of evidence choices (overall, by condition, and by parameter set), there was a decisive amount of information overlooked – calculated via Bayesian one sample t-tests (test value = 0). This significant amount of overlooked information can be attributed to the sub-optimal undervaluing of E1 (i.e. the zero-sum fallacy) in all cases barring common priors, unequal likelihoods (bottom row, Table 3). In this latter parameter set, E2 in fact yielded the most information, but was not chosen sufficiently often across participants.

Table 3. Overlooked information; overall, split by condition, and split by parameter sets.

	M	*SD*	*N*	*>0 (BF_{10})*	*δ*	*δ 95% CI*
Overall	.045	.048	712	$5.79*10^{95}$	0.934	.847, 1.021

Conclusions

Previous work has shown that evidence equally predicted by multiple explanations is often erroneously dismissed due to the misplaced assumption that support for one hypothesis (of interest) must come at the detriment of another (the zero-sum fallacy; Pilditch, Fenton, & Lagnado, 2019). In the present work, we show that this fallacy results in poor decisions regarding evidence selection, and that such selections come at a quantified cost of overlooked information. Crucially, we also show that participants are sensitive to priors and likelihoods parameters, with different evidence preference patterns as a consequence. However, the general pattern of overlooked information holds despite this sensitivity.

Foremost, the present work confirms the presence of zero-sum reasoning, showing that it is active in people's choice of which evidence to examine. It also highlights the potential costs of the fallacy, via the quantification of (costly) overlooked information. In this way, we argue for the inclusion of different question methods and information measures when investigating reasoning errors – whether across simple or complex structures. This would not only contribute to understanding how violations of normative frameworks of human information acquisition relate to known violations of information evaluation, such as the

[3] If evidence items were equally informative, then participants were pragmatically correct, in terms of information, with any preference (including "They are the same"), and thus scored 0. However, if participants erroneously judged the evidence items the same, the amount of overlooked information was taken from the KL-D of the most informative option.

zero-sum fallacy, but it would allow for the exploration of how consequential sub-optimal evidence selection choices are, in laboratory as well as real-world settings.

Given that information-seeking is a critical aspect of so many areas of decision making – including intelligence analysis, legal reasoning, and medical diagnosis – the use of zero-sum reasoning is a strong concern. Future work will seek ways to alleviate this bias, and shift people towards more normative information gathering.

Abstract

We provide new evidence concerning two views of episodic associations: The independent associations hypothesis (IAH) posits that associations are unidirectional and separately modifiable links (AB; AB); the associative symmetry hypothesis (ASH) considers the association to be a holistic conjunction of A and B representations. While existing literature focuses on tests that compare the correlation of forward and backward associations and favors ASH over IAH, we provide the first direct evidence of IAH by showing that forward and backward associations are separately modifiable for semantically related pairs. In two experiments, participants studied 30 semantically unrelated and 30 semantically related pairs intermixed in a single list, and then performed a series of up to eight cued-recall test cycles. All pairs were tested in each cycle, and the testing direction (A-? or B-?) alternated between cycles. Consistent with prior research, unrelated pairs exhibited associative symmetry accuracy and response times improved gradually on each test, suggesting that testing in both directions strengthened the same association. In contrast, semantically related pairs exhibited a stair-like pattern, where performance did not change from odd to even tests when the test direction changed; it only improved between tests of the same direction. We conclude that episodic associations can have either a holistic representation (ASH) or separate directional representations (IAH), depending on the semantic relatedness of their constituent items.

Word frequency affects binding probability not memory precision

Vencislav Popov

Matt So
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Lynne Reder
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Abstract

Normative word frequency has played a key role in the study of human memory, but there is little agreement as to the mechanism responsible for its effects. To determine whether word frequency affects binding probability or memory precision, we examined working memory for spatial positions of words. Each of three experiments included 300 trials in which five words were presented sequentially around an invisible circle followed by one of those words shown in the middle of the circle as a probe to test its location. Participants had to click on the associated location and the degree of error around the circle was the dependent measure. Across experiments we varied word frequency, presentation rate and the proportion of low frequency words on each trial. A mixture model dissociated memory precision, binding failure and guessing rates from the continuous distribution of errors. On trials that contained only low- or high-frequency words, low-frequency words lead to a greater degree of error in recalling the associated location. This was due to a higher word-location binding failure and not due to differences in memory precision or guessing rates. Slowing down the presentation rate eliminated the word frequency effect by reducing binding failures for low-frequency words. Mixing frequencies in a single trial hurt high-frequency and helped low-frequency words, but frequency composition and presentation rate did not interact. These findings support the idea that low-frequency words require more resources for binding and that the binding fails when these resources are insufficient.

Exploring the role that encoding and retrieval play in sampling effects

Keith Ransom (keith.ransom@adelaide.edu.au)

Abstract

A growing body of literature suggests that making different sampling assumptions about how data are generated can lead to qualitatively different patterns of inference based on that data. However, relatively little is known about how sampling assumptions are represented or when they are incorporated. We report the results of a single category generalisation experiment aimed at exploring these issues. By systematically varying both the sampling cover story and whether it is given *before* or *after* the training stimuli we are able to determine whether encoding or retrieval issues drive the impact of sampling assumptions. We find that the sampling cover story affects generalisation when it is presented before the training stimuli, but not after, which we interpret in favour of an encoding account.

Keywords: categorisation; generalisation; memory; sampling assumptions;

Introduction

For most of the reasoning tasks with which we are routinely faced, it is impossible to draw conclusions that are logically entailed by what we know already. Instead, we must by necessity make inductive generalisations on the basis of the limited data we have. In order to make the most of that data, it is important to accurately assess its evidentiary weight – to recognise precisely what kind of generalisations it supports. Doing this assessment accurately depends on understanding the context in which it was observed.

To illustrate why, imagine that you need to buy a present for a colleague as a part of your workplace Secret Santa. You don't know this colleague that well, but while helping them move offices you see a box containing the CDs that they listen to while at work. Sensing an opportunity to re-gift an unwanted copy of *Taylor Swift*, you take a closer look. Upon realising that almost all of their collection consists of 80s Billboard Hits, you conclude that their musical taste is dated[1] and reluctantly decide that Taylor Swift is not for them.

Suppose, instead, that you had seen the exact same data (a box of CDs) but in the context of helping your colleague move their entire music collection – many dozens of boxes worth – and that box just happened to be the only open one. Now the same data is no longer quite so representative: instead of being a carefully culled and chosen set of favourites, it is one of many. Thus, it tells you much less about whether your colleague would like Taylor Swift.

As this example illustrates, knowing something about why one saw the data that one did (and not some other data) enables people to make more valid inferences. Put another way, being able to reason about the generative process behind a set of observations tells people about the weight of evidence that those observations supply. These assumptions about the generative process are often referred to as the *sampling assumptions* that people bring to inference problems. Different sampling assumptions appear to drive qualitatively distinct patterns of generalisation (e.g. Hendrickson, Perfors, Navarro, & Ransom, 2019; Hayes, Navarro, Stephens, Ransom, & Dilevski, 2019), support epistemic trust (Shafto, Eaves, Navarro, & Perfors, 2012) and epistemic vigilance (Landrum, Eaves, & Shafto, 2015; Ransom, Voorspoels, Perfors, & Navarro, 2017), fuel pragmatic implicature (Goodman & Frank, 2016), and promote accelerated learning (Shafto, Goodman, & Griffiths, 2014).

Despite this wealth of empirical support for the utility and importance of sampling assumptions in generalisation, little is known about either how they affect the encoding and retrieval of the data, or how they affect people's mental representations. Is the evidentiary weight of data under a given sampling assumption computed only at the point at which the data is later retrieved? Or is it encoded at the time of learning, thus shaping the underlying representation from the beginning? And how is inference affected as people's memories of the data begin to fade?

Using a single-category learning task, we explore these questions here for the first time. We manipulate both the sampling assumptions people make about the training data (via cover story) as well whether that cover story is available before or after learning. As we explain in the next section, if sampling assumptions affect generalisation at retrieval, we expect no difference in performance regardless of when the cover story was revealed. Conversely, if they affect how the data are encoded, we expect different patterns of generalisation depending on when the cover story was available.

Sampling assumptions and inductive generalisation

The Bayesian generalisation approach of Tenenbaum and Griffiths (2001) provides a useful framework for our research question. In the context of our single category generalisation experiment, we are interested in how the learner decides whether or not to extend the target category c to a novel item y on the basis of previously observed examples x. Within the framework, this decision is assumed to be probabilistic, based on the available evidence. That is:

$$P(y \in c|x,s) = \sum_{h \in \mathcal{H}_c : y \in h} P(h|x,s) \quad (1)$$

where s represents the learner's assumption about the process generating the data x, and $\mathcal{H}_c$ represents the set of alternative hypotheses the learner considers concerning the true extent

[1] The fact that your colleague still uses CDs may have told you this already.

of the category c.[2] In other words, the evidence in favour of category membership is effectively combined across all hypothetical versions of the category containing the novel item. Using a straightforward application of Bayes' rule the term $P(h|x,s)$ may be expressed as:

$$P(h|x,s) \propto P(x|h,s)P(h). \quad (2)$$

This formulation assumes, for simplicity, that the learner entertains a single sampling assumption (i.e. $P(s) = 1$), which we presume was given to them by a cover story describing the generative process.

It is the likelihood function $P(x|h,s)$ that is critical for our current purposes. Substituting different likelihood functions into this system of equations yields different predictions about the way that people generalise from given data. For instance, strong sampling implies a likelihood that embodies the size principle, such that each subsequent datapoint serves as evidence to further tighten one's generalisations around the data; weak sampling uses a different likelihood which implies no such tightening (Tenenbaum & Griffiths, 2001). Thus, the likelihood may be thought of as representing different ways of calculating the weight of evidence that the data provides for the hypothesis under a given sampling assumption.

Our first question here is *when* the likelihood is calculated: when the data is first encoded, or when it is retrieved? If learners do not need to rely on their memories and the sampling cover story is available from the beginning, it is impossible to disentangle these two possibilities. However, if we manipulate when participants are aware of how the data were sampled (i.e., before or after learning), then different possibilities yield different predictions. We consider two main possibilities in detail.

Retrieval. If the likelihood is calculated upon retrieval, then encoding need only involve storing the raw data x in some form. The likelihood calculation would be shaped by whatever sampling assumption was in play during retrieval, regardless of what was assumed during learning. In this sense, the calculation would resemble the conventional or "idealised" interpretation of the Bayesian generalisation model. However, while the conventional interpretation assumes perfect recall of exemplars, a failure to retrieve some data would imply that the likelihood calculation was effectively over a reduced dataset (i.e., smaller sample size). The precise effect that this has will depend on the sampling assumption and on the particular items forgotten. For example, if the diversity of the dataset is largely unaffected by the failure to retrieve certain items, then generalisation under a strong sampling assumption should be wider in this case than under perfect recall. Under weak sampling, in contrast, it is the diversity of the sample and not its size that has an effect on generalisation; thus, a reduction in sample size without a change in diversity would mean that generalisation was unaffected. More generally, as the level of retrieval failure increases, the Bayesian model predicts generalisation increasingly in line with the prior distribution.

[2] In the case that the data x varies over a continuous dimension $\mathcal{H}_c$ will represent a continuum of hypotheses and the sum is replaced with an integral.

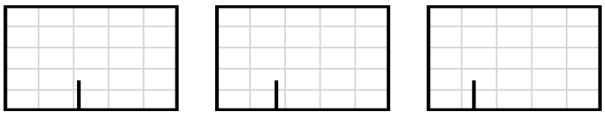

Figure 1: **Example stimuli**. Items varied only in the position of the short black vertical line along the bottom edge of the rectangle.

Encoding. If the likelihood is calculated upon encoding, then the strength of evidence that it represents would have to be stored in some way. In this case, the precise effect of later retrieval failure might vary depending on *how* evidence is encoded. For example, if evidence is stored and retrieved with each exemplar individually then failure to retrieve a given exemplar would mean that subsequent generalisation operates over a smaller dataset, as in the retrieval account (although, unlike the retrieval account, using the sampling assumption that was in play at the time of encoding). If instead, evidence were stored and retrieved in aggregate form (via the hypotheses, for example) then failure to recall any particular exemplar need not imply that the associated evidence was lost. In this way, generalisation might still proceed with all the available evidence (presuming the same hypotheses were accessed). The details of representation notwithstanding, if the likelihood is calculated and stored during encoding, and not at retrieval, then generalisation would be shaped by the sampling assumptions available during learning, even if those assumptions are changed at retrieval.

Method

Our experiment involved a single-category generalisation task modelled on previous work demonstrating that sample size and sampling cover story affect people's willingness to extend category membership to novel examples (Hendrickson et al., 2019; Ransom, Hendrickson, Perfors, & Navarro, 2018). Although we employed stimuli identical to those used in that experiment, we modified the method of presentation so that each stimulus was removed from screen after a (typically brief) period of self-paced study. Using a consistent experimental framework allows us to directly compare our results with the previous findings, and thus to determine if the effect of sampling assumptions on generalisation changes as the memory of training examples decays.

One of our manipulations involved the nature of the cover story people received. Either they were told that the data was given by a HELPFUL teacher (which corresponds to a strong sampling assumption and implies that generalisations should be tighter) or they were given a cover story implying that it was chosen at RANDOM (which corresponds to a weak sampling assumption and implies that generalisations should be looser). Critically, we manipulated whether people were given the sampling story BEFORE or AFTER they saw the training stimuli. If sampling assumptions affect how

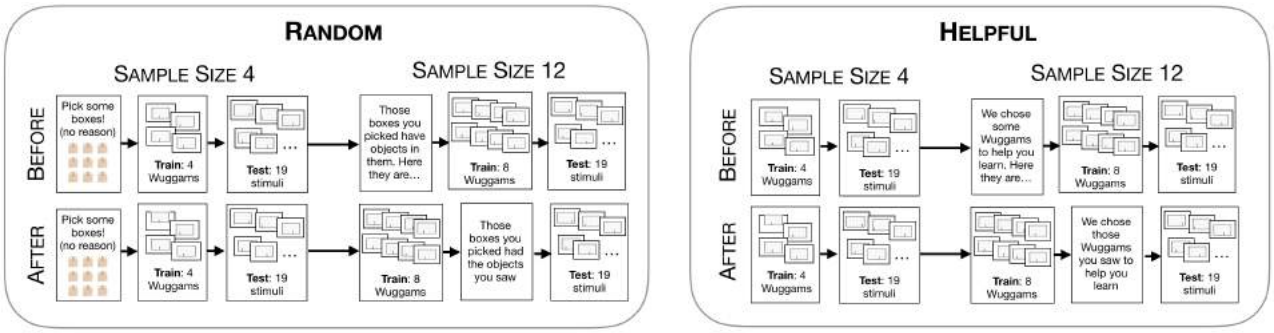

Figure 2: **Experiment design**. Our 2x2x2 design varied Sample Size within-subject and Sampling Explanation and Presentation Sequence between-subjects. All participants began by seeing four individually-presented exemplars followed by a generalisation task to novel stimuli. Those in the RANDOM condition were then given a cover story in which the subsequent eight items were chosen at random from boxes that they themselves had previously selected. Those in the HELPFUL condition were told that the items were selected by a helpful teacher. In the BEFORE condition, the cover story was given before seeing the eight new items; in the AFTER, it came after. In all conditions the experiment ended with a repeat of the generalisation test.

the data are encoded then people should generalise differently depending on when they received the story.

Participants

We recruited 999 people via Amazon Mechanical Turk who were each paid $1.70USD for 5-10 minutes participation. 56% were female, with age varying between 18 and 75 (median: 37 years), drawn predominately from the U.S. population (99%). All participants passed a screening for English language competency prior to participation.

Stimuli

Stimuli were black rectangles containing a vertical black line inside, attached to the bottom edge (see Figure 1). They varied along a single dimension (the *stimulus value*): the horizontal position of the line within the rectangle. Participants were told that this was the way in which stimuli varied. Evenly spaced light grey "guide lines" were drawn within each rectangle in order to improve discriminability. There were 12 training stimuli in total, whose stimulus values ranged from 21% to 43% in increments of 2%. They were divided into two sets corresponding to the two training phases, as described below.

Design and procedure

As shown in Figure 2, our experiment employed a $2 \times 2 \times 2$ mixed factorial design. Two factors (Sampling Explanation and Presentation Sequence) were manipulated between-subjects while another (Sample Size) varied within-subject. People were thus allocated at random to one of four experimental groups.

Across all groups, the experiment involved presenting people with a number of examples of a novel 1D category and then observing whether they generalised category membership to new items based on the examples they had been shown and what they had been told about those examples.

Sample Size To facilitate a baseline against which the effect of additional exemplars could be compared, the experiment involved two rounds of testing. The first (Size 4) occurred after a training phase involving four training examples, and the second (Size 12) after seeing eight more.

Stimuli for the first training phase consisted of the two extreme examples (with values of 21% and 43%) and two others selected at random from the ten whose values lay between the extremes. The eight remaining stimuli formed the second training set and were presented in random order.

Presentation Sequence This between-subjects manipulation varied when the sampling cover story was presented in relation to the second training set. People in the BEFORE condition were told the cover story (RANDOM or HELPFUL, described below) *before* viewing the second set of training items, while people in the AFTER condition were offered the explanation only after all training items had been presented.

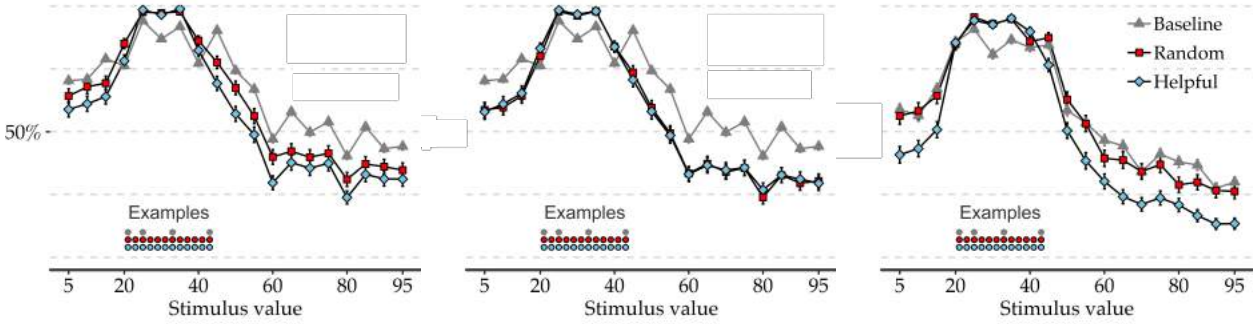
Sampling Explanation The other between-subjects manipulation varied the details of the cover story explaining how the data in the second training phase were generated. The initial training phase, however, was identical for all participants. No explanation was given for how the exemplars were chosen. People were told only that the purpose of the experiment was to see how people judged whether or not unfamiliar objects were in the same category as known examples. In the second training phase people were given one of two different cover stories explaining how the items were selected.

Helpful. People in the HELPFUL condition were told:

> We have a bunch of boxes containing examples of the full variety of «Wuggams». We have chosen 8 of these boxes especially to help you learn the «Wuggam» category, bearing in mind the four training examples we showed you originally.

at which point an array of eight icons resembling open packing boxes were displayed in an adjacent panel. Participants in the BEFORE condition then viewed the eight stimuli one by one. Those in the AFTER condition saw the identical explanation (with verb tenses adjusted) only after all eight stimuli in the second training phase had been shown.

Random. The RANDOM condition was designed to encourage people to believe that each training item was selected



(a) BEFORE. (b) AFTER. (c) Ransom et al. (2018).

Figure 3: Performance on a one category generalisation task as a function of presentation sequence, sampling procedure (manipulated between-subjects) and sample size (manipulated within-subject). The graphs show the proportion of positive responses to the question: "Do you think this object is in the «Wuggam» category?" for each of the test stimuli. People's performance after seeing four examples of the target category with no sampling explanation given (grey line) is contrasted with their performance after seeing all 12 examples and being given an explanation of how the additional examples were selected (black lines). (a) When the sampling explanation was given prior to the presentation of the final 8 examples (BEFORE condition), people tightened their generalisations as more data was observed, but the extent of tightening was affected by the sampling manipulation; those people who actively sampled the additional examples at random (red squares) tightened their generalisation less than those that were told that the items had been selected by a helpful teacher (blue diamonds). (b) In contrast, when the sampling explanation was given only after all training stimuli were presented (AFTER condition), the sampling manipulation had no effect, with people tightening their generalisation equally in both cases. (c) Using the same experimental framework and stimuli, but keeping the training stimuli on-screen during the testing phase, Ransom et al. (2018) demonstrated the effect of sampling manipulation seen only in the BEFORE condition. But when people must rely on their memory of observed examples, their generalisation is wider overall.

at random and that it was at least theoretically possible to see examples not in the target category. To achieve this, people in the RANDOM condition were presented with an additional phase preliminary to the first training round. In this phase, a 6×5 arrangement of packing boxes was displayed on screen, and people were asked to select boxes in any order (but not told why this was necessary). After selecting 11 boxes, people were told that the contents would be revealed later in the experiment. Following this, the first training phase commenced, which was identical for all participants.

During the second training phase, participants in the AFTER condition were immediately shown the eight remaining training items without explanation. Those in the BEFORE condition were told that we had many boxes containing examples from our catalogue, and that these examples included but were not limited to Wuggams. After this, the original array of (closed) boxes was displayed, indicating the ones that the participant had previously selected. People were then told:

> At the start of the experiment we asked you to choose some of these boxes at random. These are the boxes that you selected. We're going to open them now and show you whatever kind of item we find inside.

In order to reinforce the notion that it might have been possible to see items from categories other than Wuggams, the display was updated at this point to reveal eight open boxes and three closed ones. People were told that some of the boxes they had chosen were stuck but that we would show them the contents of the boxes that did open. Participants in the AFTER condition received exactly this cover story (with verb tenses adjusted) only after seeing all eight training examples.

Generalisation test

Immediately after both the first and second training phase, participants in all conditions performed the same generalisation test. In it, they were shown 19 stimuli one at a time in random order; this sequence was repeated four times. The stimuli consisted of 19 items with stimulus values ranging from 5% to 95% in increments of 5%. The test query was a yes or no question: "Do you think this object is in the «Wuggam» category?" Neither training stimuli nor the sampling explanation remained on-screen during testing, requiring people to rely on their memory when making judgements.

Results

Our work is focused on understanding how memory and sampling assumptions interact to affect generalisation. Do we replicate previous findings showing that differences in sampling assumptions lead to differences in generalisation? Does this difference in people's patterns of generalisation change if the sampling manipulation occurs before or after stimulus encoding? We address each question in turn below.

First: do we replicate previous results? Our RANDOM BEFORE and HELPFUL BEFORE conditions are very similar to that of a previous study (Ransom et al., 2018), but are different in one key way. In our version, the training stimuli were removed from the screen after initial presentation; in Ransom et al. (2018) and much of this literature the training stimuli stay visible for the entire experiment. We therefore investigate whether these previously observed effects of sampling manipulation are replicated even when people must rely on their memory of the training stimuli.

To investigate this we first analysed the responses of all participants having seen only the first four exemplars, for which no sampling explanation was given. Against this baseline we separately compared the responses of people in the RANDOM BEFORE and HELPFUL BEFORE conditions. The resulting generalisation curves shown in Figure 3(a) reveal

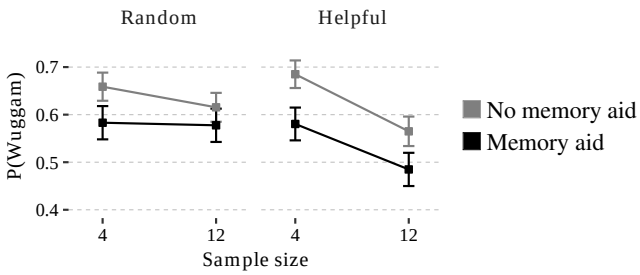


Figure 4: The mean effect of additional exemplars on the marginal probability of generalising the learned category to novel stimuli, as a function of sampling assumption and the presence of a memory aid. When training exemplars remained on-screen throughout the testing phase participants were less willing overall to generalise the target category to novel items than when no memory aid was present. In magnitude, the effect of the memory aid on generalisation was comparable to the effect of observing the eight additional exemplars.

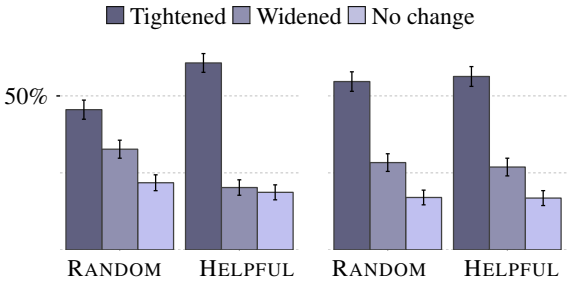


(a) BEFORE (b) AFTER

Figure 5: The proportion of people who either tightened ($\Delta_p < 0$), widened ($\Delta_p > 0$) or showed no change ($\Delta_p = 0$) in their region of generalisation, after seeing additional examples (where Δ_p reflects an individual's change in rates of responding in favour of the learned category). People are grouped according to the explanation they received about the sampling of extra items, and whether it was given before or after the examples themselves. Error bars show standard error of proportion. (a) In the BEFORE condition, where the sampling explanation was given prior to the presentation of the additional examples, the sampling manipulation had an effect. The majority of people who were told that the items had been selected by a helpful teacher tightened their region of generalisation, while the (slight) majority of people in the RANDOM condition, who actively sampled their own additional examples, widened their region of generalisation or showed no change. (b) In contrast, when the sampling explanation was provided after the additional stimuli had been presented (as in the AFTER condition), the majority of people tightened their generalisations regardless of the explanation given.

that the HELPFUL sampling manipulation led to tighter generalisation than the RANDOM manipulation. This replicates a key finding of Ransom et al. (2018), shown in Figure 3(c). To examine the strength of evidence for this finding we analysed generalisation curves for the second test phase (Size 12), calculating the generalisation probability for each person and stimulus separately. A Bayesian ANOVA revealed that a model of generalisation probability including stimulus value and sampling manipulation as predictors is strongly preferred to a model containing stimulus value only ($BF_{10} > 10^6$).

Although we replicated the qualitative difference between sampling conditions, it is evident on visual comparison of Figure 3(a) and (c) that people appeared to generalise further when they had to rely on their memory of the training stimuli. To determine the overall effect that this had on generalisation we calculated the marginal probability of extending category membership to novel items as a function of test phase (4 or 12 items) and sampling manipulation (RANDOM or HELPFUL). We then compared this probability between our experiment (the BEFORE conditions) and Ransom et al. (2018).

The results, shown in Figure 4, demonstrate that the absence of a memory aid had a uniform but significant effect on generalisation overall ($BF_{10} > 10^{100}$).[3] After seeing 12 exemplars, participants in our study (who had no memory aid) showed a willingness to generalise to novel items comparable to participants in Ransom et al. (2018) after seeing only four items that remained on screen throughout. Thus, overall, we find that the *difference* in generalisation according to sampling assumption did replicate, but generalisation was consistently higher when people had to rely on their memory more.

Our second question was whether the effect of sampling manipulation changes when the sampling cover story is given after the training stimuli rather than before. We therefore repeated our analysis for people in the RANDOM AFTER and HELPFUL AFTER conditions, and found that it does: there is no longer a difference in generalisation based on sampling assumption. As Figure 3(b) shows, people tighten their generalisations to a remarkably similar degree across the two conditions, despite the fact that they had opposing sampling cover stories (Bayesian ANOVA now favours the model with stimulus value as the only predictor: $BF_{01} = 42$).

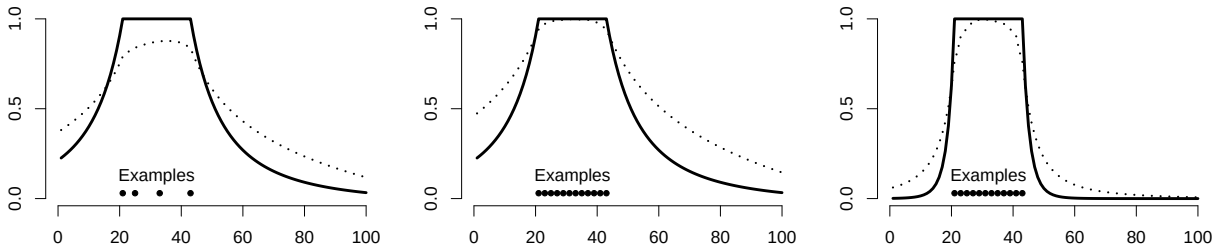
To further assess the effect of our sampling manipulation on the qualitative patterns of responding, we compared each individual's responses between the two test phases, after seeing 4 and 12 exemplars. Figure 5 shows the proportion of people who either tightened, widened or showed no net change in their generalisation (marginalised across test items). Consistent with the patterns at the aggregate level, it is evident that the explanation given to participants regarding the source of the additional exemplars does affect the trajectory of generalisation as more examples are observed. But this explanation only has an effect if it is given before the exemplars are observed ($BF_{10} = 300$) and not after ($BF_{01} = 2.8$).[4]

Discussion

To our knowledge, our work here is the first to explore *when* sampling assumptions affect generalisation, and by extension when the likelihood is calculated. Our results demonstrate that the sampling cover story only had an effect when it was made explicit prior to the presentation of the data. When it was presented at retrieval, then whatever likelihood was the default at the time of encoding (which, in this case, ap-

[3] Based on a Bayesian logistic regression comparing a model of yes/no responses that included stimulus value, sampling manipulation and memory aid as predictors to one without memory aid.

[4] Bayes' factors are based on a multinomial logistic regression comparing a model of qualitative effect (tighten, widen, no net change) with sampling manipulation as a predictor against an intercept only model.



(a) BASELINE. (b) RANDOM. (c) HELPFUL.

Figure 6: Simulated performance on a one category generalisation task as a function of exemplar recall, sampling assumption and sample size. The graphs plot the probability of generalising the learned category as a function of stimulus value. Solid lines represent generalisation performance on the assumption that all exemplars are perfectly recalled at decision time – the default assumption of the Bayesian generalisation model. Dashed lines represent generalisation performance on the basis of imperfect recall. For illustration purposes, the simulation uses an independent probability of recall for each exemplar ($p = 0.5$). Failing to recall exemplars leads to wider generalisation overall. (a) Simulated performance in the BASELINE condition (4 exemplars), assuming the default (strong) sampling. When the sample size is small, the effect of forgetting on generalisation reflects a balance of two forces: the reduction in diversity may reduce generalisation within the range spanned by the exemplars, while the reduced sample size leads to wider generalisation outside the range. (b) Simulated performance in the RANDOM condition (12 exemplars), assuming the BASELINE performance as a prior and that the 8 additional exemplars are weakly sampled. In the case of imperfect recall, the simulation predicts that the 8 additional items, although imperfectly recalled, lead to wider generalisation as a result of increased diversity. (c) Simulated performance in the HELPFUL condition (12 exemplars), assuming the BASELINE performance as a prior and that the 8 additional exemplars are strongly sampled. Under strong sampling, generalisation tightens quickly around the sampled range with each extra exemplar, thus the predicted effect of forgetting is less in this scenario.

peared to have been strong sampling) was the likelihood that shaped generalisation – even though the cover story at retrieval should have contradicted it. While we cannot altogether rule out the influence of sampling assumptions at the point of retrieval, our experiment provides evidence in favour of an encoding account. Under this account, the evidence for different hypotheses is assessed according to the sampling assumption that prevailed at the time that the data were originally presented.

This finding has a variety of interesting implications. First, it suggests that there is no such thing as a "theoryless" learner: at no point do people simply encode the raw data in a veridical fashion. Rather, from the start they are actively engaged in making sense of it for future generalisation even though there is no current need to generalise. The question remains as to how automatic this is: would people be able to inhibit the likelihood calculation if requested to remember each specific data point as precisely as possible, or if they didn't think that a generalisation task would be forthcoming?

This has implications for effective pedagogy as well. It is known that learners benefit from assuming that their teacher is selecting the most informative examples possible given the learner's current beliefs. Such reciprocal assumptions can lead to a highly leveraged form of generalisation in which concepts can quickly be acquired from minimal input (Shafto et al., 2014). Under the idealised account of pedagogical learning, people's inferences should not depend on when the sampling process becomes apparent. However, our results suggest that it is important for the teacher to make the sampling process clear as early as possible.

In a similar way our finding has implications for how people process misinformation and corrections to misinformation. Ransom et al. (2017) found, for example, that people can use truthful but limited data in their efforts to mislead others by attempting to manipulate their counterpart's sampling assumption. Our work suggests that subsequently learning that an information source was biased may not be sufficient to correct the bias. It therefore offers another explanation for the well-established finding that retracting misinformation does not eliminate its influence (Johnson & Seifert, 1994; Ecker, Lewandowsky, Swire, & Chang, 2011). If people are encoding data in such a way that it cannot be disentangled from their theory at the time, interpreting that data under a new theory may be extremely difficult.

Another interesting aspect of this work regards the role of memory. By adopting the experimental procedure of Ransom et al. (2018) but requiring participants to view the simuli one-by-one, we were able to assess how memory decay would interact with sampling assumptions in shaping generalisation. We found that people tightened their generalisations less when they had to rely on their memory more. A simulation of the generalisation task used in our experiment verified our intuition that this should be the case (see Figure 6). Our finding is consistent with previous work using complex linguistic and non-linguistic data rather than a simple one-dimensional category (Perfors, Ransom, & Navarro, 2014), which suggests that the result is reasonably robust.

Our memory manipulation (albeit across two experiments) also provides some basis to distinguish between two possible encoding accounts. One possibility is that evidence is stored and retrieved with each exemplar individually and any failure to retrieve an exemplar would mean that computation occurs over a smaller dataset. A second possibility is that evidence is stored in aggregate (across all data points) and retrieved via the hypotheses. In this case, the contribution of each exemplar would be accounted for at the point of encoding, and so the computation should proceed as if the full dataset were retrieved. The two possibilities suggest contrasting predictions.

In the first case, we would expect generalisation in the present experiment to be wider than in the previous (Ransom et al., 2018, where perfect recall was supported). In the latter case, we should expect the results of the two experiments to be broadly in line with each other. As already noted, we found that manipulating how easy it was to remember exemplars did affect generalisation in a manner consistent with some degree of recall failure. We interpret this as weak evidence favouring the "exemplar encoding" account over the "hypothesis encoding" account: the data is stored in such a way that the strength of evidence is in some way integral to the encoding of the exemplar, at least to the extent that failure to later retrieve the exemplar equates to a failure to incorporate the associated evidence. Our evidence is only weak, however, because it is not entirely clear what "forgetting" in the context of the hypothesis encoding account would amount to. Fleshing out these distinctions more and testing them more systematically is a goal for future work.

While the present experiment should be taken in the spirit of a "proof of concept", our research nonetheless suggests that memory, sampling, and generalisation are intertwined in ways that are still not fully understood. By manipulating when different information is available as well as the cognitive load during learning, it is possible to further illuminate this complex relationship.

Abstract

"No Valid Conclusion" (NVC) is one of the most frequently selected responses in syllogistic reasoning experiments and corresponds to the logically correct conclusion for 58% of the syllogistic problem domain. Still, NVC is often neglected in computational models or just treated as a byproduct of the underlying inferential mechanisms such as a last resort when the search for alternatives is exhausted. We illustrate that NVC represents a major shortcoming of current models for human syllogistic reasoning. By introducing heuristic rules, we demonstrate that slight extensions of the existing models result in substantial improvements of their predictive performances. Our results illustrate the need for better NVC handling in cognitive modeling and provide directions for modelers on how to integrate it into their approaches.

Keywords: cognitive modeling; heuristics; syllogistic reasoning; no valid conclusion

Introduction

Syllogistic reasoning is one of the core domains in human reasoning research (for a review see Khemlani & Johnson-Laird, 2012). It is concerned with gaining insight into the cognitive processes driving the inference mechanisms for categorical assertions featuring quantifiers ("All", "Some", "Some ... not", and "No") and terms which are inter-related by two premises. The traditional experimental paradigm presents participants with problems of the form "All A are B; All B are C" (substituting A, B, and C with common groups such as gardeners, musicians, etc.) and usually asks "What follows?", i.e., which conclusion can be inferred logically from the premises (generation task; Morley, Evans, & Handley, 2004). Depending on the arrangement of terms, the syllogism is categorized into one of four figures, a property that was found to have a substantial influence on human inferences (Johnson-Laird & Bara, 1984):

	Figure 1	Figure 2	Figure 3	Figure 4
Premise 1	A-B	B-A	A-B	B-A
Premise 2	B-C	C-B	C-B	B-C

For reasons of clarity, syllogistic problems are usually referred to by abbreviating quantifiers with single uppercase letters and the figure number: "All" (A), "Some" (I), "No" (E), "Some ... not" (O). The syllogism "All informative things are useful; Some websites are not informative things" is therefore referred to as AO2. Possible conclusions for syllogistic problems combine the end terms A and C via one of the four quantifiers. Additionally, it is possible to respond with "No Valid Conclusion" (NVC) indicating that the premises have no valid conclusion in accordance to first-order logic. Out of the 64 distinct syllogistic problems, 37 are invalid (58%), i.e., only NVC can be derived.

Experimental investigations have shown that NVC represents one of the most frequently selected conclusions (Khemlani & Johnson-Laird, 2012). Because of this, the role of NVC in syllogistic reasoning is important. However, current models of syllogistic reasoning rarely make explicit statements about NVC. On the extreme, there are heuristic models which do not possess the capability of generating NVC at all. On the other hand, models that do integrate NVC as a conclusion candidate often treat it as a termination criterion when searches for alternatives fail. Currently, there are no strategies to directly infer NVC responses. Additionally, even when going beyond the level of predictions, models are unable to account for statistical phenomena related to NVC responses, such as variations in reaction times (Ragni, Dames, Brand, & Riesterer, 2019).

In this article, we tackle this problem by proposing a set of heuristic rules for generating NVC conclusions based on findings from the syllogistic literature. By attaching these rules to existing models, we show that inadequate NVC handling is indeed one of the core problems of the current state of the art. The following text is split into five sections. After introducing the syllogistic domain of reasoning as well as the current state of the art in modeling (Section 2), we will analyze contemporary models in terms of their capabilities in predicting a human NVC response (Section 3). Section 4 then takes up those results and presents alternative strategies for predicting NVC responses. In Section 5 we evaluate the syllogistic models augmented with the identified strategies for NVC and finally, in Section 6, discuss our results, illustrate the potential with respect to improving models, and give directions for future work in the field of cognitive modeling of human reasoning.

*Both authors contributed equally to this manuscript.

Table 1: Models and their NVC prediction proportions for valid and invalid syllogisms. For models with multiple prediction candidates for a single syllogism, the ratio of NVC is used. Model predictions are taken from Khemlani and Johnson-Laird (2012).

Model	Valid	Invalid
Conversion	44%	86%
Mental Models Theory (MMT)	14%	30%
PSYCOP	0%	100%
Verbal Models	32%	51%
Atmosphere	0%	0%
Matching	0%	0%
Probability Heuristics Model (PHM)	0%	0%

Related Work

Computational modeling is a central part of today's research of human syllogistic reasoning. As of today, at least twelve theories about syllogistic inferences exist. In a meta-analysis, Khemlani and Johnson-Laird (2012) found that the theories have distinct advantages and drawbacks when predicting experimental data obtained by aggregating individual participants' responses. The following paragraphs briefly introduce the different approaches for which the authors were able to provide predictions for the 64 syllogisms. They will be used throughout the following analyses.

The **Conversion Hypothesis** is an attempt at explaining erroneous conclusions resulting from human reasoning processes originally introduced by Chapman and Chapman (1959) and later formalized as a testable model by Revlis (1975). The hypothesis states that while encoding a syllogistic premise, a conversion operation is applied which swaps the direction of the categorical expression (e.g., "All A are B" is interpreted as "All B are A"). As a result, a new syllogism is produced with conclusions that might be inappropriate for the original problem (e.g., Revlin, Leirer, Yopp, & Yopp, 1980). NVC is predicted if the new problem is logically invalid.

The **Mental Model Theory** (MMT; Johnson-Laird, 1975) is a cognitive theory which has successfully been applied to various domains of reasoning (Johnson-Laird & Byrne, 2002; Khemlani & Johnson-Laird, 2012; Ragni & Knauff, 2013). It is based on the assumption that inferential mechanisms operate on mental representations constructed for the given premises. MMT's inference process is composed of a series of phases: model construction, conclusion generation, and the search for counterexamples. First, an initial mental model is constructed integrating the information of the premises, i.e., the relation between the terms of the premises. Second, a candidate conclusion is formulated in accordance to the initial model. Finally, alternative models consistent to the premises are constructed in search of a situation in which the conclusion is false (Ragni, Khemlani, & Johnson-Laird, 2014). If the initial model construction fails, or counterexamples can be found for all models, NVC is returned.

The **Psychology of Proof** model (PSYCOP; Rips, 1994) is a cognitive model of human syllogistic reasoning that claims deduction as a fundamentally human capability (Khemlani & Johnson-Laird, 2012). PSYCOP defines a set of psychologically plausible inference rules approximating the human inferential mechanisms. By applying rules in a deductive forward-inference fashion as well as an inductive backwards-inference fashion, a path between premise information and conclusion is constructed. PSYCOP does not have a guaranteed way to conclude NVC. While it supports exhaustive searches for conclusions and the generation of NVC as fallback option, this behavior is not enforced in its original formulation (Khemlani & Johnson-Laird, 2012).

Verbal Reasoner (Polk & Newell, 1995) is an approach to modeling syllogistic reasoning that assumes that human inferences are fundamentally verbal. It encodes the premise information into a mental model that differentiates between more accessible information (the subject of the premise) and less accessible information (the object of the premise). By defining procedures to extract different degrees of intermediate implicit knowledge about the reasoning problem, the model is able to generate conclusions following more or less complex inferences. The verbal model theory treats NVC as a last-resort option. If no conclusion can be derived from the mental model, the verbal reasoner enters a reencoding loop in search for a solution. NVC is produced when it gives up.

The **Atmosphere Hypothesis** (Woodworth & Sells, 1935) is able to account for a portion of errors in human syllogistic reasoning when compared with formal logics (Revlis, 1975). It is based on a feature extraction step that identifies whether the given premise information is positive/negative ("All", "Some" vs. "Some not", "No") and universal/particular ("All", "No" vs. "Some", "Some not"). By following a combination procedure, the quantifier of the conclusion is determined. Because it only extracts and combines features based on quantifiers, the atmosphere hypothesis is not able to provide information about the direction, i.e., the order of terms in the syllogistic conclusion, and is not able to generate NVC.

The **Matching Hypothesis** (Wetherick & Gilhooly, 1995) reflects a different approach for accounting for errors made in human syllogistic reasoning. It employs a matching strategy which states that the conclusion quantifier is equal to the most conservative quantifier in the premises. Conservativeness in this sense is defined as a preference order of $E > O = I \gg A$ following the estimated number of individuals a quantifier makes a statement about. Similar to Atmosphere, Matching is unable to predict NVC, because it always picks a quantifier from the given premises.

The **Probability Heuristics Model** (PHM; Chater & Oaksford, 1999) is an approach to modeling reasoning that is based on the fundamental idea that reasoning relies on heuristics. PHM defines the inferential process via two phases. First, a conclusion is generated by applying the *min-heuristic* selecting the least informative quantifier from the premises ($A > I > E \gg O$). Second, *probabilistic entailments* can be

applied generating alternative conclusions based on the min-heuristic's result that could probably be true. Next, a third heuristic, *attachment*, is applied to determine the order of terms in the conclusion. Finally, the *max-heuristic* is applied to assess the confidence of the conclusion based on the informativeness of the premises. If confidence is low, the probability of returning NVC instead of the solution candidate rises. Additionally, the *o-heuristic* is applied which states that O-responses should be avoided in favor of NVC.

In Khemlani and Johnson-Laird (2012)'s prediction table, which we use as the source for the models' predictions, PHM is reported without an inclusion of the max- and o-heuristic (Baratgin et al., 2015). While potentially distorting for model comparisons, this does not affect our evaluation of NVC. The max- and o-heuristics are attached to PHM's inference mechanisms (min-heuristic, attachment, and probabilistic entailment) in similar spirit to what we propose as general extensions of cognitive models further below.

The present article investigates the theories based on their NVC prediction capabilities. Table 1 summarizes the models' NVC response proportions in accordance to the prediction data reported by Khemlani and Johnson-Laird (2012) for valid and invalid syllogisms. The table highlights the difference between the cognitive models. While some models are unable to predict NVC at all, the other approaches have a stronger tendency toward responding with NVC for invalid syllogisms. This behavior is expected due to NVC being the logically valid response for invalid syllogisms. PSYCOP reflects formal first order logic in its NVC response behavior. Because all valid and no invalid syllogisms have categorical conclusions, it predicts 0% and 100% NVC, respectively. In the following analyses, we evaluate the models based on their ability to predict the most frequently selected responses.

Analysis State of the Art

Modeling Task

In this article, we aim at uncovering the latent potential of the current state of the art by investigating their prediction capabilities with a special focus on NVC. Hence, we adopt a predictive scenario as the core evaluation setting of the following analyses: Given a dataset of reasoning data, we first compute the most frequent answer (MFA) and assess each model's performance by comparing its predictions with the aggregated response given by the participants.

The dataset used for this article was recorded as an Amazon Mechanical Turk web experiment in 2016 and consists of $N = 139$ participants providing conclusions to all 64 syllogistic problems, each. Participants were asked to select one of the nine syllogistic response candidates following from the premises. After a training phase consisting of four easy syllogisms, the remaining task sequence and order of response options was fully randomized.

The predictions for the model candidates were taken from Khemlani and Johnson-Laird (2012). This prediction data does not feature single explicit conclusions for each model and task. Instead, only sets of possible conclusions can be provided for each model and syllogism. To account for this in our prediction setting, weighted scores were computed for the following analyses via $S(P,T) = |P \cap T|/|P|$, where P and T denote the sets for predicted and true responses, respectively (e.g., Copeland, 2006).

All materials used for the following analyses are openly available via Github[1].

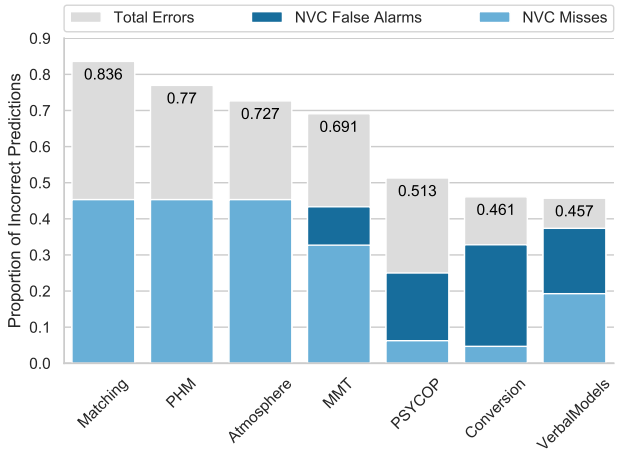

Figure 1: Proportion of model prediction errors (grey) for the 64 syllogisms. False alarms (dark blue), i.e., incorrect, and missed NVC predictions (light blue) are represented as proportions of the prediction error.

State of the Art

Figure 1 illustrates the predictive capabilities of the models in accordance to the prediction table of Khemlani and Johnson-Laird (2012). The grey bars reflect the proportion of incorrect predictions on the 64 syllogisms' MFA responses. Dark blue and light blue bars denote the parts of incorrect responses which can be attributed to unwanted and missed NVC responses, respectively. As an illustrating example, PSYCOP incorrectly predicts 51% of the syllogisms. About 6% of those errors can be attributed to missed NVC responses whereas 19% of the errors were due to false alarms.

The plot highlights the difference between the models in today's state of the art. As expected, the models which are unable to predict NVC responses (Matching, PHM, Atmosphere), perform worst. For the remaining models, the general performance is better. However, NVC-based errors still account for the large parts of the incorrect predictions. As a particularly striking example, more than half of Conversion's errors are due to incorrect NVC predictions.

The depicted results highlight the need for a better understanding of NVC. In the following, we propose strategies for predicting NVC based on results from the literature on human syllogistic reasoning. Since embedding these strategies

into the assumptions stemming from the high-level theoretical ideas of the models exceeds the scope of this article, we focus on formulating the NVC strategies as rules which can be attached to arbitrary models. If a rule does not predict NVC, the underlying model is queried. This allows us to examine the benefits and assess potential shortcomings of an improved NVC handling in modeling human syllogistic reasoning. Because our rules are purely additive, we expect models with high numbers of NVC misses to benefit most from the proposed strategies. The challenge lies in minimizing the inevitable increase in false alarms.

Towards a Model of NVC

To tackle the problem of missed NVC responses, we introduce a set of heuristic rules detecting NVC which are based on different observations.

The first heuristic, the *Figural Rule* is based on the figural effect, a core result of syllogistic reasoning research. Early studies found that the figure of premises induces a reliable bias on participants' responses: Figure 1 encourages A-C responses while Figure 2 leads to higher proportions of C-A responses (Johnson-Laird, 1975). In a later study it was found that the syllogistic figure also has an effect on the proportion of NVC responses (Johnson-Laird & Bara, 1984): NVC is preferred for syllogisms of Figure 3 and 4. This finding is transformed into a rule generating the NVC response whenever a syllogism of Figure 3 and 4 is encountered. For the remaining figures, the attached model is queried.

The next set of rules draws from the notion of informativeness of quantifiers as a criterion for determining NVC. Informativeness is a driving factor for two models in the current state of the art of syllogistic reasoning. The probability heuristics model (Chater & Oaksford, 1999) assumes an informativeness ordering of $A > I > E \gg O$ based on how unexpected truth about a statement is conceived by humans. Matching, on the other hand, introduces the notion of conservativeness based on the number of individuals a premise makes an assertion about: $E > O = I \gg A$ (Wetherick & Gilhooly, 1995). Both orders assign the least amount of information to the negative quantifiers "Some ... not" (O), and "No" (E). The *negativity rule* integrates both orders by being defined on the assumption that the amount of information encoded by two negative premises does not suffice to license a valid conclusion. This rule relates to PHM's max-heuristic in the sense that it assumes a threshold for insecurity with a generated conclusion candidate that is exceeded for E and O quantifiers. In doing so, it also subsumes PHM's o-heuristic. In analogy to negativity, the *particularity rule* is defined based on the limited information encoded in the particular quantifiers "Some" (I) and "Some ... not" (O). They make assumptions about limited and unspecified sets which might cause the reasoning process to fail. Finally, we define a third rule, *PartNeg* by combining both particularity and negativity: If the syllogism only consists of quantifiers with limited information, i.e., does not contain "All", NVC is predicted.

The last rule, *EmptyStart*, focuses on the syllogisms where information can be propagated transitively through the premises. This is possible for figure 1, i.e., "A-B, B-C", or figure 2, i.e., "B-A, C-B", which can be converted into figure 1 by swapping the premises and substituting C with A and A with C. The heuristic assumes that an information propagation is constructed (A-B-C for figure 1, C-B-A for figure 2). Inferences can only be drawn if the quantifier relating the two terms in the beginning of the chain makes an assertion about a non-empty set of individuals. If this premise features "No", i.e., the most conservative premise (Wetherick & Gilhooly, 1995), no information can be propagated through the chain and NVC is inferred. If we consider syllogism IE1, the chain A-B-C can be extracted starting with quantifier "Some". The reasoner is able to identify a selection of elements from A which can be annotated as B. The information from the second premise can now be integrated easily into the elements from A. If we consider EI1 on the other hand, the reasoner is unable to identify an initial set of elements from A. Therefore, premise 2 cannot be related to elements from A. As a result, there is a higher chance to respond with NVC.

Analysis

Figure 2 depicts the syllogisms for which the introduced heuristics predict NVC along with the syllogisms for which NVC is the most frequent answer (MFA). Comparing the strategies our results show that different parts of the space of syllogisms are covered by different rules. For instance,

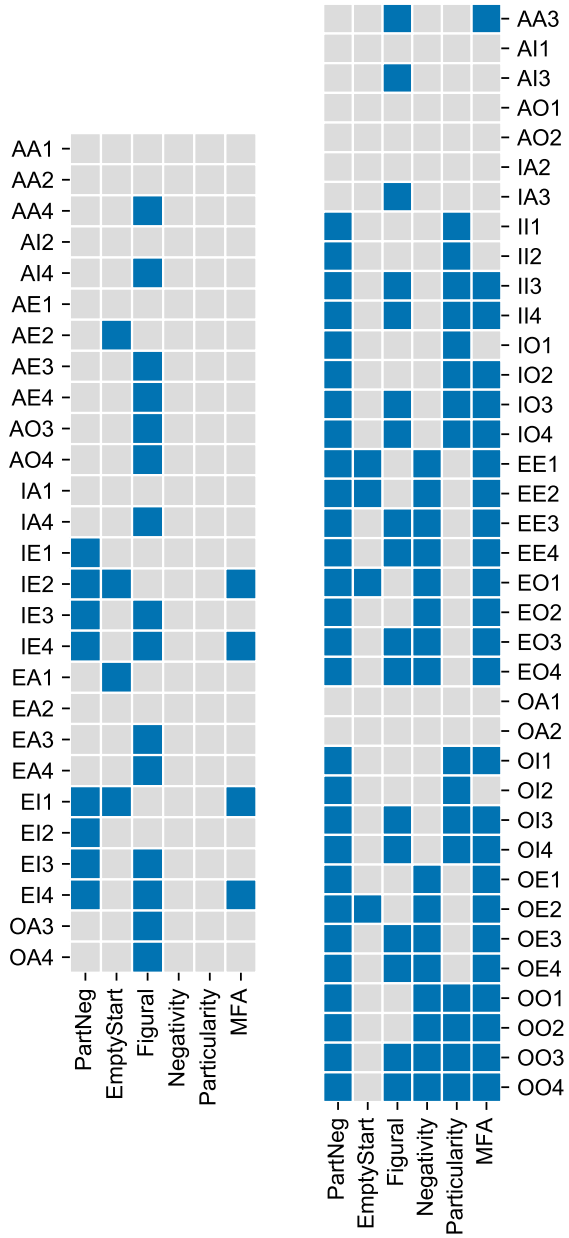

Figure 2: NVC Predictions of the individual rules on valid (left) and invalid syllogisms (right). Syllogisms are abbreviated with the encoded quantifiers of both premises "All" (A), "Some" (I), "No" (E), and "Some ... not" (O), and the figure.

negativity and particularity do not predict NVC for valid syllogisms, because there only exist invalid syllogisms characterized by being fully negative or particular. Figural on the other hand generates NVC for large parts of the syllogistic domain regardless of the validity of the underlying problem. When compared with MFA, the rules vary in predictive performance. PartNeg is capable of covering large parts of the invalid syllogisms correctly and only makes few errors for the valid cases. In contrast, figural's predictions show a more substantial difference in performance between valid and invalid syllogisms.

More generally, the plot also illustrates that most responses were not given by following standard logics. This is especially apparent in the case of the 37 invalid syllogisms where only 25 (68%) of the MFA responses correspond to NVC.

Integrating NVC into Models

To determine the effectiveness of our NVC rules, we attach them to the original state-of-the-art models and evaluate their change in performance. This is depicted in Table 2. It presents the raw improvement of the syllogistic models achieved by attaching the respective NVC rule. Additionally, the decrease in misses (light blue) and increase in false alarms (dark blue) are illustrated. In general, larger improvements (percentages), fewer misses, and fewer false alarms indicate better performance.

Table 2 draws a convincing picture about the qualities of the NVC rules. With the exception of the figural rule, all strategies result in substantial improvements over the standard models. PartNeg achieves the overall peak performance improving up to 42.2% when compared to the base model. EmptyStart has the overall lowest changes in performance but introduces only few additional errors. As expected, models which do not generate NVC at all benefit most from the capability of responding with NVC achieving an improvement of 21.3%, 20.3%, and 20.1% on average across all NVC rules, respectively. PSYCOP (0.9% on average) and Conversion (-1.4% on average) do not benefit from the additional NVC rules with Conversion's performance even decreasing slightly. Surprisingly though, MMT is improved substantially by the additional NVC rules (14.9% on average) even though it already has the capability of generating NVC.

To gain additional insight into the performance of the models, Figure 3 replicates the introductory plot from Figure 1. It depicts the errors in the predictions of the models extended with PartNeg, the overall best NVC rule. Again, the plot depicts the proportion of incorrect predictions (grey) as well as the fractions corresponding to false alarms (dark blue) and misses (light blue).

The figure illustrates that the attached rule, PartNeg, manages to effectively remove NVC misses from the models' predictions. Simultaneously, it achieves this without introducing substantial amounts of false alarms. Consequently, in combination with PartNeg, a heuristic rule was found that is able to nuancedly relate human reasoner's tendencies towards concluding NVC to the syllogistic quantifiers. The fact that the improvement in handling NVC caused a substantial increase in performance for most of the models further strengthens the claim that NVC is one of the core weaknesses of the current state of the art in modeling human syllogistic reasoning.

Figure 4 illuminates the qualities of NVC rules on an individual level. For each model, the values refer to the number of participants for which a certain rule achieves highest

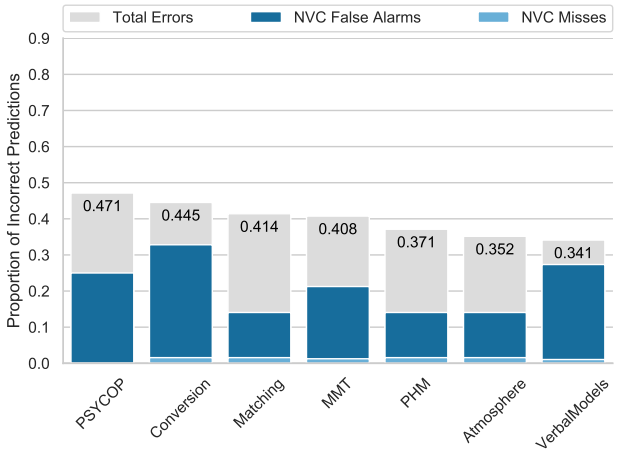

Figure 3: Proportion of the prediction errors (grey) achieved by the models extended with PartNeg, the overall best NVC heuristic, on the 64 syllogisms. False alarms (dark blue), i.e., incorrect, and missed NVC predictions (light blue) are represented as proportions of the prediction error.

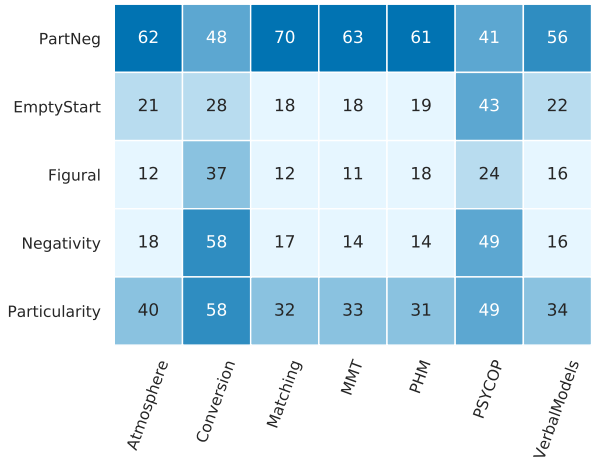

Figure 4: For each model, the values denote the number of participants for which the corresponding NVC rules performs best. In case of ties, the subject is counted for both rules.

performance. The figure illustrates that while PartNeg is the overall best rule, there is quite a substantial number of participants which can be accounted for better by other rules. This suggests that NVC response behavior is dependent on inter-individual differences of reasoning processes.

General Discussion

As the correct response for 58% of syllogisms as well as one of the most frequently given responses by human reasoners (Khemlani & Johnson-Laird, 2012), "No Valid Conclusion" (NVC) is an important response for computational models to capture.

Our results demonstrate that the current state of the art in modeling human syllogistic reasoning is lacking the capabilities for handling NVC correctly. While some other approaches do not feature the ability of producing NVC at all, even the more complex approaches yield false alarm rates of up to 25% (Conversion) and misses of up to 30%. The high miss rates highlight a lack of precision in identifying the problems where NVC responses are adequate.

We combat these shortcomings by introducing five heuristic rules for predicting NVC based on prominent phenomena and properties of syllogistic reasoning (e.g., figural effect; Johnson-Laird, 1975; Johnson-Laird & Bara, 1984, or informativeness of premises; Chater & Oaksford, 1999). By attaching these rules to the cognitive models taken from Khemlani and Johnson-Laird (2012), a substantial improvement can be observed for the majority of models. Models without the capability of predicting NVC could achieve an increase in performance of up to 20% on average across all rules. Combined with PartNeg, the overall best NVC rule, we were able to demonstrate a substantial decrease of misses across the board. Even though these rules introduce low numbers of additional false alarms, this effect is negligible when compared to the substantial reduction of misses.

In conclusion, our work contributes to research in the domain of syllogistic reasoning both on a theoretical and practical level. We isolate NVC as one of the core flaws of the current state of the art in modeling syllogistic reasoning. By demonstrating substantial improvement when attaching NVC predictors, we highlight the remaining potential for modelers to tap into. The next step for cognitive modelers is to integrate these findings into future iterations of their models and derive additional rules from cognitive theories. With PartNeg, we provide a first rule which represents a valuable heuristic candidate for explaining NVC response behavior.

Furthermore, our results show the potential that lies in isolating and improving parts of the problem domain. By highlighting their shortcomings, modelers are given the chance to iteratively improve on their computational models and underlying theories. Apart from NVC, another candidate for improvement is the conclusion direction. Currently, there exist models which completely ignore direction as a predictive factor (e.g., Atmosphere) and others which actively integrate it into their underlying formalisms (e.g., Conversion).

Still, even though PartNeg captures the majority of MFA responses, it is not the optimal choice for each individual. There still is potential left for making better predictions if the relation between individual reasoners' characteristics and their response behavior can be understood. Our results suggest that there is no single rule capable of accounting for all individuals. Therefore, one goal of future models is to determine and use discriminative features enabling the detection of the reasoning strategy most fitting to a specific reasoner.

Event Participants and Verbal Semantics: Non-Discrete Structure in English, Spanish and Mandarin

Abstract

Verbs are widely analyzed as functions taking a discrete number of arguments (e.g., *drink* has two arguments but *give* has three). Recent studies, however, suggest that English verbs encode Instruments as more or less salient (e.g., the Instrument is more salient for *slice*, less salient for *eat*). We conducted a judgment task with adult speakers of Spanish and Mandarin and found that verbs in these languages also encode Instruments as having a relative degree of salience, inconsistent with the discrete model of participant encoding.

Keywords: verbal semantics; argument structure; experimental semantics; thematic roles; event representation

Introduction

A fundamental debate in cognitive science concerns whether mental representations have discrete vs. non-discrete structure (Aarts, 2007; Bod, Hay & Jannedy, 2003; Rosch, 1975; Smolensky & Legendre, 2006). This debate arises for theories of verbal semantics. Verbs convey relationships between event participants: *eat*, for example, involves someone who eats and a substance that is eaten. Such relationships have commonly been modeled in logical terms: that a verb is a function taking a discrete number of arguments: *die* has one, *eat* has two, and *lend* has three (Dummett, 1981; Jackendoff, 1972). Theorists have long noted, however, the limits of this logical analogy (Carlson & Tanenhaus, 1989; Parsons, 1990; Williams, 2015). *Eating,* for example, seems to require that the eater have a mouth – is the mouth then one of the arguments of the function *eat*? Although there is broad consensus that verbs encode relations between participants, how precisely these relations are represented is unresolved.

A second unresolved question is whether participant relations are the same for semantically similar verbs across languages. As described by Bowerman and Brown (2008: 10), there is a widespread assumption that "languages will agree on the number of semantic participants there are in events of various types (e.g., one for 'laughing', two for 'pushing', three for 'giving')". There is reason to question this assumption: Wilkins (2008) argues that whereas the English verb *see* has two arguments, in the aboriginal language Arrernte, the translationally equivalent verb *are-* has three: the person who sees, the thing that is seen, and the place where the thing that is seen is located. While differences in argument realization are well-documented across languages (Levin & Rappaport-Hovav, 2005), variability such as described by Wilkins (2008) has received little attention. If variability in how verbs encode participants is widespread, then the mapping from conceptual to linguistic structure is less constrained than previously thought, posing an additional learning challenge to children.

In this study, we address whether discrete argument structures are good models for how verbs encode event participants, as well as whether verbal participant relations are variable across languages. We report the results of a judgment experiment with speakers of Spanish and Mandarin and compare these results with English data previously reported by Rissman, Rawlins and Landau (2015).

Previous Evidence for Semantic Gradience

One of the benefits of the discrete model of verbal participant encoding is that it fits well with syntactic theories of how event participants are overtly expressed: isomorphic mappings can be drawn between a verb's arguments and the surface constituents in a clause. For example, in *Jodi lent a book to her sister*, the arguments <Source, Theme, Recipient> map to the phrases <DP, DP, PP>. The distinction between a verb's arguments and its non-arguments (or "modifiers") is not dichotomous, however (Croft, 2001; Dowty, 2003; Vater, 1978), one reason being that verbal semantics and syntax are sometimes not isomorphic (Haspelmath, 2014; Koenig, Mauner & Bienvenue, 2003). Consider, for example, instrumental participants, as in *Jodi sliced the broccoli with a knife*. Verbs such as *slice* and *chop* activate an Instrument concept during sentence comprehension (Andreu, Sanz-Torrent & Rodríguez-Ferreiro, 2016; Koenig et al., 2003). Nonetheless, instrumental *with*-phrases pattern like modifiers (i.e., not like arguments) given syntactic argument diagnostics (Rissman et al., 2015; Schutze, 1995). For example, *what Jodi did with the knife was slice the broccoli* is acceptable but not **what Jodi did to her sister was lend a book.*

As a result of this mismatch between semantic and syntactic argument diagnostics, researchers cannot rely on syntactic diagnostics to understand how verbs semantically encode event participants. Alternate methods for probing verbal semantics include studies of sentence processing, sentence completion and semantic judgments (Barbu &

Toivonen, 2016; Boland, 2005; Koenig et al., 2003; Rissman et al., 2015; Wittenberg & Snedeker, 2014). In the judgment task in Rissman et al. (2015), English speakers read a paragraph stating that verbs have "arguments," defined as something "essential to the meaning of a verb but not part of the verb itself." This category was elaborated through positive examples, e.g. that *want* has two "arguments" because wanting involves someone who wants and something that is wanted. We distinguish the experimental category "argument" from the theoretical notion of argument.

Following this instruction, subjects judged which of the words in a sentence constituted the "argument" of the verb, for untrained verbs and participant types. Subjects read sentences such as in (1) and had to choose whether either the first or second bracketed phrase was an "argument" of the verb, or whether neither phrase was an "argument":

(1) a. [Last Tuesday] Martha SLICED something [with a steak knife].
b. Tania TAUGHT something [to the students] [in the classroom].

Rissman et al. (2015) hypothesized that if verbs like *slice* and *chop* discretely encode three arguments, an Agent, Patient and Instrument, then they are in an equivalence class with dative verbs such as *teach* and *lend,* which encode a Source, a Theme and a Recipient (Larson, 1988). By prediction, subjects would therefore be equally as likely to choose "with a steak knife" in (1a) as to choose "to the students" in (1b).

Instead, subjects selected Instruments less often than Recipients. In addition, there were differences across the instrumental verbs: an Instrument was selected more often for *slice* and *chop* than for *eat* and *break,* for example. Thus *slice* patterned like neither a 2-argument verb nor a 3-argument verb. Rather, Instruments appeared to have a moderate degree of salience: more salient than a time or a location, but less salient than a Recipient, inconsistent with the discrete model of participant encoding.

A variety of evidence indicates that this judgment task reflects abstract knowledge of verbal meaning. First, on control trials with prototypical arguments and modifiers, subjects almost always chose the Theme in sentences such as "John CARRIED [the books] [in a tote bag]" and almost never chose one of the modifiers in sentences such as "Martha CHOPPED something [on Monday] [in the forest]. Subsequent experiments showed: 1) that the difference between the Recipient and Instrument judgments was likely not driven by the difference in animacy (Recipients were animate whereas Instruments were inanimate), 2) that the Instrument judgments were not correlated with estimates of how often people use tools for these events, and 3) Instrument and Recipient judgments for each verb did correlate with how often people produce Instruments and Recipients in a corpus. Finally, Rissman (2018) found strong positive correlations between Instrument and Recipient judgments for each verb and rates of producing Instrument/Recipient completions for sentence fragments such as *Martha sliced the bread* _____ and *Tania taught the material*____.

Current study

We ask whether Spanish and Mandarin speakers also judge Instruments as having a moderate degree of salience. Such a finding would provide additional evidence against the discrete model of participant encoding. Investigating verbal semantics across multiple languages helps ensure that theoretical developments are not based on English alone.

We also ask whether non-discrete encoding of participants is itself cross-linguistically variable. Although *slice* patterns neither as a 2-argument nor a 3-argument verb, this does not preclude semantically similar verbs in other languages (e.g., Spanish *cortar*) from discretely encoding the Instrument. Languages differ widely as to which semantic role properties are relevant to syntactic argument realization (Bornkessel, Schlesewsky, Comrie & Friederici, 2006; Croft, 2001; Levin & Rappaport-Hovav, 2005). Verbal semantics is also highly variable across languages, with verbs in the same semantic space bundling semantic features in different ways (see Majid, Boster & Bowerman, 2008 for cutting and breaking events and Talmy, 1985 for motion events). In Mandarin, for example, the verb *jie4* encompasses both English *borrow* and *lend*. In the current study, we ask whether instrumental verbs in Spanish and Mandarin encode the Instrument in a discrete way, unlike in English.

For each of the verbs studied by Rissman et al. (2015), we selected semantically similar verbs in Spanish and Mandarin. For these similar verbs, we asked three questions:

1) Do judgments of Instrument salience parallel judgments of Recipient salience, unlike in English?
2) Do some verbs highlight an Instrument more strongly than other verbs, as is true for English?
3) Do verbs with similar meanings across languages give rise to similar judgments of Instrument salience?

In choosing Spanish and Mandarin, we compared one language that is genetically related to English (Spanish) and one language that is genetically distant (Mandarin). These languages both differ from English with respect to argument production: Spanish is a pro-drop language, allowing subject omission, while Mandarin allows both subject and object omission. We can thus test whether in languages that allow pervasive argument omission, subjects are less likely overall to judge that a particular phrase is an "argument."

Experiment 1

Participants

35 native Spanish-speaking adults (F = 22) and 32 native Mandarin-speaking adults (F = 23) participated. Spanish speakers were tested in Chicago and in Baltimore; all Mandarin speakers were tested in Baltimore. All participants reported having some knowledge of English. The Spanish speakers originated from throughout the Spanish-speaking world; Mandarin speakers originated from throughout China and Taiwan. All participants had attended or were currently attending college. Participants received $12 or course credit.

Design and Materials

Native speaker consultants translated the Rissman et al. (2015) materials into Spanish and Mandarin. The prior study tested two types of verbs: 1) verbs compatible with an Instrument ("Instrument verbs"), ranging from strongly to weakly instrumental (e.g., *slice, chop* vs. *eat, drink*), and 2) verbs compatible with a Recipient ("Recipient verbs"), ranging from strongly to weakly Recipient-encoding (e.g., *lend, teach* vs. *bounce, kick*). We selected Spanish and Mandarin verbs by describing to the consultants a set of events that exemplified core uses of each English verb (e.g., *chop* ~ chopping an onion, chopping wood). The consultants then provided the dominant verb in Spanish and Mandarin that would be used to describe these events. If no verb could be found that closely matched the meaning of the English verb and was compatible with the syntactic frames in (2-5), then no verb was tested. Tables 1-2 show the Spanish and Mandarin verbs that were tested, including omissions ("---").[1]

Each sentence in the experiment featured a single verb and two bracketed phrases: participants' task was to choose one of the bracketed phrases as an "argument" of the verb, or to choose that neither phrase was an "argument." Example Instrument and Recipient sentences are shown in (2-3) and (4-5) with English glosses and translations.

(2) Rachel REBANÓ algo [con una hoja de afeitar] [en el puerto].
Rachel slice-3PST something with a razor blade in the port
"Rachel sliced something with a razor blade in the port."

(3) 【在去年復活節那天】小琴 用【一把短柄小斧】⁞砍了⁞一些東西。
in last Easter Sunday Xiaoqin use one hatchet chop-PFV something
"Last Easter Sunday, Xiaoqin used a hatchet to chop something."

(4) [A las 6 am] Ruby le PRESTÓ algo [al nadador].
At 6 AM Ruby 3SG lend-3PST something to the swimmer.
"At 6 AM, Ruby lent something to the swimmer."

(5) 克洛伊【在街上】⁞賣了⁞一樣東西【給演員】。
Chloe in street send-PFV something to actors
"In the street, Chloe sent something to the actors."

The two bracketed phrases constituted several contrasts between two possible participant types. In the main trials of interest, Instruments and Recipients were pitted against prototypical modifiers (location, time and manner phrases). If Instruments and Recipients are arguments, these should be chosen significantly more often than modifiers.

There were two types of control trials. In the first, Themes were pitted against various phrase types including participant locations (e.g. *Layla LLEVÓ [los comestibles] [en una cesta];* "Layla CARRIED [the groceries] [in a basket]") and beneficiaries (e.g. *Jen LEYÓ [el mensaje] [para el detective]*; "Jen READ [the message] [for the detective]"). We predicted that subjects would choose the Theme as an "argument." In the second type of control trial, prototypical modifiers were pitted against each other, as in *Rachel REBANÓ algo [tristemente] [en el puerto]* ("Rachel SLICED something [sadly] [in the port]"). We predicted that in modifier vs. modifier trials, participants would judge that neither phrase was an "argument" of the verb. These control trials assess

Table 1: Instrument verbs

Eng	Span	Mand	Eng	Span	Mand
beat	golpear	qiao1da3	eat	comer	chi1
hit	pegar	da3	drink	beber	he1
touch	tocar	peng4	break	quebrar	da3po4

sell	vender	mai4	push	empujar	tui1
lend	prestar	chu1zu1	slide	---	---
pay	pagar	fu4	take	llevar	na2
offer	ofrecer	ti2gong4	bounce	---	---

[1] In Mandarin, serial verb constructions are common and productive (Li 1990). In Table 1, the verbs *da3po4* ('break'), *da3kai1* ('open'), *yi2dong4* ('move') and *ju2qi3* ('lift') are compound constructions rather than non-compound multi-character verbs. These verbs were included to maintain a close equivalence between the numbers of verbs and the semantic space of the verbs tested in English and Mandarin.

whether subjects distinguish prototypical arguments from prototypical modifiers.

The order of the bracketed phrases was counterbalanced such that some participants saw a trial such as in (2), whereas others saw a structure with a sentence-initial modifier such as *[En el puerto] Rachel REBANÓ algo [con una hoja de afeitar]* ("[In the port] Rachel SLICED something [with a razor blade]"). Each Instrument and Recipient verb appeared six times. In addition, each verb was paired with six unique Instrument/Recipient tokens (e.g., *con una hoja de afeitar* ("with a razor blade"), *con tijeras* ("with scissors")). There were both typical and atypical tokens for each verb. Summing across the experiment, Spanish/Mandarin participants saw a total of 312/318 trials.

Procedure

Participants received a Spanish/Mandarin version of the "argument" instructions from Rissman et al. (2015); the category labels *argumento* and *lun4yuan2* were used in Spanish and Mandarin, respectively. The instruction consisted of two phases: in the first, participants read a prose description about "arguments." Participants were told, for example, that "arguments" are essential to the meaning of a verb but are not part of the verb. Participants were given primarily positive examples, e.g. that *querer/yao4* ('want') has two "arguments," someone who wants and something that is wanted. Participants were also told that "arguments" are not necessarily syntactically required in a sentence. Participants read two negative examples, e.g. in *John ran until he was sick*, the phrase *until he was sick* is not an "argument". In the second phase of the instruction, participants completed practice trials where they read a verb and were asked to indicate the "arguments" of the verb. For example, Spanish participants read the sentence *Jim estaba cocinando* ("Jim was cooking"), were told that *cocinar* has two "arguments," and had to indicate which "argument" of *cocinar* was present and which was absent in the sentence. In another type of practice trial, Mandarin participants were asked to list the "arguments" of *"看"* ('look'); where the correct answer is two "arguments," someone who looks and something that is looked at. Feedback was given on all practice trials in the second phase of training. Across the entire instruction, explicit information was not given about the verbs or participant types that participants would be tested on. The instructions/practice trials were administered by native or near-native speakers of Spanish/Mandarin.

Results and Discussion

Spanish and Mandarin speakers performed as expected on the two types of control trials. For Theme trials (e.g., English ~ *John CARRIED [the books] [in a canvas bag]*), Spanish speakers chose the Theme as an "argument" on 93% of trials (CI_{95} = 1%), and Mandarin speakers chose the Theme on 95% of trials (CI_{95} = 1%). For modifier vs. modifier trials (e.g., English ~ *John CUT something [carefully] [last night]*), Spanish speakers chose the "neither" option on 89% of trials (CI_{95} = 1%) and Mandarin speakers chose "neither" on 96% of trials (CI_{95} = 1%). Thus speakers of Spanish and Mandarin, like the English speakers tested in Rissman et al. (2015), sharply distinguish prototypical arguments from prototypical modifiers in their judgments.

Figure 1 shows the main results, how often Spanish and Mandarin speakers judged Recipients and Instruments to be "arguments" for each verb.[2] The English-*with* data were previously reported in Rissman et al. (2015). These data suggest that Recipients are better examples of "arguments" than Instruments. To test whether Spanish and Mandarin speakers judged Instruments as having the same level of salience as Recipients, and whether these judgments varied across English, Spanish and Mandarin, we modeled the probability of choosing the Instrument or the Recipient (i.e., the *Target*) as an "argument" using mixed-effects logistic regression. Participants almost never selected one of the modifiers as an "argument;" we therefore collapsed the modifier and "neither" responses and modeled these data as a binary choice: whether or not participants chose the Target as an "argument." We fit regression models in R using the *glmer* function in the lme4 package (Bates & Maechler, 2009); models were evaluated through nested model comparison. Possible fixed effects in the model were Language (English vs. Spanish vs. Mandarin), Target type (Instrument vs. Recipient) and Competitor Type (location vs. time vs. manner); Subject was a possible random effect.

The best-fitting model of the data in Figure 1 contained the Subject random effect and the Target fixed effect: participants selected Recipients more often than Instruments (β = 2.53, SE = .05, $p < .001$). None of the following contributed significantly to the model fit: Language, Competitor Type, interaction between Language and Target Type and interaction between Target Type and Competitor Type (p-values for χ^2 tests all > .1). This analysis shows that in both Spanish and Mandarin, Recipients are more prominent for Recipient verbs than Instruments are for Instrument verbs, as in English.

We also observed variation across the individual Instrument verbs, in both Spanish and Mandarin. In Spanish, the rates of selecting the Instrument ranged from 11% (*comer*, 'eat'; CI_{95} = 7%) to 38% (*picar* 'chop'; CI_{95} = 9%). The 95% confidence intervals for these verbs do not overlap, indicating significant variation across verbs. Similarly, for Mandarin, Instrument judgments ranged from 19% (*chi1*, 'eat'; CI_{95} = 9%) to 41% (*ci4*, 'stab'; CI_{95} = 10%). The 95% confidence intervals for these verbs do not overlap.

Finally, we tested the relationship between individual verb

[2] In pilot studies, some Spanish-speakers reported that a Recipient phrase was incompatible with some Recipient verbs. Given this intuition, Spanish participants completed an acceptability questionnaire after the judgment task. If an individual participant judged a verb to be "unnatural" in the Recipient frame, this participant's data for this verb were excluded from analysis. The following percentages of trials were excluded for each verb: *patear* (*'kick'*): 49%; *empujar* (*'push'*): 74%; *llevar* (*'take'*): 11%; *tirar* (*'throw'*): 14%.

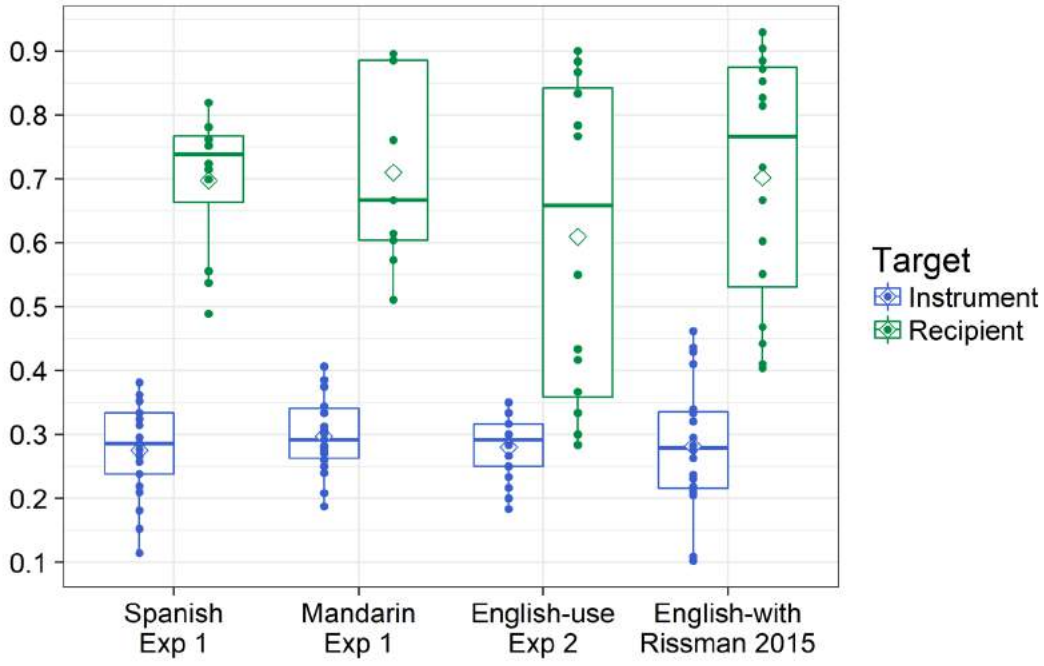

Figure 1. Rates of choosing the Instrument or the Recipient as an "argument" in each experiment. Box plots show median and second and third quartiles; diamonds show the mean; dots represent single verbs

meanings and "argument" judgments across languages, using the verb pairings shown in Tables 1-2. Judgments for individual verbs correlated significantly with each other for each verb category (Spanish-English Instrument verbs: $r(19) = .80$, $p < .001$; Mandarin-English Instrument verbs: $r(22) = .59$, $p < .01$; Spanish-English Recipient verbs: $r(11) = .79$, $p < .01$; Mandarin-English Recipient verbs: $r(11) = .72$, $p < .01$). These correlations show common trends in how verbal semantic features influenced the judgments in each language.

These results provide answers to the three questions raised above: in Spanish and Mandarin, judgments of Instrument salience do not parallel judgments of Recipient salience; some verbs highlight an Instrument more strongly than others; and verbs with similar meanings across languages give rise to similar judgments of Instrument salience. These findings support a gradient theory in which participants can have moderate degrees of salience, and suggest that verbs encode participants in similar ways across languages.

All participants had some knowledge of English. To assess whether English familiarity influenced the judgments, we calculated for each participant the correlation between that participant's judgments for each verb and the mean for the corresponding English verbs, combining Instrument and Recipient verbs. We then calculated correlations between the age at which a participant started learning English and the strength of their correlation with the English data. The correlation with age was non-significant for both Spanish ($r(33) = -.02$, $p > .1$) and Mandarin ($r(30) = -.08$, $p > .1$).

Experiment 2

In the English study, Instruments were introduced by the preposition *with*, whereas Mandarin Instruments were introduced by the verb *yong4*, 'use'. Thus in the English sentences, the Instrument was in the same clause as the main verb, while in the Mandarin sentences, the Instrument was in a separate clause. To assess a possible effect of these different syntactic structures, we collected judgments from English speakers who encountered Instruments in a *use*-frame.

Participants, Design, Materials and Procedure

Twenty English-speaking adults from Baltimore participated ($F = 14$). All subjects reported being native speakers of English. Subjects received $12 or course credit.

Each of the *with*-sentences from Rissman et al. (2015) was converted to a *use*-sentence. As in Experiment 1, the verb *use* was not included in the Instrument bracket. We used two different word orders for each Instrument vs. modifier contrast, e.g., *Jordan used [a shotgun] [in the driveway] to ATTACK someone* and *[In the driveway] Jordan used [a shotgun] to ATTACK someone*. All other trials were the same as in Rissman et al. (2015), as was the instruction.

Results and Discussion

Figure 1 shows the rates of choosing the Instrument/Recipient as an "argument" for Experiment 2. In a mixed-effects logistic regression model of the *with* data from Rissman et al. (2015) and the *use* data from Experiment

2, frame type (*use* vs. *with*) did not significantly affect the likelihood selecting the Instrument ($\chi^2(1) = .04$, $p > .1$). In addition, there was a significant positive correlation between the individual verb means for the English *use* data and the Mandarin data: $r(22) = .76$, $p < .001$. These results show that viewing the Instrument in a *use* frame did not decrease English speakers' likelihood of selecting the Instrument, mitigating the concern that the Mandarin stimuli from Experiment 1 underestimate the extent to which Mandarin verbs highlight Instruments.

General Discussion

Our results suggest that in Spanish and Mandarin, a discrete model of verbal participant encoding does not adequately capture how verbs encode the presence of an Instrument. Some theorists distinguish syntactic arguments from semantic arguments (Jackendoff, 2002). Such a distinction does not help explain our results, however, as both types of argument structures are assumed to be discrete.

It is possible that the gradient judgments we observe reflect probabilistic retrieval of discrete semantic structures (see Hale, 2001; Levy, 2008; among others). This approach, however, does not make an explicit connection between the semantics of a verb and the degree to which an Instrument is salient. Verbal semantics appears to matter: *picar*, 'chop' but not *comer*, 'eat' specifies that the Instrument has a particular physical form (a bladed/pointed shape). If *comer* and *picar* are both associated with 2 and 3-place frames, it is unclear how the semantic difference between the verbs accounts for the different rates of frame retrieval.

An alternate possibility is that the representation wherein verbs encode participant relations is itself gradient. This possibility has been characterized in multiple ways. Langacker (1987) proposes that verbs are conceptually dependent, and dependence is a gradient notion. For example, in *Jim sliced the bread with a knife*, the verb *slice* is dependent on the instrumental phrase *with a knife* because the instrument elaborates a salient substructure within the meaning of *slice,* the bladed-object feature. This salient substructure is not as salient, however, as the substructure indicating the entity that gets sliced, leading to gradient patterns of intuitions.

Similarly, Williams (2015) proposes that the "participant roles" of a verb are given by the "sketch" associated with that verb, a "psychological perspective…engaged by default" (85). Participant roles are entailed, explicit constituents within the sketch. Although Williams does not explicitly describe the sketch as non-discrete, he characterizes the elements of the sketch as psychologically "prominent." The results of Experiments 1-2 could be explained within this framework if: 1) an Instrument is a participant role for verbs such as *picar*, 'chop' and *ci4*, 'stab', and 2) the Instrument is less prominent in the sketch for these verbs than the Recipient is prominent in the sketch of dative verbs.

Rissman et al. (2015) propose a distinction between "primary" and "secondary" participants in event representation: the former are contributed by a discrete argument structure, whereas the latter are generated by the root semantics of the verb. Slicing events, for example, have two primary participants: the agentive causal force and the patient that becomes sliced. Through its root meaning, *slice* encodes that a bladed object comes into contact with the patient, and this bladed object is therefore a secondary participant within the event structure required by the verb. See Rissman and Rawlins (2017) for a proposal for how the instrument-phrase meaning interacts with this event structure.

More recently, Kim et al. (2019a,b) propose that the argument/adjunct distinction is gradient based on an idea from Dowty: certain phrases describing event participants can be *gradient argument/adjunct blends* in the framework of Smolensky et al (2014), i.e. they can be both arguments (to some degree) and adjuncts (to some degree). Kim et al. establish empirically that many prepositional phrases illustrate gradience in terms of whether native speakers categorize them as arguments or adjuncts. Their main aim is to explain variation and gradience in judgments about specific linguistic diagnostics that are supposed to provide evidence for the argument/adjunct distinction, e.g. that adjuncts allow pseudoclefts and that adjuncts are always omissible. Across all of the types of PPs they look at, lexical effects coming from particular verbs are a major factor in determining this gradience, and in particular, verbs vary in the degree to which they prefer for some potential event participant role to be filled; different syntactic frames vary in how much they prefer adjunct phrases. While this proposal makes no specific claims about instrument marking, it does generally predict that verbs will have gradient representations in terms of how they license event participants, something consistent with our results. An open question is whether the very general kinds of verb preferences that Kim et al. show across many PP types can explain the role-specific preferences demonstrated here and in Rissman et al. (2015).

Argument omission is more widespread in Spanish and Mandarin than in English. We did not, however, find a main effect of Language on the judgments. In addition, English speakers' judgments were largely unchanged when they encountered Instruments in a *use*-frame rather than a *with*-frame. These results suggest that the judgments reflect verbal meaning rather than syntactic prominence per se. Given this hypothesized dissociation between syntactic and semantic prominence in this task, we predict that if participants judged whether *the key* is an "argument" in *[The key] OPENED the door*, they would be unlikely to do so.

Across Spanish, Mandarin and English, we observe similarity rather than variability: there are verbs in all three languages where the Instrument has an intermediate level of salience (e.g., *picar*, 'chop,' and *ci4*, 'stab'). We leave future research to explore the interaction of discrete and non-discrete structures that give rise to these gradient judgments.

Parametric control of distractor-oriented attention

Abstract

Traditional models of cognitive control account for a host of classic findings, but these classic tasks have limited our ability to test a broader range of model predictions. In particular, such models predict that control should vary parametrically in response to cognitive demands and that control adjustments should be targeted towards task-relevant stimulus features. We developed a task to probe these predictions across two experiments. Participants responded to one dimension of a stimulus while ignoring the other, and we parametrically varied the conflict between those dimensions and the predictability of this conflict across trials. We found that control adjustments (1) varied parametrically in response to cognitive demands, (2) were sensitive to the predictability of those demands, and (3) were primarily targeted towards task-irrelevant dimensions. These results raise interesting questions about the structure of cognitive control and demonstrate the utility of rich tasks for constraining model predictions.

Keywords: cognitive control; attention; conflict adaptation

Introduction

Cognitive control is vital for adaptive behavior, allowing the brain to balance the consistency of automatic behavior against the flexibility to rapidly perform arbitrary tasks (Miller & Cohen, 2001). Influential models of cognitive control have proposed supervisory processes that parametrically adjust the strength of task-relevant information based on conflict or (dis)utility (Botvinick, Braver, Barch, Carter, & Cohen, 2001; Shenhav, Botvinick, & Cohen, 2013). While these models have successfully explained a host of classic findings in executive control, the evidence from these classic tasks is limited in its ability to constrain models of control. In this experiment, we sought to test several key assumptions of cognitive control using enriched tasks that can better discriminate between different model architectures.

The first feature of control models that has been virtually untested is the parametric nature of adjustments to control. Control adjustments are often examined in reaction to response conflict, but existing paradigms typically vary such conflict in an all-or-none fashion (i.e., stimulus dimensions activate only one response or they activate responses that are fully congruent or fully incongruent). Researchers have studied more granular control adjustments over longer timescales, for instance by varying the overall proportion of incongruent trials at the list level (Logan & Zbrodoff, 1979; Bugg, Jacoby, & Toth, 2008), however parametric manipulations at the single-trial level remain largely unexplored. As a result of this methodological gap in the literature, little is known about how the intensity of control changes when response congruence varies parametrically. A secondary benefit to parametric congruence is that it allows participants to more accurately track changes in congruence over trials, providing clearer evidence for learning-based adjustments (Jiang, Beck, Heller, & Egner, 2015).

The second feature of control models that we sought to test was the assumption that control primarily acts to enhance attention towards targets ('target-oriented' control; Botvinick et al., 2001; Egner, 2007). This assumption is poorly constrained by most studies of response conflict, as they typically only vary the strength of the distractor dimension, and not the target dimension. As a result, existing data cannot distinguish between conflict-related control adjustments that are primarily oriented toward targets, distractors, or both.

To address these gaps in the literature, we developed a novel cognitive control task that varies the strength in the target and/or distractor dimensions of a stimulus, resulting in fine-grained variation in response congruence. We also varied the predictability of this congruence, in order to measure how participants learn to control attention. We found that participant's performance depended on both parametric task demands and parametric control adjustments. In periods when distractor congruence was highly predictable, participants became more sensitive to distractor information. Finally, we found that participants primarily controlled their attention towards distractor dimensions, counter to the predictions of prominent cognitive control models. These experiment demonstrate the need for richer cognitive control tasks that can better distinguish between models of executive functioning.

Experiment 1

Experiment 1 sought to test (1) whether there is a parametric relationship between performance and response congruence; (2) whether participants parametrically adjust control based on recent task demands; and (3) how these control adjustments depend on the learned task demands over longer timescales.

Method

Participants Fifty-eight individuals participated in Experiment 1 for course credit or pay (Mean(SD) age = 20.9(2.6);

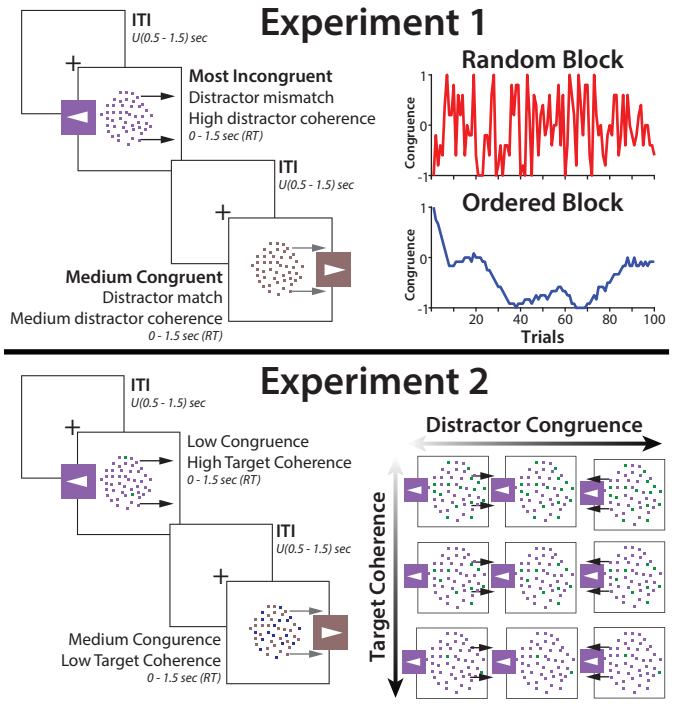

Figure 1: Top Left: In Experiment 1, participants responded to the color and ignored the motion of an array of pseudo-randomly moving dots. Motion coherence induced variable levels of congruence across dimensions. Top Right: Participants performed blocks in which the congruence changed randomly (red) or predictably (blue). Bottom Left: In Experiment 2, both the color and motion dimensions had variable coherence. Bottom Right: These color and motion dimensions were orthogonal

41 females). All participants across all experiments provided informed consent in compliance with our University's Institutional Review Board.

Parametric Conflict Task We developed a parametric version of a previous Simon-like conflict task (Danielmeier, Eichele, Forstmann, Tittgemeyer, & Ullsperger, 2011). On each trial, participants viewed an array of moving dots, presented in one of four colors (see Figure 1). Participants were instructed to press either the left or right key associated with the color of the dots. Each keys was mapped to two possible colors. The direction of the dot motion (leftward or rightward) was task-irrelevant and could be consistent with the response hand for the correct color response (*congruent* trials) or it could be inconsistent with this response hand (*incongruent* trials). To avoid feature priming (Hommel, Proctor, & Vu, 2004), colors did not repeat on adjacent trials.

Uniquely in this experiment, we parametrically varied the *degree* of response congruence on a given trial by varying the coherence of the dot motion (the % of dots moving in a given direction). Congruence was evenly sampled between 100% coherent congruence and 100% coherent incongruence, and was treated as a continuous variable in statistical analyses.

To maintain the salience of the motion dimension throughout the session, participants alternated between blocks of the task above (*color-response* trials) and blocks where participants were instructed to instead indicate the direction of motion (*motion-response* trials; cf. Schneider & Shiffrin, 1977). Mirroring color-response trials, motion coherence was held constant (maximal) during motion-response blocks, while color coherence (the proportion of one color vs. another) was varied across trials.

Procedure Participants first performed 100 motion-only training trials (0% coherent color) and 100 color-only training trials (0% coherent motion) to learn the stimulus-response mappings. During the main experiment, participants performed two types of trial blocks. During *Random* blocks, the distractor congruence varied randomly from trial-to-trial. During *Ordered* blocks, congruence linearly increased and decreased in a predictable manner (see Figure 1).

Variants Data for Experiment 1 incorporate several similar versions of this task. The main differences across versions was the number of congruence levels (mean(range) = 13.5(11-15) levels for Random blocks, mean(range) = 15.4(11-25) levels for Ordered blocks), as well as the number of trials in each block type (mean(range) = 469(300-700) for Random blocks, mean(range) = 643(300-800) for Ordered blocks). We did not find significant differences in performance across versions, nor interactions between task version and our effects of interest, and so our analyses collapse across these versions. Importantly, versions only differed in ways that should produce random rather than systematic error, potentially making our positive findings more conservative.

Results

All analyses were performed using linear mixed effects modelling in MATLAB (lmefit and glmefit). The dependent variables across analyses were log-transformed reaction time (RT) and accuracy. All models included a 'maximal' random effects structure at the participant level and intercept terms (not reported). All analyses excluded trials with RTs faster than 200ms, RT analyses excluded incorrect trials, and adaption analyses required the previous trial to also be accurate and have an RT longer than 200ms. We estimated the effective degrees of freedom with the Satterthwaite approximation for RT models, and used $(n_{Participants} - n_{Predictors})$ for accuracy models. Models were compared on the basis of Akaike Information Criterion (AIC), a goodness-of-fit metric that penalizes model complexity.

Parametric Within-trial Interference Effects Within Random blocks, we found that RT and accuracy varied linearly with our parametric manipulation of congruency (see Figure 2; Table 1). As confirmation that performance varied parametrically across congruence levels, we found that a model that treated congruence as a single continuous variable

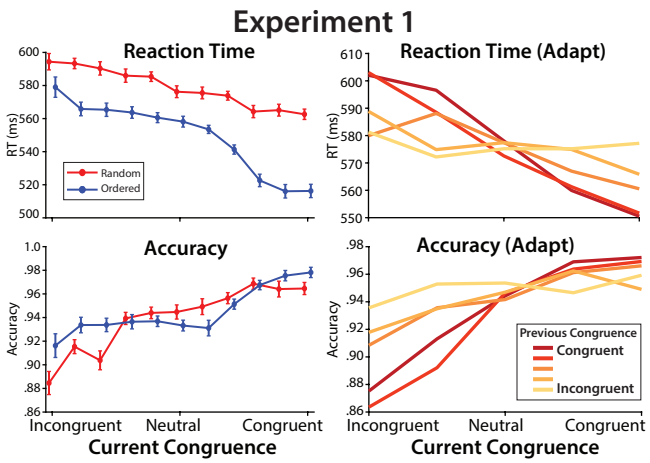

Figure 2: Left: RT (top) and accuracy (bottom) linearly depended on the degree of distractor congruency, moreso in Ordered blocks (blue) than Random blocks (red). Right: The influence of congruence on RT (top) and accuracy (bottom) linearly depended on the previous level of congruence. In all graphs, error bares indicate within-participant SEM.

fit better than a model that treated congruence as a binary variable (congruent vs. incongruent) and a model with separate congruence slopes for trials with target-compatible vs. target-incompatible coherence levels (i.e., levels of congruency vs. levels of incongruency).

Table 1: Parametric Congruence (Exp 1)
performance $\sim$ *congruence*

accuracy	cong	0.74	9.6(57)	8.2e-14

Parametric Between-trial Adaptation Effects These initial analyses suggest that we were successful in parametrically varying cognitive demands across trials. To test whether this manipulation in turn led to parametric variations in the strength of *control* allocated to the task, we tested how participants' performance changed after a trial that was more or less demanding (i.e., the 'Gratton' or conflict adaptation effect; Gratton, Coles, & Donchin, 1992). Consistent with previous findings of such adaptation effects, we found that RT and accuracy on the current trial was predicted by the interaction between the congruence of the current and previous trials, with stronger congruence on one trial predicting stronger distractor sensitivity on the next trial. Importantly, these adaptation effects were present over and above the effect of current-trial congruency and – like those within-trial effects – *also* varied parametrically (see Figure 2; Table 2).

Interestingly, we found that the previous trial's congruence alone had little influence on current-trial performance, instead modulating the degree to which performance was facilitated by or interfered with by the distractor's current congruence. When the distractor was previously more congruent (i.e., more associated with a correct response), participants incorporated more distractor information into their response; when the previous distractor was more incongruent, participants' performance was virtually independent of the current degree of congruence.

Influence of Demand Predictability on Control Allocation To determine how control adjustments changed when task difficulty was highly predictable, we compared congruence effects across Random and Ordered blocks (see Figure 2; Table 3). We predicted that participants would match their control allocation to local demands, resulting in weaker congruence effects during Ordered blocks, and better overall performance. While we found that participants were overall faster in Ordered block, they were less accurate, and we found that RTs were in fact more influenced by congruence during Ordered relative to Random blocks.

Table 3: Block Effects (Exp 1)
performance $\sim$ *block*(congruence + coherence)*

In addition to the block difference in congruence, we found that participant's performance was enhanced when there was greater distractor coherence in Ordered blocks, regardless of whether the distractor was congruent or incongruent with the target. This is consistent with participants learning to use distractor information, i.e., responding in the same or opposite direction of the distractor. In sum, the influence of distractors

on choice was enhanced when the they could be used to make accurate responses, with a stronger bias towards distractor-congruent trials. Interestingly, these effects were present in spite of most participants reporting that they had not noticed the predictability manipulation.

Relative Automaticity of Motion vs. Color Processing We designed our task under the assumption that the response compatibility of the motion dimension would make responding to it more automatic than responding to the color dimension. To validate this assumption, we tested whether these dimensions would interfere with one another asymmetrically (Schneider Shiffrin, 1977). Consistent with this prediction, we found that when participants were instructed to respond based on the motion dimension (rather than color), we did not observe any interference effects associated with the congruency of the color dimension (logRT: b = 5.9e-4, p = .33; accuracy: b = 0.031 p = .088; compare to Table 1), in stark contrast with the results reported above for color-response trials.

Discussion

Experiment 1 sheds new light on how attention is parametrically controlled based on local and long-term task demands. First, we observed that performance depends on the continuous degree of interference, supporting participants' ability to track parametric task demands and control their attention accordingly.

The second major observation from this experiment was that participants parametrically adjust their sensitivity to distracting information based on the degree of interference they previously experienced. Interestingly, we found that participants' performance was not strongly modulated by previous congruence per se, but that the previous congruence influenced distractor sensitivity. This is largely consistent with traditional conflict adaptation effects, which are commonly attributed to a controlled increase in attention towards targets following incongruent trials, which reduce the influence of distractors as a secondary effect (Botvinick et al., 2001; Egner, 2007). In contrast to these models' predictions, the effect of previous congruence was evaluated when the current congruence was neutral (0% coherence), the situation where target enhancement should should be most obvious. Our results are more consistent with changes in distractor processing than target processing.

Finally, we found that under conditions of high predictability, participants increased their attention towards distractors when they were informative (i.e., provided coherent evidence for or against a response), but with a strong bias towards distractors that provided target-congruent evidence. This observation is consistent with the literature on the proportion congruency effect (i.e., weaker congruency effects in blocks of majority-incongruent trials; Logan & Zbrodoff, 1979), originally attributed to participants' learning the predictive value of different stimulus dimensions. This strict learning account does not predict a bias towards distractor-congruent information, making our results more compatible with models that combine learning to weight different cues with adjustments based on the recent history of conflict (Jones, Cho, Nystrom, Cohen, & Braver, 2002).

In sum, these results suggest that participants controlled their attention towards the distracting dimension based on both the learned value of this cue and a bias towards congruent distractors. However, this preliminary evidence for distractor-oriented control is limited by the standard convention of only manipulating distractor congruence. To better isolate control adjustments towards targets and distractors, in Experiment 2 we manipulated the coherence of each dimension to better measure where participants controlled their attention.

Experiment 2

Experiment 2 sought to further characterize the targets of control adjustment in this task. In particular, we examined the degree to which participants adjust their attention towards targets and distractors in response to the demands associated with each dimension. We measured this by independently manipulating the coherence of both the target and distractor dimensions. By 'tagging' these different stimulus dimensions, we sought to determine where participants adjust attention. The traditional target-oriented attention account makes two key predictions: first, if distractor sensitivity is a byproduct of control towards targets (e.g., due to lateral inhibition; Botvinick et al., 2001), then the influence of target and distractor information should strongly interact within a trial. Secondly, we should find that trial-to-trial adjustments to control should primarily influence the sensitivity to the target dimension.

Method

Participants Thirty-three individuals participated in Experiment 2 for course credit or pay (Mean(SD) age = 18.9(0.45); 24 females).

Task & Procedure This task was similar to Experiment 1, except that we varied the coherence of both the distractor (motion) and target (color) dimensions. As in Experiments 1, motion coherence varied from 100% leftward to 100% rightward (11 levels of congruence). Target coherence (i.e., the proportion of dots whose color indicates a leftward or rightward response) varied from 65% to 95% (11 levels of coherence). Participants only performed Random blocks (1200 color-response trials with interleaved motion-response blocks, as in Experiment 1), with the target coherence and distractor congruence independently sampled on every trial.

Results

We used the same linear mixed effects regression approach here as we did in Experiment 1. Target coherence was mean-centered within participants to aid in interpretability.

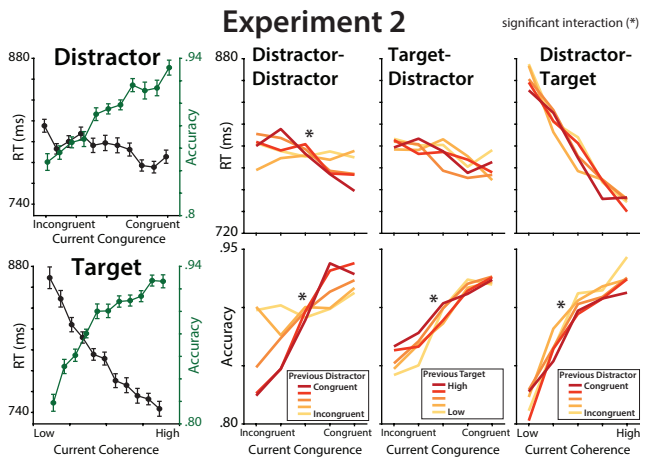

Figure 3: Left: RT (black) and accuracy (green) linearly depended on both distractor congruence (top) and target coherence (bottom). Right: Conflict adaptation was stronger and more consistent for the distractor dimensions. Asterisks indicate significant interactions.

Within-trial Effects of Target and Distractor Information As predicted, we found that performance improved with both greater target coherence and greater distractor congruence within each trial (see Figure 3; Table 4). Interestingly, these dimensions influenced performance largely independently of one another. The interaction between target and distractor information had a significant effect on accuracy ($p<0.01$) but not RT ($p=0.79$), However, relative to models with only main effects, models that included these interaction terms did not improve overall model fit for either RT (Δ AIC = 14) or accuracy (Δ AIC = 0.80).

Table 4: Target & Distractor Within-Trial (Exp 2)
performance $\sim$ *(distractor * target)*

DV	IV	β	*t*(df)	*p*

	dist:targ	-0.0038	-0.26(53)	.79
accuracy	dist	-0.46	-8.6(32)	8.2e-10
	targ	2.3	11(32)	6.1e-12
	dist:targ	-0.44	-2.8(31)	.0094

Target- vs. Distractor-Dependent Adaptation While both target coherence and distractor congruence influenced participants' performance within a given trial, our primary interest was how participants adjust attention from trial to trial. To investigate this, we measured how participants' sensitivity to target and distractor information changed as a function of the previous trial difficulty. The prediction of traditional target-oriented accounts is that previous task demands will most strongly change sensitivity to the target dimension.

We found that the previous distractor congruence strongly influenced participants' sensitivity to the current distractor congruence, replicating our parametric conflict adaption results from Experiment 1 (see Figure 3; Table 5). In contrast to traditional models, we found that the previous distractor had an inconsistent influence over participants' sensitivity to the current target coherence, appearing in the domain of RT but not accuracy. Interestingly, the previous trial's congruence had opposing effects on targets and distractors: more incongruent trials were followed by weaker sensitivity to distractors and stronger sensitivity to targets, albeit with substantively weaker adjustments to target sensitivity.

Table 5: Distractor-Dependent Adaptation (Exp 2)
$performance_t \sim distractor_{t-1} * (distractor_t + target_t)$

DV	IV	β	*t*(df)	*p*
logRT	$dist_{t-1}$	-8.9e-5	-0.03(94)	.97
	$dist_t$	-0.031	-7.2(33)	4.6e-8
	$targ_t$	-0.20	-12(32)	3.4e-13
	$dist_{t-1}$:$dist_t$	-0.028	-6.5(191)	7.3e-10
	$dist_{t-1}$:$targ_t$	-0.012	-0.26(406)	.39
accuracy	$dist_{t-1}$	-0.07	-2.1(32)	.047
	$dist_t$	0.41	8.1(32)	3.4e-9
	$targ_t$	2.3	11(32)	3.2e-12
	$dist_{t-1}$:$dist_t$	0.46	7.6(31)	1.5e-8
	$dist_{t-1}$:$targ_t$	-0.39	-2.1(31)	.043

We also tested a model where the previous target coherence could influence sensitivity towards the current target and distractor (see Figure 3; Table 6). We found, again, no evidence in reaction time that previous target coherence influenced the current target or distractor sensitivity. However, in accuracy we found that weaker previous trial target coherence predicted a stronger reliance on distractor information on the next trial, with no change to the reliance on target information.

Table 6: Target-Dependent Adaptation (Exp 2)
$performance_t \sim target_{t-1} * (distractor_t + target_t)$

DV	IV	β	*t*(df)	*p*
logRT	$dist_t$	-0.031	-7.2(32)	3.0e-8
	$targ_t$	-0.20	-12(32)	3.7e-13
	$targ_{t-1}$	-0.011	-0.98(32)	.34
	$targ_{t-1}$:$dist_t$	-0.0028	-0.18(37)	.86
	$targ_{t-1}$:$targ_t$	0.038	0.73(43)	.47
accuracy	$dist_t$	0.42	8.5(32)	1.2e-9
	$targ_t$	2.3	11(32)	2.9e-12
	$targ_{t-1}$	0.12	1.1(32)	.28
	$targ_{t-1}$:$dist_t$	-0.41	-2.5(31)	.012
	$targ_{t-1}$:$targ_t$	-0.12	-0.22(31)	.83

Overall, target- and distractor-dependent adaptation seem to support a similar mechanism, in which the response-relevance of a dimension modifies the extent to which it is subsequent used for choice, with a strong bias towards modifying the distractor dimension. When the target dimension is incongruent with the response, participants are subsequently more influenced by target and less influenced by distractors. When the target provided weak evidence for the response, participants were subsequently more sensitive to distractors.

Discussion

Experiment 2 replicated the within- and between-trial congruence effects observed in Experiment 1. Critically, Experiment 2 also provided unique evidence in favor of distractor-oriented attentional control in this task.

Within trials, we found that both target and distractor information influenced task performance, there were only weak interactions across dimensions. This runs counter to the predictions from models that posit competitive interactions between the processing of targets and distractors, in which distractor sensitivity changes as a byproduct of target-oriented control (Botvinick et al., 2001; Egner, 2007).

Across trials, we found that adjustments to control primarily acted on distractors, in contrast with traditional models of conflict adaptation. When the previous trial was difficult, participants suppressed distractors if the difficulty was due to incongruent distractors, and enhanced distractors if the difficulty was due to low-coherence targets. It is notable that the latter effect of distractor enhancement appeared to be specific to accuracy, whereas the suppression effect was observed in both speed and accuracy. Whether these reflects different forms of control adjustment (e.g., related to evidence accumulation versus response threshold) demands further investigation with models that can distinguish these processes (e.g., the drift diffusion model).

In addition to these distractor adjustments, we also observed adjustments to target sensitivity in one condition (distractor-dependent adaptation effects in accuracy). However these adjustments to target processing were very subtle, compared to the strong and reliable adaptation effects observed for the distractor dimension, and could plausibly represent a byproduct of these dominant adjustments to distractor processing.

General Discussion

We developed a novel task aimed at examining parametric adjustments of control towards targets and distractors. Across our two experiments, we found consistent evidence that participants parametrically controlled their attention towards distractors based on the recent history of task demands. In Experiment 1, we found that participants adjusted their sensitivity to distractor congruence based on both whether distractors could predict the accurate response, alongside the bias towards congruency predicted by conflict monitoring. In Experiment 2, we narrowed down the sources and targets of this process of control adaptation. We found that participants adjusted attention towards distractors much more than they did towards targets. Together, these results provide strong confirmation for many aspects of existing models of cognitive control, while challenging models that propose unbiased or target-oriented attentional control.

Our experiments leave open the question of why participants would be biased towards distractor-oriented attention. One reason for this asymmetry may due to a primacy for inhibition in cognitive control, exemplified by the well-characterized 'hyperdirect' control of striatal decision-making (Wiecki & Frank, 2013) and the common inhibition factor found across several executive control tasks (Friedman & Miyake, 2017). This may describe why it is easier to (dis)inhibit attention towards distractors, rather than enhance attention to targets, but offers little explanation for *why* there is this preference for inhibition. Another reason for our asymmetry may be that our distracting motion dimension, like many distractors, is easier to control because of its salience. Insofar as attention control requires some form of feature selection, it may be easier to select a distractor's stimulus features to act upon. Finally, this experiment cannot rule out that there is something about motion *per se* that makes it easier to control. Future experiment should test the robustness of these results across multiple stimulus domains and forms of congruence before making more provocative conclusions about the nature of cognitive control.

Abstract

We provide a definition of 'memory' that is broad enough to apply to both natural and artificial systems. Inspired by computation and information theory, we define memory as a process that preserves information through time while maintaining its usefulness as an object to be computed. We defend the extensiveness of our definition by explaining how it applies to both brains and modern computers. We then consider potential objections to our definition. Our primary goal is to provide a definition of 'memory' that is broadly applicable across various cognitive sciences subfields.

Keywords: memory; computation; representation; information

Introduction

Memory is a central topic within the cognitive sciences and its various contributing disciplines, such as computer science, neuroscience, and psychology. One likely reason for this is its centrality to various conceptions of cognition. Be it brains or modern computers, memory typically plays a central role. However, it is often unclear if 'memory' is used the same across contexts. What is apparent, however, is the efficacy of computational theory in the cognitive sciences. Given the successes computational theory has provided the study of cognition, and given that memory is central to computation, it follows that a computationally-inspired approach to memory can provide useful insights into the general nature of memory. As such, it is necessary for us to explicate the relevant features of information and computation before discussing our definition of memory.

We begin with Piccinini and Scarantino's (2011) definition of 'computation' as the processing of objects according to rules. Next, we connect that definition to Gallistel and King's (2010) interpretation of Shannon's classic information theory—that is, the reduction in uncertainty regarding the properties of an object—in order to show how computation allows for useful decisions about the world to be made. We then discuss some of the properties necessary for effective information processing and generic computation that describe modern computers, which may also be usefully applied to descriptions of brains as well. We pay special attention to the topic of representation. The ability of the definition to allow for determination of the boundaries of a computational system's memory are examined. Finally, we present and respond to some potential critiques of the definition.

The definition these claims and terms are applied to is as follows: *Memory is a process that carries information forward in time, preserved in a fashion that maintains its usefulness as an object to be computed for the system to which the memory is said to belong*.

Defining Computation and Information

Before presenting our definition of 'memory,' we must first establish definitions for 'information' and 'computation.' We begin with information because, as will be discussed below, computation does not necessarily need to involve information—though it can be more useful when it does. Gallistel and King relate Shannon's definition of 'information' as originating from a source, undergoing a process that 'encodes' the information into a 'signal,' and traveling to a receiver that 'decodes' the signal to derive a 'message' from it (2010, p. 2). The amount of information contained by the signal is determined not only by the signal, but by the receiver as well. The following example will make these points more evident.

Suppose an unseen coin is flipped and you are told, as a hint, that it might be heads or tails. You most likely already knew that and are wondering if this is really a hint at all. This highlights two important criteria for evaluating a signal's informational content: First, a signal must be selected from a possible set of signals. How much information has been transmitted regarding an object depends on how the range of possible object states has been affected. The hint you received does not affect the range of possible outcomes from the coin flip, and thus holds no information. Second, the relative probability of the possible states under consideration plays an important role in evaluating the quantity of information transmitted. A coin is not a truly two-

dimensional object. There is a small possibility that it has landed on its side. The hint you received actually has some informational content, it is just small because the eliminated state is unlikely. Note that Shannon's definition of information does not restrict the types of objects and states that it describes. It may be something as quantitative as numerical data. Likewise, it may be something difficult to quantify numerically, such as the emotions of another. The key point is that there is a spectrum of possible properties and that the signal reduces their domain.

Computation invokes many concepts similar to information. In fact, as Piccinini and Scarantino point out, computation and information processing are often mistakenly held to be synonyms (2011, p. 3). We utilize Piccinini and Scarantino's definition of computation in general: "We use 'generic computation' to designate the processing of vehicles according to rules that are sensitive to *certain vehicle properties* and, specifically, to differences between different portions of the vehicles" (2011, p. 10; italics added). In the case that these vehicles are signals containing information, information processing *is* a form of computation as just defined. However, not all computation involves the processing of information. Informational content is not an intrinsic property of an object. It is relative to an observer and depends on how much the message reduces the observer's uncertainty (Gallistel & King, 2010, p. 7). Consider a computation that outputs 'cuidado' if the input is 'el horno esta encendido' and provides no output if the input is 'el horno esta apagado.' To an English-only-speaking observer, this computation does not process information—the objects have no meaning. But to a Spanish-speaker, this cautions them that the oven has been switched on. The computation performed is the same, regardless of the observer. Even if Spanish is forgotten, and the computation's objects cease to be meaningful to *anyone*, it is still the same computation. Thus, computation does not necessarily process information.

This definition of computation is clearly quite broad. It is so broad, in fact, that some philosophers believe that such an understanding of computation implies that everything performs computation, that is, 'pancomputationalism' (Piccinini & Scarantino, 2011, p. 5; cf. Chalmers, 2011; Copeland, 1996). It may be true that one could pick just about any physical phenomenon and find an arbitrary function that it computes (e.g., a rock; Chalmers, 1996). For "computation" to be a useful concept regarding research on cognition—such as memory—in the cognitive sciences, its scope must be appropriately pared down.

Recall that, based on the above definition, a computation is only sensitive to *certain* properties of objects, not necessarily all of them. A function that determines whether or not a neuron fires may only be sensitive to the firing/pre-firing properties of other neurons. Any additional physical variables are irrelevant to the purposes of the computation at hand, namely, modeling the dynamics of single-neuron activity. Pancomputationalism draws attention to the worry that "computation" may be a meaningless concept in research if it does not refer to some finite range of properties (or messages) that determine the results of the computations carried out by some system. In other words, its properties must have informational content that are relevant to the system.

With these conceptions of information and computation at hand, we can present a way to understand how they are present in the brain. Various brain processes can be usefully understood as computational, for example, the brain's ability to draw conclusions (Gallistel & King, 2010, p. 59). Consider the recognition of an image containing text (Figure 1). The optic nerve transmits visual stimuli to the brain, but it does not interpret the text's meaning. This is the role of a different portion of the brain. In this process there are signals (i.e., visual stimuli) that come from a set of possible messages (i.e., one image is distinguishable from another), which can be understood as processed in accordance to a set of rules that are sensitive to the signal's properties (i.e., the shape of the image is that of a word, and the word has meaning independent from the image). Here we have all the characteristics of computation being used to process information.

An important point to address is that of representation. In our discussion of information, we spoke of it as being encoded. In other words, it is represented within a certain syntactic structure. This encoding is what allows for reliable interpretation of the signal's contents. Modern computers contain a type of software called a "driver." Each driver instructs the computer how to interface with a certain type of peripheral device, such as a mouse or external hard drive. Despite the fact that both of these devices can communicate via a universal serial bus (USB) connection, the computer must use a very different set of rules when interfacing with a mouse than with a hard drive. Similarly, a computational description of the brain must refer to some syntactic structure when describing how the brain processes its signals. However, not any syntax will suffice. Both brains and computers are faced with a tremendous variety of possible objects to represent. A much simpler device than the brain is the TI-84 calculator. The largest number it can represent is approximately 10^{100}. If it was forced to have a unique character for each value, the number of unique characters would exceed the number of atoms in the known universe. The calculator avoids this conundrum by constructing its representations from a small number of symbols (i.e., 0/1 for binary, 0-9 for its decimal display) in a way that is sensitive to their relative positions. Similarly, the English language is represented through the use of twenty-six visual symbols (i.e., the alphabet) and forty-four audible symbols (i.e., phonemes) in a syntax that is sensitive to their relative positions in space and time respectively. All of these methods of representation are "compact," that is, the resources required to construct a representation grow logarithmically as the range of possible messages increases (Gallistel & King, 2010, p. 76). If even the humble TI-84 requires a robust syntax capable of compact representation, it follows that any

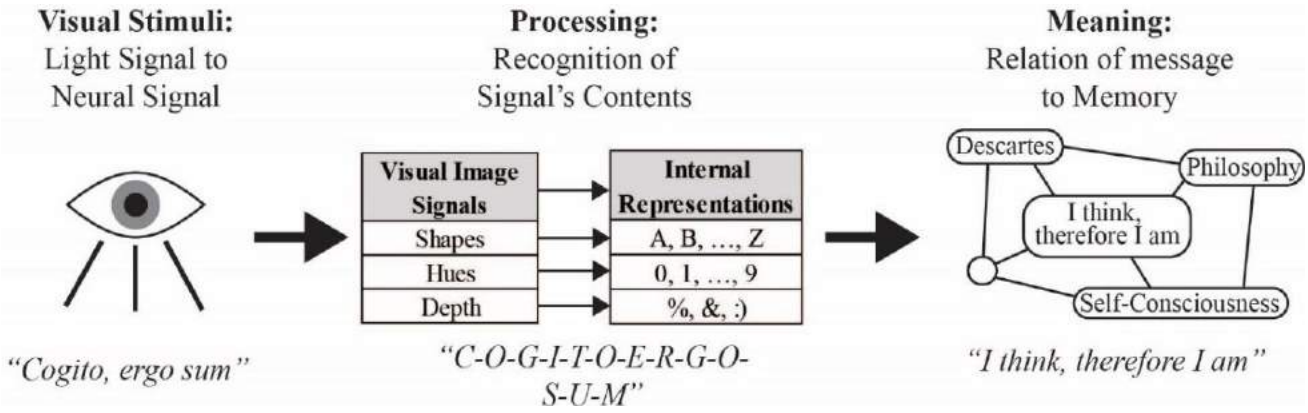

Figure 1: Reading text as the computational processing of information.

syntax that the brain may possess must also be capable of compactly representing the tremendous variety of messages it encounters (Gallistel & King, 2010, p. 82).

Like binary or decimal, the brain's syntax must be capable of constructing representations from a fairly small selection of basic elements. Otherwise, the incredible variety of sensory stimuli and the brain's practically unlimited creative capacity cannot feasibly be represented. These basic elements need not be numerical, and they need not be universal throughout the brain. Different portions of the brain perform different functions, and different syntaxes may be used. There will need to be commonalities between regions that facilitate their interaction, but there may be specialized computations (e.g., facial recognition, speech comprehension, etc.) that take place within regions. These computations might use a specialized syntax internally but use a shared syntax for computations that interact with other portions.

Having discussed computation, information, and representation, as well as what they mean in both the contexts of modern computers and the brain, we now move on to address how these ideas relate to memory and the role memory plays in the aforementioned contexts.

Memory in Computers and Brains

The property that distinguishes memory from other information-carrying signals in a brain or computer is its persistence through time. A fundamental requirement for a signal to be informative is that it is selected from a set of possible messages. There must be some way for this domain of possible messages to be established. When the layman enters an airliner cockpit, the array of dials and knobs are quite mysterious. To a trained pilot, each item denotes a meaningful piece of information. They know if an instrument's reading is alarming or typical. They know this because of their prior experience—information which was presented to them in the past and has persisted. In other words, their memory. Memory is the process that establishes the informational content of new signals.

Memory plays the same role in a modern computer. Without memory, a computer's only information regarding its past is that which is implicitly contained within its current state. As a result, whatever computation it performs must capture every relevant aspect of the computer's current state in order to determine the next state. Computers are often called upon to perform complex tasks that are combinations of a few basic functions (Gallistel & King, 2010, p. 109). Without a compact method for storing and preserving the results of past steps, any practical computation requires an absurdly large number of bits to define its state. Each instruction in a computer's program would have to shepherd hordes of bits. Suppose an instruction were as simple as providing a 1 (ON) or 0 (OFF) for each pixel in a display. To control every pixel of a typical 1080p resolution display, such an instruction would require *two million* bits. For comparison, modern central processing units (CPUs) typically use a humble sixty-four bits for their instructions. For a computational system to deal with these sorts of situations, a system is needed that has accessibility to the information contained in previous states as well as current—memory is needed (Gallistel & King, 2010, p. 131).

How does our definition of memory tackle this issue? In a modern computer, a CPU is the device that actually carries out most of the computations. In order to be able to perform computations quickly, it does not capture all of the information that it needs to perform all of its functionality within itself. If a CPU modifies an image, one cannot look at the CPU a few seconds later and determine how or what modification it performed. Instead, the CPU stores the image in a memory device to be retrieved later as needed. Later, when it needs to use the image in a computation, it calls upon the memory, which loads the image into the CPU. This transfer of bits constitutes a message to the CPU that informs it of the image's contents. The key point is that this is done without repeating the initial computation that resulted in the memory's message. Without the ability to call upon this *persistent information*, a modern computer would be as

cumbersome as a pilot that has to be retrained for dial-reading every time.

Despite the similarity in the role of memory in brains and modern computers, there is a much greater degree of plasticity in the execution of the brain's memory processes. In certain environments, the way the brain remembers events can be highly vulnerable to suggestion (Loftus & Palmer, 1974, p. 588). This supports the idea that memory plays a role in establishing the informational content of new signals and highlights the dynamic nature of the brain's syntax. In Loftus and Palmer's experiment, use of the verb 'hit' versus 'smash' served to alter the subjects' syntax by priming them to think in certain terms. This in turn changed the message they obtained when they referenced their memory regarding the presence of broken glass at the scene of an accident. In this way, our definition addresses the inconsistency of the brain's memory—the syntax being used to interpret the stored information is constantly changing. These changes need not result in an insensible message. Rather, they result in a new interpretation. This differs from modern computers, where even slight changes in syntax can cause total malfunctions.

Explicating the neurobiological processes underlying memory in brains is not necessary for our project. The scope of our definition is readily understood in terms of Marr's three levels of description of information-processing systems (Marr, 1982/2010, p. 24). The first and most abstract level is the *computational theory*, which establishes the general feature of the system being investigated, such as vision, language, or memory. Next, is the *representation and algorithm* level, which describes the procedures for achieving said system feature. The final level is *hardware implementation*, which is concerned with the physical substrate forming the representations and carrying out the algorithms. In terms of explanatory strategies, these levels can be investigated individually. From this perspective, our definition is appropriately understood as working in the first two levels. Although we aim for our definition to be applicable to real systems, we leave work of explicating its physical implementation to others.

For our purposes, we merely note that if our definition of memory is appropriate for the cognitive sciences, then it can guide research that successfully identifies brain regions and processes that facilitate the kind of persistent information seen in modern computers as sketched above (cf. Srimal & Curtis, 2008). If our definition is incorrect, then there will be no empirical evidence of such persistent information. This follows from one consequence of our definition, namely, that in both the brain and in modern computers, memory serves the role of preserving information and establishing the possible set of messages from which new signals arise. In the next section, we explain how our definition of memory provides a way to delineate boundaries around the system in which memory occurs.

The Boundaries of Memory

For a memory to be computationally useful in the system it belongs to, a consistent syntax must be utilized during the encoding process—that is, preservation and representation—of signals. For example, the alphanumeric symbol '6' must always denote the quantity six, and not three or four. This stipulation helps establish who or what a certain memory belongs to. The boundaries of the physical system that consistently realizes a computational system's syntax then defines the boundaries of its memory.

As discussed earlier, a computation is sensitive to some properties of an object but not necessarily all. Specifically, it is reactive to particular forms of content, that is, information. When this computation handles information, the rules of its sensitivity must match up to the syntax in which the information is represented. This feature allows one to determine what contributes to a computational system's memory or not. In order to be memory, a process must not only carry some physical state forward in time, but the state it preserves must be preserved in accordance with the syntactic structure of that to which the memory is said to belong.

Modern computers possess a set of memory addresses, much like a set of street addresses in a neighborhood, that they have access to. Proper usage of these addresses is part of the syntactic structure of the memory process. Searching for an address outside of this range causes the memory process to malfunction. The signal the computer finds with such an address might be encoded using a different syntax, or there might not even be a physical signal present. Either way, if the sought signal is not represented in accordance with the syntax of the memory it is trying to find, it is not a part of the computer's memory. The signals found may inform the computer, but the information will not be accurate.

In many natural and artificial systems, it seems obvious where to draw the boundaries of—at least some of—their memory systems, for example, a human's hippocampus and a laptop's hard drive. In such cases, the syntax used by the computations are consistently applied only within the physical brain and hard drive. Accordingly, such memories are realized within an individual body or casing. With that said, our definition of memory is not a priori confined to brains and hard drives. As long as such features as information preservation and consistent syntax are maintained, the boundaries of memory systems are potentially quite broad. Though we aim here to apply our definition of memory to more traditional work in the cognitive sciences, we leave open the possibility of applying it to cases such as distributed cognition (e.g., shared remembering by couples; Harris et al., 2014) and cultural transmission (e.g., Rowlands, 1993).

The possibility of distributed or extended memory systems should not be controversial. A removable USB storage stick is external memory for any modern computer with a USB port and appropriate software. The memory is only available

when the stick is plugged in, but a large number of different computational systems can all potentially access it. A written grocery list is external memory available to anyone who finds the list and can read the language it is written in (cf. Wagman & Chemero, 2014). The exact message the list presents will vary based on the individual's own internal memory—recall that the informational content of a signal is determined by the observer. Nevertheless, it is information carried forward in time. As long as the list's characters and words represent the intended message in a manner consistent with the reader's understanding of the language, the list can function as contributing to an external memory system.

We have attempted to show that our definition of memory is applicable to both narrow conceptions of cognition (e.g., isolated in brains), as well as more widespread notions (e.g., distributed cognition). Given that we discuss memory in terms of information processing, it is likely that the type of proponent of narrow conceptions who would readily accept our definition are those who think embodied, extended, and distributed cognition are still computational and representational in nature even if cognition is not isolated in brains (e.g., Barsalou, 2008; Hutchins, 1995; Wilson, 1994). On the other hand, it seems far less likely that anti-computational and anti-representationalists regarding cognition would accept our definition. We provide reasons why proponents of more "radical" conceptions of cognition could accept our definition by presenting experimental work involving affordances and memory.

Affordances are opportunities for behavior, and are based on the properties of the organism and environment (Gibson, 1979/1986). A doorway, for example, affords passing through for a human with narrow enough shoulders. Experimental work involving affordances stem from Gibson's ecological psychology (1979/1986). Contrary to representational approaches to perception, Gibson and his proponents argue that perception-action is not properly understood as centering on indirect representations. Visual perception, for example, is not a matter of an organism generating a mental image of the world, but instead is about an organism directly perceiving opportunities the world affords it.

Experimental work on affordances and memory have motivated conceptions of memory that do not appeal to computations or representations of the kind ecological psychologists and their proponents have resisted (e.g., Thomas & Riley, 2014; Vicente & Wang, 1998). Boschker, Bakker, and Michaels (2002), for example, conducted a set of experiments on the visual perception of climbing walls by experts and novices. When asked to recall information concerning the locations and orientations of holds on climbing walls, results suggested that experts can recall more information, clusters of information, and focus on functional aspects of walls (i.e., affordances); whereas novices did not recall clusters and focused on the structure of walls and not their functionals aspects. Boschker et al. argue that their findings show that differences in skill level correspond to differences in visual perception and memory. A central finding is that experts have memory that is better and of a more functional nature because they have more experience of perceived action possibilities than novices. In other words, their increased recall is tied to their increased perception of affordances. Note that this work does not appeal to computations or representations. Yet, our definition still applies: Experts have better task memory because the "information" relevant to action capabilities carries forward in time over the course of experience, and it does so in a manner that maintains its usefulness (i.e., affordance) to be "computed" (i.e., used) by the system (i.e., climber) for which the information belongs. The relationship between our definition and non-computational and anti-representational conceptions of cognition requires further fleshing out. However, we have attempted to demonstrate that the areas are not necessarily mutually exclusive. Having presented our definition of memory and discussed related issues, we now respond to several critiques.

Criticisms of a Computation-Based Definition

The appropriateness of utilizing our definition of memory in the cognitive sciences is contingent on the notion that it is explanatorily fruitful to describe the brain as performing computations. Computational approaches in the cognitive sciences are not without challenge. One source of opposition stems from forceful arguments claiming that phenomena investigated in the cognitive sciences are in no substantial way "computational," that is, "rule-governed manipulations of internal representations" (van Gelder, 1995). Therefore, our understanding of brains and cognition are set back by assuming they are like computers (Barrett, 2012). Another challenge centers on the claim that the prevalence of computationalism results from the prominent role of computers in modern society. Like other metaphors that were popular during their time, so too will the mind-as-computer metaphor pass (e.g., hydraulic pump, steam engine, etc.; Marshall, 1977). A third challenge is that many concepts underlying computational approaches have long and storied histories of imprecision. For example, many definitions of 'memory' now seem outdated in light of further technological advancement (Roediger, 1980). Addressing those challenges is far beyond the scope of the current work. Here, we respond to these criticisms in order to motivate the claim that complete rejection of a "computational" approach in the cognitive sciences is ultimately unwarranted.

First, unlike artifacts such as clay tablets or conveyor belts, computational theory is a set of formalized principles that are independent of any particular physical realization (Gallistel & King, 2010, p. 105). Computational theory becoming obsolete would be more akin to the obsolescence of calculus than that of the cellular phone. Computation is a field of mathematics, not a transient technology. While it is possible that computationally-based theories could be supplanted by

non-computational ones (e.g., Chemero, 2011; Edelman, 1993; Kelso, 2009; van Gelder, 1995) for explaining all forms of cognition, such a shift would likely occur due to conceptual, methodological, and theoretical advances in the cognitive sciences, and not due to a technology's life-cycle.

Second, appealing to computational theory to investigate memory in both brains and computers does not necessitate that both compute digitally or numerically, or that their objects are both numeric or symbolic. Computational theory, in the form we appeal to, is consistent with identifying both modern computers and brains as "computational," even if the objects being computed differ. This is because what matters more than the realizers of particular processes is the syntax. Because modern computers manipulate digital objects (i.e., binary '1s' and '0s'), they are readily able to handle syntax involving computations of large digits, such as multiplication and division. Human brains, on the other hand, may not explicitly manipulate digital objects, which could account for the difference in speed of calculation. Specifically, brains may manipulate analog objects, which may not be as fast at processing syntax involving calculations of discrete numerical values. This would serve to explain why brains and modern computers have a different set of strengths and weaknesses and are better suited for performing different kinds of computation that are computations nonetheless.

A third reason to consider computation in some form is to appeal to the primary motivation for the cognitive revolution, namely, the need to posit "internal" states to more fully account for some kinds of cognition, action, and perception (Gardner, 1985). To be more precise, those cognitive capacities that occur without externally observable processes, for example, predicting and learning. Cognitive systems can make accurate predictions following very complex causal chains. An electrical engineer can look at a wiring diagram and tell what will open a certain contact without interacting with the real circuit. A complete explanation of this capability implies some internal process for simulating events and evaluating them according to a syntax. Cognitive systems can learn to perform behaviors without actually doing them. If a hobbyist reads an article on how to solder a wire before attempting for first time, they will certainly do better than if they had tried with no prior study. From these examples we do not further claim that cognitive systems are not embodied, that learning via action is likely necessary during developmental stages, or that physical practice improves abilities. Yet, such examples motivate the need to appeal to internal processes to fully explain some cognitive phenomena. In some cases, the most parsimonious explanation for these capabilities is the presence of internal representations and rules for consistent execution. All of this suggests that appealing to some form of computation to explain certain cognitive phenomena is well-motivated.

If we are correct that at least some cognitive capabilities (e.g., memory) are appropriately explained via internal processes of some sort, then the nature of how those processes represent must be accounted for as well. Although a tremendous deal of research and effort has gone into mapping and studying brain activity, there is yet to be evidence of a discernible syntax. This could be seen as evidence against computation in the brain. However, this may be a case of a lack of evidence not being evidence of absence. Gallistel and King explain that the more efficient and robust an encoding scheme is (i.e., representation), the less it resembles its message (2010, p. 4). The sheer variety of stimuli the brain is presented with suggests that its syntax would be extraordinarily complex, far more so than binary (e.g., neurons as on-off switches). Additionally, recall that it is not necessary for these representations to be discrete *or* numerical in nature. They might not even be expressible in terms of language. The brain has been produced by natural selection, not a highly-organized team of computer scientists. As such, there is no reason to believe that any criteria other than effectiveness for survival and reproduction has played a role in its development. There has been no force in natural selection pushing the brain's representations to be legible to outside observers. With all this in mind, it is no surprise that the brain's syntax remains a mystery.

The definition of memory posited in this paper proposes a broader definition of computation and representation than are typically applied to the brain. It also does not propose computation as an explanation of brain structure and function. Rather, it appeals to computation to describe memory processes. The aim of this is to enable a discussion that escapes some of the limitations traditionally associated with computationalism. This paves the way for the utilization of computation as a descriptive tool without rejecting other accounts of cognition (e.g., dynamical). While some systems are better explained by either computational or dynamical models (van Gelder, 1995), others benefit from the use of multiple explanatory strategies (Favela & Chemero, 2019). Depending on the goals at hand, one model may be preferable to another, and it is possible that neither can give an all-encompassing account of the system. Here, we are chiefly concerned with defining what memory is, and not the computations or dynamics that explain how it is realized in systems.

Conclusion

We have presented and defended a definition of memory. We began with Gallistel and King's (2010) formulation of Shannon information and highlighted the feature of observer dependence. We then presented Piccinini and Scarantino's (2011) broad conception of computation as the processing of objects according to rules sensitive to certain properties of those objects. Computational systems are distinguished from one another based on what properties they're sensitive to. If the objects being processed are signals with informational content, then the computational system processes information. Both the brain and modern computers can be described as such systems. Casting memory in terms of

computation and information effectively describes memory as playing a role in establishing the meaning of new signals, that is, determining their informational content. The rules according to which these messages are interpreted are their syntax. In order to accommodate the wide variety of messages they represent, both the syntaxes used by brains and computers should be compact, that is, the resources required for representation should grow only with the logarithm of the number of possible signals. Having specific syntax for the purpose of carrying information forward in time allows for delineating boundaries around memory systems. We referred to ecological psychology's concept of affordances in order to illustrate that our definition is not necessarily incompatible with non-computational and anti-representational conceptions of cognition. We defended our use of computation as a tool for describing brain processes. Despite its challenges, computation's status as a set of formalized principles, as well as the ability of representations to serve as a succinct explanation of certain cognitive phenomena, make it well-suited for use as a descriptive tool. By limiting our use of computation to the *description* of memory, we remain nonpartisan as to the methods suitable for explaining its realization. As such, the following definition of memory is broadly applicable across the cognitive sciences: *Memory is a process that carries information forward in time, preserved in a fashion that maintains its usefulness as an object to be computed for the system to which the memory is said to belong*.

Asking goal-oriented questions and learning from answers

Anselm Rothe[1], **Brenden M. Lake**[1,2], **and Todd M. Gureckis**[1]
[1]Department of Psychology, [2]Center for Data Science, New York University

Abstract

The study of question asking in humans and machines has gained attention in recent years. A key aspect of question asking is the ability to select good (informative) questions from a provided set. Machines—in particular neural networks—generally struggle with two important aspects of question asking, namely to learn from the answer to their selected question and to flexibly adjust their questioning to new goals. In the present paper, we show that people are sensitive to both of these aspects and describe a unified Bayesian account of question asking that is capable of similar ingenuity. In the first experiment, we predict people's judgments when adjusting their question-asking towards a particular goal. In the second experiment, we predict people's judgments when deciding what follow-up question to ask. An alternative model based on superficial features, such as the existence of certain key words in the questions, was not able to capture these judgments to a reasonable degree.

Keywords: Bayesian modeling; active learning; information search; question asking

Introduction

The ability to ask questions is a core quality of human cognition. By asking questions, we can actively seek out information that helps us learn about the world and achieve our goals. Skilled question asking involves the ability to adjust questions towards a particular goal as well as a sensitivity to the context, including what was previously asked.

In contrast, machines have difficulty capturing these aspects of human inquiry. Recent work with neural networks has made progress on generating sensible questions about images, such as "What caused this accident?" for an image displaying a crashed motorbike lying on the street (Mostafazadeh et al., 2016; Jain & Schwing, 2017), or about passages of text (Du, Shao, & Cardie, 2017). Such questions can initiate a conversation between human and computer, however these networks are not able to make sense of any answer they might get to their question. As an intermediate solution, neural networks have been trained to predict the answer to their own questions (Johnson et al., 2017). Another ambitious approach has been to train neural networks end-to-end on entire sequences of questions and answers (Lee, Heo, & Zhang, 2018; Strub et al., 2017). However, the networks still learn a fixed question asking strategy and cannot adapt to new goals that were not included in the training regime.

Unlike neural network approaches, people can flexibly adapt their questions based on their goals and the answers they have received. Previous work has looked at how people ask questions based on specific goals (e.g., Graesser, Langston, & Bagget, 1993), or ask follow-up questions (e.g., Nelson, Divjak, Gudmundsdottir, Martignon, & Meder, 2014; Ruggeri, Lombrozo, Griffiths, & Xu, 2016), but little modeling work has been done to test these aspects directly in naturalistic tasks. Here, we study an intuitive question asking task amenable to formal modeling. By systematically manipulating core components of question asking such as goals and previously asked questions, we can compare people's behavior to an ideal observer in a more naturalistic question asking environment. For this purpose, we extend the computational framework by Rothe, Lake, and Gureckis (2018) to handle these facets of flexible question asking.

In the next section, we will introduce the question asking environment, followed by the computational framework and its extensions. We then report two experiments, in which we test people's ability to identify question quality under changing goals (Experiment 1) and after being provided with answers to previous questions (Experiment 2). Finally, alternative models are discussed.

Battleship game environment

We adopt the Battleship task used by Rothe et al. because it enables intuitive question asking for people while still being amenable to formal modeling. In the Battleship task, participants try to discover geometric shapes (i.e., battleships) on a grid (i.e., game board). These ships have varying shapes, colors, and locations (Figure 1). In our setting, there were always exactly three ships on a 6x6 board and each ship got a unique color from the set {blue, red, purple}. Each ship is a rectangle with a width of 1 and a length sampled from the set {2, 3, 4} and its orientation is sampled from the set {horizontal, vertical}. Each ship is randomly placed on the grid, ensuring they do not overlap.

In our experiments, participants face a partly revealed game board, together with a set of natural-language questions that could reveal more information about the board. Participants rank order these questions by quality taking either a particular goal or an already-answered question into account (Figure 2).

Modeling

We develop a Bayesian ideal-observer model of the task, as used in prior work, and discuss extensions to handle goals and previously answered questions.

Bayesian-ideal observer model

What does the hidden game board look like? The player begins with maximal uncertainty about the game board, modeled as a uniform prior belief distribution $p(h)$ over all possible game boards. Then, the player updates this prior via Bayes rule based on the information d presented by the partly revealed game board,

$$p(h|d) = \frac{p(d|h)p(h)}{\sum_{h' \in H} p(d|h')p(h')}, \quad (1)$$

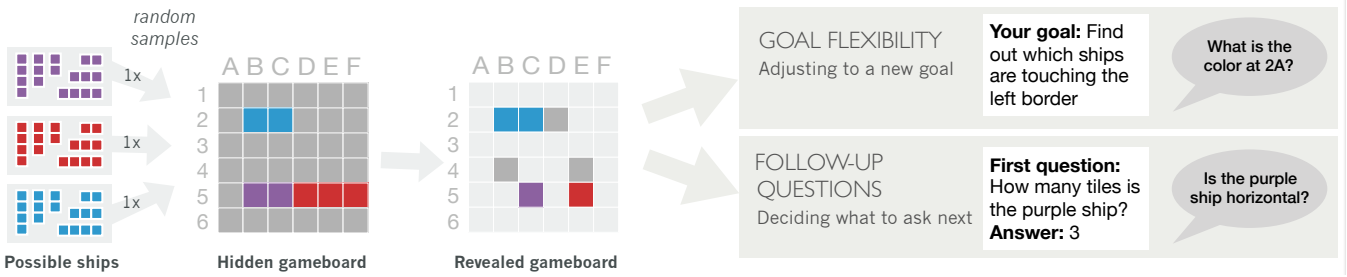

Figure 1: In the Battleship task, three ships are randomly positioned on a game board. The color at each location indicates a ship (blue, red, or purple) or water (dark gray). Participants view a game board that only shows some tiles revealed and many tiles yet unknown (light gray). They can then ask questions to obtain more information. Can people adjust their questions towards specific goals (Experiment 1)? For example for the game board shown above, when the goal is to find out which ships are touching the left border, a question targeting the color of tile 2A would be more useful than the question whether the red ship is horizontal. Do people adjust their questions based on already-answered questions (Experiment 2)? For example, after learning that the red ship is three tiles long, participants might be inclined to keep asking questions about the red ship before addressing the other ships.

where H is the hypothesis space of 1.6 million game boards and $p(d|h)$ the likelihood function, which is 1 if d is consistent with board h, and otherwise 0. The player can now ask a question x to learn more. The answer to the question is assumed to come from an oracle that knows the hidden game board and answers truthfully. We use d again as the label for the answer since it plays the same role as the partly revealed game board before. The likelihood function is again 0 if answer d is inconsistent with board h. Otherwise it is $\frac{1}{n}$, to account for cases where there is more than one valid answer, from which the oracle then chooses uniformly. For instance, for the question "What is the location of one purple tile?" the oracle would indicate the location of one of the n purple tiles on the true game board. Usually though, in our setting there is only one valid answer, $n = 1$ (e.g., yes or no). We now generalize to include the history of previous questions X and their answers D, resulting in

$$p(h|d,D;x,X) = \frac{p(d|h;x)p(h|D;X)}{\sum_{h' \in H} p(d|h';x)p(h'|D;X)}, \qquad (2)$$

where the semi-colon notation indicates that x and X are parameters rather than random variables (for the first question, X and D are empty).

In preparation for the next section, we can compute the posterior predictive probability that d will be the answer to question x via

$$p(d|D;x,X) = \sum_{h \in H} p(d|h;x)p(h|D;X). \qquad (3)$$

Expected Information Gain (EIG)

The player's uncertainty about the hidden game board is measured by the Shannon entropy of the belief distribution (Shannon, 1948; see Crupi, Nelson, Meder, Cevolani, & Tentori, 2018, for a discussion of alternative measures). The Information Gain (IG) of a question x is then defined as the amount by which this uncertainty is reduced when receiving answer d. Since the player does not know the answer at the time of asking, we compute an expected value:

$$\begin{aligned} EIG(x) &= \sum_{d \in A_x} p(d|D;x,X)\Big[I[p(h|D;X)] - I[p(h|d,D;x,X)]\Big] \\ &= \mathbb{E}_{d \in A_x}\Big[I[p(h|D;X)] - I[p(h|d,D;x,X)]\Big], \end{aligned}$$

where $I[\cdot]$ is the Shannon entropy, and A_x are the possible answers to question x. EIG has been used to describe a range of information sampling behavior (see Coenen, Nelson, & Gureckis, 2018, for an overview).

EIG for goal-directed questions. So far, EIG aims to reduce all uncertainty in $p(h)$. In order to only reduce the uncertainty that is relevant for a particular goal, we introduce the goal state space g. To illustrate with an example in the Battleship task, the goal "Find out which ships are touching" has as goal states g the various possibilities of ships that could be touching (i.e., *none*, *blue*|*red*, *blue*|*purple*, etc). Furthermore, g is defined as a projection of the hypothesis space h. Table 1 provides a minimal example of such goal projection. We can now measure the quality of a question x with respect to goal g via

$$EIG_{goal}(x,g) = \mathbb{E}_{d \in A_x}\Big[I[p(g|D;X)] - I[p(g|d,D;x,X)]\Big]. \qquad (4)$$

In detail, we compute the belief distribution over the goal states by marginalizing over h (here shown for the posterior, the equivalent is to be done for the prior)

$$p(g|d,D;x,X) = \sum_h p(g|h)p(h|d,D;x,X),$$

where $p(g|h)$ is 1 if h is goal-projected onto g, and 0 otherwise. More simply stated, for each goal state, we sum the belief values from the hypotheses that are projected onto the goal state. The EIG with respect to this goal is then the expected uncertainty reduction in the belief distribution over

Table 1: Simple example of a goal projection. Four hypotheses in h are projected onto two goal states in g. The projection results in a prior belief $p(g)$ of 0.2 for goal state 1, and 0.8 for goal state 2.

p(h)	h	g
0	1	1
0.2	2	1
0.4	3	2
0.4	4	2

these states. For convenience, we will subsume EIG_{goal} under the label EIG outside of this section.

EIG for follow-up questions. With the setup explained so far, the ability to take an already answered question into account comes out-of-the-box for the EIG model. Observed data D can be the visual information provided by the partly revealed board, as well as the verbal information from the answers to previous questions. The resulting knowledge is encoded in the posterior belief distribution, $p(h|d,D;x,X)$.

Experiment 1 – Asking goal-directed questions

In general, people ask different questions when they have different goals. When their goal changes, people should be able to flexibly adapt the questions they want to ask. In this experiment, we investigate whether people's evaluations of question usefulness are sensitive to specific goals.

Participants

Forty participants recruited on Amazon Mechanical Turk, with restriction to the United States pool, were paid a base of \$2 with a performance based bonus of up to \$4.86.

Method

In order to lead participants into a situation in which they wanted to ask a question, we took a number of steps to make them familiar with the Battleship task. First, participants went through a tutorial that presented the game board and the possible colors, sizes, orientations, and positions of the ships. This key information was shown on the side over the whole experiment and additionally checked in a comprehension quiz after the tutorial. Next, participants went through a warm-up phase, in which they began with a completely unidentified game board and clicked on the grid tiles to turn over their color, revealing more of the game board step by step.

Then, participants started the main phase, which consisted of 18 randomized trials. The schema of a trial is shown in Figure 2. Participants first viewed a partly-revealed game board and received a goal. They then ranked six natural-language questions "such that good questions are at the top and not so good questions are at the bottom" by dragging and dropping each question into a sortable list. To make sure that people paid attention to the questions, we displayed them one by one in a random order and people had to press the correct button

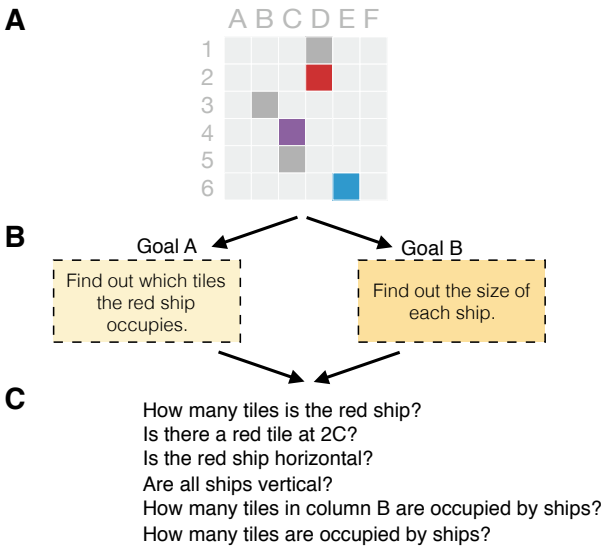

Figure 2: Experimental design of Experiment 1. In a given trial, (A) participants view a partly revealed game board. (B) Participants then receive one of two goals, randomly assigned. (C) Participants rank six questions by quality with respect to the goal. In Experiment 2, Goal A and Goal B are each replaced with an already-answered question.

that described the answer type of the question (either a color, a coordinate on the grid, a number, or yes/no). For each correct response, a bonus of \$0.045 was awarded. Allocating bonuses in this way, rather than basing it on their ranking of questions, discouraged participants from attempting to infer a researcher-preferred ranking of questions.

All participants viewed the same 18 partly-revealed game boards and corresponding question sets. But, as Figure 2 illustrates, the goal they received was randomly chosen from a predefined set of two goals for each context. The 18 game boards and the corresponding questions were the same as in Rothe et al., to ensure maximal comparability across studies (see Rothe et al., 2018, for details on the design of the boards and question sets).

The goals were designed as follows. We created a list of goals that seemed interesting but intuitive, such as "Find out which ships are touching the top border", "Find out which tiles the red ship occupies" which would allow people to ignore the blue and purple ship, or "Find out the size of each ship" which would allow them to ignore the orientation and location of the ships.

For each context, we determined via computer simulation a pair of opposing goals, such that the resulting EIG model scores of the questions were maximally different when evaluated against each goal (as measured by correlation). Examples of these opposing goals are shown as titles of the panels in Figure 3C. The average correlation between model scores within the goal pairs was $r = -0.28$.

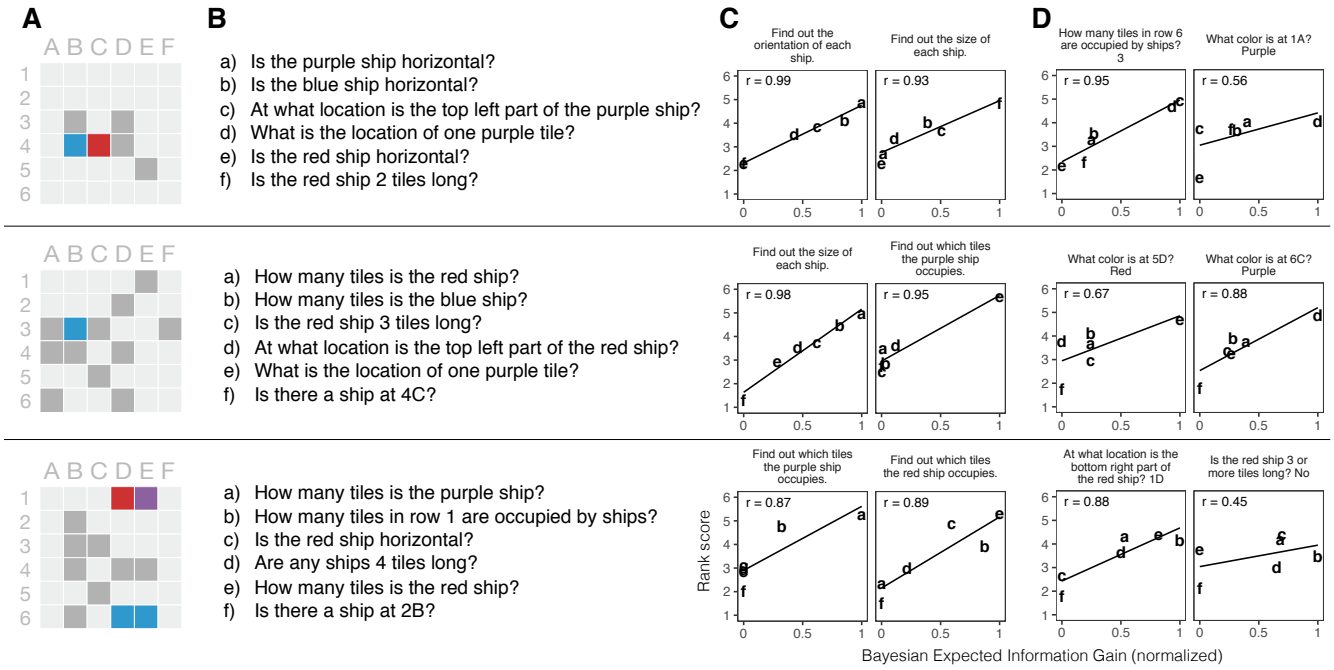

Figure 3: Contexts and questions together with human rankings and model predictions. Three selected trials exemplifying (A) the partly revealed game board, (B) the sets of six questions that were ranked by participants, (C) correlations of human rankings (y-axis; higher is better) and model scores (x-axis) for these questions in Experiment 1, and (D) Experiment 2. The letters a-f in the scatterplots correspond to letters marking the questions to the left. Error bars for $\pm 1SE$ are not plotted as they are only as large as the letters. Model scores are normalized to a maximum of 1.

Results

People's preference for questions were highly sensitive to the specific goals they had. Figure 3C shows how people's rankings of the same questions varied widely depending on the different goals. For example, in the first row in Figure 3, the question "Is the purple ship horizontal?" (marked with the letter **a**) was ranked best for the goal "Find out the orientation of each ship" but very low for the goal "Find out the size of each ship." The different rankings of this and other questions were well captured by the EIG model, which took the respective goal that participants had into account. Figure 3C shows several examples with strong correlations between EIG and human rank scores. Across all contexts, the average Pearson correlation between model scores and human rankings was $r = .84$. In contrast, when we let the EIG model hypothetically take the respective *opposite* goal into account, correlations dropped to an average $r = -.16$.

We also computed an "ignorant" model that ignored the specific goal and instead tried to obtain as much information as possible for the complete game board. A participant whose ratings are well captured by this model is probably ignoring the specific goal and instead plays the original Battleship game. The average correlation for this model was $r = .42$.

Instead of comparing correlation coefficients, we conducted a more sensitive model comparison that takes guessing behavior into account. Model scores were transformed into choice probabilities via the softmax function

$$p(x) = \frac{e^{-\beta M(x)}}{\sum_x e^{-\beta M(x)}},$$

where $M(x)$ is the model score (e.g., EIG(x)) and β is the free temperature parameter, capturing more guessing behavior as $\beta \to 0$. For each model, β was fit per participant to the rankings, and the resulting log-likelihood of the top ranked question computed.

In direct comparison, EIG had higher log-likelihood than EIGopposite, which took the opposite goal into account, for 38 out of 40 participants (95%). EIG also had a higher log-likelihood than EIGignore, which ignored the goal, for 35 out of 40 participants (88%).

We can conclude from this that people are very sensitive towards the specific goals when making question evaluations in our task, and that their evaluations are well predicted by our goal-oriented Bayesian ideal-observer EIG model with zero free parameters.

Experiment 2 – Asking follow-up questions

We test the EIG model further with the very natural task of deciding what to ask next, after a question was already answered.

Participants

A separate set of forty participants recruited on Amazon Mechanical Turk, with restriction to the United States pool, were paid a base of $2 with a performance based bonus of up to $4.86.

Method

The materials and procedure were identical to Experiment 1, except that instead of a goal, a question and its answer were displayed. That is, for each context, there was a predefined set of two already-answered questions from which one was randomly chosen for each participant (cf. Figure 2).

As for the pairs of goals in Experiment 1, we identified via computer simulation pairs of already-answered questions that were as anti-correlated as possible. The following procedure was repeated for each game board context. From a list of 136 unique questions we simulated all possible answers to each question. For example, the question "How many tiles in row 6 are occupied by ships?" (Figure 3D, first panel) has the possible answers {0, 1, ..., 6}. Then, for each question-and-answer combination, we computed what the resulting EIG scores would be for the six questions (Figure 3B) that now served as follow-up question candidates. As before, we created pairs of already-answered questions that had the most different model scores for the follow-up question candidates, as measured by the lowest correlation. The average correlation between model scores within the pairs was $r = 0.02$.

Results

People's rankings of the follow-up questions are generally sensitive to the information provided by the already-answered question. Figure 3D shows the correlations between the EIG model and human rankings. Overall, the average Pearson correlation was $r = 0.71$. When computing EIG by hypothetically taking the opposed already-answered question into account, the average correlation dropped to $r = 0.29$. When computing EIG that ignores the information from the answered question, the average correlation was $r = 0.60$. This suggests that people evaluated the usefulness of the follow-up questions by integrating the verbal information provided by the first question and its answer.

Again, instead of comparing correlation coefficients, we modeled people individually via a softmax function. EIG had a higher log-likelihood than EIGopposite for 28 out of 40 participants (70%). Using a softmax function again and modeling people individually, EIG had a higher log-likelihood than EIGopposite for 28 out of 40 participants (70%). Surprisingly, EIG had a higher log-likelihood than EIGignore for only 21 out of 40 participants (52%). The latter comparison suggests that a fair number of participants were not sensitive to the information from the answered question.

To inspect this result more carefully, we set up a hybrid model that balanced between EIG and EIGignore with a free parameter, $\theta EIG(x) + (1-\theta)EIG_{ignore}$. The balancing parameter θ was fit simultaneously with the softmax guessing parameter β for each person. The resulting distribution suggests

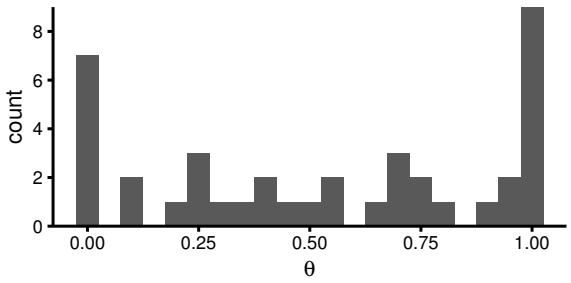

Figure 4: The θ values among participants. A participant's θ could be taken as an indicator for how much she considered the information from the answered question in Experiment 2. The binwidth is .05.

that nine participants (23%) took the information that the answered question provided accurately into account ($\theta > .95$), seven (18%) completely ignored the information ($\theta < .05$), and 24 (60%) exhibited a mixed strategy (Figure 4). Under this analysis it is still possible that the in-between participants used a different strategy, neither captured by EIG nor EIGignore. Yet, the log-likelihoods for these participants were as good as for the others suggesting that they did indeed use a mix of EIG and EIGignore. Thus, a participant's θ could be interpreted as the amount to which she considered the verbal information from the answered question.

Word-based model. We further considered an alternative model that takes a word-based approach. One strategy people might exhibit is to keep focusing on getting information about the ship they already have some details on. For instance, if the answered question provides information that the red ship is horizontal, they might prefer to learn about the size of the red ship before moving on to the next ship. Thus the word-based model looks for signal words that match the already-answered question and the follow-up question. Formally, the Color feature compares the color words {*blue, red, purple, water*} in the answered question with those in the follow-up question candidates. If there exist color words in both questions and they are the same, then the Color feature assigns a 1 to the follow-up question, else a 0. To illustrate, consider the right panel in the third row in Figure 3D. The already-answered question "Is the red ship 3 or more tiles long?" mentions the red ship. Therefore, the model would prefer the follow-up questions **c** and **e** because they also mention the red ship. Indeed, **c** and **e** were both ranked somewhat higher than predicted by the EIG model. Overall, questions that were ranked as best by people had more often matching color words (23%) with the already-answered question than the lower ranked questions (12-21%).

Another strategy that people might employ is to prefer a question of the same type as of the one that was already answered. The Type feature categorizes questions into mutually exclusive groups of *ship orientation, ship size, adjacency, region, location,* and *demonstration* questions. This classifica-

tion follows the one described in Rothe et al. (2018). The Type feature simply assigns a 1 if both questions are classified into the same type, else 0. Illustrating for the same case as above, the feature classifies the answered-question into the *ship size* type, to which also follow-up questions **a**, **d**, and **e** belong, which therefore get a higher score. Overall, questions that people ranked worst were more often of the same question type as the already-answered question (30%) than the higher ranked questions (21-23%).

The word-based model combines both features in a linear combination. We fitted a linear regression using both features as predictors and participants' average rank scores as criterion. However, only little variance in people's rankings could be explained this way, $R^2 = 0.05$.

Discussion

We tested people's preference for questions in two crucial situations: when asking goal-directed questions and when asking follow-up questions. In Experiment 1, we manipulated the goal that people had, while keeping everything else constant. People's rankings of question quality dramatically shifted based on the goal they were assigned. The rankings were well predicted by our Bayesian ideal-observer model of Expected Information Gain (EIG) with zero free parameters. In Experiment 2, we manipulated what already-answered question people received, while keeping everything else constant. Again, people's rankings shifted strongly based on the answered question. However, the picture was less clear than in the first experiment. While generally people's rankings were well predicted by the EIG model, detailed analysis suggested that people varied in the amount to which they integrated the information provided by the already-answered question. An alternative model that approximated question usefulness based on superficial features could not explain human rankings.

So far, neural network approaches to question asking generally struggle with the flexibility that is necessary to take previous answers and goals into account. To reach competitive performance in simple tasks they already need training on large data sets with tens of thousands of questions. In order to add sensitivity towards specific answers and goals would require additional training likely in orders of magnitude more.

One of the strengths of the Bayesian approach is the seamless integration of visual and verbal information. The visual information from the partly revealed game board and the verbal information from the answered question were both integrated into a unified posterior. In our current analysis we only considered varying degrees to which people considered the verbal info from the answered question. It is also possible that people did not perfectly take the visual information from the partly revealed board into account. In future work, we will further explore people's integration of high-level information.

We extended the computational framework to two aspects of question asking—more needs to be done. In our setting, we assumed a reliable, all-knowing oracle that is providing the answers. However, the relationship between question, ground truth, and generated answer is not as deterministic in many real-world settings. For example, in social settings, people need to take into account the knowledge state and goals of their communication partner. This aspect has been elegantly modeled in the Rational Speech Act framework, where a questioner has an internal model of the answered that she simulates recursively before deciding what to ask (Hawkins & Goodman, 2017). We see our approach as complementary to this RSA model. Future work should aim to integrate both.

Abstract

Music training is commonly thought to have a positive impact on children's cognitive skills and academic achievement. This belief relies on the idea that engaging in an intellectually demanding activity helps to foster overall cognitive function. We here present a meta-analysis of music-intervention studies in children (N = 3,780, k = 204, m = 43). Consistent with the substantial findings in the field of cognitive training, the overall effect size was small ($\bar{g}$ = 0.117, p < .001). Moreover, when active controls were implemented, the effect was practically null ($\bar{g}$ = 0.032, p = .477) and highly homogeneous (ω^2 = 0.000 and τ^2 = 0.000). Finally, we observe that several independent research groups have concluded, via different methodologies, that music skills acquired by training do not generalize to non-music skills. Thorndike and Woodworth's (1901) common elements theory finds thus further support.

Keywords: music; cognitive training; meta-analysis; transfer of skills.

Introduction

Many parents encourage their children to play a musical instrument. Their hopes sometimes go beyond proficiency in playing music: they enroll their children in violin or piano lessons not only to nurture their musical talent but also because they assume that music training will help their children to get better at school or even become more intelligent.

The idea that learning how to play an instrument improves one's cognitive abilities and academic achievement is popular. Music ability is often associated with talent and superior cognitive skills. Blogs and newspapers often report enthusiastically on the benefits of music for the intellect (e.g., Jaušovec & Pahor, 2017). Even the popular TV series *The Simpsons* has echoed this common belief by defining musical instruments as "the way to encourage a gifted child."

The conviction that music training enhances cognitive ability and academic achievement relies on the assumption that music skills acquired by training can generalize to non-music domains. However, what does the scientific research in the field tell us about music training? Is this assumption correct?

Why Should Music Training Enhance Cognition?

As just mentioned, music training has been claimed to improve a broad range of cognitive and academic skills. However, how is music training supposed to provide such diverse benefits? The standard hypothesis relies on the idea that it is possible to train domain-general cognitive abilities by engaging in intellectually demanding activities. Learning how to play a musical instrument engages executive functions such as cognitive control and working memory (Bialystok & Depape, 2009). In addition, music training requires focused attention and learning complex visual patterns. Schellenberg (2006) has thus proposed that the most likely explanation for the presumed broad set of benefits provided by music training is that it enhances individuals' overall cognitive function and general intelligence. These cognitive skills are major predictors of academic achievement (e.g., Deary et al., 2007), and it might be the case that some domain-specific abilities acquired by music training generalize to other non-music skills.

One further theoretical foundation for the hypothesis according to which music training exerts a positive influence on overall cognitive ability is neural plasticity. Neural plasticity is the ability of the neural system to modify and adapt under the pressure of the environment (Strobach & Karbach, 2016). In turn, the changes in the neural system are supposed to account for improvements in cognitive tests. In fact, musicians do exhibit specific anatomical and functional neural patterns. An increased density of gray matter in musicians has been observed in areas involved in cognitive skills such as auditory localization (right Heschl's gyrus; Bermudez et al., 2009) and language production (Broca's area; Sluming et al., 2002).

With regard to functional differences, expert musicians seem to show, for example, enhanced bilateral activation of the Rolandic operculum (for a review, see Neumann, Lotze, & Eickhoff, 2016). This activation probably reflects superior ability in the processing of auditory information (Koelsch et al., 2006). While there is empirical support for the hypothesis that music training induces significant anatomical and functional changes in the brain, which sometimes lead to unexpected behavioral skill differences (e.g., superior memory for randomized music-related material; Sala &

Gobet, 2017a), the evidence that these neural changes lead to increased cognitive function is much weaker, as discussed in the following sections.

Correlational Evidence

There is strong empirical evidence for a link between superior cognitive ability and musical skill. In a study by Ruthsatz et al. (2008), a group of professional musicians outperformed a group of novices in a standardized measure of fluid intelligence (Raven's Progressive Matrices). Lee, Lu, and Ko (2007) found a correlation between music skill and working memory. In the same vein, Saarikivi et al. (2016) found that neural sound discrimination predicted performance on an inhibition task and a set-shifting task in a sample of children and young adolescents. Finally, Schellenberg (2006) reported positive, yet moderate, correlations between engagement in musical activities and IQ in a group of children and undergraduates. Critically, this positive relationship remained even after controlling for parental income and education.

Music ability correlates with academic skills as well. Anvari et al. (2002) found that music perception skills correlated with reading abilities in preschool children. Similarly, Forgeard et al. (2008) reported that music discrimination skill correlated with phonological processing ability in a group of dyslexic and typically-developing children. In line with these studies, Wetter, Koerner, and Schwaninger (2009) reported a positive relationship between engagement in musical activities and overall academic attainment.

Experimental Evidence and Present Study

As just seen, music skill is positively associated with measures of fluid intelligence, memory, and academic achievement. However, while music skill and cognitive ability are correlated, to date there is no clear evidence of a causal relationship from engagement in music training to superior cognitive function.

A meta-analysis of all the available studies (Sala & Gobet, 2017b) has expressed pessimism about the actual possibility of music-training interventions to enhance children's cognitive and academic skills. All the studies included in this meta-analysis are true experiments: individuals with no (or negligible) music experience are allocated to a music-training group and one or more control groups. This meta-analytic review has found modest or null effects of music training on cognitive abilities such as intelligence, memory, spatial ability, and phonological processing (see also Gordon, Fehd, & McCandliss, 2015). Similar modest or null effects have been found with academic skills such as mathematics and literacy. Furthermore, meta-regression analysis has highlighted that the between-study variability is moderated by the type of control group (active or passive) and the type of allocation to the groups (randomized or nonrandomized). While the studies with no random allocation and passive control groups show some positive effects, when the music-trained groups are randomly allocated and compared to an active control group, the effects are null.

Although Sala and Gobet's (2017b) meta-analytic review suggests pessimism, numerous new experimental studies have been carried out in the last three years. Some of these studies have reaffirmed the idea that music training has a positive influence on children's cognitive and academic skills. However, the impact of these new studies on the overall evaluation of the field of music training has not been assessed yet.

The present study intends to update Sala and Gobet's (2017b) meta-analysis and test the recent claims about the presumed cognitive and academic benefits of music training (e.g., Habibi et al., 2018). To achieve this goal, we (a) extend the literature research to the last three years (from January the 1st 2016 to December the 31st 2018), (b) apply a more advanced modeling approach, and (c) provide stricter inclusion criteria to improve, compared to Sala and Gobet (2017b), the average quality of the studies included in the meta-analytic review.

Method

Literature Search

A systematic search strategy was implemented (Moher et al., 2009). Using the following Boolean string search ("music" OR "musical") AND ("training" OR "instruction" OR "education" OR "intervention"), ERIC, Psyc-Info, and ProQuest Dissertation & Theses databases were searched to identify all the potentially relevant studies. In addition, all the studies included in Sala and Gobet (2017b) were reevaluated for inclusion. Also, we e-mailed researchers in the field (n = 8) asking for unpublished studies, clarifications about the study design, and inaccessible data.

Inclusion Criteria

We kept the same inclusion criteria as Sala and Gobet (2017b). The study had to include (a) a cognitively-demanding music-training program (e.g., learning to play instruments, Kodály method,[1] etc.; no correlational studies were included), (b) at least one control group, (c) non-music-related cognitive or academic outcomes,[2] and (d) participants aged between 3 and 16 with no diagnosed clinical condition or previous formal music experience.

In order to improve the overall quality of the reviewed empirical evidence, the present meta-analysis added three more criteria: (e) the article had to report (or the author had to provide) the means and standard deviations in order to calculate the effect size and sampling error variance; (f) the participants had to be allocated by the experimenter to a

[1] The Kodály method is a well-known educational protocol that focuses on singing, ear training, and the creative skills of musicianship. For more details, see http://kodaly.org.uk/.

[2] For a discussion about the potential benefits of music instruction on non-cognitive/academic skills, see Aleman et al. (2017).

group (randomly or nonrandomly); that is, they were not allowed to decide to which group (experimental or control) they would be allocated; and (g) the experimental group and the control group had to include comparable populations (e.g., same grade, comparable baseline IQ, etc.). These additional criteria led to the exclusion of eight studies previously included in Sala and Gobet (2017b).

Moderators

We chose (a priori) five potential moderators that were included in the meta-regression analysis:

1. Allocation (dichotomous variable): Whether the children were randomly allocated to the groups;
2. Type of control group (active or passive; dichotomous variable): Whether the WM training-treated group was compared to an alternative activity (e.g., visual arts) or a do-nothing (passive) control group. This moderator was necessary to check for placebo effects;
3. Baseline difference (continuous variable): The standardized mean difference (Hedges's *g*) between the experimental and control groups at baseline.[3] A negative regression coefficient would suggest the presence of some true heterogeneity due to regression to the mean;
4. Age (continuous variable): The age of the participants in years;
5. Outcome Measure (categorical variable): The effect sizes were clustered into four broad categories: non-verbal ability (e.g., reasoning, mathematical, and spatial skills); verbal ability (e.g., vocabulary and reading skills); memory (e.g., digit-span and working-memory tasks); and speed (e.g., processing speed and inhibition tasks).[4] The interrater agreement was perfect ($\kappa = 1$).

Modeling Approach

We extracted the effect sizes for each relevant dependent variable reported in the studies using the formulas provided by Schmidt and Hunter (2015). Several studies presented multiple-group comparisons – for example, between one experimental group and two control groups (one active and one passive), or between two experimental groups and one control group. In these cases, we calculated as many effect sizes as the number of comparisons.

We grouped all the effect sizes from the same study into the same cluster. Then, we employed *robust variance estimation* (RVE; Hedges, Tipton, & Johnson, 2010) to model statistically dependent effect sizes and calculates adjusted (i.e., increased) overall standard errors. Also, RVE provides estimates of within-cluster true (i.e., not due to random error) heterogeneity and between-cluster true heterogeneity (ω^2 and τ^2, respectively). We ran (a) intercept models to calculate overall effect sizes and (b) meta-regression models to assess the amount of true heterogeneity explained by the moderators.

Publication Bias

To control for publication bias, we first merged the effects from the same study with the method designed by Cheung and Chan (2014; individual-samplewise procedure). The method averages the effect sizes from the same cluster (in this case, the study) and calculates a corrected sampling error variance in order not to miscalculate standard errors and true heterogeneity. Then, we ran a random-effect model with the merged effect sizes and applied the trim-and-fill publication-bias detection method (Duval & Tweedie, 2000; estimators *L0*, *R0*, and *Q0*).

Results

The search yielded 2,462 records, of which 72 studies were thoroughly evaluated for inclusion. Forty-three studies, 13 of which not included in Sala and Gobet (2017b), met the inclusion criteria with a total of 204 effect sizes (Sala & Gobet, 2017b, included 118 effect sizes). The total number of participants was 3,780. Three researchers replied to our emails. The supplemental materials including details about the studies, techniques employed, additional analyses, data, and R codes, can be found at this link: https://osf.io/2gce3/.

Main Model

The intercept model did not include any covariate (i.e., moderator). The overall effect size of the RVE intercept model was $\bar{g} = 0.117$, 95% CI [0.063; 0.170], $m = 43$, $k = 204$, $df = 17.25$, $p < .001$, $\omega^2 = 0.010$, $\tau^2 = 0.005$. The overall impact of music-training interventions was thus small ($\bar{g} = 0.117$, 95% CI [0.063; 0.170]), albeit statistically significant ($p < .001$).

After merging the effects from the same cluster (i.e., the study), the results of the random-effect model were very similar: $\bar{g} = 0.140$, 95% CI [0.064; 0.217], $p < .001$, $k = 43$, $\tau^2 = 0.018$. The trim-and-fill analysis indicated some publication bias (estimates ranging between 0.046 and 0.122).

Meta-Regression Analysis

The meta-regression model included the five moderators described in the Method section. Baseline and Type of control group were the only two significant moderators ($p = .019$ and $p = .003$, respectively). These two moderators explained almost all the observed true heterogeneity ($\omega^2 = 0.000$ and $\tau^2 = 0.005$). We also checked all the pairwise comparisons for the outcome measures with the Holm's method (for details, see the supplemental materials). None of the comparisons yielded significant differences (all ps $\geq .610$).

Finally, we sorted the effect sizes by the moderator Type of control group. The overall effect size of the RVE model including only passive-control comparisons was $\bar{g} = 0.173$,

[3] Five studies implemented an only-post-test design. In those cases, baseline differences were assumed to be null to keep these studies in the moderator analysis.

[4] A more fine-grained categorization was also analyzed (for details, see supplemental materials).

95% CI [0.094; 0.253], $m = 33$, $k = 112$, $df = 19.02$, $p < .001$, $\omega^2 = 0.008$, $\tau^2 = 0.019$. The overall effect size of the RVE model including only active-control comparisons was $\bar{g} = 0.032$, 95% CI [-0.068; 0.132], $m = 19$, $k = 92$, $df = 7.09$, $p = .477$, $\omega^2 = 0.000$, $\tau^2 = 0.000$. Thus, while a small positive and significant effect was observed when passive controls were implemented, no substantial effect occurred when music-treated subjects were compared to controls involved in other activities (Table 1).

Table 1: Summary of the results.

Sample	$\bar{g}$ [95% CI]	p-value
All	0.117 [0.063; 0.170]	.000
Exp. vs passive	0.173 [0.094; 0.253]	.000
Exp. vs active	0.032 [-0.068; 0.132]	.477

Discussion

The present meta-analysis has aimed to update and check the findings of the most recent and comprehensive meta-analysis about the impact of music instruction on children's non-music-related cognitive and academic skills. It has included new studies and nearly doubled the number of effect sizes compared to Sala and Gobet (2017b). Nonetheless, the results of this meta-analysis confirm most of the findings reported in Sala and Gobet (2017b). Most importantly, when only those designs implementing an active control group are considered, the effect of music training is practically null ($\bar{g} = 0.032$, $p = .477$) and highly consistent ($\omega^2 = 0.000$, $\tau^2 = 0.000$). On the other hand, the comparison between music-trained groups and passive controls yields a minimal overall effect ($\bar{g} = 0.173$, $p < .001$) that is easily accounted for by placebo effects. Therefore, the effects of music training on children's cognitive skills and academic achievement are unspecific. Consistent with this explanation, there were no differences between outcome measures, which suggests that the effects of music training (when any) are unspecific.

Finally, beyond supporting Sala and Gobet's (2017b) findings, this meta-analysis highlights new aspects. First, the lack of randomization does not seem to affect the outcomes. On the other hand, compared to Sala and Gobet (2017b) using more rigorous inclusion criteria (e.g., no studies with self-selected participants) lowers the overall effect size (from 0.173 to 0.117) and, most notably, the amount of true heterogeneity (from $\omega^2 = 0.088$ to $\omega^2 = 0.010$, and from $\tau^2 = 0.023$ to $\tau^2 = 0.005$).[5] Second, regression to the mean appears to explain a significant amount of true heterogeneity. This finding does not imply that baseline differences have affected the overall effects. Rather, it means that some of the observed true heterogeneity is spurious (i.e., due to a statistical artifact).

[5] These statistics were obtained by reanalysing Sala and Gobet's (2017b) original dataset with the same multilevel approach used in the current meta-analysis (i.e., RVE).

Triangulation

Beyond meta-analytic evidence, our findings are supported by substantial research into the field of music cognition using different methodologies. Mosing et al. (2016) have shown that music-trained twins do not have a higher IQ than the relative non-music-trained co-twins. The study thus suggests that the level of IQ is determined, to a significant extent, genetically and that engaging in music has no effect on it. Also, Swaminathan, Schellenberg, and Khalil (2017) have recently shown that music aptitude, but not the amount of music training, predicts intelligence in a sample of adults. The association between intelligence (Raven's progressive matrices) and music training is evident until music aptitude is taken into account and added to the regression model.

Strong support for our conclusions is also provided by the fact that the same pattern of results has been found in other domains, including chess training, working-memory training, and brain training. Expertise in chess has been found to correlate with a broad range of cognitive skills such as fluid intelligence, processing speed, short-term memory, and spatial ability (e.g., Burgoyne et al., 2016). Moreover, expert chess players differ from novices and non-players in terms of neural anatomical and functional patterns (e.g., Bilalić et al., 2010; Hänggi et al., 2014). However, chess training does not seem to trigger any genuine improvement in overall cognitive ability or academic achievement (Sala & Gobet, 2016). Analogously, fluid intelligence and working memory capacity are strongly correlated, yet working memory training exerts no effect on fluid intelligence (e.g., Melby-Lervåg et al., 2016). The absence of far-transfer effects is observed even in the presence of functional neural changes (Clark, Lawlor-Savage, & Goghari, 2017). A similar pattern of results has been reported in brain training as well (for a review, see Simons et al., 2016). This outcome upholds the idea that such neural patterns underlie domain-specific skills (e.g., performance in working-memory tasks) rather than overall cognitive function.

These similarities between the results obtained with training studies in different domains induce further pessimism about the concrete possibility of enhancing domain-general cognitive skills through the engagement in intellectually demanding activities. In brief, the idea of enhancing overall cognitive ability through training appears, to date, scientifically implausible (Sala & Gobet, 2019).

Concerning the observed neural patterns in musicians, understanding their actual significance is essential. It is doubtful that functional changes occurring after a music-training intervention represent domain-general improvements in cognitive function. Instead, it is probable that such neural patterns underlie the enhancement of music-related skills such as pitch discrimination (e.g., Nan et al., 2018). It is thus imperative not to erroneously interpret – as sometimes happens (e.g., Habibi et al., 2016) – that

functional neural changes in brain areas involved in domain-general cognitive abilities are evidence of cognitive enhancement. The same applies to anatomical neural changes (e.g., increased density of gray matter). Such patterns frequently observed in professional musicians are most likely neural correlates of their domain-specific expertise rather than superior overall cognitive ability.

Theoretical and Practical Implications

Taken together, the findings of the research into music expertise and music training depict a consistent picture: while a positive relationship between music skill and cognitive ability does exist, the benefits of music training do not go beyond the acquisition of music-related skills. In other words, engaging in music does not make people smarter. Instead, as suggested by the research of Mosing et al. (2016) and Swaminathan et al. (2017), smarter people seem to be more likely to engage and succeed in music.

Two major theoretical implications stem from the above results. First, the lack of generalization of music skills acquired by training provides further corroboration for Thorndike and Woodworth's (1901) common elements theory and theories based on the mechanism of chunking. According to Thorndike and Woodworth's theory, transfer of skills is a function of the extent to which two (or more) domains overlap. Thus, transfer of skill between two (or more) domains only loosely related to each other (i.e., far transfer) hardly occurs. Similarly, chunking and template theories (Chase & Simon, 1973; Gobet & Simon, 1996) predict modest or no transfer across different domains or even subdomains of expertise (for a review, see Gobet, 2016). This is because these theories uphold the idea that skill acquisition is based, to a large extent, on perceptual information (i.e., perceptual chunks and templates), which is hardly transferable across different domains given its highly domain-specific nature. Conversely, theories predicting the generalization of trained skills across different domains (e.g., Strobach & Karbach, 2016) are not supported by these outcomes.

Second, the observed correlation between music skill and cognitive ability, together with the lack of broad cognitive effects following music training, suggests that talent is an essential requisite for achieving expertise in music (Schellenberg, 2015). In line with the conclusions of Macnamara, Hambrick, and Oswald (2014), substantial research into music confirms that the amount of deliberate practice alone cannot account for the individual differences in music expertise.

Beyond theoretical aspects, the obvious practical implication is that music training should not be used as a tool for cognitive enhancement. In fact, music training has failed to offer any specific advantage in terms of both cognitive enhancement and academic achievement. These conclusions are made even stronger if we take into consideration that music training has been found substantially ineffective even at enhancing those skills traditionally believed to be tightly close to music skill, such as phonological processing and literacy (e.g., Kempert et al., 2016).

Recommendations for Future Research and Conclusions

As seen, music training does not affect any non-musical cognitive or academic skills. Importantly, the lack of generalization of music skills acquired by training has been established by different research teams using diverse research methodologies (twin studies, hierarchical multiple regression, and meta-analysis of treatment studies).

We briefly discuss some possible avenues of research. As noted above, the quality of experimental designs is inversely related to the size of the effects of music-training interventions and cognitive-training interventions in general (Moreau, Kirk, & Waldie, 2016). Therefore, future studies should strive for high-quality experimental designs regardless of the particular outcome variables and population under investigation. We thus recommend including both active and passive control groups, random allocation of the participants, pre-, post-, and follow-up assessment, multiple measures of the same constructs, and large samples.

It is worth emphasizing that the findings reported here about the null effects of music training do not imply that music is a worthless activity. Rather, the purpose of this article has been to clarify what are the real effects of music training in order to allow people to make informed decisions. Educators and policymakers should be aware that music training provides no benefits on non-music-related cognitive or academic skills (e.g., Nan et al., 2018). As far as we are concerned, even in the absence of other cognitive or academic benefits, it is worthwhile learning an art present in nearly all the cultures in human history.

Do cross-linguistic patterns of morpheme order reflect a cognitive bias?

Abstract

A foundational goal of linguistics is to investigate whether shared features of the human cognitive system can explain how linguistic patterns are distributed across languages. In this study we report a series of artificial language learning experiments to test a hypothesised link between cognition and a persistent regularity of morpheme order: number morphemes (e.g., plural markers) tend to be ordered closer to noun stems than case morphemes (e.g., accusative markers) (Greenberg, 1963). We argue that this typological tendency may be driven by a bias favouring orders that reflect scopal relationships in morphosyntactic composition (Bybee, 1985; Rice, 2000; Culbertson & Adger, 2014). We taught participants an artificial language with noun stems, and case and number morphemes. Crucially, the input language indicated only that each morpheme preceded or followed the noun stem. Examples in which two (overt) morphemes co-occurred were held out—i.e., no instances of plural accusatives. At test, participants were asked to produce utterances, including the held-out examples. As predicted, learners consistently produced number closer to the noun stem than case. We replicate this effect with free and bound morphemes, pre- or post-nominal placement, and with English and Japanese speakers. However, we also find that this tendency can be reversed when the form of the case marker is conditioned on the noun, suggesting an influence of dependency length. Our results provide evidence that universal features of cognition may play a causal role in shaping the relative order of morphemes.

Keywords: linguistic universals; artificial language learning; morpheme order; case; number

Introduction

Human languages are incredibly diverse in the way they combine meaningful units, i.e., morphemes; nevertheless, certain regularities are apparent. For example, some patterns of morpheme order occur more frequently across the languages of the world, while others are rare or even unattested. The typological regularity in morpheme order we target here concerns number and case morphology, specifically, languages in which there is a boundary between these morphemes. For example, in agglutinating languages such as Hungarian or Turkish, there is distinct set of number morphemes (marking plurality) and case morphemes (marking grammatical roles). In such languages, when overt morphemes of both number and case are present on a stem, and both follow or both precede the noun stem, the expression of number is almost always realised closer to the noun stem than the expression of case (Universal 39; Greenberg, 1963). There are a number of candidate explanations for this phenomenon, which intersect with high-level hypotheses about how morpheme (and word) order is determined in language more generally. For example, it has been proposed that semantic or compositional relationships among morphemes, sometimes called *scope*, determine linear order (Bybee, 1985; Wunderlich, 1993; Rice, 2000; Culbertson & Adger, 2014).[1] On one formulation, morphemes which more directly affect or modify the semantic content of the stem have narrower scope (Bybee, 1985; Rice, 2000). Wider-scope morphemes modify the larger semantic constituent which includes any lower scoping morphemes. Perhaps the best-known example of this is the order of derivational and inflectional morphemes (e.g., 'neighbor-hood-s'). On this account, derivational morphemes are ordered closer to the stem because they change its lexical meaning. Inflectional morphemes scope higher, modifying grammatical properties of the stem plus any derivational morphemes. Similarly, it has been claimed that the linear order of nominal modifiers (e.g., adjectives, numerals, demonstratives) reflects semantic scope relations (Culbertson & Adger, 2014; Bouchard, 2002). In the case of Universal 39, the idea would be that case scopes higher than number because number directly modifies the entity referred to by the noun, while the case morpheme signals an external relationship between the entity and some event. Following Culbertson and Adger (2014), we call orders which reflect scope relations *scope-isomorphic*.

A second possible explanation appeals to frequency and its effects on processing. For example, Ryan (2010) shows that in some cases morpheme order reflects the frequency of stem+morpheme bigrams (see also Baayen, 1993; Rice, 2011). Along similar lines, Hay (2001) argues that when a stem is more frequent alone than with a particular affix, then that affix is easier to parse (decompose) from the stem. This in turn determines linear order: more parsable affixes appear farther from the stem than less parsable ones (see also Hay & Plag, 2004; Plag & Baayen, 2009; Manova & Aronoff, 2010). How might this explain Universal 39? It could be that

[1] Related theories argue that universal morphosyntactic hierarchies, potentially reflecting semantics, determine order (Baker, 1985; Grimshaw, 1986; Cinque, 2005).

number tends to be expressed more often than case, or that case morphemes tend to be more parsable than number morphemes. On this account, there is nothing about the semantics of these morphemes that determines their relative order. Indeed, a third possibility is that their relative order reflects patterns of diachronic change: it could be that languages tend to grammaticalise number before case (Givón, 1979).

To date, there is no direct behavioral evidence adjudicating among these potential explanations for Universal 39. In fact, there is no independent evidence beyond the typology to show that placing number closer to the noun stem than case is in fact preferred over the reverse. In a series of three artificial language learning experiments, we test the link between this typological generalisation and a bias towards linear orders that mirror scopal relationships (henceforth scope-isomorphic orders). To summarise, we find support for this hypothesis across two language populations (English, and Japanese) independent of morpheme position (before or after the noun stem), degree of boundedness, and frequency. All things equal, learners therefore prefer scope-isomorphic orders. However, we also find that conditional allomorphy between the stem and the case marker can reverse participants' preferences. We interpret this as a competing bias for local dependencies. This result adds to the growing body of work using these experimental methods to investigate how learning and use shape morphology and word order (Hupp, Sloutsky, & Culicover, 2009; Fedzechkina, Jaeger, & Newport, 2012; Culbertson & Adger, 2014; Culbertson, Smolensky, & Legendre, 2012; Tabullo et al., 2012; Futrell, Mahowald, & Gibson, 2015; Fedzechkina, Chu, & Jaeger, 2018).

Experiment 1

Methods

The artificial language learning experiments described here use an extrapolation paradigm (called 'Poverty-of-the-stimulus' paradigm elsewhere, Wilson, 2003; Culbertson & Adger, 2014). This means learners are trained on input that is designed to be ambiguous between (at least) two patterns of interest: here, two potential ways of ordering case and number morphemes. Learners are exposed to a miniature artificial language with nouns, and case (accusative) and number (plural) morphemes. Crucially, their input indicates whether these morphemes generally precede or follow the noun, but does not include any examples in which the two morphemes co-occur within the same noun phrase. At test, they are asked to produce utterances, including these held out examples. The order they infer will indicate whether they have a preference for placing number closest to the noun (e.g., Noun-Number-Case rather than Noun-Case-Number). All experiment materials and data discussed here are available at osf.io/9fa3v/, and the preregistered design and analysis plan for Experiment 1 is accessible at osf.io/8xuc9.

Participants Forty-one native English speakers were recruited from the University of Edinburgh's Careers Services database. Participants were paid £6 for a 35-min-long experimental session. Participants (N=1) whose vocabulary accuracy was lower than 60% were excluded; testing trials with incomplete sentences were also excluded.

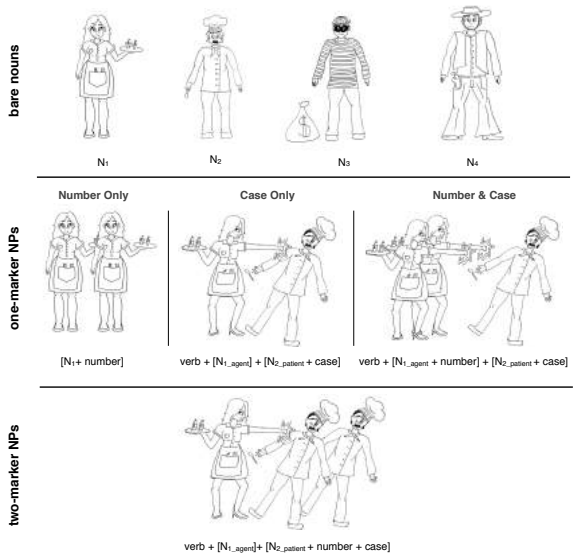

Figure 1: Example visual stimuli and corresponding descriptions. Top to bottom: the four characters in the miniature language in isolation; example events with one marker (either number or case); example event requiring two markers (number and case, testing only).

Input language The lexicon includes three semi-nonce verbs, four nonce nouns, and two nonce markers (one number marker indicating plural; one case marker indicating accusative). All words have initial stress. The three semi-nonce verbs are taken from the English-based creole Tok Pisin: 'kikim'([ˈkʰɪkɪm]), 'poinim'([ˈpʰɔɪnɪm]) and 'straikim'([ˈstraɪkɪm]), which refer to 'kicking', 'pointing' and 'punching' respectively. The (disyllabic) nouns are 'negid'([neʒɪd]), 'nork'([ˈnɔrk]), 'tumbat' ([ˈtʰʌmbət]) , 'vaem' ([ˈvæm]) (based on Fedzechkina et al., 2012), naming four characters: a burglar, a chef, a cowboy, and a waitress. The noun-character mappings are random for each participant. The two markers were randomly mapped to number and case from the set: 'gu' ([ˈguː]), 'sa'([ˈsɑː]), and 'ti'([ˈtʰiː]). Word order in sentences was Verb-Agent-Patient. Half of participants were trained on a language with post-nominal morphemes (case and number morphemes appeared after the noun stem), half with pre-nominal morphemes (case and number morphemes appeared before the noun stem). [2]

Participants are trained on three different NP types: a bare noun, a noun with overt number morphology, and a noun with

[2]We use the terms *pre-* and *post-nominal* instead of *prefixal* and *suffixal* morphology to account for both bound and unbound orthographic representations of case and number morphology.

overt case morphology. Note that singular, and agent case (nominative) are unmarked. During training, participants get descriptions of characters in isolation (singular or plural), or events with a singular patient; plural patients (requiring both number and case morphology) are held-out until testing. See Figure 1 for examples. Crucially, number and case markers appear with the exact same frequency (i.e., absolute, and relative to each given noun) both during training and testing phases, controlling for any potential frequency effects.

The input language is presented both orthographically and auditorily during training. Auditory stimuli were recorded in a sound-attenuated room by a 26yo male speaker of American English. Noun phrases were recorded without a pause between nouns and markers but each marker is orthographically presented surrounded by spaces and thus not bound to the noun.

Experimental procedure The experiment was conducted in a quiet room, with all instructions provided in English, and an English-speaking experimenter. Participants were told that they would be learning part of a foreign language. The session proceeded as follows.

Phase 1, noun training and testing. Participants are first trained on the four nouns in isolation (Figure 1, top row) during a block of 24 trials (6 per noun). In each trial, a single character appears, and its description (a bare noun) is displayed (orthographically and auditorily). Participants are instructed to repeat each description aloud. Participants are then tested on the noun vocabulary using a noun-selection task and an oral production task (12 trial per block, 3 per noun). In noun-selection trials, a character appears, and participants must select the correct noun from 2 choices. The foil noun is randomly selected at each trial. Feedback is provided (an (in)correct-answer sound effect along with the image and correct noun; if incorrect, the audio of the noun is also played). In oral production trials, a character appears, and participants must say the corresponding noun aloud. Feedback is provided (the correct noun is displayed visually and auditorily after participants submit their answer).

Phase 2, one-marker NP training. Participants are next trained on noun phrases with a single marker, either number or case. There are three trial types (Figure 1, middle row): (1) a group of the same characters (2, 3, or 4) in isolation (Number only), (2) an event with (different) singular agent and patient (Case only), or (3) an event with a plural agent, and a singular patient (Number & Case, where crucially each marker belongs to a different noun phrase). On each training trial, participants see an image, and its description is presented (orthographically and auditorily). There are 62 trials total (randomised): 8 bare noun, 18 Number Only (six per character), 18 Case Only (randomly chosen from the 36 possible), and 18 Number & Case images (again randomly chosen).

Phase 3, one-marker NP comprehension test. Participants are then tested on their comprehension of one-marker NPs in a image-selection task. On each trial, they get a description and must select the corresponding image out of an array of two. Feedback is provided (an (in)correct-answer sound effect along with the image and correct orthographic description; if incorrect, the audio description is also played). The foil image is selected according to the trial type. For bare noun and Number Only trials, the foil image is the same character with wrong numerosity (e.g., singular instead of plural). For Case Only and Number & Case trials, the foil is the same event type with agent and patient reversed. There are 34 trials total (randomised): 4 bare noun, 10 each of the three one-marker NP trial types.

Phase 4, one-marker NP written production test. Participants are then tested on their ability to produce one-marker NP descriptions. On each trial, participants see a image and are required to type in the corresponding NP(s). Verb forms are provided for Case Only and Number & Case trials. Feedback is provided (an (in)correct-answer sound is played, along with the image and correct description). There are 16 trials total (randomised): 4 trials for each of the types they have been trained on so far.

Phase 5, two-marker NP production tests. In the two critical testing blocks, participants must provide first written, then oral descriptions which include the held-out phrase type: two marker NPs, with plural patients (Figure 1, bottom row). The written production task is identical to Phase 4, except it only includes the held-out trial types (12 trials, 3×4 events randomly chosen) and no feedback is given. This written task is added with the purpose of familiarising participants with the held-out trial types prior to the final oral production test phase and will not be included in our analyses.

Finally, participants are asked to produce oral descriptions for *all* trial types in the language. On each trial, participants see a image and are asked to provide a description aloud. As in the previous written production trials, participants are provided with the corresponding verb form when necessary. Feedback is provided (as described above) *only* when the target description does not contain a two-marker NP. There are 58 trials total (randomised): 36 two-marker NP trials, 6 trials of each of the three one-marker NP trial types, and four bare noun trials.

Results

Recall that, based on Universal 39 (Greenberg, 1963), participants are predicted to produce number markers closer to the noun stem than case markers. This should hold for both the pre- and post-nominal conditions. Our working hypothesis is that these orders are preferred because they reflect the scopal relations among morphemes. Figure 2 is a stacked histogram, showing the percentage of participants whose oral productions follow scope in 0-100% of trials across both conditions. Experiment 1 results (with English speakers) are on the left-hand side. For critical trials, 95% of participants are (almost) perfectly consistent, producing two-marker NPs in the predicted order 95-100% of the time. We ran a logistic mixed-effects regression model predicting use of scope-isomorphic morpheme orders on two-marker NPs dur-

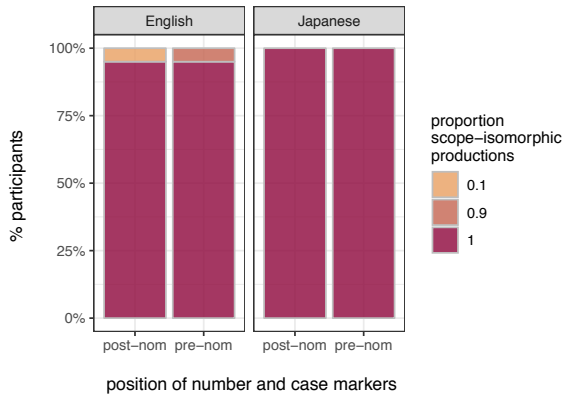

Figure 2: Percentage of participants in Experiments 1 (English) and 2 (Japanese) who produced scope-isomorphic responses a given proportion of the time (rounded to one decimal), ranging from 0% of the time (yellow) to 100% of the time (dark red). Results are split by Marker Position (pre- vs. post-nominal).

Table 1: Model output for Experiment 1.

	β	*SE*	*z*	$Pr(>\|z\|)$
(Intercept)	13.398	3.213	4.169	< 0.001
Marker Position	−0.219	2.428	−0.090	0.928

ing oral production by Marker Position (pre-nominal vs. post-nominal).[3] As shown in Table 1, the intercept (grand mean of scope-isomorphic productions across participants in both conditions) is positive and significant, confirming that the average proportion of scope-isomorphic productions ($P \approx 1$) is above chance. The effect of Marker Position is not significant, confirming that this preference holds regardless of the pre- or post-nominal positioning of the markers.

Experiment 2

The results of Experiment 1 are consistent with the hypothesis that scope relations—here between number and case morphemes—determine proximity to the noun stem. Importantly, we can rule out the effect of raw or bigram frequency in driving our results, since these were held constant in our stimuli. However, an alternative explanation is that our result reflects the fact that English overtly marks (plural) number but it does not have morphological case marking (aside from perhaps the genitive). Exactly how this would lead to a preference for placing number closer than case is not totally clear. Perhaps familiarity with, or accessibility of the number marker leads English speakers to place it closer to the noun. To rule this out, we replicated Experiment 1 with native speakers of Japanese. In contrast to English, Japanese overtly marks cases (including accusative) via suffixation; however, the marking of plurality is exceptional (Nakanishi & Tomioka, 2004). The closest thing to number marking *on nouns* are the associative plural classifiers or collectivising suffixes (*-kata*, *-tachi*, *-ra*, *-domo*). Number is typically expressed instead via plural words (which appear after the case inflected noun), reduplication or numeral words (which precede the noun). Japanese speakers should therefore have no trouble acquiring a novel accusative case marker, and if anything should find the case marker more familiar/accessible than the number marker.

Methods

Experiment 2 is identical to Experiment 1, with one difference: the input lexicon. Rather than using a language with English-like phonotactics, the lexicon for Experiment 2 matched Japanese phonotactics. The preregistered design and analysis plan for Experiment 2 is accessible at osf.io/akcyp.

Participants Forty native Japanese speakers were recruited from Waseda University's student database. Participants were paid ¥1000 for a 35-min-long experimental session. Note that all participants spoke English as an L2.

Input language Lexical items in the language were displayed in Katakana (instead of Latin) script. The three seminonce verbs (which contain the stem of the existing verbs in Japanese) are: ケルラ ([keˈrura]), ナグラ ([naˈgura]) and サスラ ([saˈsura]), which refer to 'kicking', 'punching' and 'pointing' respectively. The (trisyllabic) nonce nouns are: ソギナ ([sogiˈna]), ダクメ ([dakuˈme]), ネチビ ([neˈʧibi]), and タソヌ ([tasoˈnu]), naming four characters (a burglar, a chef, a cowboy, and a waitress). The two nonce markers (one for number, one for case) are randomly chosen from the following set: セヒ ([seˈhi]), ギト ([giˈto]), ヨザ ([yoˈza]). Word order in sentences was Verb-Agent-Patient. Half of the participants were assigned to each of two conditions as per Experiment 1 (i.e, pre-nominal or post-nominal morphology). Auditory stimuli were recorded in a sound-attenuated room by a 28yo female speaker of Japanese.

Procedure The experiment was conducted in a quiet room, with all instructions provided in Japanese, and a Japanese-speaking experimenter. Participants were told that they would be learning part of a foreign language. The session proceeded exactly as outlined for Experiment 1.

Results

The proportion of participants whose oral productions follow scope in 0-100% of trials are shown in Figure 2. The results from Experiment 2 are on the right-hand side. All participants produced number consistently (95-100%) closer to the noun than case. This was true in both the pre-nominal or post-nominal marker conditions. We ran a logistic mixed-effects

[3] In all models, fixed effects were sum coded unless stated otherwise, and random intercepts for both items (noun) and participants were included. The DV consists of a binary variable marking the presence and absence of scope-isomorphism in each oral production trial (1 for a scope-isomorphic pattern, 0 for an anti-scopal pattern).

Table 2: Model output comparing Experiment 1 and 2.

	β	*SE*	*z*	$Pr(>\|z\|)$
(Intercept)	12.112	1.966	6.160	< 0.001
Marker Position	−0.0295	1.302	−0.227	0.821
Experiment	−0.012	1.303	−0.009	0.993
Marker Position × Experiment	0.05	1.302	0.038	0.970

model predicting scope-isomorphic productions by Marker Position (pre- vs. post-) and Experiment (Japanese vs. English). As shown in Table 2, the intercept is positive and significant, confirming that the proportion of scope-isomorphic productions is above chance. The non-significant effects of Marker Position and Experiment confirm that this preference holds regardless of pre- or post-nominal positioning of the markers, and regardless of the native language of participants.

Experiment 3

Experiments 1 and 2 demonstrate that learners have a natural preference to produce number morphology closer to the noun stem than case. These results hold for pre- and post-nominal orders, suggesting that the preference is not driven by linear order: number appears before case in post-nominal orders, but after case in pre-nominal orders. Our results hold for speakers of both English and Japanese, suggesting that they are not driven by L1 knowledge: familiarity with a particular morpheme (number or case respectively) does not mean it is placed closer to the stem. Frequency cannot explain the preference either: markers for case and number occur with equal frequency, as does each stem+morpheme bigram. The parsability of the morphemes is also the same, since frequencies of stem+morpheme forms relative to stems alone is the same for each. We thus conclude that the results obtained so far are consistent with a bias towards scope-isomorphism.

While our results suggest the bias is very strong (almost all participants uniformly preferred scope-isomorphic orders), in natural language, competing pressures may be present. One such pressure, prominent in models of morphological learning comes from the notion of locality. Dependencies between morphemes (e.g., between an allomorph and the stem that triggers it) tend to be local, or adjacent (Embick, 2010; Moskal, 2015; Bobaljik, 2012). In Experiment 3, we test the strength of the scope-isomorphic bias in the face of a competing locality bias. To do this, we use contextual allomorphy: the form of the case marker is dependent on the lexical and phonological identity of the noun. Because this creates a dependency between the noun stem and the case marker, a locality bias would predict that these two elements should be adjacent. The effect of the scope-isomorphism bias uncovered in Experiments 1 and 2 may override the effect of a locality bias. Alternatively, the locality bias may interfere with the placement of number in closer proximity to the noun stem, leading to a higher proportion of anti-scopal order productions (typologically rare) in the presence of stem-dependent case allomorphy.

Methods

Participants Forty-four English speakers were recruited and compensated as for Experiment 1. They were evenly divided between four conditions, as described below. Following our exclusion criteria, the data of four participants were excluded from analysis.

Input languages

This was a 2x2 design, with Marker position (pre- and post-) and Allomorphy (no allomorphy vs. case allomorphy) varying between-subjects. The input language in no allomorphy conditions was as in Experiment 1, except that case and number markers appeared as bound morphemes (i.e., affixes) on the noun when presented in text form (no spaces). The input language in the case allomorphy conditions differed additionally in having *two* accusative case markers, which alternated based on the length of the noun: one marker appeared with bisyllabic nouns ('negid', 'tumbat'), the other with monosyllabic nouns ('vaem', 'nork').

Procedure The procedure was identical to Experiment 1, except that in two-marker written trials, participants could not advance to the next trial until they typed the correct number of characters. This encouraged participants to produce both two markers together.

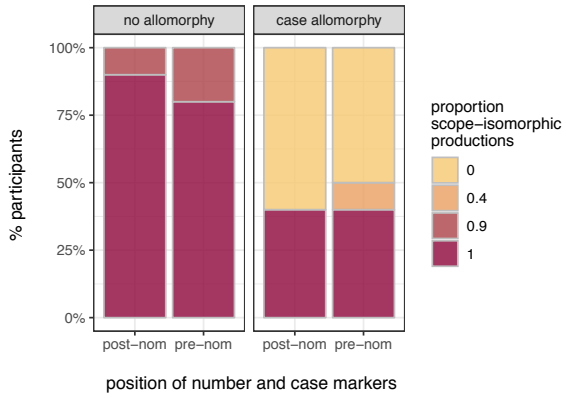

Figure 3: Percentage of participants in Experiment 3 who produced scope-isomorphic responses a given proportion of the time, ranging from 0% of the time (yellow) to 100% of the time (dark red). Results are split by Marker Position (pre- vs. post-nominal) and Allomorphy (no allomorphy vs. case allomorphy).

Results

Figure 3 shows the percentage of participants whose oral productions follow scope in 0-100% of trials across all four conditions. For the no allomorphy conditions, we replicate our previous findings: participants strongly prefer the scope-isomorphic order, with the number marker closer to the noun than case. By contrast, in the case allomorphy conditions,

Table 3: Model output for Experiment 3

	β	*SE*	*z*	$Pr(>\|z\|)$
(Intercept)	15.148	4.557	3.324	< 0.001
Marker Position	0.381	4.355	0.087	0.930
Allomorphy	−27.506	5.386	−5.107	< 0.001
Marker Position × Allomorphy	−0.529	4.691	−0.113	0.910

this pattern is reversed, with most participants producing case closer to the noun. This was confirmed by a logistic mixed-effects regression model predicting use of scope-isomorphic order by Marker Position, and Allomorphy[4]. As shown in Table 3, there is a significant drop in the use of scope-isomorphic orders in the case allomorphy condition.

Discussion

In the experiments reported here, speakers are trained on a language with distinct number and case morphemes, but the relative order of those morphemes is held out. When required to produce both morphemes together during testing, we found that participants' default inference is to place number closer to the noun stem than case (regardless of whether the markers were pre- or post-nominal). This bias provides a potential causal link between human cognition, and a typological generalisation known as Universal 39 (Greenberg, 1963). Importantly, we found strong evidence for this bias across two populations which differ in terms of their prior experience with case and number markers; English marks number but not case, while Japanese marks case but not number. This suggests our results cannot be explained by relative familiarity with these markers. Furthermore, the observed preference is not dependent on distributional information in the input: case and number markers never appear together, and have the same frequency during training. We have suggested that this bias is driven by scope relations among the markers. In particular, case (which marks the grammatical role of the noun in the event) scopes higher than number (which modifies the set properties of the entity), and linear proximity should reflect scope (Bybee, 1985; Rice, 2000; Culbertson & Adger, 2014). While this order is inferred by default, results from Experiment 3 revealed that the presence of stem-dependent contextual allomorphy for case led many participants to place the case morpheme closer to the conditioning noun. This suggests that the default preference may interact with other constraints—i.e., imposed by morphophonological rather than semantic dependency relationships—as predicted by theories of locality (e.g., White et al., 2018; Embick, 2010). Whether such allomorphy patterns are sensitive to locality in natural language points to the need for additional typological research (although see Moskal, 2015).

[4]The fixed effect of Allomorphy was treatment coded (instead of sum coded) so we could directly compare case allomorphy to the baseline no allomorphy.

Conclusion

Our results show that in the absence of explicit evidence, language learners default to a typologically common order of morphemes: with number more proximal to the noun stem than case. This supports a hypothesised link between human cognition and Greenberg's Universal 39. However, this observed bias in principle interacts with constraints on locality driven by morphophonological dependencies.

Data accessibility

The data that support the findings of this study are openly available in the Open Science Foundation repository at https://doi.org/10.17605/OSF.IO/9FA3V.

Abstract

The unique cumulative nature of human culture has often been explained by high-fidelity copying mechanisms found only in human social learning. However, transmission chain experiments in human and non-human primates suggest that cumulative cultural evolution (CCE) might not be dependent on high-fidelity copying after all. In this study we test whether CCE is possible even with a *non-copying* task. We performed transmission chain experiments in Guinea baboons and children where individuals observed and reproduced visual patterns on touch screen devices. In order to be rewarded, participants had to avoid touching squares that were touched by a previous participant. In other words, they were regarded for innovation rather than copying. Results nevertheless exhibited two fundamental properties of CCE: an increase over generations in task performance and the emergence of systematic structure. However, CCE arose from different mechanisms across species: children, unlike baboons, converged in behaviour over generations by copying specific patterns in a different location, thus introducing alternative copying mechanisms into the non-copying task. We conclude that CCE can result from non-copying tasks and that there is a broad spectrum of possible mechanisms that will lead to CCE aside from high-fidelity transmission.

Keywords: social learning; transmission chain; copying; cumulative cultural evolution; Guinea baboons; children;

Introduction

Human culture evolves over time with the gradual accumulation of modifications, from social norms (Nichols, 2002), to art (Morin, 2013), to language (Keller, 2005). In contrast, evidence for cumulative culture has been extremely difficult to find in other animal species (but see, e.g., Grant & Grant, 2010; Garland et al., 2011), and even difficult to induce through experimental manipulations (but see, e.g., Sasaki & Biro, 2017; Fehér, Wang, Saar, Mitra, & Tchernichovski, 2009). It has been proposed that this sharp contrast between human and non-human animal cultures can be explained by the lack of copying fidelity in the social learning of non-human animals (Tomasello, Kruger, & Ratner, 1993; Kempe, Lycett, & Mesoudi, 2014; Lewis & Laland, 2012). Faithful transmission can prevent the loss of cultural modifications and consequently result in cultural accumulation (Tomasello et al., 1993); therefore, the ability to faithfully transmit information through high-fidelity social learning has been taken as a requirement for cumulative culture. However, it is unclear whether there is a critical level of fidelity required to observe cumulative cultural evolution (CCE) and whether that required level of fidelity can ever actually be achieved by social learning mechanisms (Claidière & Sperber, 2009).

Transmission chain experiments have further shown that CCE can occur with learning mechanisms that exist in non-human animals, suggesting that cumulative culture is not after all dependent on special cognitive capacities found only in humans (Caldwell & Millen, 2008; Claidière, Smith, Kirby, & Fagot, 2014; Zwirner & Thornton, 2015). Claidière et al. (2014) for instance, performed a transmission chain study in which baboons observed and reproduced visual patterns on touch screen computers. Transmission led to the emergence of cumulative culture, as indicated by fundamental aspects of human cultural evolution such as (i) a progressive increase in performance and (ii) the emergence of systematic structure. Surprisingly, these results were achieved with an extremely low fidelity of pattern reproduction during the first generations of transmission, suggesting that high-fidelity copying may not always be the cause of cumulative culture and may in fact itself be a product of CCE. Individuals may transform input variants in accordance to their prior biases, and if those biases are shared at the population level, we expect transfor-

mations in the same direction to accumulate at each transmission step. Claidière et al. (2014)'s study therefore shows that cultural transmission may give a misleading impression of high-fidelity transmission when in fact cultural evolution tends to produce variants that become more faithfully transmitted. Similar results have been found in transmission experiments with human participants, for example where the transmission of miniature languages results in the emergence of languages which can be easily learned, even if the initial languages in each chain of transmission are transmitted only with very low fidelity (e.g. Beckner, Pierrehumbert, & Hay, 2017; Kirby, Cornish, & Smith, 2008).

Can we observe CCE in a non-copying task?

Most experiments on social learning and cultural transmission focus on copying tasks in which the individuals goal is to reproduce the input behaviour (for a thorough review, see Mesoudi & Whiten, 2008). However, other mechanisms through which humans and other animals learn, use and transmit information remain under-explored. Encouraged by the results of Claidière et al. (2014) showing that CCE can also result from initially low transmission fidelity, we decided to test whether CCE could occur in a transmission task that did not require direct copying. If high-fidelity copying is essential to CCE, we might not observe it in a task that does not involve copying.

To test this hypothesis, we performed an experiment with baboons and human children using the same protocol as in Claidière et al. (2014) but with a "non-copying" task in which the individuals were trained to avoid directly reproducing the patterns touched by a previous individual. In Claidière et al. (2014)'s original task participants were presented with a grid of 16 squares, four of which were briefly highlighted, and the task was to touch the squares that had been highlighted. The squares touched by one individual then became the highlighted squares for the next individual in the chain of transmission. In our new version of the task, the highlighted squares were instead to be avoided; the squares that one individual touched were the ones the next individual needed to avoid in order to be rewarded.

There are grounds for expecting this change in the pay-off structure of the task would prevent CCE from happening. In every trial, 495 different possible responses lead to a reward (a 27% likelihood of being correct by chance), creating a vast space of "correct" responses in every generation that are all different from the previous individual's response but which all will be rewarded. As well as directly penalising copying behaviour, the fact that the space of possible correct responses is so large and rather unconstrained by the input pattern suggests that any early accumulation of modifications (e.g., incipient structure in the system of patterns produced) could easily be wiped out by any individual in a chain of transmission, preventing cultural accumulation. However, participants could use non-copying alternative strategies that would result in convergent behaviour over generations. For instance, if participants try to minimise the effort of retaining and/or producing non-overlapping patterns, this might progressively cluster the responses on patterns of four connected squares (i.e., tetrominoes, which are easier to retain in memory and produce). This in turn might lead to increased performance over generations because such structured input patterns will be easier to avoid. Thus, if the search in the large evolutionary space is biased and there are alternative strategies which will lead to convergent behavioural output over generations, it might be possible to observe cumulative effects in transmission chains with a non-copying task.

Methods

Guinea baboons

Participants and testing facility Twelve Guinea baboons (Papio papio) belonging to a large social group of 25 from the CNRS Primate Center in Rousset-sur-Arc (France) participated in this study. They were 6 males (median age 8 years, min = 5, max = 11) and 6 females (median age 8 years, min = 5, max = 12).

The study was conducted in a facility developed by J.F. (for further information, see Fagot, Gullstrand, Kemp, Defilles, & Mekaouche, 2014).The baboons live in an outdoor enclosure ($700m^2$) connected to an indoor area which provides shelter when necessary. The outside enclosure is connected to 10 testing booths each equipped with a touchscreen. The key feature of this facility is that baboons have free access to computerised testing booths that are installed in trailers next to their enclosure. Identification of the subjects within each test booth is made possible thanks to two biocompatible 1.2 by 0.2 cm RFID microchips injected into each baboon's forearm. The baboon can thus participate in an experiment whenever they choose, and do not need to be captured to participate. The test program allows an independent test regime for each baboon, irrespective of the test booth it is using. Grains of dry wheat are used as reward. Baboons were neither water- nor food-deprived during the research. Water was provided *ad libitum* within the enclosure. Baboons received their normal ratio of food (fruits, vegetables and monkey chow) every day in the afternoon. The baboons were all born within the primate centre.

This research was carried out in accordance with French and EU standards and received approval from the French Ministère de l'Education Nationale et de la Recherche (approval # APAFIS-2717-2015111708173794-V3). Procedures were also consistent with the guidelines of the Association for the Study of Animal Behaviour.

Computer-based task Each trial began with the display of a grid made of 16 squares, 12 white and four green. Touching this stimulus triggered the immediate abortion of the trial and the display of a green screen for 3 s (time-out). After 400 ms all the green squares became white and, in order to obtain a food reward, the baboon had to select and touch four squares in this matrix which were not previously shown in green colour. Touching these four square could be done in

any order. Squares became black when touched to avoid being touched again and did not respond to subsequent touches. A trial was completed when four different squares had been touched with less than 5 s between touches. If four correct squares were touched, then the trial was considered a success and the computer triggered the delivery of 3-4 wheat grains. If less than four correct squares were touched (i.e. at least one previously green square was touched), then the trial was considered a failure and a green time out screen appeared for 3 s. The stimuli consisted of 80x80 pixel squares (white or green) equally spaced on a 600×600 pixel grid and were displayed on a black background on a 1024×768 pixels screen. The inter-trial interval was at least 3 s, but could be much longer since baboons chose when to initiate a trial.

Training to criterion Twenty-five members of the colony underwent a training procedure to enable them to participate in the transmission chain experiment: only those animals who reached our final criterion (N=12) were admitted to the transmission chain study described below. Training followed a progressive increase in the complexity of the task, starting with one white square and one green square, followed by a stage with an increasing number of white squares (up to six, one green and 2-5 white), then by a progressively increasing number of white and green squares up to 12. Training blocks consisted of 50 non-aborted trials (aborted trials were immediately re-presented, and the abortion rate was very low: mean = 2.2%, min = 0.23% and max = 4.6% for the 25 baboons included in the training). Progress through training was conditioned on performing above a criterion of 80% success on a block of 50 random trials (excluding aborted trials).

Transmission procedure We followed the transmission procedure described in (Claidière et al., 2014) and therefore only report the main elements here. Testing began when all 12 baboons reached the learning criterion with four targets (green squares) and 12 distractors (white squares) randomly placed on the grid. For each transmission chain, a first baboon was randomly selected, and this subject received a first block of 50 transmission trials consisting of randomly-generated patterns. Once the first subject had been tested, its behavioural output (the actual pattern of squares touched) on these 50 transmission trials became the set of target patterns (randomly reordered) shown to the next individual in that chain.

When the individuals were not involved in the transmission chain, they could perform random trials that were generated automatically by the computer and were not part of the transmission process. We ran nine such chains each with 10 generations (i.e., 10 individuals in each chain), each initialised with a different set of randomly-generated trials. We also made sure that each baboon did not appear more than once in each chain and performed at least 500 random trials between sets of transmission trials to avoid interference between chains.

Children

The experimental procedure for children was as similar as possible to the experimental procedure for baboons; in this section we detail the differences.

Participants and materials Participants were 90 English speaking children between the ages of 5 and 7 years old (42 female, mean age = 6 yo), recruited at the Edinburgh Zoo's Budongo Trail. Four further participants were excluded from the study because they failed the pre-established criterion to achieve at least 2/3 successful trials during training. The experiment was carried out in accordance with the research ethics procedures of the Edinburgh Zoo's Bundongo Trail and of the department of Linguistics and English Language at The University of Edinburgh (Ref # 325-1718).

The experiment was conducted on iPads using the iOS application Pythonista 3, in a single session of approximately three minutes. The experiment took place in the hall of the the Edinburgh Zoo's Budongo Trail, with the child seated on a chair and the experimenter beside them throughout, providing all instructions verbally. The experimenter also provided encouragement to the child but no informative feedback during critical trials. All participants were rewarded with stickers at the end of the experiment.

iPad-based task The experiment was divided into two phases, a training phase and a testing phase. The training phase followed a progressive increase in the complexity of the task over three blocks, starting with a grid of two squares (one white, one red)[1], then a grid of four (two red, two white) followed by the final grid of 16 (four red, 12 white). Training blocks consisted of three trials each. We excluded participants who failed to produce a minimum of two successful trials during the last two training blocks (grids of four and 16). During testing, each trial (20 total) began with the display of a grid made of 16 squares as in the baboons' version, 12 white and four red. If four correct squares (any four of those which were not displayed in red) were touched the trial was considered a success and the smiley face of a monkey emoji was displayed along with a reward sound effect. Otherwise, the face of the monkey emoji was displayed with both hands covering the mouth along with a child-friendly incorrect answer sound effect. After the monkey emoji faded away, the screen remained black for 1 s before the next trial began. At the end of the experiment, irrespective of the participants performance, the display filled with animated stars while a reward melody was played.

Transmission procedure

The transmission procedure was exactly as described for the baboons' version, with the only difference being the size of the testing/transmission set, which was 20 trials in the child version instead of 50. We ran nine transmission chains with

[1]We decided to change the colour of the squares in the input patterns to follow the western colour conventions in which red is associated with prohibition.

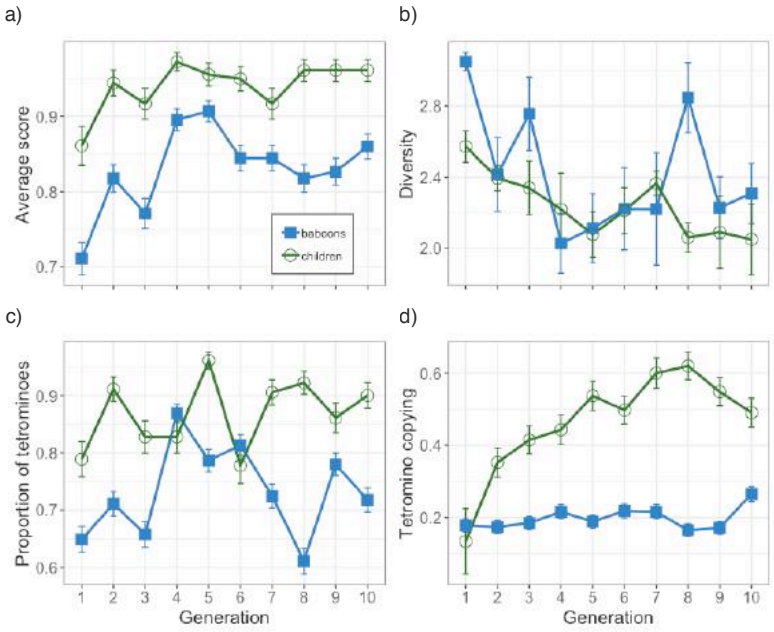

Figure 1: Blue squares and green circles illustrate the results for baboons and children respectively. (a) Average score, defined by the proportion of successful trials. (b) Average Shannon's diversity index within the set of responses. (c) Average proportion of tetrominoes produced. (d) Average proportion of observed tetrominoes which are copied.

a total of 10 generations (i.e., 10 children); each chain was initialised with a different set of randomly-generated trials.

Statistical analyses

The aim of our analyses is to evaluate the strength of the evidence for cumulative culture in baboons and children considering the two criteria highlighted in the introduction, that is, to test (i) a progressive increase in task performance over generations, and (ii) the emergence of systematic structure.

To analyse the results we used mixed-effects Growth Curve Analysis (GCA); the type of model, logistic or linear, will vary according to the dependent variable. All models contain three fixed effects: Generation, a quadratic polynomial for Generation (Generation^2), and Experiment (baboons as the baseline, and children). They also contain two interaction terms, between Generation and Experiment, and between Generation^2 and Experiment. To control for the non-independence within a given transmission chain, all models also contain random intercepts for Chain as well as by-Chain random slopes for the effects of Generation and Generation^2.

Results

Increase in task performance The average score was high across children and baboons, and we found a progressive increase in performance over generations of transmission across children and baboons (see Figure 1a). Using a dependent binary variable (success or failure for each trial) to analyse the evolution of success over generations, the results of the logistic GCA model show a significant effect of Generation ($\beta = 0.307, SE = 0.054, z = 5.700, p < 0.001$) and no significant interaction with Experiment ($z = 0.006, p = 0.995$), suggesting that task performance increases over generations of participants across children and baboons. We also found a significant effect of Generation^2 ($\beta = -0.027, SE = 0.005, z = -4.911, p < 0.001$) and no significant interaction with Experiment ($z = 0.351, p = 0.726$), suggesting that the increase in performance abates as we move along generations of participants. There was a further significant effect of Experiment ($\beta = 1.043, SE = 0.257, z = 4.062, p < 0.001$), suggesting that children generally scored higher in the task than baboons.

Emergence of systematic structure One indicator of the emergence of structure is a progressive decrease in response diversity due to a focus on a subset of responses (Kirby et al., 2008). We observed a reduction of diversity among sets of grids during transmission (see Figure 1b). Using the same model structure as previously specified, and the Shannon's diversity index of the systems of responses (equal to Shannon entropy: Shannon, 1948) as the dependent variable, a linear GCA model reveals a significant effect of Generation ($\beta = -0.237, SE = 0.069, t = -3.535, p < 0.001$) and no significant interaction with Experiment ($t = 1.467, p = 0.144$), suggesting that the diversity of the systems decreased over generations of participants across children and baboons. We also found a significant effect of Generation^2 ($\beta = 0.022, SE = 0.007, t = 2.982, p = 0.003$) and no significant interaction with Experiment ($t = -1.597, p = 0.112$), suggesting that the decrease in diversity deflates as we move along generations of

participants (across species). Moreover, the marginal effect of Experiment ($\beta = -0.356, SE = 0.19, t = -1.853, p = 0.068$) does not provide strong evidence to suggest a difference between children and baboons.

To explore the type of structures that emerged during transmission which might guide the observed decrease in diversity, we looked at the main structures found in Claidière et al. (2014), that is, tetrominoes (grids where all four squares are connected—lines, squares, L-shapes, T-shapes, S-shapes; tetrominoes will be familiar to anyone who has played Tetris). Figure 1c shows the proportion of tetrominoes produced over generations. The results from a logistic GCA model with a binary dependent variable representing the presence or absence of a tetromino suggest that children and baboons have a significant tendency to produce tetrominoes ($\beta = 0.688, SE = 0.225, z = 3.058, p = 0.002$) and that children produced them significantly more than baboons ($\beta = 1.046, SE = 0.353, z = 2.961, p = 0.003$). We also found a weak effect of Generation ($\beta = 0.252, SE = 0.112, z = 2.263, p = 0.024$) and no effect of its interaction with Experiment ($\beta = -0.214, SE = 0.177, z = -1.206, p = 0.228$), suggesting that the proportion of tetrominoes produced slightly increase with generation in baboons as well as in children. However, the significant effect of Generation^2 ($\beta = -0.026, SE = 0.012, z = -2.080, p = 0.038$) and the non-significance of its interaction with Experiment ($\beta = 0.030, SE = 0.020, z = 1.517, p = 0.129$) suggest that such increase in the production of tetrominoes reduces with generation.

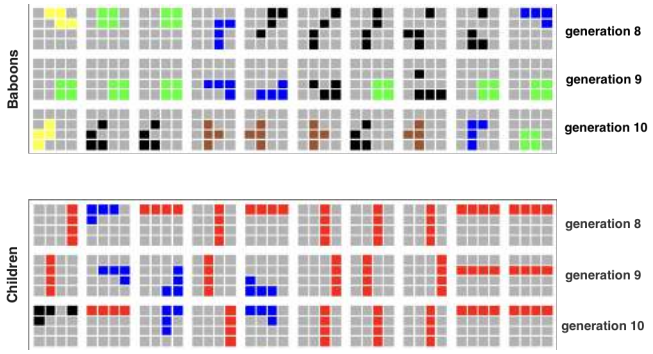

Figure 2: Baboons' and children's example responses, rows correspond to 10 example grids in generations 8-10 of a given chain (from top to bottom). Colouring of each grid reflects the tetromino class each pattern belongs to (green for squares, blue for L-shapes, brown for T-shapes, yellow for S-shapes, and black for non-tetrominoes).

Copying in a non-copying task So far, the general tendencies in the results found in children are very similar to those found in baboons—the only difference so far is that children score higher and produce more tetrominoes than baboons on average. However, an inspection of patterns produced (see e.g. Figure 2) suggested that children tended to copy the overall shape of the response of the previous individual (but shifted its position to avoid direct copying of the observed pattern). Figure 1d indicates that while baboons tend not to copy the overall shape of input tetrominoes in their responses, children seem to do so increasingly over generations. A logistic GCA model confirms that while baboons copy input tetrominoes significantly below chance ($\beta = -1.27, SE = 0.174, z = -7.336, p < 0.001$) constantly across generations (Generation, $z = -1.416, p = 0.157$; Generation^2, $z = 0.012, p = 0.100$) , children increasingly copy input tetrominoes over generations ($\beta = 0.559, SE = 0.121, z = 4.602, p < 0.001$) and more so initially than later on, where the increase abates (as indicated by the interaction between Generation^2 and Experiment, $\beta = -0.048, SE = 0.012, z = -4.620, p < 0.001$).

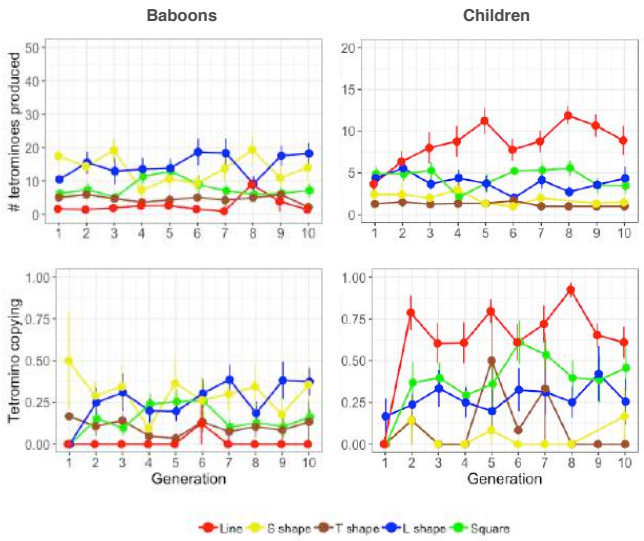

Figure 3: Top row: Average number of tetromino shapes produced by baboons (left) and children (right) for each of the five tetromino classes (over 20 and 50 trials respectively). Bottom row: Average proportion of tetrominoes that are copied from one generation to the next for baboons (left) and children (right).

We further explored the difference in copying in children and baboons by examining specific tetromino shapes because the inspection of the patterns produced (Figure 2) also suggested that children tended to produce many lines and that they copied them more so than any other pattern. Figure 3 shows the average number of tetrominoes produced as well as the proportion of tetromino copying subset by each of the five possible tetromino shapes. A visual inspection of Figure 3 reveals a clear preference for lines over other tetrominoes in children. Moreover, lines are the only pattern that shows an increase in production over time in children. We thus ran a logistic mixed-effects regression model (without the quadratic term, and with an added fixed effect for Tetromino Type with an interaction term) to test whether this observed increase in the production of lines over generations in children could be

accompanied by an increase in tetromino copying specific to lines. Results suggest that children copy lines significantly more than baboons ($\beta = 5.055, SE = 2.075, z = 2.436, p = 0.015$), who in contrast produce lines below chance ($\beta = -4.24, SE = 2.065, z = -2.052, p = 0.040$) equally across generations ($\beta = 0.001, SE = 0.356, z = 0.004, p = 0.997$). Results further suggest that lines are the most copied tetrominoes in children ($\beta = -0.048, SE = 0.012, z = -4.620, p < 0.001$; the smallest difference is shown with square tetrominoes: $\beta = -4.105, SE = 2.096, z = -1.958, p = 0.05$) but that this tendency to copy lines does not change over time ($\beta = -0.017, SE = 0.358, z = -0.047, p = 0.962$). We did not find a single significant interaction of Generation in the model (biggest effect: $z = 0.343, p = 0.732$). Altogether, these results suggest that children have a constant tendency to copy lines (above other tetrominoes), and once lines are introduced in the system, they are maintained. This in turn results in their accumulation and increase in number over time as new lines are introduced.

Discussion

The idea that faithful copying is essential to CCE is both intuitive and appealing: if socially-learned behaviours are not faithfully transmitted, modifications to what is being transmitted will not be passed on to other generations of individuals and will therefore be lost (Tomasello et al., 1993). In a process closely similar to biological replication, faithful copying could guarantee the transmission of modifications and therefore naturally lead to CCE. However, cultural evolution is much broader than biological evolution because it does not fundamentally derive from a process akin to replication and is therefore not constrained to certain modes of transmission (Claidière & André, 2012): several studies illustrate the fact that transmission can be of low fidelity and still lead to CCE (Caldwell & Millen, 2008; Claidière et al., 2014; Kirby et al., 2008; Claidière & Sperber, 2009).

The purpose of this study was to add to this research by examining the possibility of finding CCE with a non-copying task across human and non-human primate species. Results from children and baboons exhibited the two properties of CCE examined: (i) an increase in task performance linked to (ii) the emergence of some type of systematic structure. Despite the presence of a large evolutionary space (1820 possible responses for any single grid) and a very lenient reward function (27% chance of being correct by chance on any trial), we found the emergence of structure. This pattern probably emerged because the participants tended to cluster their responses in tetrominoes.

Although results from children and baboons were strikingly similar we found that, unlike the baboons, children introduced alternative copying mechanisms into the non-copying task by copying the shape of the input pattern in a different location, which was not prevented in the task (the non-copying task only forbid them from copying the exact grid pattern in the input, which included both the shape and location of the stimulus). This strategy adopted by children might in turn potentially explain (at least partially) their higher scores and tetromino production in comparison to baboons.

This observed copying strategy could be in line with children's tendency to high-fidelity copy even when not required in the task (Lyons, Young, & Keil, 2007; Whiten, McGuigan, Marshall-Pescini, & Hopper, 2009). Complementarily, it could also be partly explained by the fact that children, unlike baboons, only saw grids of two and four squares during training before the target grid of 16, and in these grids, the rewarded output is necessarily the mirror image of the input. However, we only observe high-fidelity copying of specific shapes (i.e., tetrominoes), which are potentially already preferred by children. Once these preferred shapes are in the system, they are maintained. Results thus suggest that the observed bias is not a copying bias (at least uniquely), but a bias towards tetromino shapes (stronger than in baboons; on average, almost 80% of responses are tetrominoes in childrens first generations), which results in high-fidelity copying once these patterns are introduced. Further inspection of the results showed that children tended to produce many line tetrominoes as well as to copy them from the input (more so than any other pattern), altogether suggesting that the bias towards tetromino shapes could be particularly strong for line tetrominoes. This bias towards copying and producing lines could be cognitive or task-specific (i.e., lines could potentially be easier and faster to produce altogether or in the context of an iPad game where one finger instead of two is mostly used), or it could simply reflect that lines are particularly salient to children (e.g., because of drawing or colouring).

Conclusion

Our study demonstrates that CCE can be observed in a non-copying task in baboons and children. Results across species exhibited two crucial properties of CCE: (i) an increase in task performance over generations and (ii) the emergence of systematic structure. However, these seemingly similar properties of CCE across species arose from different mechanisms: children, unlike baboons, converged in behaviour across generations by copying specific patterns (i.e., tetrominoes, and in particular lines) in a different location thus introducing biased copying into what was set up as a non-copying task. Together, our results suggest that CCE does not necessarily depend on (at least unbiased) high-fidelity copying and that there is a broad spectrum of possible transmission mechanisms that will lead to CCE; these mechanisms that are not based solely, or even mainly, on high-fidelity copying remain to be further explored.

Data accessibility

The data that support the findings of this study are openly available in the Open Science Foundation repository at https://doi.org/10.17605/OSF.IO/ZA265.

Abstract

Dotov, Nie and Chemero (2010) conducted a set of experiments to demonstrate how phenomenology, particularly the work of Martin Heidegger, interfaces with experimental research in embodied cognitive science. Specifically, they drew a parallel between Heidegger's notion of readiness-to-hand and the concept of an extended cognitive system (Clark 2008) by looking for the presence or absence of interaction-dominant dynamics (Holden, van Orden, and Turvey 2009; Ihlen and Vereijken 2010) in a hand/mouse system. We share Dotov, Nie and Chemero's optimism about the potential for cross-pollination between phenomenology and cognitive science, but we think that it can be better advanced through a shift in focus. First, we argue in favor of using Maurice Merleau-Ponty's phenomenological theory as the philosophical foundation for experimental research in embodied cognitive science. Second, we describe an audio-visual tracking task in virtual reality that we designed and used to empirically investigate human-environment coupling and interactivity. In addition to providing further support for phenomenologically-inspired empirical cognitive science, our research also offers a more generalizable scientific treatment of the interaction between humans and their environments.

Keywords: phenomenology; embodiment; interactivity; agent-environment systems

Introduction

Dotov, Nie and Chemero (2010) illustrated how insights from the philosophical tradition of phenomenology can contribute to experimental research in embodied cognitive science. In a set of experiments, they had participants play a computer game using the mouse cursor to herd a moving target to a designated area of the screen. In the middle of the experiment, the connection between cursor and mouse was briefly "broken," making the cursor move randomly on screen, independently of mouse movements of the participant, until, after a short period of time, normal operation was resumed. The authors recorded time series data of the mouse/hand position and subsequently submitted it to a detrended fluctuation analysis (Kantelhardt et al., 2001), which estimates a measure of temporal correlation within a time domain signal. They found that when the mouse malfunctioned, there was a shift in the fractal scaling of the mouse/hand movements which they took to correspond to the degeneration of interaction-dominant dynamics into component-dominant dynamics (Holden, van Orden, and Turvey 2009). Following Heideggerian phenomenology, they framed this as a transition from the mouse being *ready-to-hand* to being *present-at-hand* for the participant.

For Heidegger (1927), we perceive objects and tools pragmatically as "something in-order-to": for example, you experience the sheet of paper on your desk as *something to write on* and the pen as *something to write with*. In typical circumstances, these objects are "ready-to-hand" in that, while using them, you can focus on the end goal (writing a letter, say) without having to explicitly attend to the tools themselves. But if something goes wrong and the pen runs out of ink, for example, then the pen becomes "present-at-hand": i.e., it suddenly comes to the forefront of your attention, as something that needs to be confronted explicitly and directly before you can resume your work. It is in this sense that Dotov, Nie and Chemero characterize the mouse in their experiment as shifting from being "ready-to-hand" to "present-at-hand" when it becomes unresponsive.

We agree with Dotov, Nie and Chemero about the potential for cross-pollination between phenomenology and cognitive science. In this paper we explore how this interdisciplinary collaboration can be further promoted through a shift in focus. The object of our investigation is perception-action coupling and interactivity in agent-environment systems: as we propose, understanding how agents engage with features of their environment encompasses a broader range of cognitive phenomena that includes, but is not limited to, tool use. In what follows, we first present Maurice Merleau-Ponty's phenomenological theory as providing the philosophical foundation for this shift. Next, to illustrate what this shift looks like experimentally, we describe findings from a novel audio-visual tracking task in virtual reality that we created. We conclude by discussing how this approach offers a more widely-applicable perspective for phenomenologically-inspired empirical research in embodied cognitive science.

Merleau-Ponty, Embodiment and Interactivity

Maurice Merleau-Ponty (1945) introduces the term "bodily schema" to describe the "sensori-motor unity of the body" (p. 114). This unity entails, at once, the integration of each of our senses with one another and the integration of perception with action. Seeing and hearing are "pregnant with one another" and they work together as much as our two eyes complement one another. At the same time, seeing and hearing operate in conjunction with our legs and arms to produce walking and grasping: "my body is, not a collection of adjacent organs, but a synergic system, all the functions of which are exercised and linked together in the general action of being in the world" (p. 272).

Merleau-Ponty's famous example of the blind person navigating the environment with a cane or stick shows how this integrated bodily schema is *fluid* and can *change* over time. If you are adept at getting around using a stick, that is because you no longer perceive the stick itself but you perceive the world "at the end of the stick," which involves an expansion of your integrated sensorimotor bodily schema:

> "To get used to a hat, a car or a stick is to be transplanted into them, or conversely, to incorporate them into the bulk of our own body. Habit expresses our power of dilating our being-in-the-world, or changing our existence by appropriating fresh instruments" (1945, p. 166).

Considered by itself, Merleau-Ponty's example of the blind person's cane is compatible with Heidegger's ideas reviewed above: after all, the cane could be said to be ready-to-hand to the expert user in normal circumstances whereas it would become present-at-hand if it suddenly broke in half, just as it would also be initially present-at-hand to a sighted adult who was trying out the cane for the first time while blindfolded. Yet, Merleau-Ponty's understanding of the bodily schema is much broader than the blind man's cane example suggests and, for this reason, it is also better suited for informing empirical research in embodied cognitive science.

First, although the Heideggerian notions of readiness-to-hand and presence-at-hand help make sense of how we use tools (as in the case studied by Dotov, Nie and Chemero), it is not at all clear how this understanding generalizes to a broader range of cognitive phenomena, such as ordinary instances of perception and action that do *not* involve tool use. In contrast, Merleau-Ponty's richer notion of bodily schema is more versatile, applying to embodied experience no matter the degree of "dilation" and regardless of whether it involves the incorporation of tools. In a telling passage, Merleau-Ponty claims:

> "In the gaze we have at our disposal a natural instrument analogous to the blind man's stick. The gaze gets more or less from things according to the way in which it questions them, ranges over or dwells on them." (1945, p. 177).

As this quote suggests, Merleau-Ponty sees our body and our senses as being tool-like in their instrumental or functional character; yet the bodily schema explicitly applies primarily to our basic embodied activity and only secondarily to literal tool use (such as using a hammer or a mouse) as a particular type of bodily activity.

Second, besides applying to a broader range of cognitive phenomena, Merleau-Ponty's notion of bodily schema is also more theoretically attractive because of how it relates to different views in ongoing debates in cognitive science. Dotov, Nie and Chemero interpreted the ready-to-hand mouse as forming, with the body, an *extended cognitive system*. With this, they explicitly tied their account to the hypothesis that cognition may *sometimes* "leak out" of an individual and into parts of the world that the individual is interacting with (Clark 2008). The extended cognition hypothesis is contentious, to say the least: for many cognitive scientists, cognition just is the name of the processing that goes on within the individual's mind/brain; and for advocates of radical embodied cognitive science (e.g., Chemero 2009), the proper object of study just is the animal-environment system as a whole (Gibson 1979).

Merleau-Ponty's notion of bodily schema does not entail a commitment to the contentious hypothesis of extended cognition, and it thereby circumvents the controversy. In a key passage, Merleau-Ponty explains: "With the notion of the bodily schema we find that not only is the unity of the body described in a new way, but also, through this, the unity of the senses and of the object" (1945, p. 273). Above we saw that the bodily schema entails the sensorimotor unity of the body, that is, the integration of the senses and between perception and action. This quote adds, further, that the bodily schema entails also an integration between subject and the objects of experience. This captures an essential feature of the radical embodied and Gibsonian approaches to studying agent-environment systems, namely the focus on the complex interactivity between agent and environment: in this view, "patterns of an organism's behavior are best understood as the emergent property of the interactions of the organism with its environment" (Kelty-Stephen, Palatinus, Saltzman, and Dixon 2013, p. 2) and "perception and action are best understood in the broader context of the task and environment within which coordination of those biological nuts and bolts takes place" (p. 3). As such, we suggest, embodied agency or "being in the world" is always characterized by an integration of agent and environment through interaction. Interactivity may change qualitatively with changes in task and in the availability of task-relevant information, but it is always present: an agent's perception-action never becomes fully detached from her environment, and understanding this relation is independent of whether some internal feature of the agent "leaks out" into the world or not.

As an illustration of interactivity, imagine an ordinary situation such as trying to track a bumble bee so as to avoid being stung. Although you may initially catch sight of the bee and follow it with your gaze, the bee's erratic movement might cause it to disappear against a cluttered background.

Your desire to avoid being stung persists and you maintain an awareness of the bee's position by listening, trying to regain sight of it. You swivel your head, accommodating for the subtle shifts in interaural sound intensity, allowing your ears to guide your continued search for the bee. Furthermore, the bee may fly along your sagittal plane, momentarily escaping your efforts to track it by sound until, finally, you are able to regain auditory or visual tracking. This dance, between you and the bee, may persist until the bee exits your immediate surroundings. Although it may be true that, at times, the differences in mode and strength of your sensory coupling to the bee change, nothing is ever "broken." There may be differences in how your head or eyes move relative to the bee, but no aspect of this system can be said to transition from readiness-to-hand to presentness-at-hand. Furthermore, the system maintains interactivity throughout. Even though the specific dynamics of a particular aspect of the system may change, the system continues to be unified through the ongoing pursuit of the goals that are implicit to the task (e.g. avoiding a sting). The experiment described below was designed to capture this point.

Method

Undergraduate students (N = 10) at the University of Cincinnati participated in a virtual audio-visual tracking task for class credit. At the start of the experiment, each participant put on an Acer mixed reality headset and a pair of in-ear monitors (IEMs). The virtual scene that they were presented with (depicted in Figure 1) consisted of a white room and a semi-circular line spanning 180 degrees of the participant's visual field on which a black and yellow sphere (henceforth, "the bee") would travel over time, moving in a roughly brownian fashion similar to the moving target from Dotov, Nie and Chemero (2010).

Participants were instructed to track the bee throughout the task by continuously pointing their center of vision, indicated by a small sphere, to its location. They were told that the source would begin emitting a buzzing sound when the experiment started and that it would be necessary to use this sound to continue tracking the bee because the bee would shortly become invisible. The spatial information present in the sound of the bee was imparted by a set of generalized head-related transfer functions (Zhong and Xie 2014). Unbeknownst to the participants, after the bee had been invisible for 12 seconds, the sound spatialization would be removed, making it impossible for the participant to effectively track the bee. After a period of time, the sound spatialization would be added back and then, finally, the bee would reappear. In total, the task consisted of two 12 second periods of audio-visual tracking (at the beginning and at the end), two 12 second periods of audio-only tracking, and one 12 second period of tracking with no spatial information (in the middle). The order of this sequence is illustrated in Figure 2. During the entire experiment, the angular difference between the participant's center of vision and the position of the bee was recorded at 100 hz.

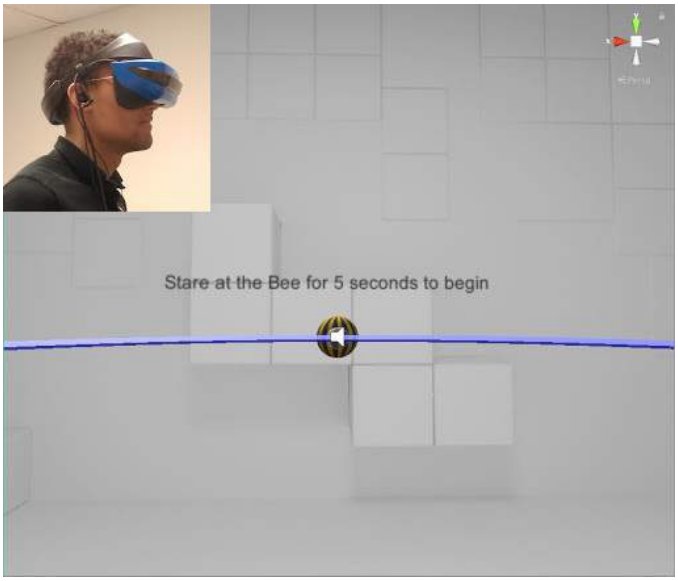

Figure 1: An image of what a participant would see upon starting the experiment, including the bee, the instructions for starting a trial and the line upon which the bee moved.

Fractal Analysis

We submitted the time series data from each trial and condition (Audio-Visual Information (AV), Audio Information Only (AO), and No Spatial Information (NI)) to a detrended fluctuation analysis (DFA) which allows for temporal correlations within a signal, at different scales, to be captured by a single value. Detrended Fluctuation Analysis (DFA) is a form of fractal analysis, which describes a power-law that captures the relationship between the size and occurrence rate of fluctuations for a given time series (Ihlen 2012). Fractal analyses have previously been used to illuminate the nature of embodied cognitive activity by examining continuous measures of agents embedded in environments (Kello, Beltz, Holden & Van Orden 2007).

The DFA measurement of the time series of angular error between gaze and target for each information condition (AV, AO and NI) yields a Hurst exponent and a closely related Alpha value, both of which describe the power-law relationship within the time series. In Dotov, Nie and Chemero (2010), Alpha values were calculated at repeated intervals to identify changes in tool-use behavior that were caused by the perturbation of mouse function. Here, we calculated Hurst exponents for each condition in order to index how gaze activity changes across the information conditions in the bee tracking task, as is visually exemplified in the time series data shown in Figure 2. Our DFA used a minimum window size of 2 samples and a maximum window size of roughly one third of each condition time series, which were each 1200 samples in length.

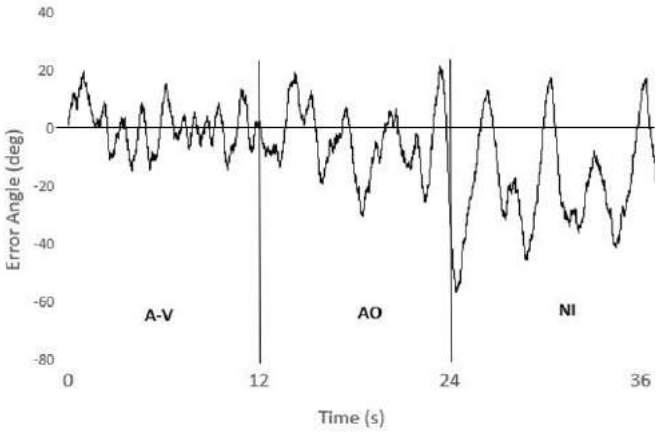

Figure 2: The timeseries above shows the first 36 seconds (x-axis) for the error angle (y-axis) between a participant's center of vision and the bee during the tracking task. The different information conditions are indicated by the lines, Audio and Visual information (AV), Audio information only (AO) and No spatial information (NI). In this particular case, the size and frequency of error clearly changes between the information conditions: error is minimized in the audio-visual condition (AV), increases in the auditory only condition (AO), and displays large, shifting values in the no spatial condition (NI) when the bee target auditory signal switches from stereo to mono.

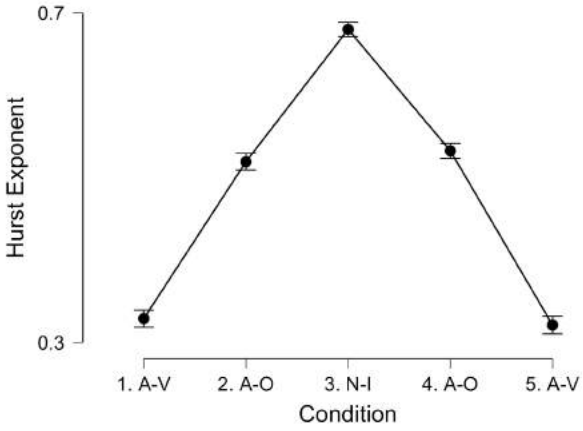

Figure 3: The x-axis indicates the changing conditions between audio-visual information (AV), auditory information only (AO), and no spatial information (NI). The y-axis indicates the value of the mean Hurst exponents and standard error bars for each condition.

Results

The Hurst exponents, calculated for each information condition and trial (AV, AO and NI) were submitted as dependent variables to a repeated measures analysis of variance to examine changes across trials as well as conditional differences.

Neither the within subject main effect of Trial, $F(4,180) = 0.125$, $p = 0.97$, or Trial by Condition interaction effect, $F(16,180)$, $p = 0.1$ were significant. The effect of Condition was significant, $F(4,45) = 86.38$, $p < .001$, $n^2 = 0.88$. It is worth noting that Tukey post-hoc analysis revealed significant differences between the condition types, but not their separate time occurrences: both AV conditions are not significantly different from one another, and both AO conditions are not significantly different from one another. Further details are provided in Table 1 and in Figure 3.

Table 1: Descriptive Statistics

	Mean Hurst Exponents by Condition				
	1. A-V	2. A-O	3. N-I	4. A-O	5. A-V
Mean	0.3290	0.5194	0.6800	0.5326	0.3212
Std. Dev.	0.0641	0.0406	0.0327	0.0459	0.0664

Discussion

Our experimental results reveal differences in the fractal scaling of movement across shifting task conditions. In this way, our results were similar to what was found by Dotov, Nie and Chemero (2010). The key difference between the two experiments lies in our focus. Their investigation is centered on the agent; ours follows radical embodied cognitive science (Chemero 2009) by being primarily concerned with the agent-environment system as a whole. This difference in focus informed both our choice of dependent measure and our interpretation of interactivity.

Because they were trying to find support for the extended cognition hypothesis, Dotov, Nie and Chemero (2010) measured raw hand movement at the tool/hand interface. This meshes well with their goal of demonstrating a shift, from the agent's perspective, between a tool being ready-to-hand to becoming present-at-hand—but this approach misses out on capturing the rest of the agent-environment system. In contrast, we adopted a collective measure at the task performance level. By measuring the error angle between the gaze and the bee's position, we were able to detect shifts in the overall agent-environment dynamics. In this context, specific Hurst exponent values are useful and explicate the nature of the system. For example, in the Audio-Visual Information condition, the low Hurst value indicates that the system corrects for increases in error similarly across timescales, exhibiting anti-persistent dynamics (Riley et al 2012). This makes sense because participants are likely very good at visually orienting to the position of objects. The higher Hurst values from the Auditory Only and No Information conditions show that there is a shift in how error is accommodated for at different scales. In the Auditory Only condition, for example, the

participant may be able only to accommodate for movements of the bee very slowly, but is ineffective at tracking its faster movements. This shift can be characterized as a shift towards persistent system dynamics (Riley et al 2012), which continues in the same direction as information is reduced further in the No Information condition.

A similar interpretation could have been applied to the herding task of Dotov, Nie and Chemero (2010) if the dependent measure had reflected the collective dynamics of the agent-environment system. In their case, it's not that when the tool breaks it is noticed as a tool, external to the system. Rather, the tool appears broken within the context of a task and is used as such. Movements exhibited by participants experiencing a broken mouse are sensible as movements meant to fix or disambiguate the nature of the brokenness of the mouse. Similarly, the movements of our participants who had no information about the bee's position are sensible as exploratory procedures (Riley et al 2002), i.e., movements meant to pick up information. These movements do not reflect a degeneration of interaction, but only a shift in the nature of the ongoing interaction between agent and environment. A participant in either task is never truly decoupled from the specific environment implied by the overarching task.

Dotov, Nie and Chemero characterize the distinction between interaction-dominant dynamics and component-dominant dynamics as follows: "In component-dominant dynamics, behavior is the product of a rigidly delineated architecture of modules, each with predetermined functions; in interaction-dominant dynamics, on the other hand, coordinated processes alter one another's dynamics, with complex interactions extending to the body's periphery and, sometimes, beyond" (2010, p. 3). This characterization works well with their agent-centered approach and their focus on cognition as an internal feature of the agent that can potentially extend out into the world. But when the object of study becomes the agent-environment system, as proposed in radical embodied cognitive science (Chemero 2009), this characterization fails. The dynamic variation in a proper collective measure of a complex agent-environment system will always be governed by the interaction between agent and environment. The system may be redefined across tasks, but can never become broken in the way that Dotov, Nie and Chemero would require. Because interactivity is a universal feature of agent-environment systems, rather than looking for signs of a shift from interaction-dominance to component-dominance, it is more appropriate to inquire into the specific nature of the interactivity. This means focusing on task specific coordination (Turvey, Saltzman and Schmidt 1991), rather than the dynamics that play out at the interface between human and tool.

As seen above, the choice of focus of investigation—whether centered on the agent or on the agent-environment system as a whole—is directly linked to the choice of dependent measure and to the interpretation of interactivity. The focus of investigation is also intimately associated to the phenomenological theory adopted in each case. Heidegger's theory is agent-centric and lends itself to application for investigating the dynamics of tool use and cognitive extension. Merleau-Ponty's theory, on the other hand, motivates thinking in terms of an integration between subject and object, or between agent and environment. This makes it more apt for making sense of a broader range of cognitive phenomena, beyond tool use, where interaction may occur. Merleau-Ponty's approach is thus better suited for conceptually framing research into perceptually driven human-environment interactivity in the ecological and embodied cognitive sciences.

Sources of knowledge in children's acquisition of the successor function

Rose Schneider

David Barner
UC San Diego, San Diego, California, United States

Abstract

The successor function a recursive function S which states that for every natural number n, S(n) = n+1 underlies our understanding of the natural numbers as an infinite class. Recent work has found that acquisition of this logical property is surprisingly protracted, completed several years after children master the counting procedure. While such work links successor knowledge with counting mastery, the exact processes underlying this developmental transition remain unclear. Here, we examined two possible mechanisms: (1) recursive counting knowledge, and (2) formal training with the +1 rule in arithmetic. We find that while both recursive counting and arithmetic mastery predict successor knowledge, arithmetic performance is significantly lower than measures of recursive counting for all children. This dissociation suggests children do not generalize the successor function from trained mathematics; rather, we find evidence consistent with the hypothesis that successor knowledge is supported by the extraction of recursive counting rules.

Examining the multimodal effects of parent speech in parent-infant interactions

Sara E. Schroer (seschroe@iu.edu)

Abstract

Parental input in the form of visual joint attention is hypothesized to serve a critical role in the development of infant attention, acting as a training ground by scaffolding an infant's ability to sustain visual attention in real-time. We extended this hypothesis by studying the effects of parent speech on infant visual and manual attention. Thirty-four toddlers and their parents participated in a free-play study while wearing head-mounted eye trackers. Infant multimodal behaviors were measured in four ways: visual attention, manual action, hand-eye coordination, and joint visual attention with their parent. Overall, we found that longer durations of attention were accompanied by parent speech. Moreover, sustained attention, defined as behaviors lasting 3s or more, almost always occurred with parent speech. Individual differences in parent-infant coordination were also explored. These results suggest that parent-infant interactions create multimodal opportunities for infants to practice sustaining attention.

Keywords: attention, children, cognitive development, eye-tracking, interactive behavior

Introduction

Infants are active learners – they seem to be self-motivated to explore and make predictions about their world. Early development is not solely an individual process, however – it is also embedded in a highly social context as young infants are taught and supported by caregivers. Parents provide scaffolding to their infants in many different ways and in many different contexts, such as recruiting the child's attention, reducing degrees of freedom, and providing demonstrations (Wood, Bruner, & Ross, 1976). Parent scaffolding has been shown to support the development of executive functioning (Bibok, Carpendale, & Müller, 2009) and verbal skills (Smith, Lamdry, & Swank, 2000). In early language learning, parents use infant-directed speech (Thiessen, Hill, & Saffran, 2005), intersensory redundancy (Gogate & Bahrick, 1998), and selective labeling of objects based on infant behaviors (Pereira, Smith, & Yu, 2014) to support word learning. The idea of parental scaffolding has even been adapted by robotics and AI researchers to build a robotic arm that can learn grasp affordances (Ugur, Nagai, Celikkanat, & Oztop, 2015). Understanding how the mature partner influences the sensorimotor experiences and actions of the young infant to support early development and learning is a key question in cognitive development.

Recent work by Yu & Smith (2016) revealed significant effects of parent behaviors on an infant's capacity for sustained attention. In the study, infants and their parents sat at a table while playing with a set of novel toys. Using head-mounted eye tracking, the authors identified moments when parents and infants jointly attended to (or shared attention to) an object and when infants sustained attention on the same object for at least 3s. When the dyad engaged in joint attention, the duration of the infant's sustained attention bout significantly increased, suggesting that 12-month-old infants' ability to sustain attention is scaffolded by parent attention.

Built upon this finding, a recent study (Suarez-Rivera, Smith, & Yu, in press) provided evidence that the social scaffolding effects from parents are not only limited to parent looking behavior. When parent visual attention was accompanied by other types of parent actions – such as talking and manual actions on objects – infants' sustained attention was further improved. Similarly, this redundancy of parent behaviors has been shown to promote joint attention with younger infants (3-to-11-months-old; Deák, Krasno, Jasso, & Triesch, 2018). In parent-infant interactions, both social partners generate various actions moment-by-moment to create multimodal dependencies of looking, talking, and touching, both within the infant's own system and between the two partners. If multimodal behaviors from parents have effects on infants' visual attention, then parent behaviors may also have effects on other, multimodal infant behaviors. The overarching hypothesis in the present study is that parent speech has cascading effects on not only infant visual attention but a suite of multimodal behaviors in parent-infant interactions.

We chose parent speech to study parent scaffolding because it plays a critical role in early communication and early language development. Hart & Risley (1995) famously demonstrated that the amount parents talk to infants is predictive of the varying language abilities of 3-years-olds in different socioeconomic strata. Subsequent studies show both quality and quantity of parent speech is predictive of later language outcomes (Tamis-LeMonda, Bornstein, & Baumwell, 2001; Hirsh-Pasek et al., 2015). While past research has focused on how parent speech and its linguistic properties, such as infant-directed speech and wh-questions

in speech, predict later child vocabulary size (e.g., Rowe, 2012; Weisleder & Fernald, 2013), the present study will examine the non-linguistic effects of parent speech.

Studying the role of parent speech in the micro-level dynamics of parent-infant interactions is a crucial next step in the field. Although joint visual attention facilitates infant sustained attention (Yu & Smith, 2016), we know that joint attention during toy play does not result from infants following the gaze of their caregivers and does not require any overt bid for the partner's attention (Yu & Smith, 2017a; Deák et al., 2018). During play, adult object manipulations (often coupled with other behaviors, such as speech), are the most promotive of joint attention (Deák et al., 2018). However, maternal speech is tightly linked to object manipulation and occurs frequently in an interaction as a response to infants' visual attention to objects, handling of multiple objects, and vocalizations (Chang, de Barbaro, & Deák, 2017). Parents verbally respond to a suite of multimodal infant behaviors, potentially serving as scaffolding for not only joint attention but also other forms of sustained attention.

To test the multimodal effects of parent speech, we chose four infant behaviors from parent-infant interactions that have been shown to be important in early development: 1) visual attention; 2) manual action; 3) hand-eye coordination; and 4) joint attention. Visual attention was chosen because infant sustained visual attention predicts later language learning and cognitive development (Kannass & Oakes, 2008; Lawson & Ruff, 2004; Yu, Suanda, and Smith, 2018). Manual action was chosen because motor skills, including object exploration, are known to play a major role in early language development (Iverson, 2010). Hand-eye coordination was chosen because both infants and parents attend to their own actions and their partner's object manipulations in free play (Yu & Smith, 2017b). Lastly, joint attention between infant and parent was chosen because dyadic differences in the frequency with which parents and children engage in episodes of joint attention predict individual differences in child vocabulary size (Tomasello & Todd, 1983). For all of these behaviors, we will be looking at sustained attention, defined as when infants attend to an object for a long duration (e.g., greater than 3 seconds). While sustained visual attention is known to predict later outcomes (Kannass & Oakes, 2008; Lawson & Ruff, 2004, Yu, Suanda, and Smith, 2018), the ability to sustain attention in other modalities has not been explicitly studied.

The present study had two goals. In Study 1, we examined the multimodal effects of parent speech by measuring the durations of the four types of multimodal behaviors when they were accompanied by parent speech and comparing with when they were not. We hypothesized that parent talk increases infants' ability to sustain their multimodal behaviors. In Study 2, we focused on individual differences in parent speech, given that some parents generated more speech than others did in free play. We examined whether varying amounts of parent speech create different effects on infants' multimodal behaviors.

Methods

Thirty-four toddlers (mean age = 18.67mos [range: 12.3-24.3]; female = 16) and their parents participated in a study on naturalistic parent-infant interactions during free play. An additional 5 dyads were included in the experimental data set but were excluded from the current analyses due to missing parent eye-tracking (n = 2) and non-transcribable speech (n = 3).

Data Collection

Parents and infants played with 24 toys on a carpeted floor in a playroom for an average of 7.15 minutes (range 3.93-11.64). At the beginning of the play session, the toys were randomly spread out across the floor. Parents were instructed to play as they would at home and that they could sit in any orientation (behind, next to, in front of their infant), but were asked to keep their infant sitting on the floor due to the eye tacker's cable.

During the play session, both parent and infant wore a head-mounted eye tracker (Positive Science LLC). The eye tracker system used a scene camera on the participant's forehead to record images from the wearer's perspective with a visual field of 108°. A second, infrared camera pointed to the participant's right eye to record saccades and fixations. Both cameras sampled at a rate of 30Hz. The infant's eye tracker was affixed to a hat and the parent wore their eye tracker like a pair of glasses. Additional cameras were placed in the room to capture traditional third-person views of the dyad (Figure 1).

Figure 1: Experimental set-up (left) and the infant's first-person view, the cross-hair indicates infant gaze (right).

The experiment was run by two researchers. The session began by one researcher placing the eye tracker on the parent and adjusting the scene and eye cameras, while the other researcher engaged with the infant. Afterwards, both researchers worked together to place the eye tracker on the infant. One researcher, and the parent, continued to distract the infant with exciting toys (e.g. a pop-up toy that played music) as the other researcher set up the eye tracker on the infant. After both members of the dyad were wearing their eye trackers, the researchers ran a brief calibration procedure. A large board that had lights and produced sounds was placed in front of the infant (approximately 30 cm away). One of the researchers controlled the board and lit up one of the lights

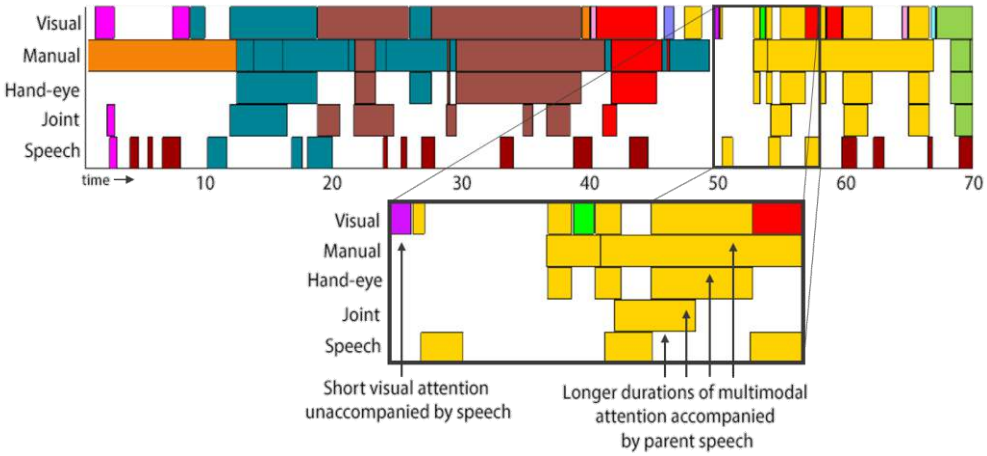

Figure 2: Data streams of infant visual attention, manual action, hand-eye coordination, joint attention, and parent speech over 70s of an interaction. Each block represents a behavioral event and each color represents a different object. The color of parent speech represents the object being named, dark red indicates no naming in that utterance.

until both the parent and infant shifted their gaze to that location. This procedure was repeated for 15 light locations.

The researchers monitored the experiment from an adjoining room. If the infant's eye camera was bumped or moved during play, the researchers reentered, adjusted the camera, and completed an abridged calibration procedure.

Coding and Analyses

Following the experiment, the eye tracking videos from the scene and eye cameras were synchronized and calibrated with a software program to generate a cross-hair that indicated where the participant was looking during each frame of the video (Figure 1). Parent and infant visual gaze were then coded manually using the first-person view (from the scene camera) with the cross-hair overlaid. Using an in-house program, the coder annotated which region of interest (ROI) the cross-hair overlapped with during a fixation. There were 25 ROIs – one for each toy and the social partner's face.

The scene cameras and third-person views were then used to annotate the objects being handled by a participant, frame-by-frame, in an in-house program. If a hand was touching an object, the object was considered "in hand". Participants' left and right hands were coded separately.

Parent speech was transcribed using Audacity at the utterance level. There was no minimum length for an utterance, but separate utterances had to be 400ms or more apart (otherwise they were collapsed together). All parent talk and vocal play (like saying "vroom-vroom" or making a crashing sound) were considered speech. Due to the 400ms criteria, chunks of speech that would be considered sentences could be split apart and separate sentences could be counted as one utterance.

In the current studies, we were interested in five behaviors: infant visual attention, manual action, hand-eye coordination, dyadic joint attention, and parent speech (Figure 2). **Visual attention** was defined as all infant fixations to the 25 ROIs. **Manual action** was similarly defined as all instances of the infant touching an object with either or both hands. **Hand-eye coordination** was defined as moments when the infant looked at and handled the same object, for any duration of time. **Joint attention** between the parent and infant was defined as any moment when the parent's and infant's visual attention fell on the same ROI. All parent utterances were counted as **speech**.

For all four multimodal behaviors (visual attention, manual action, hand-eye coordination, and joint attention) sustained attention was defined as a behavior lasting 3 seconds or longer (to match the previously used definition in Yu & Smith, 2016).

To test the effects of parent speech, we categorized each attention bout as "with speech", if the onset of a parent utterance began after the onset of the attention bout and before the offset of the bout. Other attention bouts, without any overlap with a parent utterance, were categorized as "without speech". With this definition, we can measure the effects of parent speech by comparing attention bouts in the two categories.

Study 1: Multimodal Effects of Parent Support

In Study 1, we tested the relationship between parent speech and the four multimodal measures of infant behavior. Corpus-level analyses were used to compare the durations of all multimodal attentional bouts with and without speech.

Each modality was analyzed separately using mixed effects models to predict the duration of a bout by whether it was accompanied by speech, with subject and attended object as random effects. Each full model was then compared to a null model, with intercept and random effect of object only, using Chi-Square difference tests. All four multimodal behaviors were found to last longer when co-occurring with speech (Figure 3, Table 1).

To specifically test whether parent speech co-occurs with *sustained* attention, an infant behavior known to predict later outcomes (Yu et al., 2018), similar models were used to analyze the subset of sustained attention bouts lasting 3s or more. Bouts of sustained attention of each multimodal

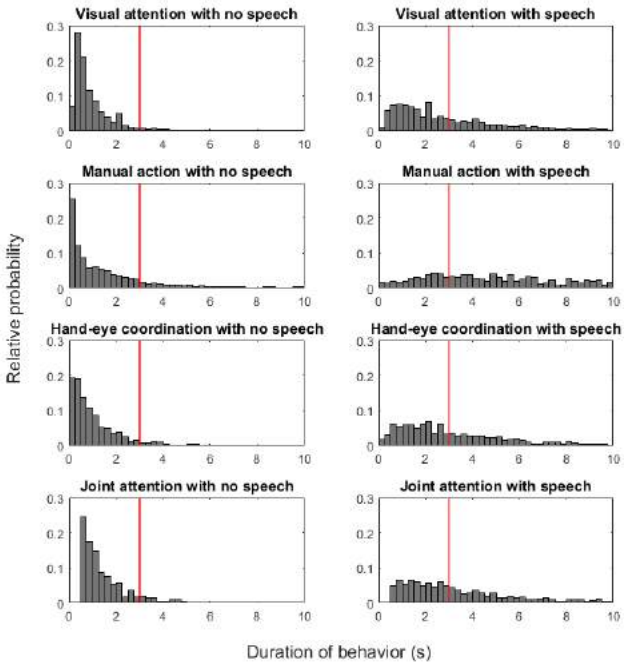

Figure 3: Durations of behaviors without speech (left column) and with speech (right column). Red line indicates the 3-second threshold for sustained attention.

behavior were also longer, and more likely to occur, with speech (Table 1).

The mean duration of **visual attention** bouts with speech was more than 3 times longer than the mean duration of bouts without speech ($M_{with\text{-}speech}$=3.769s, $M_{w/o\text{-}speech}$=1.000s). When we examined the subset of sustained attention bouts that were longer than 3s, sustained attention bouts increased in duration by 50% when accompanied by parent speech ($M_{with\text{-}speech}$=7.196s, $M_{w/o\text{-}speech}$=4.842s).

The mean duration of **manual action** bouts with speech was nearly 8 times longer than the mean duration of bouts without speech ($M_{with\text{-}speech}$=11.187s, $M_{w/o\text{-}speech}$=2.471s). Sustained manual action bouts that co-occurred with parent speech were close to double the duration of bouts without parent speech ($M_{with\text{-}speech}$=13.840s, $M_{w/o\text{-}speech}$=8.629s).

The mean duration of **hand-eye coordination** bouts with speech was nearly 4 times longer than bouts without speech ($M_{with\text{-}speech}$=4.004s, $M_{w/o\text{-}speech}$=1.084s). Sustained hand-eye coordination bouts increased in duration by 50% when accompanied by parent speech ($M_{with\text{-}speech}$=6.961s, $M_{w/o\text{-}speech}$=4.587s).

Lastly, the mean duration of parent-infant **joint attention** with parent speech was more than 2 times longer than joint attention without speech ($M_{with\text{-}speech}$=4.284s, $M_{w/o\text{-}speech}$=1.476s). As with the other behaviors, the duration of sustained attention events with parent speech was longer than sustained attention events without parent speech ($M_{with\text{-}speech}$=6.967s, $M_{w/o\text{-}speech}$=4.071s).

Across all four multimodal behaviors, the duration of infant attention is extended when the bout is accompanied by parent speech. Moreover, when we specifically examined sustained attention bouts, we saw that not only is sustained attention substantially more likely to occur with parent speech, but that bouts of sustained attention with parent speech are significantly longer.

Study 2: Individual Differences

If we view the parent as a coach, training their infant to engage in sustained attention (Yu & Smith, 2016), then we should see differences in how the dyads practice, since different coaches may have different coaching styles. Parents may vary in the "drills", or amount of speech, they use in practice. If so, infants may react differently to parent's coaching which will influence how much they "score" in sustained attention. To understand the individual differences in the coordination of parent speech and infant attention, we examined whether more or less parent talk has different effects on the infant's ability to sustain attention.

Parents varied in how much they spoke to their infants. The average parent produced 16.819 utterances/minute (*SD* =3.844), though the quietest parent only spoke 9.597 times/minute and the most "talkative" parent generated 25.144 spoken utterances per minute. To test the relationship between parent speech and infant sustained attention, we divided the subjects into two groups based on a median split (median = 16.814 utterances/min). Parents in the high frequency speech group produced 19.905 utterances per minute while parents in the low frequency speech group produced on average 13.734 utterances per minute. The low frequency and high frequency groups did not differ in the mean duration of parent utterances (M_{low}=1.309s, M_{high}=1.330s, p = 0.871), suggesting low frequency parents

Table 1: Duration of multimodal behaviors with and without speech

		instances with speech			instances without speech			statistical comparison			
		# of bouts	mean dur	sd	# of bouts	mean dur	sd	beta	p-value	95% CI	null model comparison

Table 2: Sustained attention in dyads with low frequency and high frequency parent speech

	low frequency group			high frequency group			statistical comparison			
	# bouts	mean dur	sd	# bouts	mean dur	sd	beta	p-value	95% CI	null model comparison
sustained visual attention	401	7.636	6.125	585	6.894	4.490	-0.523	0.121	[-1.185 0.136]	$\chi2 = 2.425$, p = 0.119
sustained manual action	604	14.946	18.215	751	12.950	15.881	-2.424	0.008	[-4.220 -0.619]	$\chi2 = 6.928$, p = 0.008
sustained hand-eye coordination	199	7.404	5.918	217	6.555	4.500	-0.822	0.144	[-1.838 0.195]	$\chi2 = 2.511$, p = 0.113
sustained joint attention	198	7.865	6.571	308	6.389	3.649	-1.165	0.009	[-2.035 -0.298]	$\chi2 = 6.911$, p = 0.009

were truly producing less speech, not just fewer, longer utterances. Therefore, the durations of spoken utterances in the two groups would not be a factor to influence infant's attention.

We then compared the durations of sustained attention bouts produced by infants in the low frequency and high frequency groups. To directly measure the effects of parent speech, we only analyzed sustained attention bouts that were accompanied by parent speech. As in Study 1, each type of multimodal behavior was analyzed separately using mixed effects models, with object attended to as a random effect, and then compared to a null model with intercept and random effect of object only.

For manual actions and joint attention, we found that the duration of attentional bouts was longer for infants in the low frequency group (Table 2). The mean duration of sustained **manual action** bouts was 2 seconds longer in the low frequency group (M_{low}=14.946s, M_{high}=12.950s). The mean duration of sustained **joint attention** bouts was more than a second longer in the low frequency group (M_{low} =7.865s, M_{high} =6.389s). There were no differences between the low frequency and high frequency groups in the durations of sustained visual attention or hand-eye coordination.

We present evidence of two groups of dyads, classified by how much speech parents produced in an interaction. These two groups coordinate their attention in different ways – in the low frequency group, there are less occurrences of speech-attention overlap in all four types of behavior. But, when parent speech co-occurs with manual action or joint attention, infants in the low frequency group had significantly longer durations of sustained attention than infants in the high frequency group. This finding suggests two possible phenomena: 1) parents who talked less may be more selective in when they choose to talk; or 2) infants whose parents talked less are more responsive when their parent does talk.

Discussion

With the current studies, we examined the dynamics of parent-infant interactions, specifically the role of parent behaviors in influencing infant attention. We demonstrated that the duration of infants' visual attention is longer when accompanied by parent speech, extending prior work that focused primarily on parent's visual attention (Yu & Smith, 2016). Furthermore, we measured the relationship between parent speech and multiple infant sensory-motor behaviors beyond visual attention – manual action, hand-eye coordination, and joint attention – and found a similar coordination between parent speech and infant sustained attention. Sustained attention of each of these multimodal behaviors is more likely to occur, and lasts longer, when accompanied by parent speech.

There were, however, individual differences in the observed parent-infant coordination. Parents that spoke less during the interaction had infants with longer durations of sustained manual attention and dyadic joint attention, relative to their talkative peers. This relationship could have two (non-mutually exclusive) causes. One possible explanation is that infants with less talkative parents are more responsive to their parent's speech. Using the coaching analogy, those infants may not get coaching signals very often and therefore they respond to the signals better when they receive them. Another possible explanation is that parents that talk less are more selective in when they choose to talk. Rather than "coach" all the time, irrespective of their infant's attentional state, these parents may find optimal moments to support their infants. Regardless, it suggests that dyads with less talkative parents are still having high-quality practices. Parents that talk more can scaffold their infant's ability to sustain attention more frequently, creating more opportunities for the infant to score. Dyads with less talkative parents, however, appear to employ more effective drills during their practices – even though these infants "score" less, the durations of their sustained manual action and joint attention bouts are longer. Thus, there are two different pathways through which parents can support their infants. Future research needs to examine potential qualitative and quantitative differences between the two pathways used by more and less talkative parents, and how different dyads adjust and adapt to different interaction patterns based on the history of their experiences.

Our results present evidence of a multimodal sustained attention training ground. The coupling of parent speech and infant attention suggests that the more infants sustain their attention, the more parents respond to it, giving the infant even more time to practice. Coaching improves an infant's ability to sustain attention, increasing the time an infant can learn about the object's properties (Ruff, 1986) and creating more opportunities for the parent to talk about and label objects (Yu & Smith 2012; Pereira et al., 2014), fostering a developmental cascade yielding higher language outcomes (Yu et al., 2018). We are also among the first to study sustained attention beyond the visual modality. How

sustained manual attention, hand-eye coordination, and joint attention relate to later outcomes is still an open question to be investigated further, especially given the individual differences seen in manual attention and joint attention.

To better understand the parental scaffolding of sustained attention, we need to study the infant behaviors that elicit parent responses. It is unlikely that parents are randomly speaking during an interaction. Rather, they are responding contingently to certain infant behaviors and following non-linguistic cues like gaze, object manipulation, gesturing, smiling, and more. To create successful object labeling moments, a parent and infant need to couple their behavior so that they are attending to and naming the same object. Infants need to sustain their attention to the object long enough for the parent to provide a label, which requires the infant exhibiting behaviors indicating a readiness to learn (e.g. object-directed vocalizations; Goldstein, Schwade, Briesch, & Syal, 2010) and parents being able to follow these behaviors. One way to address this question is to analyze the temporal dynamics of parent-infant interactions. Measuring parent and infant behaviors seconds before a parent utterance and the subsequent behavioral changes after the utterance will provide further insight into how dyads coordinate their behaviors and influence one another. One possibility is that there are "signatures" that reliably predict whether a parent utterance leads to sustained attention and successful object-label mappings. Studying the temporal dynamics of infant looking and object handling before and after a naming moment revealed developmental changes from 4 to 9 months (Chang et al., 2017), positioning this form of analysis as a pertinent future direction.

Conclusion

Previous work has shown that joint visual attention supports an infant's ability to sustain attention. We extended these findings by measuring the multimodal effect of parent speech on infant visual attention, manual action, hand-eye coordination, and joint attention. When multimodal attention is accompanied by parent speech, the infant sustains their attention for longer periods of time, creating a rich training ground for early development.

Spatial Memory of Immediate Environments

Abstract

Memorizing and retrieving information about the spatial layout of one's surrounding is of crucial importance for humans. We propose a new theory of spatial memory of immediate environments and develop a corresponding computational realization. We detail how the theory explains key findings on human spatial memory (use) and show that the computational realization accounts well for human behavior from three pertinent experiments. One implication of the theory's success is that enduring spatial memory representations may best be conceptualized as flexible combinations of representation structures and reference frames.

Keywords: spatial memory; spatial reference frames; interference; perspective taking; computational modeling

Introduction

Knowledge about the location of and relation between objects in the immediate environment is crucial for everyday life. Such spatial knowledge can be obtained by perception, but many everyday activities crucially rely on memory representations of spatial information. For example, spatial memory enables avoiding collisions with objects currently outside the perceptual field (e.g., a chair slightly behind oneself when moving around the table), anticipating and planning movements from positions one has not yet reached (e.g., planning the movement to place a plate once one is next to the appropriate spot on the table), and navigating towards objects which are not directly perceivable (e.g., approaching the appropriate cupboard to retrieve the plates contained in it).

In line with its importance, spatial memory of immediate environments has received considerable attention by research in the cognitive sciences and a substantial number of theories of spatial memory has been proposed (Avraamides & Kelly, 2008; Byrne, Becker, & Burgess, 2007; Mou, McNamara, Valiquette, & Rump, 2004; Sholl, 2001; Wang, 2017). A prominent approach to investigating spatial memory of immediate environments have been *perspective taking* (PT) studies, in which people have to judge spatial relations of a previously learned object layout from imaginal perspectives. From these studies a number of main findings have emerged (May, 2007), which can be assumed to characterize key aspects of the structures and processes involved in spatial memory.

We propose a new theory of spatial memory that offers explanations for all main findings. We first describe the PT paradigm and the main findings arising from it. Subsequently, we expound our theory, how it explains the findings, and a computational realization of the theory. After briefly considering related theories, we close with a discussion of the implications of our work.

Main Findings

In typical PT studies on spatial memory of immediate environments people are first asked to memorize the location of objects in their surrounding. After learning the object layout, people are deprived of perceptual access to their surrounding (e.g., by blindfolding) and tested for their knowledge of the spatial relations between objects. Two common forms of testing spatial relations are *judgment of relative direction* and *egocentric pointing*. In a judgment of relative direction task, people are asked to point to obj_1 as if they were standing at obj_2 facing obj_3 (where obj_i are three objects of the previously learned object layout). In an egocentric pointing task, people are asked to point to obj_1 as if they were standing at or facing obj_2. The object to point to is called the *target object*. In particular, the to-be-imagined perspective (e.g., facing obj_2) is usually different from the actual bodily perspective of the participants. The imaginal perspective can differ from the bodily perspective by *rotation* (i.e., the locations of bodily and imaginal perspective coincide, but orientations of the perspectives differ), *translation* (i.e., the orientations of the perspectives coincide, but locations differ), or both (often the case in judgment of relative direction tasks).

By using such a PT approach, existing studies have uncovered many intriguing phenomena of spatial memory organization and access. In the following, we will focus on a set of phenomena, which can be considered the main findings of existing research (May, 2007):

- Taking an imaginal perspective different from the bodily perspective is hard. Indicating the direction to the target object from the imaginal perspective takes more time and is more error prone than from the bodily perspective.
- Imaginal perspectives involving rotations are harder (slower, more error prone) than imaginal perspectives involving only translations.
- The difficulty of pointing to the target object increases with increasing angular disparity between the pointing direction from the imaginal perspective and the pointing direction from the bodily perspective.

- The difficulty of responding from the imaginal perspective can be reduced, if observers are ignorant of the actual spatial relation of their body to the object layout (e.g., when being disoriented).
- Differences between the orientation of the imaginal perspective and salient orientations in the environment (e.g., orientation of axes of symmetry or orientation of learning perspective) may lead to extra processing costs.
- If people are allowed to move their body such that the bodily perspective coincides with the tested perspective, the above mentioned difficulties are reduced notably and sometimes even eliminated.

A further finding that we will consider is the influence of perspective preparation on PT performance. If people are given information about the tested perspective before they are informed about the target object, they may be able to prepare the to-be-taken perspective such that they can respond with less difficulty once the target object is presented. Several studies have investigated the influence of preparation, because preparation effects can help reveal how access to spatial memory is organized. Although preparation has been found to generally reduce processing times associated with PT (Brockmole & Wang, 2003; May, 2004), it seems hard to prepare for certain difficulties (e.g., increase of processing costs with increasing disparity May, 2004; Wang, 2005).

A Theory of Spatial Memory

As virtually all previous theories of spatial memory (Avraamides & Kelly, 2008; Byrne et al., 2007; Mou et al., 2004; Sholl, 2001; Wang, 2017), our theory assumes that one component of spatial memory is what we will call the *sensorimotor representation*. It represents self-to-object relations for (certain) objects in the immediate environment. If any movement of one's body is perceived (through vision, proprioception, etc.) these relations are updated accordingly. In this sense the sensorimotor representation is dynamic and transient. Access to this representation is quick and automatic and it serves as the default basis for motor actions.

In addition, our theory assumes a more enduring representation of the environment as a second component. We will call this component the *LTM representation*. It represents object-to-object relations between the objects in the immediate environment. One's own body can be one of the objects in the LTM representation. The LTM representation is orientation-free and not inextricably linked to some spatial *reference frame* (RF). However, the representation may be associated with a RF in the same sense as items in long-term memory are usually assumed to be associated with each other.

Because the LTM representation is orientation-free, it will be of limited use without further additions. Consider the two object layouts in Fig. 1. Both layouts yield identical representations in an orientation-free representation, but for acting on or within the layout (e.g., approaching object A) it makes a difference which situation is represented. To create the necessary correspondence between the LTM representation and the real world, that is, to anchor the representation in the real world, it has to be oriented. We argue that this is achieved by imposing a spatial RF onto the LTM representation and our theory assumes that any access to the LTM representation involves such an imposition of a RF. A common RF that people will likely employ to access the LTM representation is the *bodily* RF arising from the sensorimotor representation (i.e., a RF that is oriented as the actual body). Other RFs may be RFs associated with the LTM representation (e.g., RFs salient during encoding of the spatial layout) or an *imaginal* RF that allows assessing the spatial layout from a vantage point differing from the current bodily vantage point (e.g., when trying to identify the seats with the best view on the stage in a theater without first walking through the whole theater).

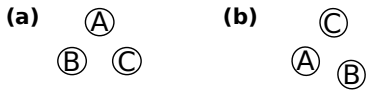

Figure 1: Two spatial layouts (a) and (b) that yield identical orientation-free object-to-object representations.

Notably, differing RFs may concurrently be available for accessing the LTM representation. Accordingly, we propose that accessing the LTM representation requires RF selection and depending on which frames are available this selection may be competitive and effortful. Specifically, our theory assumes that selection probability and effort depend on the conflict between the available frames, where conflict is a function of the salience and the (mis)alignment of the available frames (see further detail below).

According to our theory, taking an imaginal perspective involves the following steps (see also Fig. 2): First, a RF has to be selected and imposed onto the LTM representation. To perform the PT task successfully, the selected RF needs to be the one corresponding to the to-be-taken perspective or a different but aligned RF. Second, once the RF has been imposed, the LTM representation can be accessed to determine the direction towards the target object. Third, the determined target direction is used to activate a pointing movement towards the target. If the imaginal and bodily perspective differ from each other, the determined pointing direction is in conflict with the pointing direction to the target given by the sensorimotor representation. Because access to the sensorimotor representation is automatic, the disagreeing movement directions give rise to motor interference. The strength of this interference is assumed to depend on the dissimilarity of the two movements: The more the two movements' differ in direction, the stronger the interference. Note that in this process, activation of the motor response can only start after LTM access is completed. On the other hand, nothing precludes RF selection and LTM access to happen before the target direction is known. Accordingly, we propose that LTM access may start before the target object is known.

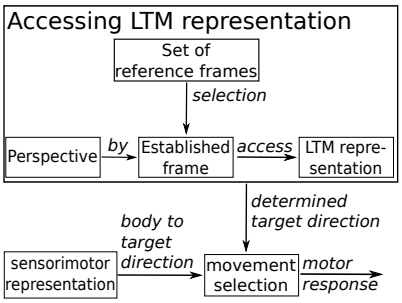

Figure 2: Processing steps in imaginal perspective taking.

Explanation of Main Findings

Our theory explains the main findings mentioned above as follows:

- Imaginal PT is difficult, because it requires RF selection to access the LTM representation. Selecting a frame when (at least) the bodily frame and the imaginal frame are in conflict takes more time than when the frames are aligned. Furthermore, an incorrect frame (e.g., the bodily frame) may be selected, which will result in an erroneous pointing response. Additional difficulty arises from motor interference such that interference leads to slower and more error prone response execution.
- Perspectives involving rotations create a misalignment between the orientation of the bodily and imaginal RF. Perspectives involving only translations do not lead to such a misalignment. Consequently, accessing the LTM representation is harder for rotations than for translations
- With increasing disparity, the difference between movement direction to the target from the bodily and the imaginal perspective increase. This leads to increased motor interference, which results in slower and more error prone responding.
- Lacking a sensorimotor representation has two effects: First, the sensorimotor representation does *not* give rise to a RF, which may otherwise have lead to conflict during LTM access. Second, motor interference is reduced or even eliminated. Accordingly, taking an imaginal perspective different from the bodily perspective can be easier without a sensorimotor representation.
- If a RF is associated with the LTM representation, it may be co-activated with the LTM representation. If this associated RF differs from the imaginal RF, it creates conflict during accessing the LTM representation. As a result, a disagreement between imaginal perspective and, for example, the learning perspective renders PT more difficult.
- Bodily movements towards the to-be-imagined perspective will lead to an accordingly updated sensorimotor representation. This means that the bodily and the imaginal RFs will be aligned and there will be little or no motor interference. Consequently, PT difficulty will be greatly reduced.
- Access to the LTM representation may proceed during preparation and thus reduce the overall processing time. However, motor interference arises only after the target object has been determined and, consequently, cannot be reduced by preparation. This explains why parts but not all of the processing costs of PT can be reduced by preparation.

Formalization

Our theory's ability to provide explanations for the main effects lends support for its assumptions. To allow comparing the behavior predicted by the theory to human behavior in more detail we formalized the theory as a computational model and applied the model to two pertinent PT studies. As a first step, we decided to use a formalization that captures the main assumptions of the theory while remaining as simple as possible. This has the advantage that any successes or failures of the model can be more directly attributed to the theory and its assumptions instead of being a result of implementation-specific detail (see, e.g., Cooper & Guest, 2014). An implementation of the theory that provides more detail on the possible mechanisms is discussed below.

Because establishing a RF and motor interference are the main factors in driving PT difficulty, the model focuses on these two aspects.

RF Selection. Establishing a RF is formalized as follows: Each of the available reference frames RF_i is assumed to have a salience sal_i such that the salience of all available reference frames sums to one. Following Botvinick, Braver, Barch, Carter, and Cohen (2001), we define the strength of conflict (cV) of RF_i with RF_j as

$$cV(i,j) = \delta * sal_i * sal_j * (1 - jConf),$$

where $jConf$ is the conflict of RF_j to all other RF (i.e., $RF_k, k \neq i$) and

$$\delta = \begin{cases} -1, & \text{for } RF_i \text{and } RF_j \text{aligned,} \\ 1, & \text{for } RF_i \text{and } RF_j \text{misaligned.} \end{cases}$$

The overall conflict of RF_i is given as the sum over all pairwise conflict values across all other RF:

$$cV_i = \sum_{j, j \neq i} cV(i,j).$$

The salience and the conflict of each frame are combined to yield an impact score imp_i. Specifically, the frame's salience is scaled based on its conflict value such that higher conflict leads to a lower impact score and $imp_i \in [0.5 * sal_i, 1.5 * sal_i]$. Probability of a frame being selected sp_i and the speed with which it can be selected st_i are proportional to imp_i:

$$sp_i = \frac{imp_i}{\sum_j imp_j},$$
$$st_i = A * (impMax - imp_i),$$

where $impMax$ is the maximum possible impact score and A serves to scale the response time to the order of magnitude of the human data.

Motor Interference. Processing time arising from motor interference is assumed to be directly proportional to the disparity $disp$ between the directions of the two interfering movements: $B * disp$, where B is a scaling factor analogous to A above. Error is determined distinguishing two cases: First, if the imaginal RF (or a frame aligned with it) is used to access the LTM representation, error is also assumed to be proportional to disparity: $C * disp$. If a frame misaligned with the imaginal frame is selected, the error will amount to the angular difference of the selected frame's and the imaginal frame's orientation.

Example. To illustrate the workings of the model, we will consider a situation, in which a person is located in the middle of a previously learned configuration of objects and asked to point to one of the objects as if facing one of the others. Let us assume that the imagined facing direction differs from the actual bodily facing direction and that the learning view coincides with the actual bodily orientation.

In such a situation, the model computes response time and error for each frame individually. The overall response time and error is given as a weighted average of all individual terms: each individual frame's time and error are weighed by the probability of selecting the frame and the resulting values are summed. To obtain the individual frame's values, the model computes the impact score of all three involved frames. Based on the impact scores, the selection probability and selection time of each frame is computed. Given any individual frame RF_i, the model computes the time from motor interference as a linear scaling of the disparity between pointing from the actual bodily perspective and the imaginal perspective given RF_i. If the selected frame is the imaginal frame, error is computed as a linear scaling analogously to the scaling of time. If any of the other two frames is selected, the error equals the orientation difference between the imaginal frame and the bodily/environmental frame. The ultimate output of the model are its prediction of response time and error in the given situation.

Given that humans are generally well able to perform PT tasks, we assumed that the imaginal frame has the strongest salience and set this salience to 0.6. The remaining salience amount of $1-0.6=0.4$ (saliences of all RF sum to 1) was distributed uniformly across all other RF. This left the scaling factors A, B, C as the only free parameters of the model.

Simulations

The first simulation addressed Experiments 2 and 3 of May (2004). These experiments provide a rich dataset of response times and pointing errors across 24 experimental conditions and also exhibit several of the main findings mentioned above.

Experiments 2 & 3 of May (2004). Participants had to perform an egocentric pointing task with to-be-imagined perspectives being either rotations or translations. Across different blocks, participants either had 1 s, 3 s, or 5 s to prepare their perspective before the target object was presented. Furthermore, the disparity between the target direction from the bodily perspective and the target direction from the imaginal perspective was systematically varied to yield levels of increasing disparity: 22.5°, 67.5°, 112.5°, 157.5°. Both experiments revealed that (a) rotations were slower and more error prone than translations, (b) response time and error increased with increasing disparity, and (c) that overall processing time but not the disparity effect decreased with increasing preparation time.

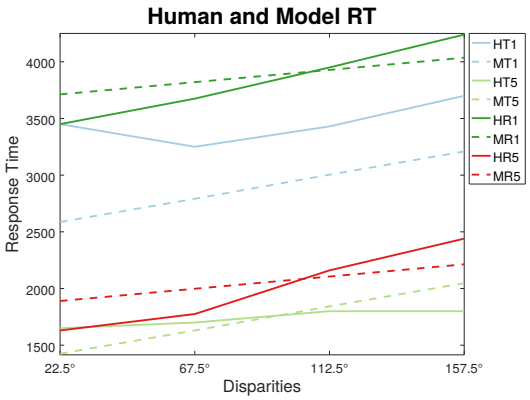

Figure 3: Human (solid lines) and model (dashed lines) response times for Experiment 2 of May (2004). Shown are translation and rotation times for two preparation durations (1 s and 5 s) each. H = Human; M = Model; T = Translation; R = Rotation; 1 and 5 indicate the duration of the preparation interval.

For simulating these experiments, we assumed that the sensorimotor representation, the bodily RF, and the imaginal RF are always present. Given the realization of the learning phase and the spatial layout of the experimental environment (see Fig. 1 in May, 2004), we also assumed the existence of an associated RF, which was—with equal probability—either aligned with the bodily RF or 45° misaligned with the bodily frame. We estimated the 3 free parameters of the model using the Metropolis algorithm (Madras, 2002) by fitting the model to response times and errors of both experiments across all conditions. Since the purpose of the simulation was to investigate the model's ability to account for key effects in the observed behavior, the objective of estimation was to maximize correlations between model and human behavior for response time and error for each of the two experiments (i.e., 4 correlations).

Model response times and errors correlated strongly with human times and errors for both experiments: $\rho = 0.91, \rho = 0.95, \rho = 0.94, \rho = 0.86$ for times and errors of Experiments 2 and 3, respectively. Model behavior is shown alongside human behavior for Experiment 2[1] in Figs. 3 and 4. As can

[1]The fit to Experiment 3 was very similar. For the sake of clarity the data from Experiment 3 are not included in the plot.

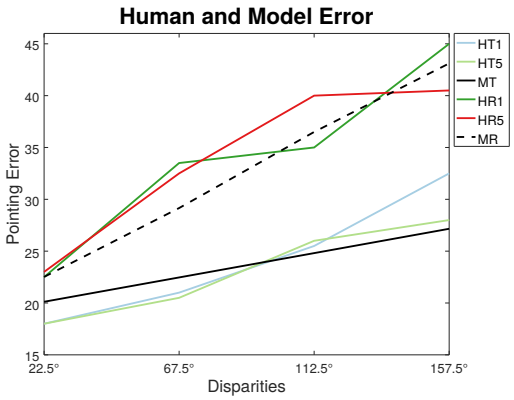

Figure 4: Human (colored lines) and model (black lines) pointing errors for Experiment 2 of May (2004). Shown are human errors for translation and rotation for two preparation durations (1 s and 5 s) each. Because model errors do not differ across different preparation durations, only rotations and translations are distinguished for model errors. H = Human; M = Model; T = Translation; R = Rotation; 1 and 5 indicate the duration of the preparation interval.

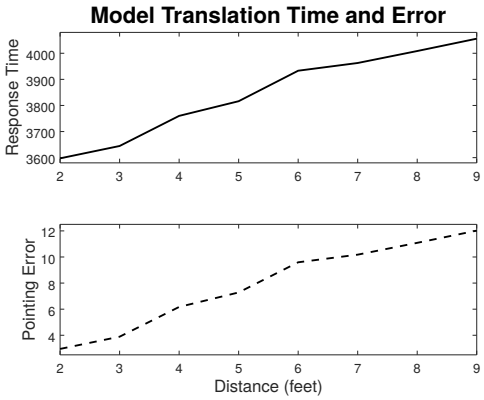

Figure 5: Model response times (solid line) and pointing errors (dashed line) when simulating Experiment 1 of Easton and Sholl (1995)

be seen from the plot, the model mirrors the main effects in the data well: (i) rotations are slower and more error prone than translations; (ii) response times and errors increase with disparity for both rotations and translations; (iii) preparation decreases the overall processing time, but does not substantially impact the disparity effect. Three further aspects of the simulation results seem noteworthy. First, humans show a stronger disparity effect for rotations than predicted by the model. Why humans should exhibit a stronger disparity effect for rotations than translations is currently unclear. Second, the model also captures that translations with short (1 s) preparation are slower than rotations with long (5 s) preparation. Third, the model correctly predicts that preparation time has no impact on error magnitude.

In sum, this first simulation lends further support to the assumptions of our theory in showing that a model based on the theory is able to closely mirror human behavior across a wide range of experimental conditions.

The second simulation will address a potential objection to our theory. Note that the theory makes no reference to mental transformations such as mental rotation or translation (e.g., Sholl, 2001). As a result the theory may seem to be at odds with findings indicating that PT time and error increases with the distance between the bodily and the imaginal perspective in translations (Easton & Sholl, 1995). Because no assumptions of our theory formulate an explicit relation between translation distance and PT performance, it seems an interesting question to what extent our theory can account for such a relationship. To address this question our second simulation models Experiment 1 of Easton and Sholl (1995).

Experiment 1 of Easton and Sholl (1995). In this experiment, participants first memorized an object layout, in which 8 objects were placed with varying distance (2 – 9 ft) from the location of the observer (see Fig. 1B in Easton & Sholl, 1995). After learning the layout, participants were provided with a target object and then a to-be-taken perspective. They were asked to point to the target object as quickly as possible. The main finding was that for translations pointing time and error increased significantly with increasing distance.

We assumed the same RFs (bodily, imaginal, associated) as for the first simulation. Because the bodily orientation was identical for learning and testing, we assumed that all three RFs were aligned for translations. For each object that indicated the position of a translated perspective, we estimated the pointing disparity when pointing to each of the other objects from Fig. 1B of Easton and Sholl (1995). Response times and errors for one translation perspective were computed as the average times / errors across pointing to all other objects from this perspective. Because the purpose of this simulation was to assess the theory's general ability to account for increasing times and errors with increasing distance, we did not fit the model to the human data, but reused the parameters estimated in the first simulation.

As can be seen from Fig. 5, the model nicely accounts for the effects observed by Easton and Sholl (1995): Both times and errors increase with increasing translation distance. Given that our theory makes no reference to mental transformations or distances, it may not be immediately clear why the theory correctly predicts the observed human behavior. It turns out, however, that—at least in Experiment 1 of Easton and Sholl (1995)—the average pointing disparity systematically increases with increasing translation distance. Since our theory assumes increased PT effort with increasing disparity, it predicts the increased effort for increased distance observed in this experiment.

The Algorithmic Level

The model described above was designed to capture the gist of the theory with as little implementational overhead as possible. Consequently, the model remains somewhat abstract and does not provide much detail on the mechanisms and representations underlying the observed behavior. In this section, we propose a more mechanistic realization of our theory.

The object-to-object representation may be realized by the type of representation structure proposed by Schultheis, Bertel, and Barkowsky (2014). This circular representation structure preserves the neighborhood relations between directions, but requires a direction root (i.e., a RF) to ground it in the real world. We further suggest that RF selection may proceed as a leaky, competitive, accumulative process as in RF selection for spatial term use (Schultheis & Carlson, 2017). Finally, we think that activation of a pointing response and interference from the bodily pointing response can appropriately be captured by dynamic field theory (Schöner, Spencer, & DFT Research Group, 2015, with different pointing directions activating different parts of the dynamic field) .

Such a realization has the twofold advantage of promising to capture the main assumptions of the theory while, at the same time, constituting a computational instantiation that is more solidly grounded in previous cognitive theorizing than the above-described model. To what extent such a realization is able to mirror pertinent human behavior will be subject of our future research.

Related Theories

Several theories of spatial memory have previously been proposed and all of them have highlighted important properties of how humans represent and recall spatial information of immediate environments (e.g., Avraamides & Kelly, 2008; Byrne et al., 2007; Mou et al., 2004; Sholl, 2001; Waller & Hodgson, 2006; Wang, 2017). However, none of the existing theories provides an explanation of all of the main findings highlighted above. For some findings the theories do not offer any explanation and for others, the theories' assumptions seem to be in contradiction with the findings. Because space restrictions do not permit a detailed critical appraisal of all theories, we restrict ourselves to a brief exemplary discussion of two of the theories.

Sholl (2001) assumes an orientation-free object-to-object representation that is subject to access by two egocentric RFs: a motor and a cognitive RF. The two frames usually coincide but can be separated. In imaginal PT the cognitive frame is assumed to be mentally rotated / translated to an appropriate place in the object-to-object representation. PT effort is assumed to be driven by the effort to separate the two frames and to mentally transform the cognitive frame. This theory has difficulties, for example, explaining why translation effort increases with pointing disparity and why rotations are generally more effortful than translations.

Mou et al. (2004) also assume an object-to-object representation. In contrast to Sholl (2001) and our theory, however, this representation is assumed to be oriented (i.e., tightly coupled to a RF). If the imaginal frame is aligned with the representation's frame, information can be directly retrieved from memory. If the frames are misaligned, the relation has to be inferred. The mechanisms underlying this inference are sometimes declared outside the scope of the theory (Rump & McNamara, 2013) and sometimes characterized as being some form of mental transformation (Mou et al., 2004, p. 156). In either case, the theory does not offer a satisfactory explanation of some of the key findings.

Conclusion

Our theory constitutes a promising account of spatial memory of immediate environments. As we have shown, the theory provides explanations for a wide range of key findings and a computational realization of the theory accounts well for human behavior in pertinent empirical studies. Moreover, the theory's view on spatial memory of immediate environments also fits well into frameworks of how larger-scale space representations are assembled as networks of more local representations of immediate environments (e.g., Chrastil & Warren, 2014; Meilinger, 2008).

Our theory suggests that enduring spatial memory representations may best be viewed as consisting of two main parts: a representation structure (e.g., the circular structure described above) and a RF. In particular, structure and RF may be flexibly combined such that the same structure / RF can yield different representations when combined with different RFs / structures. Such a view promises a more parsimonious account of spatial representations, because a comparatively small set of structures and frames may be sufficient to explain a wide range of spatial abilities. It also highlights an interesting possible connection between spatial language use and spatial reasoning through sharing RF selection mechanisms.

Future work will focus on refining the computational realization of the theory (see above) and on extending simulations to include further experiments.

Abstract

Memory researchers have studied learning behavior and extracted regularities describing learning and forgetting over time. Early work revealed forgetting curves and the benefits of temporal spacing and testing for learning. Computational models formally implemented these regularities to capture relevant trends over time. As these models improved, they were applied to adaptive learning contexts, where learning profiles could be identified from responses to past learning events to predict and improve future performance. Often times, past performance is expressed as accuracy alone. Here we explore whether a model's predictions can be improved if past performance is expressed by an integrated measure that combines accuracy and response times (RT). We present a simple, data-driven method to combine accuracy and RT on a trial-by-trial basis. This research demonstrates that predictions made using the Predictive Performance Equation improve when past performance is expressed as an integrated measure rather than accuracy alone.

Keywords: Learning; forgetting; cognitive model; accuracy; response time; integrated measure

Introduction

What data from fact learning trials are needed to predict whether a student will know the correct answer some time in the future? Does it help to know how often (and when) the student has previously answered correctly? Or how long it took them to provide the answer?

These questions are at the heart of models that describe learning and forgetting over time. Computational models are often fit to historical data to demonstrate that they can capture relevant behavioral effects exhibited by human learners (e.g. Pavlik & Anderson, 2008; Walsh, Gluck, Gunzelmann, Jastrzembski, Base, et al., 2018). Yet, the strongest test of a model is accurately predicting future performance—especially if predictions are made for each item studied by each student. The Second Language Acquisition Modeling (SLAM) challenge recently posed by Duolingo required such predictions (Settles, Brust, Gustafson, Hagiwara, & Madnani, 2018). Data from a subset of Duolingo users were made available and users submitted model performance predictions as part of a modeling competition..

As in these challenges, adaptive fact-learning systems must decide which features of the available data are taken into account to detect differences in item difficulty and participants' abilities to make accurate predictions. An obvious candidate is accuracy, since it indicates whether the student knew an answer previously. Forgetting then reduces the probability that responses are correct over time. Systems such as Duolingo (Settles & Meeder, 2016) strive to ensure that study repetitions occur *before* knowledge is forgotten.

Yet, if most responses are correct, there is very little information in the responses if only accuracy is considered, making it difficult to optimally adapt to learning and item difficulty. Response times (RT) can provide an additional source of information to differentiate between otherwise identical responses. The basic assumption is that observed RTs correlate with the difficulty of memory retrieval (e.g., Pavlik & Anderson, 2008; Pyc & Rawson, 2009). Indeed, analyses of the models submitted to the SLAM challenge support the view that RTs provide valuable information for predicting later performance (see Table 4 in Settles et al., 2018).

As accuracy and RT are often correlated (e.g., speed-accuracy trade-offs), methods have been proposed to combine them into a single performance metric. A recent suite of simulation studies discusses the merits of seven such integrated performance measures (Vandierendonck, 2017). All these measures, however, are aggregate measures: For example, the mean RT is combined with the average accuracy to express performance per participant, per condition. As this discards all information pertaining to *when* responses are given, these measures are less suited for parametrizing adaptive learning systems.

To our knowledge, there are at least two adaptive fact-learning systems that use both accuracy and RTs on a trial-by-trial level. Adaptive Response-Time-based Sequencing (ARTS; Mettler & Kellman, 2014; Mettler, Massey, & Kellman, 2016) schedules repetitions adaptively by continuously computing priority scores and presenting

the item with the highest priority. If the previous response was incorrect, that item's priority is increased drastically to ensure timely repetition. If the previous response was correct, however, the priority score is a function of the (log-transformed and scaled) RT associated with that response.

The second system is an extension of ACT-R's declarative memory module and uses the associated equations to approximate an item's memory strength (or "activation") through observed RTs (Pavlik & Anderson, 2008). Instead of using priority scores, items are repeated based on their estimated activation, a value that decreases over time (van Rijn, van Maanen, & van Woudenberg, 2009). Note that the observed RT of incorrect responses is replaced by a fixed, long RT, reflecting that it took "too long" for the correct response to be retrieved. These two examples demonstrate that combining information from accuracy and RTs is feasible in practice. Neither system really uses an *integrated* performance measure, however—they both use a transformation of RT that is conditional on accuracy.

Here, we will present an approach to computing an integrated, trial-level performance measure that combines accuracy and RT. Ideally, such a measure is purely data-driven, easy to interpret, computationally simple, and applicable to existing datasets. We are most interested in situations in which item-level data of the learning history are available and the goal is to validly predict future performance.

In the following, we will outline two datasets that we use as a test bed. Both datasets concern learning of paired associates, which provides a context in which the RT reflects relevant memory processes. We will demonstrate how our trial-level integrated performance measure can be computed for such data. Lastly, we describe how these integrated "Readiness" scores can be used as input to a computational model (the Predictive Performance Equation, Walsh, Gluck, Gunzelmann, Jastrzembski, Base, et al., 2018) to generate predictions based on past performance.

The central focus of this research seeks to explore whether use of this "Readiness score improves model predictions compared to scores that do not integrate accuracy and latency.

Methods

Datasets

We leverage two existing datasets, labelled WSU and TopiCS, to explore the idea of an integrated, trial-level performance measure. Each dataset consists of a study and a test phase. Trial-level information for response accuracy and RT is available for both datasets but they vary drastically in the structuring of the study phase and in the time between study and test. Importantly, accuracy during study is very high in both datasets (85.9% in WSU and 89.8% in TopiCS).

Washington State University (WSU) data WSU data is part of an (as of yet) unpublished multi-day fatigue study. Participants spent four days in a sleep lab and completed a battery of tests throughout that period. Here, we will focus on the paired-associates learning data of 36 participants who were not withheld any sleep (the control group). Fifty-one nonsensical line drawings—e.g.,  —were used as cues and participants learned two-digit numbers—e.g., "79"—as a response. Each paired associated was repeated 20 times according to different presentation schedules.

Table 1: Number of repetitions of an item at each test moment depending on the schedule in the WSU data. RI = retention interval between the last encounter of an item and the test.

	Study phase					Test phase
Schedule	9am	1pm	3pm	7pm	9pm	9am
Spaced	4	4	4	4	4	2 (36h RI)
Massed early	20	·	·	·	·	2 (48h RI)
Massed late	·	·	·	·	20	2 (36h RI)

We will focus on three schedules that distributed the 20 repetitions across a single day. Table 1 shows that the *spaced* schedule distributed the 20 repetitions equally among five study periods throughout the day (four repetitions each), while the *massed* schedules presented each item 20 times either *early* or *late* in the day. The test phase featured two repetitions for each paired associate, and the retention interval (RI; i.e., the temporal space between the last encounter of an item and the test) depended on which study schedule the paired associate was assigned to. Each participant studied with all schedules and encountered three unique paired associate per schedule, resulting in 6,156 observations from the study phase that were used to make predictions for the 648 observations from the test phase.

The recorded RT corresponds to the first key press. If participants did not respond within 6 seconds, the trial was recorded as incorrect (with RT set to 6 sec, hence the spike in the lower right panel of Figure 1A).

TopiCS data The TopiCS data were taken from Sense, Behrens, Meijer, and van Rijn (2016), published in Topics in Cognitive Science. Participants completed three sessions of two blocks each (six total). In each block, material was studied for 20 minutes using an adaptive fact-learning system (van Rijn et al., 2009), followed by a five-minute distractor task (Tetris), followed by a test of the studied material. Here, we will only use the first block of each session. In each of these three blocks, participants studied Swahili-English vocabulary word pairs. Each Swahili block featured 25 unique paired associates.

A total of 50,665 responses are available from 67 participants. Since the introduction and repetition schedules of items during study were governed by an adaptive model, these data do not have the controlled temporal structure of the WSU data: The number of repetitions as well as their timing varied between items and participants. The test was the same for everyone, however. After a five-minute delay, participants

were tested on all 25 potential Swahili cues at the end of each block and accuracy was recorded (4,965 observations).

The study phase was entirely self-paced and RTs correspond to the first key press recorded after a Swahili word appeared on screen. The RT distributions, split by accuracy, are shown in Figure 1A.

Computing integrated "Readiness" scores

The goal is to derive a trial-level, quasi-continuous performance metric from accuracy and RT data. This "Readiness" value can take any value between 0 and 1. Values closer to 1 correspond to a correct, fast response. There are two versions of the metric: For R_0, all incorrect responses are treated equally and set to 0. For R_c, incorrect responses are transformed such that faster incorrect responses are more severely penalized (i.e., closer to 0) than slow incorrect responses (cf. Klinkenberg, Straatemeier, & Van der Maas, 2011). The term "Readiness" is used because values close to the 1 indicate that a response was readily available, resulting in a fast RT. Overall, the higher the "Readiness" value, the better the performance. In the following, we will detail how R_0 and R_c are computed from behavioral data.

Figure 1A depicts the distribution of RTs for correct (top panels) and incorrect (bottom panels) responses from the two datasets. For a more precise depiction of the data, the axes across the panels vary and only RTs faster than 15*s* are shown for the TopiCS data (99% of all observations). Since the vast majority of responses were correct, there are fewer RTs for the incorrect responses in the bottom panels.

Figure 1B makes the mapping from observed RTs to the probability of a correct response explicit: In both datasets, the log-transformed RTs (in ms) are strong predictors of accuracy, such that slower RTs reduce the probability of a correct response. The exact mapping differs in the two datasets: Responses are generally faster in the WSU data and time out after 6 seconds. The mapping is expressed as the two coefficients estimated by a simple logistic regression, which is $\beta_0 + \beta_1 \cdot \log(\text{RT})$. For the WSU data, β_0 is 24.26 and β_1 is -3.09. For the TopiCS data, β_0 is 12.99 and β_1 is -1.39. All four coefficients differ significantly from 0 with $p < 0.001$.

The relationship shown in Figure 1B provides the quantitative basis for the "Readiness" metrics. The mapping provided by the logistic regression allows an unbound performance metric (RT) to be transformed to a continuous metric with range [0, 1].

For the first metric, R_0, all correct responses are transformed using the mapping provided by the logistic regression coefficients. *Incorrect* responses are treated as performance of 0 (as with accuracy; hence the subscript 0). Using this approach, a correct response given quickly is considered "more correct" than a correct response given after longer deliberation, which is in line with behavioral data and theoretical assumptions (Pavlik & Anderson, 2008). Numerically, R_0 is computed by taking the inverse logit (L^{-1}) of the regression formula shown above, using log-transformed RTs (in *ms*) when accuracy (A) is 1:

$$R_0 = \left\{ \begin{array}{ll} A = 0: & 0 \\ A = 1: & L^{-1}(\beta_0 + \beta_1 \cdot \log(\text{RT})) \end{array} \right\} \quad (1)$$

The second "Readiness" metric, R_c, assumes that latencies for incorrect responses are informative too. Specifically, the assumption is that a fast incorrect response is *worse* than an incorrect response given after longer deliberation, a notion also present in other learning systems (e.g., Math Garden—an adaptive, online arithmetic-learning environment used by many schools in the Netherlands—formalized the same idea in the "high speed, high stakes" scoring rule; Klinkenberg et al., 2011, see section 2.3.3. and Fig. 2 specifically). Numerically, this is formalized by using the same approach as for correct responses but then subtracting 1 and taking the absolute value[1]:

$$R_c = \left\{ \begin{array}{ll} A = 0: & |L^{-1}(\beta_0 + \beta_1 \cdot \log(\text{RT})) - 1| \\ A = 1: & L^{-1}(\beta_0 + \beta_1 \cdot \log(\text{RT})) \end{array} \right\} \quad (2)$$

For example, a correct response with an RT of 1,834*ms* would result in the same R_0 and R_c scores but they would depend on the dataset the response was observed in. In the WSU data, the "Readiness" score would be 0.739 ($L^{-1}(24.26 - 3.09 \cdot \log(1,834))$ but in the TopiCS data it would be higher ($L^{-1}(12.99 - 1.39 \cdot \log(1,834) = 0.927)$ because RTs are generally longer, which results in a different mapping (cf. Figure 1A and B). If the RT is the same but associated with an *incorrect* response, the R_0 score is simply 0 (see Eq. 1). The R_c score, on the other hand, would be 0.261 (i.e., $|0.739 - 1|$) in the WSU and 0.073 (i.e., $|0.927 - 1|$) in the TopiCS data (see Eq. 2).

Figure 1C gives an overview of the R_c values computed in the two datasets, split again by accuracy and dataset. Note that the y-axes differ due to the unequal number of observations. For both datasets, the correct responses (top panels) mostly have values between 0.75 and 1. The incorrect responses (bottom panels) are more spread across the range for the R_c metric[2]. For the TopiCS data, most incorrect responses have R_c values between 0 and 0.5 but mostly values are <0.25. In the WSU data, the values are spread more widely. The distributions of correct and incorrect responses barely overlap within a dataset, though (note the small numbers on the y-axis for incorrect reponses from the WSU data). For the R_0 metric, all values corresponding to incorrect responses are simply 0 (cf. Eq. 1).

Taken together, the approach outlined here has multiple advantages. A binary and an unbound performance metric (accuracy and RT) are combined into an integrated, trial-level measure that is continuous and bound between 0 and 1. Importantly, a trial-level performance metric preserves

[1] This could be thought of as flipping the mapping in Figure 1B along the horizontal axis at 0.5.

[2] For the WSU data, timed-out observations with RTs of 6*s* (N = 35) were transformed to the fastest observed RT (391*ms*) to make them "very wrong". If these observations are simply dropped, none of the reported results change qualitatively.

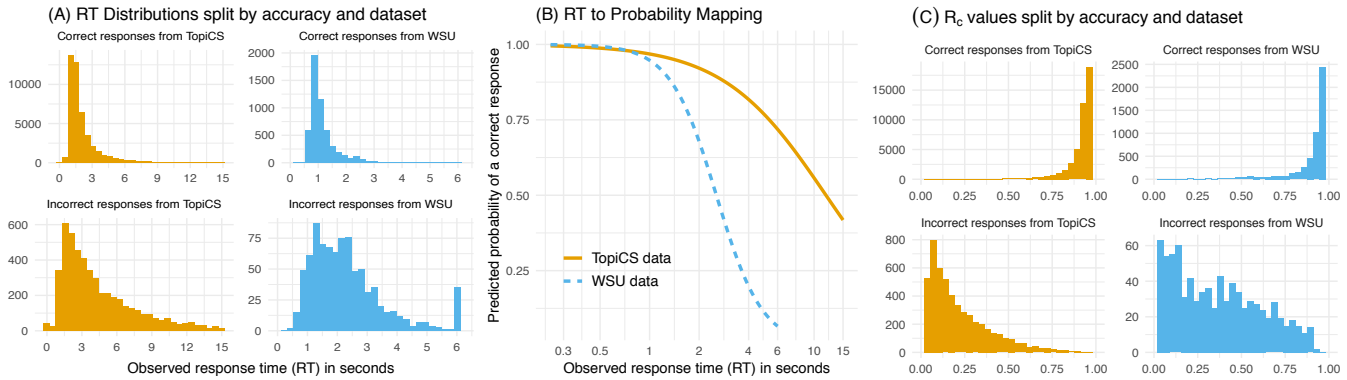

Figure 1: A: The observed RT in seconds split by accuracy and dataset; B: Logistic regression lines showing the mapping from observed RTs in seconds to the probability of a correct response; C: The continuous "Readiness" (R_c) values computed using the mapping in B, split by accuracy and dataset. In all plots, color indicates the dataset. See text for additional details.

information about the timing of individual encounters that would be lost if one simply computed, for example, the mean accuracy during study. The approach is also computationally extremely simple and makes minimal theoretical assumptions that are easily checked: Are longer RTs associated with a lower probability of giving an accurate answer? If the logistic regression's slope coefficient (β_1) does not differ significantly from 0, computing "Readiness" values is probably not sensible. Visual checks akin to Figure 1B and C also provide easy sensibility checks. Finally, the interpretation of "Readiness" values is straightforward: Higher values indicate better performance and values at the boundaries indicate faster responses.

Predictive Performance Equation (PPE)

To explore whether the "Readiness" scores are useful, we will explore their utility as input to the Predictive Performance Equation (PPE), a computational model developed to capture individual differences in learning and forgetting (for an extended description of the model see Walsh, Gluck, Gunzelmann, Jastrzembski, Base, et al., 2018). If the scores expressed meaningful individual differences, a computational model should more closely mimic a participant's learning and forgetting process than when other scores are used. The end result would be more accurate predictions of future performance based on past performance.

In two recent studies, PPE was compared to other models to test "the theoretical adequacy and applied potential of computational models" more generally (Walsh, Gluck, Gunzelmann, Jastrzembski, & Krusmark, 2018) and to shed light on "the mechanisms underlying the spacing effect in learning" specifically (Walsh, Gluck, Gunzelmann, Jastrzembski, Base, et al., 2018). Due to space constraints, we will keep the current description of the model mechanics brief and refer the interested reader to those papers for a detailed overview.

The PPE component we are ultimately interested in is the predicted performance, P, which is a logistic function of activation (M) that has two free parameters, τ and s:

$$P = \frac{1}{1 + \exp(\frac{\tau - M}{s})} \tag{3}$$

The activation M is the product of learning and forgetting, expressed as $N^{0.1} \cdot T^{-d}$. The learning term increases exponentially as a function of the number of repetitions (N) and the forgetting term decreases exponentially. The latter has two components: The elapsed time (T) is the weighted sum of the time since each previous repetition (see Eq. 3 and 4 in Walsh, Gluck, Gunzelmann, Jastrzembski, & Krusmark, 2018) and the decay rate (d), which has free intercept (b) and slope (m) parameters and is a function of the lag between consecutive repetitions:

$$d = b + m \cdot \left(\frac{1}{n-1} \cdot \sum_{j=1}^{n-1} \frac{1}{\ln(\text{lag} + e)} \right) \tag{4}$$

Model fitting In the form outlined above, PPE has four free parameters (b, m, τ, and s) and requires two pieces of information to be fit: The time point of each repetition (to compute T and d) and the observed performance at each time point. The model is agnostic with regards to what the performance metric represents and only requires it to fall in the range of [0, 1], as the "Readiness" measure provides. The best-fitting parameters are found by minimizing the error between the supplied performance metric and the predicted performance P (see Eq. 3) produced by a given combination of the free parameters. The error is defined as the summed squared error between the performance metric and P across the data available for each unique participant-item combination.

Here, we only vary the performance metric that is used during model fitting, using either accuracy, R_0, and R_c. All other factors—free parameters, allowed parameter ranges[3],

[3]The ranges for the free parameters are b = [0, 0.5], m = [0, 0.5],

and timing-related information—are held constant.

Results

For both datasets, we determined the best-fitting PPE parameters for each participant-item combination, and then computed item-level predicted performance, P, on the test. The model fit will be evaluated for the predictions—i.e., comparing predicted P with recorded accuracy—rather than fit to the study data because we consider the ability to predict future performance given historical data most relevant.

For each dataset, PPE was fit three times, using the three performance metrics outlined above: Accuracy, which is binary; R_0, which is continuous for correct responses but all incorrect responses are 0 (see Eq. 1); and R_c, which is continuous for both correct and incorrect responses (see Eq. 2 and Figure 1C). The main results of the comparison are presented in Table 2, which lists two model fit statistics for each performance metric. Also included is a baseline, which simply predicts that all responses during the test are correct.

In both datasets, performance on the test is expressed as accuracy. PPE, on the other hand, predicts the probability of a correct response. To evaluate the model predictions, we use fit statistics commonly used when evaluating performance in binary classification problems. The fit statistics are: (1) The area under the receiver operating characteristic curve (*AUC*), which can be interpreted as the probability of a randomly drawn correct response outranking (i.e., having a higher P value) a randomly drawn incorrect response. Note that the baseline condition, in which all responses are predicted to be correct, would result in an AUC of 50%. (2) *Log loss*, expressing the accuracy of a classifier by penalizing inaccurate classifications. The AUC measure can range from .5 to 1, higher values are better. Log loss is unbound and lower values are better. In Table 2, the best-performing metric is highlighted in bold for each fit statistic.

Table 2: Fit statistics for predictions made in the two datasets. The baseline predicts that all responses on the test are correct.

Dataset	Statistic	Baseline	Accuracy	R_0	R_c
WSU	AUC	0.500	0.687	0.768	**0.769**
	Log loss	19.635	6.170	1.900	**1.141**
TopiCS	AUC	0.500	0.679	0.712	**0.755**
	Log loss	1.298	3.110	1.701	**0.638**

Table 2 shows the fit statistics for the 648 predictions made in the WSU data. All three measures outperform the baseline. Of these, using accuracy as performance measure scores lowest, and there is no clear difference between the two "Readiness" scores. This impression is confirmed by statistical comparison of the AUC values, which tests the null hypothesis that the difference between two AUCs is 0 against the alternative hypothesis that it is not (DeLong, DeLong, & Clarke-Pearson, 1988). The tests yield significant differences between the accuracy- and R_0-based AUCs (z = -4.449; $p < 0.001$) and accuracy- and R_c-based AUCs (z = -3.850; $p < 0.001$) but not between R_0- and R_c-based AUCs (z = -0.063; $p = 0.950$). The log loss is very high for the baseline because the actual accuracy on the test was only 45.5%, resulting in a high penalty.

In the TopiCS data, on the other hand, the observed accuracy on the test was extremely high: 96.4% of the 4,965 responses were correct. Thus, the all-correct baseline gets less than 4% of the predictions wrong, resulting in a relatively low log loss value. Only the R_c score yields predictions that result in a lower log loss value than the baseline. Regarding the AUC values, all predictions derived from the computational model outperform the baseline. The statistical test for the comparison of the accuracy- and R_0-based AUC is inconclusive (z = -1.451; $p = 0.147$), while the R_c-based predictions are significantly better than both the accuracy- (z = -2.809; $p = 0.005$) and R_0-based predictions (z = -2.148; $p = 0.032$).

Discussion

Here, we explored the predictive power of an integrated performance measure that combines accuracy and RT information. Unlike aggregate measures (see Vandierendonck, 2017, for an overview), the "Readiness" scores presented here are computed for each observation individually. Using two datasets, we demonstrated how "Readiness" scores are computed. The practical utility of the resulting integrated performance measures was demonstrated by fitting a computational model to past performance in order to predict future performance. Statistical analyses reveal evidence that predictions are more accurate when past performance was expressed as a "Readiness" score rather than accuracy.

We present two variations of the "Readiness" score that differ in how they treat incorrect responses. The R_0 score regards all incorrect responses equally, setting them to 0 (analogously to accuracy). The continuous score, R_c, scales both correct *and* incorrect responses (see Figure 1C) such that fast incorrect responses are considered worse than slow incorrect responses. Both versions express performance as scores between 0 and 1, with higher values indicating better performance. For R_c, scores closer to either boundary correspond to responses that were given quickly.

Whether R_0 or R_c should be preferred—or whether either should be used—depends on the context and the assumptions the researcher can make, especially regarding incorrect responses. Since the "Readiness" scores are based on empirical data, the data can provide an immediate check. If the slope of the logistic regression model that provides the mapping (cf. Figure 1B) does not significantly differ from 0, the crucial assumption that observed RTs and accuracy are associated is violated and "Readiness" scores are probably

τ = [0, 1], and s = [0, 0.1].

not meaningful. As discussed in the Methods section, visualizations such as those in Figure 1B and C can also inform the researcher's choice. In a very large dataset, for example, the logistic regression model might have a significant but very small slope coefficient, resulting in a mapping (cf. Figure 1B) for which even very slow RTs result in near-ceiling performance, which would in turn yield R_c values that are quasi-equivalent to accuracy.

Exploring to which extent "Readiness" scores could be a useful expression of past performance in different contexts would be a logical extension of the current work, which presents an initial exploration of the idea in two relatively small datasets. This first exploration is promising, however, given that even though both datasets differed in a number of important aspects, the "Readiness" measure outperformed accuracy in both. Most importantly, the retention intervals differed dramatically (five minutes in the TopiCS data and 36–48 hours in the WSU data), which meant that test performance was near-perfect in the TopiCS data and lower than 50% in the WSU data. Another possible extension of the current work would be to investigate the utility of "Readiness" scores in computational models other than PPE.

In conclusion, we present a simple, data-driven way to combine accuracy and response time information into an integrated, trial-level performance measure that we call "Readiness." This approach makes minimal assumptions that are easy to check and resulting performance scores are easy to interpret. This research demonstrates that a single computational model can capture the general learning and forgetting patterns observed across two very diverse sets of paired associate learning data, and that the model's predictive validity is enhanced when past performance is expressed in terms of an integrated "Readiness measure, rather than use of simple accuracy alone.

Abstract

In Joint Action (JA) tasks, individuals must coordinate their actions so as to achieve some desirable outcome at the group-level. Group function is an emergent outcome of ongoing, mutually constraining interactions between agents. Here we investigate JA in dyads of improvising jazz pianists. Participants' musical output is recorded in one of two conditions: a *real* condition, in which two pianists improvise together as they typically would, and a *virtual* condition, in which a single pianist improvises along with a "ghost partner" – a recording of another pianist taken from a previous *real* trial. The conditions are identical except for that in *real* trials subjects are mutually coupled to one another, whereas there is only unidirectional influence in *virtual* trials (i.e. recording to musician). We quantify ways in which the rhythmic structures spontaneously produced in these improvisations is shaped by mutual coupling of co-performers. Musical signatures of underlying coordination patterns are also shown to parallel the subjective experience of improvisers, who preferred playing in trials with bidirectional influence despite not explicitly knowing which condition they had played in. These results illuminate how mutual coupling shapes emergent, group-level structure in the creative, open-ended and fundamentally collaborative domain of expert musical improvisation.

Keywords: Joint Action; Music; Improvisation; Complex Dynamical Systems; Situated Cognition

Introduction

Joint action (JA) is a fundamental facet of human life. From the earliest infant-caregiver interactions to the subtle give and take of salsa dancers, we very often coordinate our actions with others (Sebanz, Bekkering, & Knoblich, 2006). In such endeavors, group success has less to do with individual efforts considered in isolation, and more to do with the ability of individuals to successfully coordinate with one another. Understanding behavior in these settings requires shifting the unit of analysis up from the individual to the group level, as collective behavior emerges out of the ongoing interactions among individual agents (Goldstone & Gureckis, 2009).

The past decade has seen a proliferation of research investigating JA in collaborative music performance (Palmer & Zamm, 2017). Music has long been recognized as a rich and meaningful domain for cognitive science. It is a central facet of all human cultures, and music performance demands the simultaneous engagement of a variety of cognitive, emotional and perceptual-motor processes (Pearce & Rohrmeier, 2012). The richness and complexity of music increases still further when we consider collaborative musical performance, where all of these intra-individual processes must be aligned and coordinated amongst an ensemble of interacting musicians in service of a joint musical expression.

JA research has begun to elucidate how musicians meet these collaborative performance demands by examining the role of anticipatory auditory imagery in enabling performers to integrate their actions with one another, and how mutual coupling and leader-follower structures within ensembles facilitate musicians' ability to synchronize and fluidly change tempos (Chang, Livingstone, Bosnyak, & Trainor, 2017; Goebl & Palmer, 2009; Keller & Appel, 2010).

Joint Action in Improvised Music

Most of the work on music JA has taken place in the context of composed music, whereas very little has been done to examine JA in improvised music. JA in improvised music is a relatively neglected topic, and constitutes a uniquely rich and promising domain for examining joint action and complexity which is especially relevant to cognitive science.

When improvising musicians perform together they collectively generate abstract musical structures – rhythm, melody, harmony and sometimes even long-term song structures. In composed music, musicians must coordinate in terms of expressive parameters (like volume, tempo and articulation) but the abstract structure of the music is given *a priori* by the composer. The domain of interpersonal coordination in improvised music extends beyond these expressive parameters and into the formal architecture of the music. Abstract musical structures emerge out of ongoing interactions among improvisers. These interactions are nonlinear, mutually constraining and have the potential to evolve over time.

In many ways JA in improvised music is more closely aligned with other everyday JA situations than is performance of scored music. Improvisation is the norm in our daily life – group problem solving, scientific collaboration, and most of our conversations are improvised. It is actually quite rare that we perform scripted activities with others (composed music, religious ceremonies and theater performances are exceptional in this regard). Given the ubiquity of improvisation in everyday life, we might well expect some aspects of collaborative improvised music to generalize to other areas of cognition.

Despite the paucity of research in this area, some efforts to understand JA in improvised music have begun. In a notable example, coordination in jazz piano duos was analyzed as a

function of musical context (Walton et al., 2018). In the experiment, dyads of jazz pianists were studied improvising together over a swing backing track and a drone (sustained tone with no rhythmic structure). The authors performed Cross Recurrence Quantification Analysis on recordings of musicians' body movements as well as recordings of their musical output. CRQA revealed that pianists spontaneously engaged in different patterns of interpersonal coordination depending on which musical setting they were performing in.

In the current study we directly examine the effects of mutual coupling in improvised music by experimentally manipulating interaction in dyads of professional jazz pianists. Specifically, we recorded pianists improvising in one of two conditions: a *real* condition, in which two pianists improvised together as they typically would, and a *virtual* condition, in which one pianist improvised along with a "ghost partner" – a recording of another pianist taken from a previous *real* trial. In the *real* condition pianists are mutually coupled in the sense that they have the ability to respond to one another in ongoing feedback loops. Such mutual coupling is absent in the *virtual* condition – live pianists have the ability to respond to the recording, but the recording will never respond to the live musician. This feature also makes virtual recordings a nice ground-truth for assessing leader-follower roles. Subjects were blind to which condition they played in, and their musical output was recorded in the form of isolated MIDI tracks[1].

How does the presence of mutual coupling influence the music jointly produced by an ensemble of improvising musicians? This question is addressed by quantitatively comparing rhythmic structures spontaneously generated in *real* performances against *virtual* performances. Notably, these performances were obtained from elite professional pianists from the New York City jazz scene. These are individuals who have dedicated their lives to mastering their instruments and the ability to fluidly interact with others in improvised performance. Our subjects improvised freely, without any specific instructions or musical constraints (other than the implicit constraints imposed by manipulating interaction). The current study thus represents an ecologically valid and scientifically grounded approach to studying JA and mutual coupling in the creative, open-ended and fundamentally collaborative domain of expert musical improvisation.

Methods

Participants

16 professional jazz pianists from the New York City music scene participated in this study. Participant age ranged from 23-35. On average participants had 22 years experience playing piano (sd=4) and 17 years experience improvising (sd=5). All participants received formal training in piano performance and jazz studies at elite conservatories. None of our subjects had prior experience performing with one another.

Apparatus

Two MIDI-enabled keyboards were used: a Roland Juno-Di and Nord Electro 2, both of which had 61 semi-weighted keys. Both keyboards were used on every trial (i.e. virtual trials were arranged such that the live pianist played whatever keyboard their ghost partner did *not* play). Ableton Live 9 Lite (running on a MacBook Air) was used to collect isolated MIDI recordings for each musician. Ableton was also used to synthesize the audio participants heard, which allowed us to ensure time alignment of MIDI recordings, and that participants heard the same exact timbre for themselves and their partner, irrespective of condition. Participants were recorded at a music rehearsal studio in Brooklyn, NY. The studio was divided by a curtain such that participants could not see one another. Participants listened to themselves and their partners through Sony CH700N Noise Cancelling headphones. Thus, from the participants' perspective there was no visual or audible indication of their condition on a given trial.

Procedure

This study employed a within-subjects design, in which each musician played at least 3 trials[2] in both real and virtual conditions (Figure 1). Participants played with the same 'live' partner for each of their real trials and the same 'ghost' partner for each of their virtual trials. Altogether, 32 (128 minutes, 105,766 notes) trials were collected from 9 real pairs and 27 trials (108 minutes, 84,439 notes) were collected from 16 virtual pairs. To control for order effects, conditions were interleaved throughout the course of a session, and sessions were counterbalanced such that the order reversed every other session.

Participants were brought into the studio in pairs, and instructed to improvise a series of short (4-7 minute) duos. These improvisations were 'free', with no accompanying stimuli and no *a priori* musical template or constraints. Other than the suggested timeframe, the only instruction musicians were given was to do their best to improvise a compelling piece of music, as they would in a typical performance setting.

Subjects were told they would be improvising in one of the two conditions (real or virtual), but on any given trial they were not told their condition. At the start of each trial each participant was privately instructed to Play or Don't Play. At the conclusion of each trial (when the musicians had finished improvising) each player was asked to fill out a short questionnaire that had them rate the previous performance in terms of: (1) how easy it was to coordinate with their partner (2) how well coordinated they were with their partner (3) quality of the improvised piece and (4) to what degree they played a supporter or a leader role.

[1] MIDI is a format for representing music on a computer. It symbolically records the pitch, volume and timing (onset and offset) of every note played

[2] Subjects played more trials if time permitted.

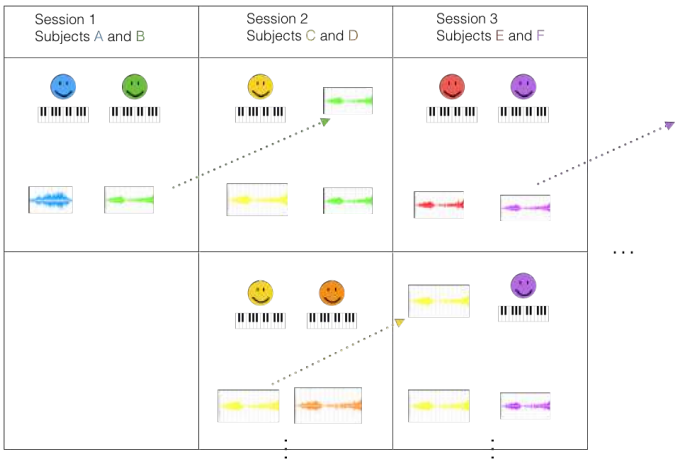

Figure 1: Sequencing of real and virtual trials. Each subject played multiple trials in each condition (repetition of trials not shown in abbreviated figure). Subjects were paired with same partner in all real trials, and a separate ghost partner for all virtual trials. Ghost recordings were taken from real trials of previous sessions, ensuring that the live musician had never heard them before.

Results and Discussion

MIDI data was collected for 32 real trials and 27 virtual trials. Each trial consists of two MIDI recordings, one for each individual (the same MIDI recordings in real trials were used as ghosts in virtual trials). 105,766 improvised note onsets were collected in real trials and 84,439 improvised note onsets were collected in virtual trials. Over 11 hours of music was collected in total. We also collected subjective ratings of participants after every trial they performed.

Figure 2 shows participants' responses to the questionnaire they were given at the conclusion of each trial. Despite the fact that participants were blind to which condition they were in in a given trial, their ratings differed systematically as a function of condition. Overall, subjects rated real trials to be of higher quality than virtual trials (paired $T(df)=15$, $p<.01$). Real trials were also generally rated as being characterized by better inter-musician coordination (paired $T(df)=15$, $p<.01$) and ease of collaboration (paired $T(df)=15$, $p<.01$).

Subjects were also asked to rate the degree to which they felt they played a leader or supporter role, which also revealed a main effect of condition (paired $T(df)=15$, $p<.05$). As expected, participants felt they mostly played a supporter role in virtual trials (in which they were playing with an unresponsive recording), whereas participants neither identified with leader or follower roles in real trials. This last result could indicate multiple things. One possibility is that musicians felt they played an equally leading and supporting role throughout the course of the performance. Alternatively, it could be that leadership roles shifted throughout the course of improvised performances. More data would be needed to differentiate between these possibilities, but in informal conversation with subjects they often alluded to the latter. At the very least, time-evolving leadership dynamics were achievable in real trials characterized by mutual coupling, but not in virtual trials characterized by unidirectional influence.

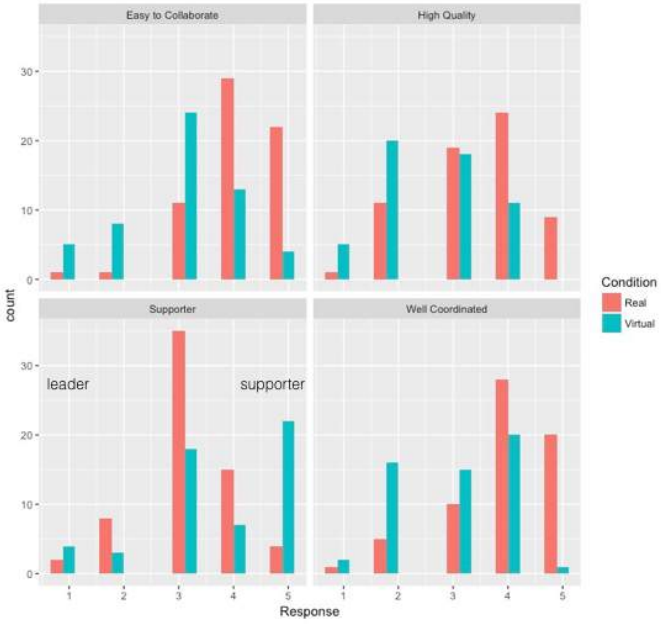

Figure 2: Subjective ratings by condition. Despite being blind to condition, participants generally rated *real* trials to be of higher quality (top right) and characterized by better inter-musician coordination (bottom right) and ease of collaboration (top left) as opposed to *virtual* trials. Participants felt they played more of a supporter role in *virtual* trials, and generally did not identify with either a leader or supporter role on *real* trials (bottom left).

Onset Analysis

MIDI recordings contain a wealth of musical information: rhythmic structure (timing of note onsets and offsets), volume, and tonal structure (sequential pitch information). In expert improvisation, interpersonal coordination occurs in each of these musical dimensions. However, we initially analyzed one clear and unambiguous aspect of the data – timing of note onsets. Timing of note onsets is a good starting point for investigating inter-musician coordination because it is simple to analyze but encapsulates an essential musical component – rhythmic structure.

Synchronization A central challenge in collaborative music making is synchronization. Musicians playing together often need to align their note onsets to occur simultaneously. Previous work has demonstrated that in composed musical settings, piano dyads' synchronize more effectively when they are mutually coupled to another another than in experimental manipulations in which auditory feedback was removed (Demos, Carter, Wanderley, & Palmer, 2017; Goebl & Palmer, 2009). It has also been demonstrated that musical

leaders play onsets of nominally simultaneous notes (notes occurring at the same metrical positions in a written score) slightly before followers (Goebl & Palmer, 2009).

To what degree does mutual coupling facilitate synchronization in improvised music? Without a written score it is difficult to assess this question, because there is no 'ground truth' for when and whether improvisers are trying to synchronize. Nonetheless, we approached the question by identifying near-simultaneous onsets, those occurring within 100ms of one another, played by co-performers. Degree of synchrony can be assessed by looking at the magnitude of asynchronies (henceforth 'asyncs') by which near-simultaneous onsets were displaced from one another. While we cannot be certain whether improvisers were explicitly trying to synchronize, this metric gives us insight into how precisely synchronization occurred spontaneously, as a joint outcome of our subjects' sensibilities and the affordances of inter-musician coupling.

Figure 3 displays the magnitude of onset asyncs colored by experimental condition. Asyncs are more peaked around 0 for real trials compared to virtual trials – indicating that when co-performers did synchronize, they did so more precisely in real conditions compared to virtual conditions. A Kolmogorov-Smirnov test confirmed a significant difference between async distributions in each condition ($p<.01$). This reproduces the result of past work showing that mutual coupling promotes greater synchronization in piano dyads in an improvised context (Demos et al., 2017; Goebl & Palmer, 2009).

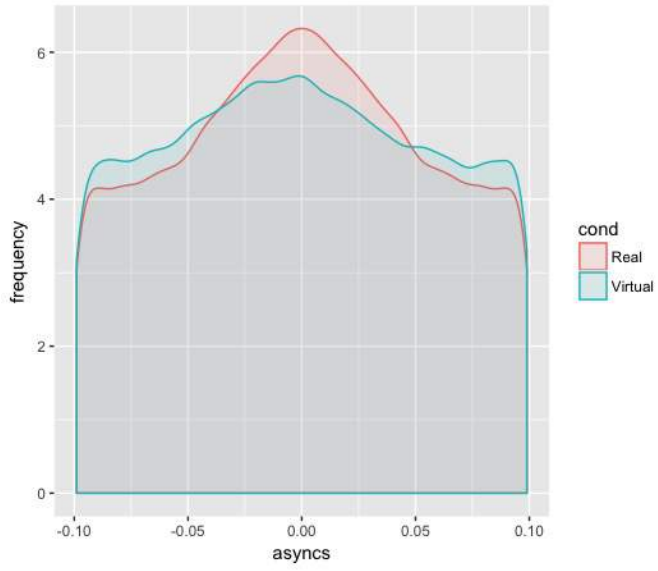

Figure 3: Mutual coupling promotes better synchronization. Density plot of asynchronies between co-performers' near-simultaneous (occurring within 100 ms of one another) note onsets. Asyncs are more tightly clustered around 0 seconds in *real* trials, in which mutual coupling is present.

Async frequency is symmetric around 0 for real trials because the same async was computed once for each partner (and thus represented twice with opposite signs). To assess asymmetries in virtual trials, asyncs were only computed by subtracting onset timestamps of ghost partners from the timestamps of live musicians. Thus positive asyncs indicate that the ghost led the live musician and negative asyncs indicate the reverse. Given past work which demonstrated musical leaders in composed settings play onsets slightly before other ensemble members, we were interested to see if ghost recordings (*de facto* leaders in virtual conditions) would lead the live players (Goebl & Palmer, 2009). However, the mean async across all virtual trials was less than 1 millisecond, indicating a symmetry between how often and how much live players led ghosts and vice versa.

Onset Density Given the lack of musical constraints, the improvised performances in our dataset exhibited high variability in rhythmic structure. Such variability could be found not just between subjects and trials, but even within particular performances. Tempos sped up and slowed down, and dyads moved in and out of "time" – sometimes playing rubato sections that lacked any steady pulse. Even within a given tempo, improvisers had the freedom to play more or fewer notes. To index all of this rhythmic variety, we compute onset density for each performer as the number of note onsets occuring within a given time window. Onset density was computed for each trial using a sliding window of 2 seconds and step size of 0.2 seconds, resulting in one onset density time series per subject-trial (Figure 4A).

How is inter-musician rhythmic coordination influenced by the presence or lack of mutual coupling? This question was approached by looking at cross-correlations between co-performers' onset density throughout the course of each trial. Cross-correlation was computed across a range of lags (+/- 5 seconds) to test for longer-term system memory and directional influence from one musician to another (Figure 4). Overall there was significantly greater cross-correlation in onset density in real trials as opposed to virtual (Figure 4B). This was confirmed with a Mann-Whitney test performed on the distributions collapsing over all time lags for all real trials (mean=.535, sd=.237) and virtual trials (mean=.356, sd=.287); $p < .01$.

Figure 4C displays how cross-correlation varies across lags as a function of condition. At each lag, the mean cross-correlation was obtained for all trials in each condition. In virtual trials we see greater cross-correlation at positive time lags, indicating that onset density of live musicians was more correlated with onset density of ghosts in previous time steps, as opposed to the other way around. This reflects the unidirectional influence inherent in virtual trials, whereby live musicians were influenced by their ghost partners but not the other way around. Onset density is symmetric around 0 for real trials, because data from each co-performer in a given trial was included. But it is interesting to note the dip

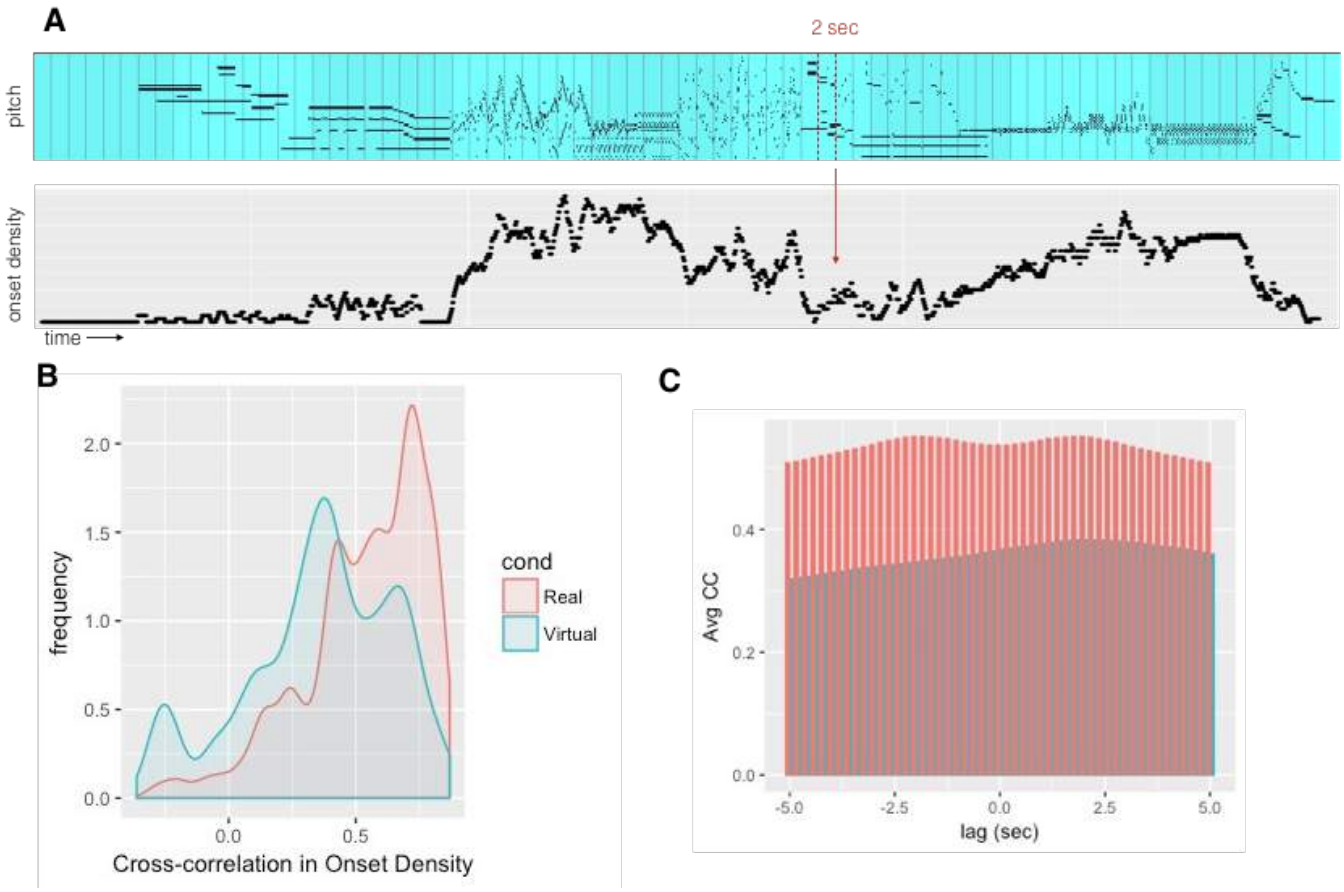

Figure 4: Mutual coupling promotes tighter coordination in onset density. (A) Time series of onset density (lower plot) are obtained by tallying the number of note onsets that occur within a 2 second sliding window of the MIDI recording (upper plot). (B) Cross-correlation in co-performer onset density, collapsing over a range of lags (+/- 5 sec). Overall there is greater cross-correlation in real trials. (C) Cross-correlation in co-performer onset density by lag, averaged across all trials in each condition. Greater cross-correlation in positive lags for virtual conditions reflects ground truth asymmetry inherent in this condition (i.e. live musician can respond to the recording, but not vice versa).

in cross-correlation around lag 0, surrounded by increased cross-correlation around lags +/- 2 sec. In real performances, co-performers' onset density is less correlated right at simultaneous time points, and more correlated at small lags of around 2 seconds. More analysis would be needed to elucidate this pattern, but it could be a result of "call and response" interplay between improvisers, whereby they exchange musical gestures in an interleaved manner.

General Discussion

In this work we have quantitatively demonstrated ways in which inter-musician mutual coupling in improvising jazz ensembles influences the music they spontaneously produce. Specifically, we showed that mutual coupling facilitates more effective coordination in jointly producing rhythmic structure. Musicians synchronized more precisely in performances where they were mutually coupled, and exhibited tighter coupling (greater cross-correlation) in onset density – a metric that captures tempo change and overall rhythmic activity. Subjects were coupled the most not at simultaneous times, but at small lags of about 2 seconds, suggesting a natural timescale of interaction. We also observed a quantitative artifact of musical leadership, as the onset density of improvisers in virtual trials was more correlated more with onset density of ghost partners at previous time points (again at about a 2 second lag). These objective results parallel the subjective intuitions of our performers, who rated trials with mutual coupling to be of higher quality and characterized by better coordination which was easier to achieve than in conditions with unidirectional influence.

When one listens to a great jazz combo, they are not merely listening to the sounds produced, but also to the complex underlying patterns of interaction which give rise to those sounds. This work provides the first controlled investigation of quantitatively measured coordination patterns demonstrated by freely interacting jazz musicians. It builds on prior research that studied the affordances of mutual coupling amongst co-performers by experimentally manipulating in-

teraction to reduce coupling in control conditions (Goebl & Palmer, 2009; Demos et al., 2017). But whereas past work focused on fine-temporal structure and movement dynamics exhibited by pianists, studying improvisers provided the opportunity to examine how mutual coupling influences larger scale musical structures (such as onset density) that are spontaneously generated in joint performance.

In the future we plan to delve deeper into the dynamics of how musicians pick up on and respond to the melodic and rhythmic offerings of their partner. One of the mesmerizing capabilities of expert jazz musicians, such as the pianists recorded in the current work, is their ability to improvise music with coherent and compelling tonal structure (melody and harmony). In ensemble performance, this melodic and harmonic structure emerges out of the ongoing interactions and musical negotiations taking place between ensemble members. In the future we plan to use this same (and expanding) dataset to delve deeper into how mutual coupling affords the emergence of stable tonal structure. Information theory offers a promising framework for inferring synergy and causality in multivariate time series of discretized, non-ordinal data, such as the musical pitches used in our data (Williams & Beer, 2010; Runge, 2018).

We also plan to extend our analyses to investigate the dynamical structure of our performances. Improvised music is essentially dynamic: the ensemble-generated musical structures evolve over time, as do the patterns of interaction between ensemble members. This is immediately evident observing the exemplar MIDI recording in Figure 4A, which appears to transition between regimes of sparse, sustained tones, and pointilistic sections characterized by short punctuated notes. Indeed, such dynamical structure is a central component of what makes improvised music so compelling.

To take another example, it could be the case that cross-correlation in onset density changes throughout performances. Imagine a performance in which there is initially negative cross-correlation between co-performers' onset density. This may transition to a period of positive cross-correlation, which could then be followed by yet another segment exhibiting no cross-correlation, in which performers go off on independent trails of rhythmic exploration. Such time-evolving interpersonal coordination would be lost on our current analysis (in fact it would obscure our results), but could be identified by computing cross-correlation over a sliding-window and analyzing how it varies over the course of a performance.

It is also likely the case that leadership roles shift throughout improvised performances. Without a well-established social structure (as exists in many forms of composed music), the distribution of leadership in ensembles is free to evolve in a self-organized fashion. Given our finding that musical leadership is associated with increased lagged cross-correlation of onset density (where followers are more influenced by the prior rhythmic activity of leaders), a sliding window analysis of onset density cross-correlation may also provide insight into the dynamical patterns governing time-evolving social structures. These kinds of higher-order analysis are a promising avenue towards contributing to the joint (mutually coupled!) efforts of empirical joint action studies and modeling of complex dynamical systems (Richardson, Dale, & Marsh, 2014).

Abstract

This study develops a cognitive model to explain the process of artistic creation in a dance domain. Many researchers in the field of psychology and cognitive science have investigated the process of creativity and developed various theories that explain this process. Their efforts have mostly focused on higher cognitive functions of artists and scientists. However, in recent years, several studies that have highlighted the importance of the interaction between idea generation and idea externalization processes suggest that people can find and develop new aspects of images and ideas by perceiving and reflecting on the images and ideas they externalize. This study develops a cognitive model that explains this interaction process in dance creation by referring to a famous theory of motor learning, the closed-loop model. We also investigate dance creation of an expert breakdancer and check the validity of our proposed model.

Keywords: creativity, artistic creation, externalization of ideas, closed-loop model, performing arts, breakdance

Introduction

How do professional artists generate their original and fascinating expressions? In the psychology and cognitive science field, many researchers have investigated the process of creativity (e.g., Dunbar, 1993; Okada & Ishibashi, 2017; Wallas, 1926). For example, Finke, Ward, and Smith (1992) proposed the Geneplore model, which explains the process of idea generation, focusing on various cognitive functions. The Geneplore model suggests that people generate and explore their ideas under several task constraints by using cognitive functions such as long-term memory, mental rotation, and concept combination. Additionally, Wallas (1926) proposed the four-stage model based on anecdotal records of several artists. This model explains the creative process in four phases: preparation, incubation, illumination, and verification.

These traditional theories have focused mainly on the cognitive process of the creators. However, in artistic creation, the process of externalizing the creators' images and ideas is also important. Artists externalize their images and ideas in the end or middle of almost all their creations (Glăveanu, 2013). For example, in a dance creation, dancers externalize their images as physical movements, and in paintings, artists externalize their images to the outside as traces, using brushes, paints, and canvases. We propose that this externalization process and the perception or reflection of those externalized images and ideas facilitate the development of the images and ideas. However, previous studies of creation have regarded this externalization process as an implementation phase, and have thus paid it little attention (e.g., Zeng, Proctor, & Salvendy, 2011). In recent years, however, some researchers came to focus on this process of idea-externalization (Glăveanu, 2013). Based on these discussions, we highlight the importance of the interaction between the idea-generation process and the idea-externalization process in artistic creation, and we develop a model that explains the influence of this interaction.

Although these studies have highlighted the importance of the idea-externalization process and its interaction with the idea-generation process, they have not proposed a mechanism as to how this interaction facilitates the creation. Regarding this mechanism, Goldschmidt (1991, 1994) and Kirsh (2009, 2010) offered useful suggestions. Goldschmidt (1991, 1994) investigated the role of sketch in design and claimed that people cannot focus on all features of their images or ideas of expression while they are generating them. For example, when people consider several components that must be included in a design, they cannot focus on the relationships or blank spaces between these components. However, people can find and focus on these features of their images and ideas if they first externalize them as sketches. Furthermore, by focusing on these hidden features, they can develop their images and ideas from different aspects and generate original and fascinating ideas (see Fig. 1). Based on this discussion, Goldschmidt (1991, 1994) emphasized the importance of sketches in design (externalization of images and ideas) and perceiving or reflecting on them. She referred to this perception and/or reflection of sketches and the subsequent development of images and ideas as interactive imagery. Also, Kirsh (2009,

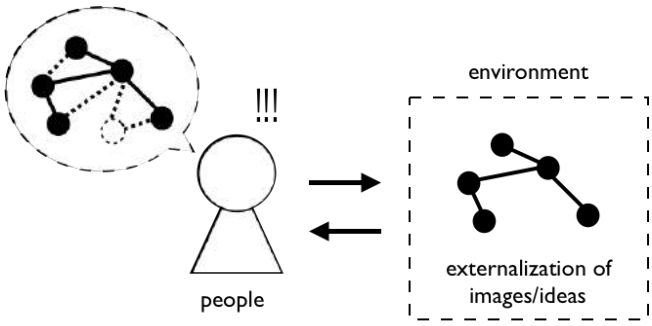

Fig. 1. Interaction between idea-generation process and idea-externalization process

2010) suggested that the idea-externalization process plays various roles in people's cognition. The process of externalization does not only save the internal memory but also facilitate the re-representation of images and the construction of the complex structure of images. He proposed that these processes facilitate the creation of artists.

Based on this discussion, this study explains how the interaction between the idea-generation process and the idea-externalization process facilitates artistic creation. To do so, we develop a cognitive model that explains the process of artistic creation in a dance domain. We also conduct a case study to investigate the creation process of an expert breakdancer and check the validity of our model.

Model development

This study develops a model to explain the influence of that interaction on creation. In particular, this study focuses on dance creation (the creation of breakdance) that existing studies have investigated over the past 10 years. The creation of breakdance is a suitable subject for this study because some fieldwork studies suggested the importance of externalizing images and ideas and perceiving or reflecting on them in breakdance (e.g., Shimizu & Okada, 2013).

To develop our model, we examined models of creation, such as the Geneplore model, reviewed discussions by Goldschmidt (1991, 1994), and referred to a famous theory of motor learning, the closed-loop model, which has been prominent in cognitive science and biomechanics. We consider that this theory provides a clear explanation about the influence of externalization of images and ideas, and the effect of perception and reflection on dance creation.

The closed-loop model emphasizes the importance of a movement-implementation process, especially the feedback error, which refers to a gap between somatosensory feedback derived from the movement and the prediction of that feedback, called efference copy, in the motor-learning process (Schmidt & Lee, 2011). This model explains the mechanism of motor learning (see dotted lines in Fig. 2), which we describe as follows: First, people perceive and identify a stimulus from their surroundings and select their reaction of movements in the cerebellum and primary motor area (movement selection). Then, to implement those

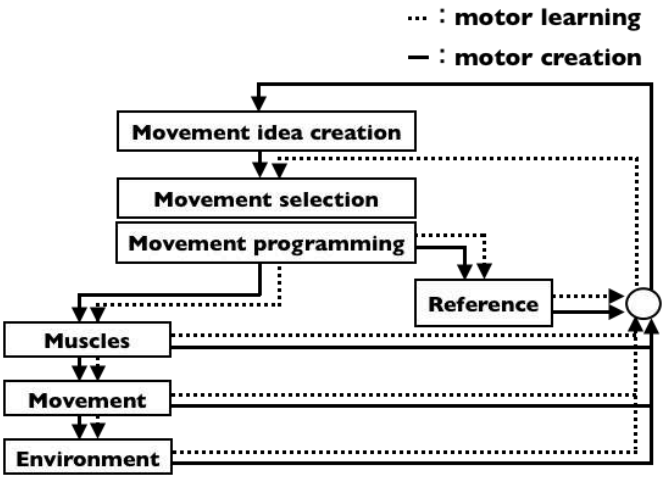

Fig. 2. Motor learning process of closed-loop model and motor creation process of our model. Dotted lines indicate the process of motor learning and solid lines indicate the process of motor creation.

movements, they send signals to the peripheral nerves in their muscles (movement programming) and conduct those movements (muscles, movement). Simultaneously, they send a copy of this motor program, called the efference copy, and generate a prediction of the somatosensory feedback derived from those movements (reference). People receive the gap between the somatosensory feedback and the prediction of that feedback, known as the feedback error, and in the next trial of movements, they refer to this error and correct their motor plan to get their movements as close to their goal (model) movements as possible (movement programming). The closed-loop model explains a mechanism as to how people improve and learn movements by these repetitive processes.

The above-mentioned process explains the mechanism of motor learning and refinement when people have a clear model of movement (i.e., a clear goal). But, how is the mechanism of motor creation achieved when people have no clear goal? In this process, people should first generate their model of movement (i.e., a goal) through cognitive functions proposed by traditional creative theory (such as the Geneplore model), and they should implement this movement plan as a movement. The roles of the feedback error in motor creation also differ from those in motor learning. In motor learning, the feedback error provides information that helps people to approximate their movements to those of the model. However, in motor creation, the feedback error provides information to find and focus on the hidden features (e.g., the relationships between components) of their proposed movement ideas (Goldschmidt, 1991, 1994). As a result, people should develop their images and ideas from various aspects and generate their original movements. In this manner, externalizing images and ideas and perceiving and/or

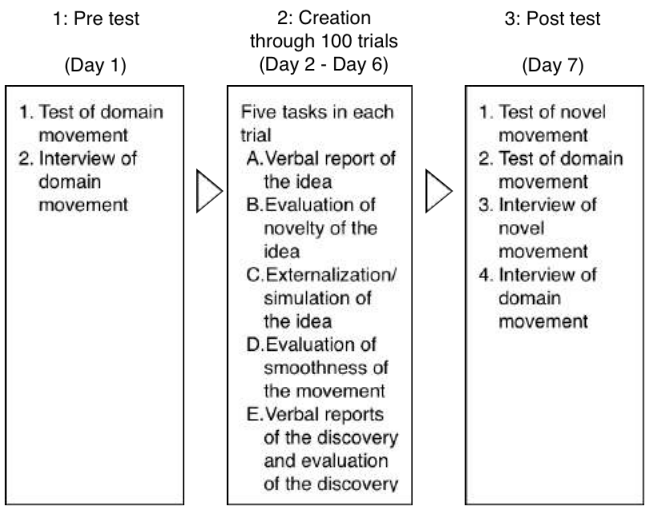

Fig. 3. Procedures of case study

reflecting on them will facilitate the creation of dance movements.

Based on these discussions, we developed a model of dance creation (solid lines in Fig. 2). This model explains the process of motor creation in dance as follows: First, people generate their ideas of movements through cognitive functions such as mental rotation and concept combination (movement idea creation). They generate these ideas by focusing on specific aspects of movements, and they send signals to implement these movements (movement programming) and conduct the movements (muscles, movement). After that, people receive the somatosensory feedback of the movements, compare those with their predictions of them (reference), and calculate the feedback error. Then, they develop and reconstruct their ideas of movements based on this feedback error and by shifting the aspects where they focus. This model thus explains the mechanism of how the interaction between the idea-generation process and the idea-externalization process facilitates dance creation. In particular, the model highlights the importance of the feedback error derived from the idea-externalization process. Notably, previous studies claimed that the feedback error plays an important role in various phenomena such as tickling (Blackmore et al., 1999) and phantom pain (Ramachandran & Ramachandran, 1996), not only in motor learning. We suppose that the feedback error has various functions in human movements.

Case study

Next, we check the validity of our proposed model by conducting a case study of an expert breakdancer's creation, and we verify whether the interaction between the idea-generation process and idea-externalization process facilitated the dance creation. We set two conditions. In the first condition, the dancer generated an original movement in an interactive condition (with the above-mentioned interaction), and in the second condition, the dancer generated an original movement in a non-interactive condition (without the interaction). We compare these two conditions and investigate the differences in the creation process. We also investigate how this interaction facilitates the dance creation by checking the creation process of the first condition in detail. With reference to these two results, we discuss the validity of our model.

Participant

An award-winning Japanese expert breakdancer with nine years' experience in breakdancing participated in our case study. He generated original dance movements over seven days in the two conditions.

Condition

The expert dancer developed original dance movements in the two conditions (interactive and non-interactive conditions). In the interactive condition, he developed his movements by repeating tasks to generate an idea (idea-generation process) and to externalize his idea as movement (idea-externalization process). In the non-interactive condition, he developed his movements by repeating tasks to generate an idea (idea-generation process) and to simulate his idea in his mind, without externalizing it as movement (idea-simulation process).

In breakdancing, dancers generate original movements by focusing on and developing specific movements in the domain (Shimizu & Okada, 2013, 2018). Therefore, in our case study, we asked the dancer to generate an original movement by developing a specific domain movement. We used different domain movements in each condition[1].

Procedure

In each condition, the dancer generated original movements through 100 trials over seven days. Fig. 3 shows the procedures. The dancer followed the same procedures in both conditions, except for task C on days 2–6 (externalization/simulation of the idea).

On days 1 and 7, we tested the domain movement (10 trials each day) using the video camera and motion capture system described in the next section. We also conducted interviews about the domain movement. We conducted further tests (3 trials) and interviews of the dancer's original movements on day 7.

On days 2–6, the dancer generated original dance movements through 20 trials per day. In each trial, he conducted five tasks. First, he generated the idea of movement, and reported its content (task A). Second, he evaluated the novelty of the idea on a one hundred-point scale using a Visual Analog Scale (VAS) (task B). Third, the dancer externalized his idea as a movement in the

[1] We used different domain movements in each condition to exclude the strong influence of the first-time creation on the second-time creation. However, we needed to be careful when interpreting the results of this study because of the different features of the domain movements in each condition.

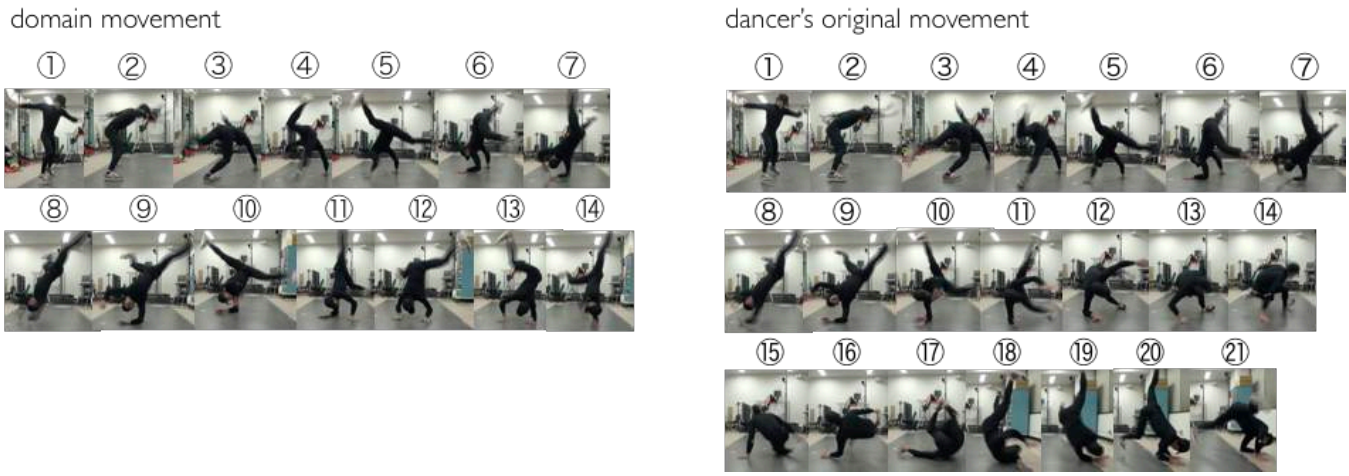

Fig. 4. Domain movement and dancer's original movement in the interactive condition. After the action of picture 14, the dancer goes into the action of picture 7 again, and repeats the rotation in domain movement (left side). In original movement, he goes into the action of picture 7 again after the action of picture 21, and repeats the rotation (right side).

interactive condition and simulated his idea in the non-interactive condition (task C). In the interactive condition, we recorded the movement using a video camera and motion capture system. Fourth, the dancer evaluated the smoothness of the movement using VAS (task D). Fifth, he reported his discovery brought by the idea-externalization and simulation tasks and evaluated the degree of that discovery using VAS (task E). The dancer repeated these five tasks a hundred times to generate his original movement. We set these tasks based on the creation process of expert dancers observed in the fieldwork study (Shimizu & Okada, 2018). We focused on tasks A (verbal report of the idea), C (externalization/simulation of the idea), and E (verbal report of the discovery) in this study because these data include the important information on the idea-generation and idea-externalization processes.

Apparatus

In this study, we used a motion capture system (OQUS 300, Optical motion capture system, QUALISYS co.) to measure the features of the movements in the creation process in the interactive condition. The dancer wore a suit for the system, attached fourteen markers to his body, and worked on the creation. We did not measure the movements in the non-interactive condition because the dancer did not conduct any movements during the creation process; however, for consistency, the dancer wore the suit and attached markers in the non-interactive condition.

Results and Discussion

Outline of the Original Movements First, we explain the outline of the movement that the dancer generated in each condition. In the interactive condition, the dancer generated the movement shown on the right side of Fig. 4 (we also show the domain movement in the left). In this original movement, the dancer stops the rotation of the domain movement by landing on his right leg, and he uses the momentum of rotation for the inverse rotation. He described this action as canceling the rotation, and he generated this original movement by developing this concept. He and another expert dancer confirmed that this was an original movement that they had never seen in the breakdance domain.

In the non-interactive condition, the dancer generated an original movement based on the domain movement called Drill. In this domain movement, the dancer lands on the ground with his head and rotates his whole body (we abbreviate the figure because of space limitations). In the original movement, the dancer lands on the ground on his back after the rotation, and then jumps up and rotates in the different direction (this rotation is similar to another domain movement called Trax). Although mixing the two domain movements seemed interesting, he was not convinced of its originality.偏

Verbal Report of the Idea In the following sections, we compare the creation process in each condition. First, we investigate the verbal report of the idea that the dancer mentioned in each trial. In the analysis, we checked and counted the frequencies of the following three aspects because the dancer mentioned them many times in his reports: (1) specific body parts (e.g., head, right arm, left arm, right leg); (2) abstract concepts of the domain movement (words such as "direction," "speed," and "axis" of the rotation); and (3) other movements in the breakdance domain (e.g., Trax, Baby Windmill, and Ninety). We summed the total frequency of each aspect in each day, divided them by the total frequency of all three aspects, and calculated the relative frequencies of these aspects for each day. These frequencies indicated which aspects the dancer focused on each day.

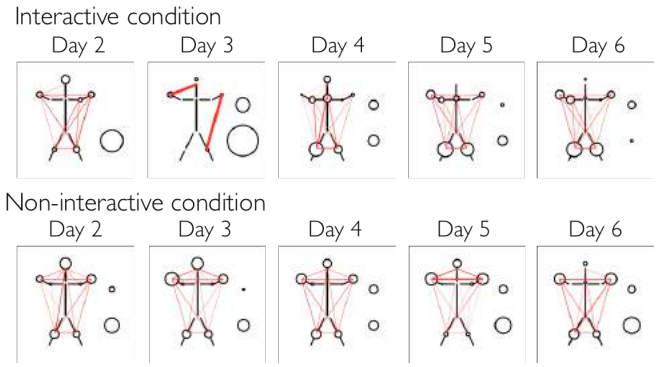

Fig. 5. Results of verbal reports of the idea. Two circles drawn to the right side indicates the frequencies of second aspect (abstract concepts of the domain movement, upper side) and third aspect (other movements in breakdance domain, lower side).

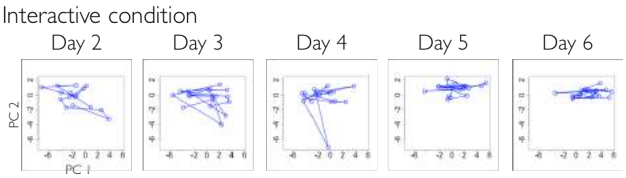

Fig. 6. Scores of PC 1 and PC 2 of the movement

We show these frequencies as sizes of circles in Fig. 5. This figure shows that, in the interactive condition, the dancer changed the aspects of his movement actively between days 2 and 4. Then, on days 5 and 6, he focused on specific aspects such as the right leg when attempting to generate the original movement (the right leg has an important role in his original movement: to stop the rotation of the domain movement). On the other hand, in the non-interactive condition, the dancer did not actively change the aspects of his movement during his creation.

Features of the Movement (Externalized Idea) Next, we investigate the features of the movement (externalized ideas) generated in the interactive condition. We calculated the kinematics data (joint angles and joint angular velocities in each segment) from the time-series position data of 14 markers using the inverse kinematics technique (Hirashima et al., 2008). Then, we conducted principal component analysis and extracted two components that had high contributions (proportions of variance) for explaining these movements (see Kadone & Nakamura, 2007), which we called PC 1 and PC 2. PC 1 and PC 2 are reduced dimensions that explain important features of the movement.

Fig. 6 shows that the scores of PC 1 and PC 2 had various values (PC 1: -7.06~3.84, PC 2: -7.10~1.34) on days 2–4. However, on days 5–6, these scores, especially scores of PC 2 converged at specific values (PC 1: -4.30~5.64, PC 2: -0.61~2.13). These results suggest that, in the interactive

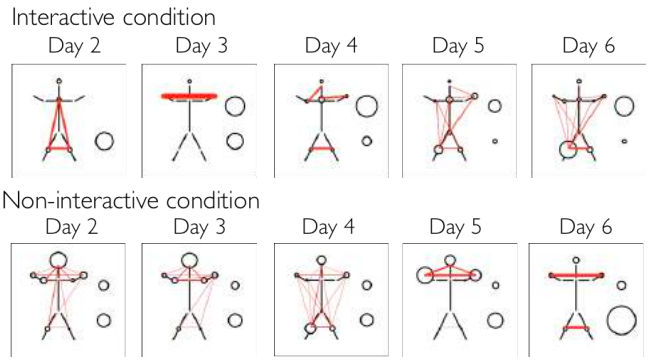

Fig. 7. Results of verbal reports of the discovery. Two circles drawn to the right side indicates the same aspects as those of Fig. 5.

condition, the dancer generated various kinds of movements that had various features in the first half of the creation. The dancer also focused on a particular movement that had a specific feature (the movement which involved stopping the rotation with his right leg) in the second half of the creation.

Verbal Report of the Discovery We investigated the discovery that the dancer mentioned when he externalized and simulated his idea. We examined the verbal report of the discovery and conducted the same analysis of the verbal report of the idea.

Fig. 7 shows that on days 2–4, the dancer actively reported his discovery in various aspects in the interactive condition. On days 5–6, however, he focused on specific aspects such as the right leg and the abstract concept, and he frequently reported his discovery of these aspects. By contrast, in the non-interactive condition, the dancer did not focus on various aspects from days 2–4. He focused on similar aspects to those on days 2–4, and he came to focus on various aspects in his discovery report on day 5.

These results of three analyses indicate that in the interactive condition, the dancer actively changed the aspects on which he focused in the early part of the creation, and in the late part, he focused on the specific aspects and on refining his idea. A retrospective interview conducted on day 7 supports this claim. The dancer mentioned that he found the idea of the original movement around trial 50, and subsequently focused on refining that movement. By externalizing his idea as movement and reconstructing his idea using the feedback error derived from that externalization, he was able to find and focus on the various and hidden aspects of his idea and generate an original movement.

Overall Picture of the Creation in Interactive Condition Finally, we provide an overall picture of the dancer's creation in the interactive condition. Before finding the idea for an original movement (stopping the rotation of the domain movement with his right leg) at around trial 50, the

Table 1. Examples of dancer's discovery reports

"I jumped and rotated in the vertical direction higher than I expected. I was surprised by it." (Discovery report in trial 32)
"This time, I tried to bend both knees when I conducted EAT. This made me jump lower in the horizontal direction than I expected. Though it did not change the final position of EAT, it increased the rotation speed horizontally. I was confused by that." (Discovery report in trial 34)

dancer explored various ideas. Fig. 5 shows that he focused on each body part on day 2, and he said that he found an important aspect of the domain movement (rotation) on day 3, which he then focused on (Fig. 7 also supports this claim). The dancer found this aspect by externalizing his idea as movement and perceiving or reflecting on the feedback error derived from that externalization. In the dancer's verbal reports of the discovery on day 3 (in trials 32 and 34), he mentioned that he was surprised at the gap between the somatosensory feedback derived from the movement and his prediction of that, and became interested in the hidden aspect of his idea: the rotation (see Table 1). After this finding, the dancer focused on this aspect, the rotation, and attempted to generate an original movement by making various changes to it. Finally, the breakdancer developed his idea for an original movement, which involved stopping the rotation with his right leg, at around trial 50. The interaction between the idea-generation process and idea-externalization process led to the findings of the hidden aspect of his idea and facilitated the generation of his original dance movement. These results suggest that the process explained by our model occurred in the expert breakdancer's dance creation.

General discussion

This study developed a model to explain the process of artistic creation in the dance domain. We also conducted a case study that investigated the creation process of an expert breakdancer and verified the validity of our proposed model. Fig. 2 shows that the model developed herein proposes the importance of interactions between the idea-generation process and the idea-externalization process in dance creation based on the closed-loop model (Shmidt & Lee, 2011), the Geneplore model (Finke et al., 1992), and discussions by Goldschmidt (1991, 1994) and Kirsh (2009, 2010). The closed-loop model shows the importance of somatosensory feedback and its error derived from the movement in motor learning. We extended the roles of the feedback error and applied them to the creation of a novel dance movement. By externalizing their idea as a movement and focusing on the feedback error derived from that movement, dancers can find new and hidden aspects of the movement and develop their idea actively. Traditional theories of creation in psychology and cognitive science paid little attention to the importance of interaction between the idea-generation process and the idea-externalization process because the creation of a novel image or idea was considered to be achieved in people's cognitive processes. On the other hand, this study highlights the importance of the interaction between idea-generation and externalization and identified the mechanism of that interaction. We suggest that the processes of idea generation and idea externalization are highly connected, and this connection has a strong influence on creation.

However, we need to consider the generalizability of the influence of this interaction with caution. Based on the hands-on nature of an artistic creation, interactions between the idea-generation process and the idea-externalization process are important in almost all artistic domains. Goldschmidt (1991, 1994) and Glăveanu (2013) proposed the importance of interactions between imagination and externalization in artistic creation. However, there are critical differences between dance creation and other kinds of artistic creation. In particular, media that artists use for externalizing their images and ideas and the feedback they receive from this externalization process are different. In dance creation, dancers externalize their images and ideas as movements through their bodies, and they mainly receive somatosensory feedback from their movements. In paintings, however, artists externalize their images and ideas as traces by using various tools such as brushes, paints, and canvases in addition to their bodies, and they mainly receive visual feedback from their paintings. We thus need to consider these similarities and differences among various artistic domains when discussing the generalizability of our model.

Our model has other limitations. As this study verified the validity of the model by investigating the creation process of only one expert dancer, we should collect data from more expert dancers. Additionally, we should set various domain movements as the base movements and take a counterbalance of those movements between the two conditions. However, to investigate the creation process of experts takes considerable time and effort. We therefore need to develop a method to investigate the creation process of many experts efficiently in more natural field situations.

Partitioning the Perception of Physical and Social Events Within a Unified Psychological Space

Tianmin Shu Yujia Peng Hongjing Lu Song-Chun Zhu

Abstract

Humans demonstrate remarkable abilities to perceive physical and social events based on very limited information (e.g., movements of a few simple geometric shapes). However, the computational mechanisms underlying intuitive physics and social perception remain unclear. In an effort to identify the key computational components, we propose a unified psychological space that reveals the partition between the perception of physical events involving inanimate objects and the perception of social events involving human interactions with other agents. This unified space consists of two prominent dimensions: an intuitive sense of whether physical laws are obeyed or violated; and an impression of whether an agent possesses intentions, as inferred from movements. We adopt a physics engine and a deep reinforcement learning model to synthesize a rich set of motion patterns. In two experiments, human judgments were used to demonstrate that the constructed psychological space successfully partitions human perception of physical versus social events.

Keywords: social perception; intuitive physics; intention; deep reinforcement learning, Heider-Simmel animations

Introduction

Imagine you are playing a multi-player video game with open or free-roaming worlds. You will encounter many physical events, such as blocks collapsing onto the ground, as well as social events, such as avatars constructing buildings or fighting each other. All these physical and social events are depicted by movements of simple geometric shapes, which suffice to generate a vivid perception of rich behavioral, including interactions between physical entities, interpersonal activities between avatars engaged in social interactions, or actions involving both humans and objects.

This type of rich perception elicited by movements within simple visual displays has been extensively studied in psychology. Prior work showed that humans possess a remarkable ability to perceive physical events and to infer physical properties (e.g., masses of objects) (Proffitt & Gilden, 1989), as well as to make causal judgment (Michotte, 1963), based on observations of the movements of two objects. Furthermore, Heider & Simmel (1944) demonstrated that humans also excel in spontaneously reconstructing social events from movements of simple geometric shapes, and describe their observations in terms of agency, goals, and social relations. These classic studies, along with a great deal of subsequent psychological research (e.g., Kassin 1981; Scholl & Tremoulet 2000; Gao et al. 2009, 2010), provide convincing evidence that human inferences about physical and social events are efficient and robust, even given very limited visual inputs.

Although many studies of both intuitive physics and social perception examined dynamic stimuli consisting of moving shapes, these research areas have largely been isolated from one another, with different theoretical approaches and experimental paradigms. In the case of physical events, research has been focused on the perception and interpretation of physical objects and their dynamics, aiming to determine whether humans use heuristics or mental simulation to reason about intuitive physics (see a recent review by Kubricht et al. (2017)). For social perception, some research has aimed to identify critical cues based on motion trajectories that determine the perception of animacy and social interactions (Dittrich & Lea, 1994; Scholl & Tremoulet, 2000; Gao et al., 2009; Shu et al., 2018). Other work focused on inferences about agents' intentions (Baker et al., 2009; Ullman et al., 2010; Pantelis et al., 2014). In contrast to the clear separation between the two research topics, human perception integrates the perception of physical and social events. Hence, it is important to develop a common computational framework applicable to both intuitive physics and social perception to advance our understandings on how humans perceive and reason about physical and social events.

In the present paper, we propose a unified framework to account for the perception of both physical events and of social events based on movements of simple shapes. We aim to construct a unified psychological space that may reveal the partition between the perception of physical events involving inanimate objects and the perception of social events involving human interactions with other agents. Specifically, we hypothesize that this unified space includes two prominent dimensions: an intuitive sense regarding whether physical laws are obeyed or violated; and an impression of whether an agent possesses intentions in the display. Note that the intuitive sense of physical violation may result from observable physical forces that can not be explained by perceived entity properties (such as motion, size, etc.) in a scene. The development of this unified space may shed light on many fundamental problems in both intuitive physics and social perception.

To construct such space, we project a video as a whole onto the space. Hence, a large range of videos can provide a distribution of observed events. We can also project individual entities in one physical or social event onto the same space, and then examine pairwise relations between the projected locations of entities in the space, which could serve as an informative cue for judging social/physical roles of entities (e.g, as an human agent or an inanimate object).

To test the hypothesized psychological space, we report experiments involving many Heider-Simmel animations in which simple moving shapes vary in degrees of physical vi-

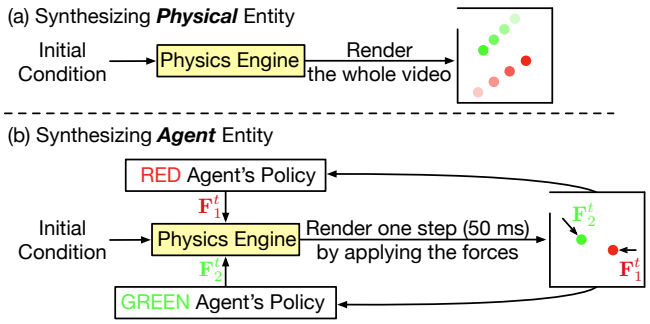

Figure 1: Overview of our joint physical-social simulation engine. For a dot instantiating a physical object, we randomly assign its initial position and velocity and then use physics engine to simulate its movements. For a dot instantiating a human agent, we use policies learned by deep reinforcement learning to guide the forces provided to the physics engine.

olation and the involvement of intention. Prior work usually created Heider-Simmel-type stimuli using manually designed interactions (Gao et al., 2009, 2010; Isik et al., 2017), rule-based behavior simulation (Kerr & Cohen, 2010; Pantelis et al., 2014), and trajectories extracted from human activities in aerial videos (Shu et al., 2018). It is challenging to manually create many motion trajectories, and to generate situations that violate physical constraints. Accordingly, we develop a joint physical-social simulation-based approach built upon a 2D physics engine (Figure 1). A similar idea has been previously instantiated in a 1D environment, Lineland (Ullman, 2015). By generating Heider-Simmel-type animations in a 2D environment with the help of deep reinforcement learning, our simulation approach is able to depict a richer set of motion patterns in animations.

This advanced simulation provides well-controlled Heider-Simmel stimuli enabling the measurement of human perception of physical and social events for hundreds of different motion patterns. We also develop general metrics to measure how well the motion patterns in an animation satisfy physics, and the likelihood that dots are agents showing intentions. These two indices were computed for each stimulus shown to human observers, allowing us to map all videos into a unified space as the two measures providing primary coordinates. In two experiments, we combined model simulations with human responses to validate the proposed psychological space.

Stimulus Synthesis

Overview

Figure 1 gives an overview of our joint physical-social simulation engine. Each video included two dots (red and green) and a box with a small gap indicating a room with a door. The movements of the two dots were rendered by a 2D physics engine (pybox2d[1]). If a dot represents an object, we randomly assigned the initial position and velocity, and then used the physics engine to synthesize its motion. Note that our simulation incorporated the environmental constraints (e.g., a dot can bounce off the wall, the edge of the box), but did not include friction. If a dot represents an agent, it was assigned with a clearly-defined goal (e.g., leaving room) and pursued its goal by exerting self-propelled forces (e.g., pushing itself towards the door). The self-propelled forces were sampled from agent policy learned by deep reinforcement learning (see more details in a later subsection). Specifically, at each step (every 50 ms), the agent observed the current state rendered by the physics engine, and its policy determined the best force to advance the agent's pursuit of its goal. We then programmed the physics engine to apply this force to the dot, and rendered its motion for another step. This process was repeated until the entire video was generated.

[1] https://github.com/pybox2d/pybox2d

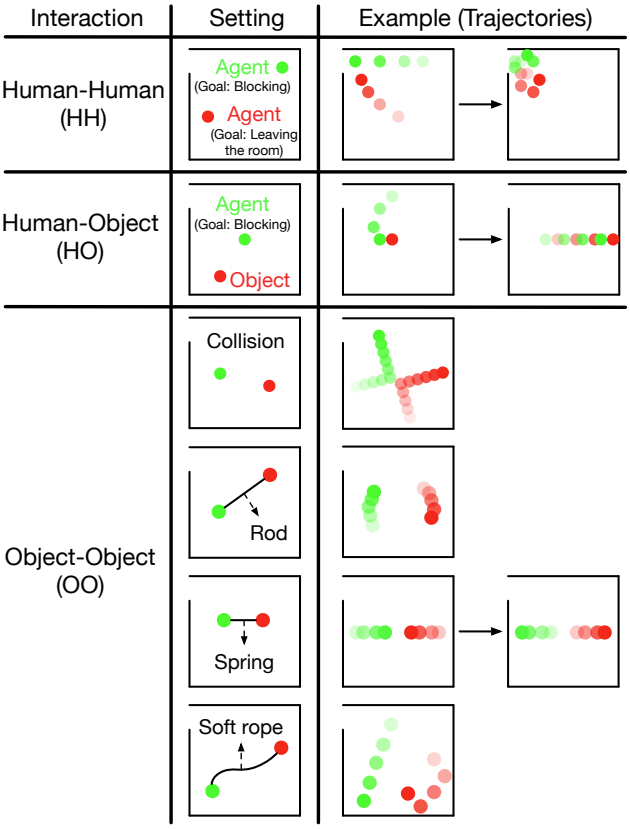

Figure 2: An illustration of three types of synthesized interactions for physical and social events. A few examples are included by showing trajectories of the two entities. The dot intensities change from low to high to denote elapsed time. Note that the connections in OO stimuli (i.e., rod, spring, and soft rope) are drawn only for illustration purpose. Such connections were invisible in the stimuli. Examples of stimuli are available at: https://tshu.io/HeiderSimmel/CogSci19.

Interaction Types

As summarized in Figure 2, we consider three types of interactions, including human-human (HH), human-object (HO)

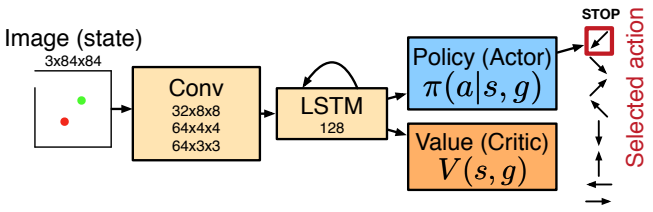

Figure 3: The deep RL network architecture for learning policy for goal-directed movements of an agent. For each goal, we train a separate network with the same architecture.

and object-object (OO) interactions, all of which are generated by the approach depicted in Figure 1. Note that in this paper we treat the terms "human" and "agent" interchangeably. When synthesizing the agents' motion, we set two types of goals for the agents, i.e., "leave the room" (g_1) and "block the other entity" (g_2). Specially, in HH stimuli, one agent has a goal of leaving the room (g_1), and the other agent aims to block it (g_2); in HO stimuli, an agent always attempts to keep a moving object within the room (g_2) and the object has an initial velocity towards the door. By randomly assigning initial position and velocity to an agent, we can simulate rich behaviors that can give the impression such as blocking, chasing, attacking, pushing, etc.

In addition to the three general types of interactions, we have also created sub-categories of interactions to capture a variety of physical and social events. For OO animations, we included four events, as collision, connections with rod, spring and soft rope. Since these connections were invisible in the displays, the hidden physical relations may result in a subjective impression of animacy or social interactions between the entities. In addition, the invisible connections between objects (rod, spring, and soft rope) introduce different degrees of violation of physics in the motion of the corresponding entities if assuming the two entities are independent. For HH animations, we varied the "animacy degree" (AD) of the agents by controlling how often they exerted self-propelled forces in the animation. In general, a higher degree of animacy associates with more frequent observations about violation of physics, thus revealing self-controlled behaviors guided by the intention of an agent. The animacy manipulation introduced five sub-categories of HH stimuli with five degrees of animacy – 7%, 10%, 20%, 50%, and 100%, respectively corresponding to applying force once for every 750, 500, 250, 100, and 50 ms. In an HH animation, we assigned the same level of animacy degree to both dots.

Training Policies

As shown in Figure 1, in order to generate social events, we need sensible policies to infer the self-propelled forces for pursuing goals. However, searching for such policies in a physics engine is extremely difficult. In this study, we use deep reinforcement learning (RL) to acquire such policies, which has been shown to be a powerful tool for learning complex policies in recent studies (Silver et al., 2017).

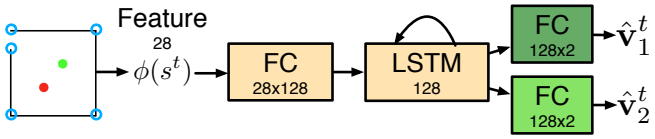

Figure 4: Network for the physical motion prediction model to emulate intuitive physics. Blue circles indicate the corners of the room used for deriving the input features.

Formally, an agent's behavior is defined by an Markov decision process (MDP), $\langle \mathcal{S}, \mathcal{A}, \mathcal{T}, R, \mathcal{G}, \gamma \rangle$, where $\mathcal{S}$ and $\mathcal{A}$ denote the state space (raw pixels as in Figure 3) and action space, $\mathcal{T} : \mathcal{S} \times \mathcal{A} \mapsto \mathcal{S}$ are the transition probabilities of the environment (in our case, deterministic transitions defined by physics), R is the reward function associated with the intended goals $g \in \mathcal{G}$, and $0 < \gamma \leq 1$ is a discount factor. To match to the experimental setup, we define two reward functions for the two goals: i) for "leaving of the room", the agent receives a reward, $r^t = R(s^t, g_1) = \mathbb{1}(\text{out of the room})$, at step t; ii) for "blocking", the reward at step t is $r^t = R(s^t, g_2) = \pm\mathbb{1}(\text{opponent is out of the room})$. To simplify the policy learning, we define a discrete action space, which corresponds to applying forces with the same magnitude in one of the eight directions and "stop" (the agent's speed decreases to zero after applying necessary force).

The objective of the deep RL model is to train the policy network shown in Figure3 to maximize the expected return $E[\sum_{t=0}^{\infty} \gamma^t r^t]$ for each agent. The optimization was implemented using advantage actor critic (A2C) (Mnih et al., 2016) to jointly learn a policy (actor) $\pi : \mathcal{S} \times \mathcal{G} \mapsto \mathcal{A}$ which maps an agent's state and goal to its action, and a value function (critic) $V : \mathcal{S} \mapsto \mathbb{R}$. The two functions were trained as follows (assuming that entity i is an agent):

$$\nabla_{\theta_\pi} J(\theta_\pi) = \nabla_{\theta_\pi} \log \pi(a_i^t | s_i^t, g_i; \theta_\pi) A(s_i^t, g_i), \quad (1)$$

$$\nabla_{\theta_V} J(\theta_V) = \nabla_{\theta_V} \frac{1}{2} \left(\sum_{\tau=0}^{\infty} \gamma^\tau r_i^{t+\tau} \pm V(s_i^t, g_i; \theta_V) \right)^2, \quad (2)$$

where $A(s_i^t, g_i) = \sum_{\tau=0}^{\infty} \gamma^\tau r_i^{t+\tau} \pm V(s_i^t, g_i)$ is an estimate of the advantage of current policy over the baseline $V(s_i^t, g_i)$. We set $\gamma = 0.95$ and limit the maximum number of steps in an episode to be 30 (i.e., 1.5 s). Note that we train a network for each goal with the same architecture. In HH animations, an agent's policy depends on its opponent's policy. To achieve a joint policy optimization for both agents, we adopt an alternating training procedure: at each iteration, we train the policy of one of the agents by fixing its opponent's policy. In practice, we trained the polices by 3 iterations.

Inference of Physical and Social Events

Physics Inference

The first type of inference assesses the degree of violation of physics for each entity. To capture this measure, we used physical events to train a deep recurrent neural network (see

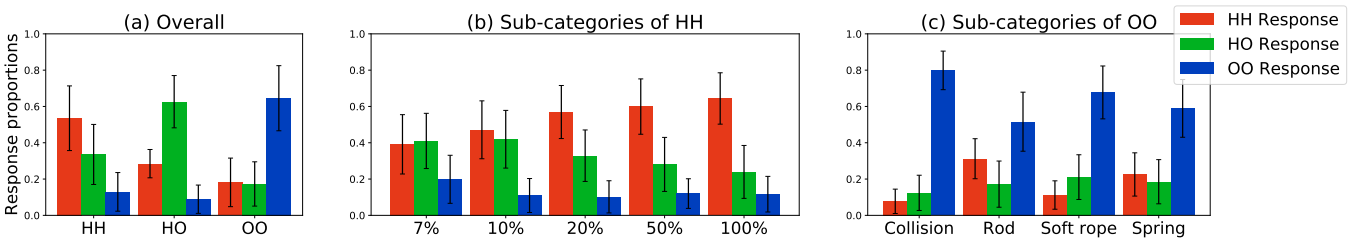

Figure 5: Human response proportions of interaction categories (a) and of the sub-categories (b,c) in Experiment 1. Error bars indicate the standard deviations across stimuli.

Figure 4) as an approximation to emulate intuitive physics. The network can predict the velocities of the two objects $\hat{\mathbf{v}}_i^t$, $i = 1,2$, given their past trajectories $\Gamma_i^t = \{s_i^\tau\}_{\tau=1}^t$. At each step, we feed a 28-dim feature vector to the network by concatenating the two dots' positions in the room, their relative positions to each other and to the five corners highlighted by the blue circles in Figure 4. We generated 2000 collision OO videos and trained the network on these videos with a 4-fold cross-validation. Using the trained network, we then conducted a step-by-step prediction of an entity's movements assuming it is an object. By comparing with the ground truth $\mathbf{v}_i^t$, we can evaluate to what degree an entity's motion is inconsistent with physics predictions:

$$D_i = \frac{1}{T}\sum_{t=1}^{T} ||\mathbf{v}_i^t \pm \hat{\mathbf{v}}_i^t||_2^2, \quad \forall i = 1,2. \tag{3}$$

Intention Inference

To evaluate the impression of whether a dot possesses intentions in the Heider-Simmel display, we estimate a value index (i.e., accumulated reward) from an entity's trajectory w.r.t. each possible goal. We first define a reward function:

$$R(s^t, g) = \frac{(\mathbf{x}_g^t \pm \mathbf{x}^t)^\top \mathbf{v}^t}{||\mathbf{x}_g^t \pm \mathbf{x}^t||_2 || \cdot \mathbf{v}^t||_2}, \tag{4}$$

where $\mathbf{x}^t$ and $\mathbf{v}^t$ are the position and velocity of an entity extracted from its state s^t, and $\mathbf{x}_g^t$ is the position of the goal. For "leaving the room", $\mathbf{x}_g^t$ is the door's position, whereas $\mathbf{x}_g^t$ denotes the position of the other entity for "blocking". Intuitively, this reward function evaluates whether the entity is moving towards certain goal locations. Consequently, we can compute the overall value by selecting the most likely goal:

$$V_i = \left[\max_{g\in\mathcal{G}} \frac{1}{T}\sum_{t=1}^{T} R(s_i^t, g)\right]_+, \quad \forall i = 1,2, \tag{5}$$

where $[x]_+ = \max(x, 0)$. Note that V_i defined here is different from the one in Eq. 2. Ranging from 0 to 1, a higher value of V_i indicates that the entity i shows a clearer intention and is more likely to be an agent. We remove the moments when the denominator in Eq. (4) is too small for the robustness of the value estimate. Considering the complexity of optimal planning in the continuous physical environment, the proposed value index offers a simplified measure of goal inference by inverse planning (Baker et al., 2009; Ullman et al., 2010).

Experiment 1

Participants

30 participants (mean age = 20.9; 19 female) were recruited from UCLA Psychology Department Subject Pool. All participants had normal or corrected-to-normal vision. Participants provided written consent via a preliminary online survey in accordance with the UCLA Institutional Review Board and were compensated with course credit.

Stimuli and Procedure

850 videos of Heider-Simmel animations were generated from our synthesis algorithm described above, with 500 HH videos (100 videos for each AD level), 150 HO videos, and 200 OO videos (50 videos for each sub-category). Videos lasted from 1 s to 1.5 s with a frame rate of 20 fps. By setting appropriate initial velocities, the average speeds of dots in OO videos were controlled to be the same as the average speeds of dots in HH with 100% ADs (44 pixel/s). The dataset was split into two equal sets; each contained 250 HH, 75 HO, and 100 OO videos. 15 participants were presented with set 1 and the other 15 participants were presented with set 2.

Stimuli were presented on a 1024×768 monitor with a 60 Hz refresh rate. Participants were given the following instructions: "In the current experiment, imagine that you are working for a security company. Videos were recorded by bird's-eye view surveillance cameras. In each video, you will see two dots moving around, one in red and one in green. Your task is to 'identify' these two dots based on their movement. There are three possible scenarios: human-human, human-object, or object-object." Videos were presented in random orders. After the display of each video, participants were asked to classify the video into one of the three categories.

Results

Human response proportions are summarized in Figure 5. Response proportion of human-human interaction swas ignificantly greater than the chance level 0.33 ($t(499) = 25.713$, $p < .001$). For HO animations, response proportion of human-object interaction was significantly greater than the other two responses ($p < .001$). Similarly, response proportion of object-object was greater than the other two responses ($p < .001$) for OO animations. These results reveal that human participants identified the main characteristics of different interaction types based on dot movements.

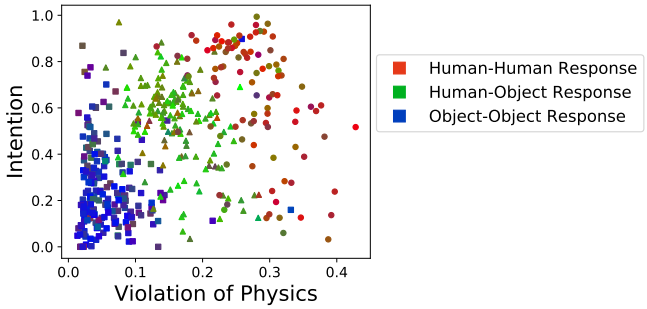

Figure 6: Constructed psychological space including HH animations with 100% animacy degree, HO animations, and OO animations. In this figure, a stimulus is depicted by a data point with coordinates derived by the model, and the colors of data points indicate the average human responses of this stimulus. The two coordinates of the space are the averaged measures between the two entities, as the measure of the degree of violation of physical laws (horizontal) and the measure of values indicating the presence of intention. The mark shapes of data points correspond to the interaction types used in the simulation for generating the corresponding stimuli (circle: HH, triangle: HO, square: OO).

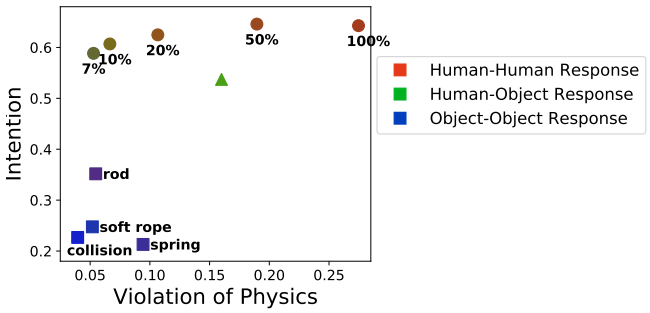

Figure 7: Centers of all types of stimuli.

Next, we examined human responses to the sub-categories within the HH and OO animations. We first used the animacy degree as a continuous variable and tested its effect on human responses in the HH animations. With increases in degree of animacy in HH, the response proportion of human-human interaction increased significantly as revealed by a positive correlation ($r = .42$, $p < .001$). This finding suggests that humans are sensitive to the animacy manipulation in terms of the frequency with which self-propelled forces occurred in the stimuli. For the OO animations, the response proportion for object-object interaction among the four sub-categories yielded significant differences ($F(3,196) = 34.42$, $p < .001$ by an ANOVA), with the most object-object responses in the collision condition, and the least in the rod condition. Pairwise comparisons among the four-categories show significant difference between collision and everything else ($p < .001$), between soft rope and rope ($p < .001$), and also between soft rope and string ($p = .018$); there is a marginally significant difference between rod and string ($p = .079$).

We then combined human responses and the model-derived measures for each animation stimulus to depict the unified psychology space for the perception of physical and social events. Figure 6 presents the distributions of 100 HH videos with 100% animacy degree, 150 HO videos, and 200 OO videos, all in this unified space. In this figure, an animation video is indicated by a data point with coordinates derived by the model, and the colors of data points indicate the average human responses of this stimulus. Specifically, the values of its RGB channels are determined by the average human-human responses in red, human-object responses in green, and object-object responses in blue. The mark shapes of data points correspond to the interaction type used in the simulation for generating the synthesized animations. The coordinates of each data point were calculated as the model-derived measures averaged across the two entities in an animation. The resulting space showed clear separations between the animations that were judged as three different types of interactions. Animations with more human-human interaction responses (red marks) clustered at the top-right corner, corresponding to great values of intention and strong evidence signaling the violation of physics. Animations with high responses for object-object interactions (blue marks), located at the bottom left of the space, show low values of intention index and little evidence of violation of physics. Animations with high responses for human-object interactions (green marks) fell in the middle of the space.

To quantitatively evaluate how well the model-derived space accounts for human judgments, we trained a classifier using the coordinates derived in the space shown in Figure 6 as input features (D and V for the indices of physical violation and intention respectively). For each ground-truth type of interactions $k \in \{\text{HH}, \text{HO}, \text{OO}\}$, we fit a 2D Gaussian distribution $p_k(D,V)$, using half of the stimuli as training data. Then for a given animation with the coordinates of (D,V), the classifier predicts $p(k|D,V) = \frac{p_k(D,V)}{\sum_k p_k(D,V)}$ for animations in the remaining half of the stimuli. The correlation between the model predictions and average human responses was 0.748 ($p < .001$) based on 2-fold cross-validation. Using a split-half reliability method, human participants showed an inter-subject correlation of 0.728 ($p < .001$). Hence, the response correlation between model and humans closely matched inter-subject correlations, suggesting a good fit of the unified space as a generic account of human perception of physical and social events based on movements of simple shapes.

We examined the impact of different degrees of animacy on the perception of social events, and how different subcategories of physical events affect human judgments on interaction types. The unified space provides a platform to compare these fine-grained judgments. Figure 7 shows the centers of the coordinates and the average responses for each of the sub-categories. We first found that, with a decreased degree of animacy, the intention index in HH animations was gradu-

ally reduced towards the level of HO animations. Meanwhile, human judgments of these stimuli varying from low to high degree of animacy transited gradually from human-object responses to human-human responses, consistent with the trend that the data points moved along the physics axis. Among all physical events, the rod and spring conditions showed the highest intention index and the strongest physical violation, respectively, resulting in a greater portion of human-human interaction responses than the other categories.

Experiment 2

In Experiment 1, human participants were asked to classify the three interaction types. But for human-object responses, the assignment of the roles to individual entities was not measured. In Experiment 2, we focused on stimuli that elicited the classification of human-object responses, and asked participants to report which dot was a human agent, and which dot was an inanimate object. Specifically, the role assignment in the human-object responses helps us identify some key characteristics in the psychological space that signal a human-object interaction.

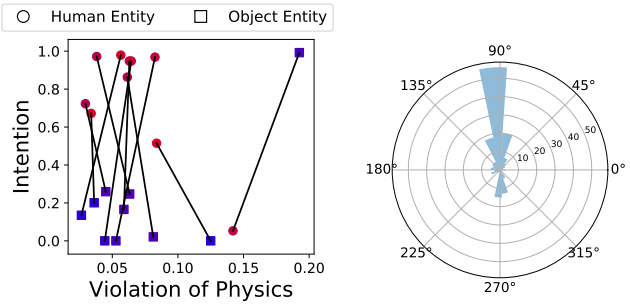
Methods

25 participants (mean age = 21.3; 19 female) were recruited from the UCLA Psychology Department Subject Pool. 216 videos were selected from Experiment 1 based on the criterion that more than 40% of subjects judged the HH videos or OO videos as human-object interaction. 201 videos were HH videos and the other 15 were OO videos.

The procedure was the same as Experiment 1 except that on each trial, subjects were asked to complete two tasks: first to judge the interaction type; then if the judgment was human-object, they were further asked to report which dot represented a human agent and which dot represented an object.

Results

We projected all entities onto the psychological space based on the model-derived measures for each individual entity, and connected a pair of the two entities that appeared in the same video. We visualized 10 animations that yielded high human-object response proportions and the most consistent role judgment among participants as shown in Figure 8a, where circles represent the dots that were frequently identified as humans, and squares represent the dots identified as objects. The resulting segments showed a common feature in that the connection of the two entities in the space depicted a near-vertical orientation, primarily due to high intention value for the human dot, and low intention value for the object dot. To further examine the orientations in the space for the human-object responses, we calculated the histogram of the orientations for animations judged as human-object interactions, which shows a high concentration around 90 degrees (see Figure 8b). This finding suggests that the two dots in the Heider-Simmel animations elicited similar degrees of physical violation, but one of them showed a much clearer intention. Note that this analysis excluded 38 stimuli in which participants did not show consistency in the role judgment (each entity was judged as a human or an object by exactly half of the participants).



(a) (b)

Figure 8: Human and model-simulation results in Experiment 2. (a) Representative cases of animations that elicited the human-object responses, located in the space with model-derived coordinates. The colors reflects average human responses of assigning a dot to the human role (red) and to the object role (blue). (b) Orientation histogram of the segments connected by the concurrent pairs of entities in an animation.

Conclusion

In this study, we propose a unified psychological space to account for human perception of physical and social events from movements of simple shapes in Heider-Simmel animations. The space consists of two primary dimensions: the intuitive sense of violation of physics, and the impression of intentions. We tested the space by measuring human responses when viewing a range of synthesized stimuli depicting human-human, human-object, and object-object interactions in the style of Heider-Simmel animations. We found that the constructed physics-intention space revealed clear separations between social and physical events as judged by humans. Furthermore, we trained a classification model based on the coordinates of each stimulus in this space. The resulting model was able to predict human classification responses at the same level as human inter-subject reliability.

The present paper provides a proof of concept that the perception of physical events and social events can be integrated within a unified space. Such common representation enables the development of a comprehensive computational model of how humans perceive and reason about physical and social scenes. Perhaps the most surprising finding in our work is that the classification result based on just the two measures reflecting the violation of physical laws and the estimate of intention can predict human judgment very well, reaching the same level as inter-subject correlation. The good fit to human responses across a range of Heider-Simmel stimuli demonstrates the great potential of using a unified space to study the transition from intuitive physics to social perception.

The main benefit of constructing this psychological space is to provide an intuitive assessment for general impressions of physical and social events. To build up such representation,

humans or a computation model may use various cues to detect intentions and/or physical violations; such cue-based detection is usually subjected to personal preferences. Instead of discovering a list of cues for distinguishing between physical events and social events, the proposed space offers an abstract framework for gauging how humans' intuitive senses of physics and intentions interplay in their perception of physical and social events.

This work provides a first step toward developing a unified computational theory to connect human perception and reasoning for both physical and social environments. However, the model has limitations. For example, the simulations are limited by a small set of goals, and the model requires predefined goals and good knowledge about the constrained physical environment. Future work should aim to extend the analysis to a variety of goals in social events (Thurman & Lu, 2014), to develop better goal inference, and to support causal perception in human actions (Peng et al., 2017). A more complete model would possess the ability to learn about physical environments based on partial knowledge, and to emulate a theory of mind in order to cope with hierarchical structures in the goal space. In addition, we have only examined human perception of physical and social events on short stimuli with only two entities. Generating longer stimuli with more entities and analyzing human perception on them will further help reveal the mechanisms underlying humans' physical and social perception.

Seeing the big picture: Do some cultures think more abstractly than others?

Abstract

Do some cultures think more abstractly than others? According to tests of formal logic and rule-based reasoning, Westerners tend to think more abstractly than East Asians. Yet, rule-based reasoning is only one type of abstract thinking. More generally, thinking abstractly involves discerning relationships and seeing the big picture. Here we argue that previous tests of attention, perception, and memory can be interpreted as showing that East Asians tend to think more abstractly than Westerners. To test this hypothesis directly we gave a validated measure of abstract thinking (Vallacher & Wegner, 1989) to Chinese and US individuals. Participants chose either abstract or concrete definitions of events. Across six independent national samples (total N=1,798), Chinese participants tended to construe events more abstractly, and US participants more concretely. Within China, more independent (Western-like) groups chose more concrete definitions. Together, these results challenge the generalization that Westerners have a greater propensity for abstract thought.

Measuring Creative Ability in Spoken Bilingual Text: The Role of Language Proficiency and Linguistic Features

Abstract

Whereas first language (L1) research has demonstrated that perceptions of creative ability are influenced by the complexity and diversity of language used to answer verbal tests of creativity, relatively little is known about the linguistic components of bilingual creative task performance. In this study, we analyze written transcripts of speech produced by 466 Japanese learners of English produced during a creative narrative task for features related to linguistic and cognitive dimensions of creativity. Then, we extract various linguistic features and test whether these features can predict human perceptions of creativity for the transcripts. Unlike L1 data, results suggest text length and L2 proficiency comprise the most parsimonious explanation of creativity scores in this L2 data. At the same time, linguistic features related to positive sentiment explained a significant yet small amount of additional variance in perceptions of creativity, suggesting texts with more positive language were perceived to be more creative.

Keywords: creativity, NLP, language proficiency, bilingualism

Introduction

The relationship between bilingualism and creativity can be approached from a number of perspectives. One is to investigate how learning a second language (L2) impacts creativity. Here, research has shown benefits of language learning, with high-proficiency bilinguals outperforming their monolingual and lower L2 proficiency peers on tests of creative ability (Kharkhurin, 2009; Leikin, 2013; Ricciardelli, 1992). Reasons for this difference have been attributed to the growth of language knowledge that naturally comes with mastering additional languages, suggesting that a specific cognitive ability (i.e., creativity) may be directly associated with language knowledge. Another approach to is to investigate the role of creativity in second language acquisition (SLA). For instance, researchers SLA have highlighted the facilitative role that creativity, play, and humor in an L2 can have on language learning (Cook, 2000; Pomerantz & Bell, 2007).

Yet another approach involves investigating links among creative ability, language use, and language knowledge in order to shed light on how language and cognition (specifically, creative ability) influence one another. One method for doing so, and the one that we adopt in the present work, is by determining whether linguistic features pattern with creativity.

The overarching objective of this study is to better understand how L2 proficiency and linguistic features relate to perceptions of creativity. To do so, this study examines linguistic features in 466 transcribed speech samples produced during an English L2 oral proficiency exam. The speech samples were part of the oral proficiency interviews found in the NICT Japanese Leaners of English (JLE) corpus (Izumi, Uchimoto, & Isahara, 2004; Tono et al., 2001). We trained raters to make creativity judgements for each of the samples. The linguistic features of the samples were then analyzed using automatic text analysis tools and associations between these features and the human judgments of creativity were assessed. This approach allowed us to examine the strength of the relations among L2 language proficiency, linguistic features of L2 speech, and expert raters' perceptions of creativity.

Creativity

Psychologists have defined creativity as a cognitive construct that represents the ability to develop novel and effective solutions to a problem (Kaufman, Plucker, & Baer, 2008; Runco & Jaeger, 2012). One common method for assessing creativity is through the use of divergent thinking tests, where a participant or group of participants generates as many

solutions to a problem that they can in a set amount of time (Runco, 2013). These tests are then most commonly scored for four measures: fluency (total number of ideas), flexibility (range of idea types), elaboration (ability to expand on ideas), and originality (uniqueness of ideas when compared to other participants' answers). In general, participants who score higher on these four features are thought to be more creative than those who score lower. Due to the frequent use of divergent thinking tests in creativity research, these four components have gained widespread acceptance as valid measures of creativity (Kaufman et al., 2008).

Bilingualism and Creativity

One specific application of divergent thinking tests has been to investigate whether bilinguals are more or less creative than monolinguals (Kharkhurin, 2009). A consistent finding from these studies is that the degree of bilingualism or relative proficiency in bilinguals' L2s is strongly related to creative performance (Kharkhurin, 2008). Specifically, language users with more balanced bilingualism (i.e., relatively similar proficiency between a user's two languages) significantly outperform those who report lower L2 proficiency compared to their L1 (Kharkhurin, 2011; Lee & Kim, 2011). These results have been replicated among different language users, including German-English and Dutch-English bilinguals (Hommel, Colzato, Fischer, & Christoffels, 2011) as well as among Hebrew-Russian bilingual children (Leikin, 2013).

Bilingual creative performance has also been identified as an important component of L2 learning. Specifically, language learners who experiment with the sounds, meanings, and forms of a language are a) better equipped to deduce the rules of a language, b) gain more agency over the language they are learning, c) construct more engaging learning environments, and d) enhance interaction with other learners (Bell, 2005; Cook, 2000). Although relatively high L2 proficiency is required to take part in complex forms of language play such as interpersonal humor (Bell, 2005), even lower proficiency L2 learners have demonstrated usage of less complex forms of play (Bell, Skalicky, & Salsbury, 2014).

Linguistic Features, Bilingualism, and Creativity

Learning a second language naturally involves increased knowledge of lexical items and word associations in that language. In English, lexical features such as polysemous word senses, hypernymic categories, and psycholinguistic measures of lexical sophistication have all been shown to change over time as learners increase their L2 English proficiency. Specifically, as L2 English learners become more proficient, they develop more polysemous and less frequent senses for English words (Crossley, Salsbury, & McNamara, 2010), more diverse hypernymic relations among word categories in English (Crossley, Salsbury, & McNamara, 2009), and demonstrate higher levels of lexical sophistication in English (e.g., more abstract lexical items that are less rooted in the immediate context; Salsbury et al., 2011).

Several of these same linguistic features have been associated with higher performance on tests of creativity in English as an L1. For example, words generated by individuals rated higher for creativity have more remote associations among concepts as measured through computationally-derived association strengths such as Latent Semantic Analysis (Acar & Runco, 2014; Beketayev & Runco, 2016; Dumas & Dunbar, 2014). Higher creativity scores are also associated with higher levels of lexical sophistication (i.e., more infrequent, varied, and complex language) and semantic cohesion (Skalicky, Crossley, McNamara, & Muldner, 2017).

Current Study

The current study has two goals. The first is to examine the extent to which L2 English proficiency is associated with perceptions of creativity during an oral picture description task among Japanese-L1 English-L2 bilinguals of eight different L2 proficiency levels. The second is to investigate whether linguistic features of the language produced during the task are predictive of perceptions of creativity. Because SLA research has demonstrated that various aspects of language such as lexical sophistication change over time as one gains proficiency in English as an L2, we examine the extent that differences in creative output based on L2 proficiency are associated with quantifiable features of language. By identifying language features associated with perceptions of creativity, we aim to further define linguistic aspects of L2 creativity, identify associations between creativity and proficiency in a second language, and provide additional explanations for differences in creative performance among bilinguals of differing proficiency levels. The following research questions guide our study:

1. What role does L2 English language proficiency have for human perceptions of creativity during an English L2 oral proficiency exam?
2. Do linguistic features explain differences in creativity scores when controlling for L2 English proficiency?

Method

Corpus

We used a subset of the NICT Japanese Learner English Corpus to collect creativity ratings for L2 speakers of English (Izumi et al., 2004). The JLE comprises over 1200 recorded speech samples of Japanese learners of English who completed an interview activity designed to assess their oral English proficiency. The JLE data also includes the oral proficiency scores for each interviewee assigned by the interviewer at the time of the interview. The scores were derived using the Standard Speaking Test scoring method (Tono et al., 2001), where 2-3 raters used a holistic rubric based on the American Council on the Teaching of Foreign Languages (ACTFL) proficiency guidelines to place

interviewees into one of nine different levels based on their oral proficiency (1 being the lowest and 9 being the highest).

Each interview was conducted between a test taker and a test administrator. The interviews lasted approximately 10-15 minutes and included three interview tasks. In this study, we focus on the final interview task, which was a picture description task where the interviewee was asked to construct a story based on information depicted in a picture or a set of pictures. We focused on this task because it provided the strongest potential for the test takers to produce creative ideas in that they were given the freedom to embellish and elaborate on events in the story as they constructed it. The interviewer provided minimal feedback beyond confirmation checks and backchanneling, ensuring that all the ideas produced during this task belonged to the interviewee. Within the picture sequence description task, there were ten possible picture sets that depicted scenes such as camping, visiting a zoo, eating at a restaurant, and shopping in a grocery store.

We constructed a subset of the JLE corpus by randomly selecting 250 texts from male and female speakers respectively ($N = 500$) while also sampling equally from each proficiency level (levels 2-9 with the exception of 1, which was rare). For each file we manually removed all text not associated with the picture sequence description task and all speech produced by the interviewer, leaving just the text that was on topic and delivered by the test taker. In order to ensure enough coverage for our linguistic measurements, we further removed any text containing less than 50 words (34 texts), resulting in a final JLE subset of 466 texts (237 female, 229 male). The average number of words per text in this final subset was 140.700 ($SD = 62.551$). The resulting distribution of proficiency levels approximated a normal distribution ($M = 5.361$, $SD = 1.744$).

Human Ratings

We developed an analytic rubric to obtain creativity ratings for each text in our dataset. The rubric contained seven different subscales with a range of 1 (does not meet the criterion in any way) to 6 (meets the criterion in every way). The subscales were divided into two larger categories: IDEAS and STYLE. The IDEAS category contained four subscales related to cognitive definitions of creativity: ideation (the speaker produced a large number of different ideas), originality (the speaker's ideas were original when compared to other speakers completing the same task), elaboration (the speaker included additional information elaborating on their ideas) and appropriateness (the speaker's ideas created an effective narrative). The STYLE category contained three subscales related to linguistic creativity: humor (the speaker produced at least one idea intending to provoke humor or amusement), metaphor and simile (the speaker produced ideas which made conceptual comparisons), and word play (the speaker played with the sounds or meanings of words).

Two native English-speaking research assistants were trained on the creativity rubric using a separate subset of 65 JLE texts. Raters were informed that the distance between each number on the rating scale was equal. After calibrating on the initial 65 texts, the raters then independently scored the remaining 466 texts for creativity. The raters were not aware that the samples were from English L2 learners. After scoring, raters were able to adjudicate disagreements greater than two for any of the subscales. Raters reported almost no instances of humor, metaphor and simile, or wordplay in the corpus, and thus these subscales were removed from the study. Table 1 displays the final, adjudicated kappa scores and correlations between the two raters for each of the remaining five subscales. After adjudication, the raters' scores were averaged for each subscale and text.

Table 1: Rater agreement

Subscale	*r*	Kappa
Ideational Fluency	0.830	0.830
Originality	0.825	0.822
Elaboration	0.739	0.738

Linguistic Feature Selection

Based on prior work reporting associations between lexical sophistication, cohesion, and creativity in L1 English research (Acar & Runco, 2014; Beketayev & Runco, 2016; Dumas & Dunbar, 2014; Skalicky et al., 2017), we hand-selected a range of lexical indices representative of these constructs. We also included features related to sentiment in order to explore whether these measures might explain further explain variance in creativity scores. We obtained our measures of lexical sophistication, sentiment, and cohesion using three freely-available automatic text analysis tools, TAALES v2.2, SEANCE, and TAACO, respectively (see Crossley, Kyle, & McNamara, 2016a, 2016b; Kyle, Crossley, & Berger, 2017).

For lexical sophistication, we included linguistic indices of word frequency, word concreteness (i.e., how abstract a word's meaning is), contextual diversity and distinctiveness (i.e., the range of different contexts a word occurs in), word meaningfulness (i.e., number of associations with other words), word polysemy (i.e., the number of different senses a word form has), and word recognition and naming norms (i.e., average time to recognize and name English words). For cohesion, we included features measuring the type-token ratio (i.e., lexical diversity) and number of repeated content words in each text. Finally, for sentiment, we used features measuring the overall valence of a text (i.e., use of positive or negative vocabulary). We used measures calculated for content words (e.g., nouns, verbs, adjectives) only.

Statistical Analysis

We first conducted a principal component analysis using the raters' scores for the four subscales in the IDEAS category from the creativity rubric to develop a single, weighted creativity score to be used as the dependent variable. We then conducted correlations between the creativity score and the oral proficiency scores provided with the JLE corpus, as well as between the creativity score and text length (i.e., number

of content word types in each text). We included text length as a variable because longer texts would include more ideas and thus be biased to higher ideation scores (and therefore higher creativity scores). Then, we controlled the linguistic features based on correlations with the dependent variable and also controlled for multicollinearity using correlations and variance inflation factors.

Next, in order to test whether L2 proficiency and the linguistic features related to lexical sophistication, sentiment, and cohesion were predictive of the creativity scores, we performed comparisons between linear regression models in order to obtain the most parsimonious model (i.e., the model that explained the largest amount of variance with the fewest number of predictor variables).

Results

Principal Component Analysis

A principal component analysis (PCA) was conducted on the averaged ratings of ideation, originality, elaboration, and appropriateness from the analytic rubric for the 466 texts in our subset of the JLE corpus. A Bartlett's test of sphericity was statistically significant ($\chi^2 = 717.179$, $df = 6$, $p < .001$), and the Kaiser-Meyer-Olkin measure of sampling adequacy reported .672, representing acceptable ability for the PCA to yield distinct, reliable factors (Field, 2013). A single component containing all four variables accounted for 59.463% of cumulative variance with an eigenvalue of 2.378. The individual subscale loadings were: ideation = .913, elaboration = .892, appropriateness = .782, originality = .369. In order to calculate a single score reflective of the different strengths of these loadings we multiplied each human score for each subscale for each text by its respective loading and summed these values per text, obtaining a weighted sum component score for each text (DiStefano, Zhu, & Mîndril, 2009), which we refer to as the creativity score (Min = 8.238, Max = 14.780, $M = 12.526$, $SD = 1.545$).

Linguistic Feature Reduction

Using the output from the automatic text analysis programs, we first reduced the number of variables by only including variables of interest that had a significant and meaningful linear relation (i.e., absolute $r > .1$) with the dependent variable (i.e., the creativity score). We then controlled for multicollinearity using variance inflation factors (VIF), removing any variable with a VIF greater than 2. The end result was a selection of seven linguistic indices that demonstrated no strong multicollinearity and possessed a significant linear relation with the dependent variable.

These features were: average Age of Acquisition, which is based on averaged self-reported ratings of the age English users first understood 30,000 different English words collected from over 800,000 English speakers in the United States (Kuperman, Stadthagen-Gonzalez, & Brysbaert, 2012), average Spoken Word Frequency calculated from the Corpus of Contemporary American English, The University of South Florida Free Association Norms (i.e., the average number of words a subject voices when presented with a particular word; Nelson, McEvoy, & Schreiber, 1998), LSA Average Top Three Cosine (average LSA cosine values for the top three related words in each text), Vader Positive Sentiment (compound score measuring the overall positive sentiment in a text; Hutto & Gilbert, 2014), Number of Content Word Types (our measure of text length), and Number of Repeated Content Word Lemmas (divided by total text length). Table 2 displays these variables and their correlations with the creativity score, along with the correlation between L2 proficiency level and creativity.

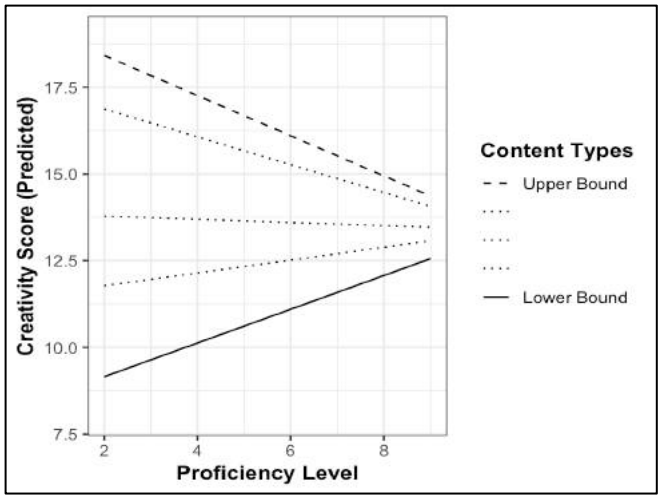

Figure 1: Interaction between English proficiency and text length (number of content word types). Upper and lower bounds represent the minimum and maximum values for number of content word types.

Regression Models

Based on the correlations among creativity, L2 proficiency level, and text length and initial model exploration, the results suggested a large amount of the variance in raters' creativity scores could be captured in a linear regression model fit with L2 proficiency, text length, and an interaction between text length and L2 proficiency. This model explained approximately 48% of the variance in raters' creativity scores ($R^2 = .475$, $F[3, 462] = 141.100$). The significant interaction between text length (i.e., number of content word types) and L2 proficiency indicated that differences in text length at higher L2 proficiency levels had significantly less effect on raters' perceptions of creativity when compared to lower levels of L2 proficiency. Specifically, at lower levels of L2 proficiency, texts with a higher number of content word types were rated significantly higher for creativity, and this effect attenuated significantly at higher levels of L2 proficiency. This interaction is visually plotted in Figure 1, and Table 3 displays the standardized beta coefficients and 95% confidence intervals for the terms in the model.

We then tested whether the separate inclusion of each of the remaining six predictor variables would significantly improve the baseline model based on changes in adjusted R^2 by comparing different linear regression models using the

anova() command in R. Table 4 summarizes the results of these comparisons. As can be seen, only the Vader Positive Sentiment index significantly increased the adjusted R^2 of the baseline model, with an increase of .07% variance explained. The remaining linguistic features did not explain any significant amount of additional variance, further suggesting that perceptions of creativity were strongly associated with L2 proficiency level and the amount of text produced by each participant.

Table 2. Correlations between predictor variables and the creativity score.

Index	*r*
Number of Content Word Types	0.643
L2 English Proficiency Level	0.449
Average Age of Acquisition	0.288
LSA (mean top three cosine)	-0.281
Free Association Norms (USF)	-0.240
Vader Positive Sentiment	0.158
Repeated Content Lemmas	0.134
Spoken Word Frequency (COCA)	0.118

Discussion

Creativity and L2 English Proficiency

Our first research question asked whether L2 English proficiency influenced raters' perceptions of creativity among our speech samples. The moderate correlation between the creativity score and L2 proficiency in Table 2 suggests a positive association between these features. This is further supported by the baseline regression model (Table 3), which included a significant positive effect for L2 proficiency (moderated by text length, see below). Together, these results provide an additional piece of evidence suggesting that a higher L2 proficiency level is associated with greater perceptions of creativity among the creativity raters. This finding aligns well with prior research into bilingual creative performance, which also reported greater creativity levels among bilinguals with higher L2 proficiency (Hommel et al., 2011; Kharkhurin, 2011; Lee & Kim, 2011; Leikin, 2013).

Our findings also suggest that this effect was moderated by text length, in that the overall length of the participants' picture description narratives (i.e., number of content word types) was more strongly associated with raters' perceptions of creativity at lower compared to higher levels of L2 proficiency. Thus, the manifestation of L2 proficiency as the ability to produce more language may be the driving determinant between higher creativity scores and L2 proficiency, as the ability to produce more language allowed for the opportunity to produce more ideas, and therefore receive higher ideation ratings and thus higher creativity scores.

Table 3: Baseline model explaining variance in raters' perceptions of creativity.

Model Term	*Estimate*	*SE*	*t*	*p*	*5% CI*	*95% CI*
(Intercept)	11.977	0.196	61.140	< .001	11.654	12.300
L2 English Proficiency Level	0.132	0.035	3.804	< .001	0.075	0.189
Text Length	1.900	0.176	10.788	< .001	1.609	2.190
L2 English Proficiency Level * Text Length	-0.178	0.028	-6.255	< .001	-0.225	-0.131
Adjusted R^2 = .475, F(3, 462) = 141.100. Estimate represents standardized beta coefficient as all predictor variables were z- scored before being entered into the model.						

Table 4: Comparisons between baseline model and models with different linguistic features.

Model Term	R^2	Adjusted R^2	*F*	*p*	R^2 Difference (Adjusted)
Baseline Model	0.478	0.475	141.099	NA	NA
Vader Positive Sentiment	0.487	0.482	109.275	0.006	0.007
Spoken Word Frequency (COCA)	0.478	0.474	105.597	0.962	0.001
Free Association Norms (USF)	0.480	0.476	106.513	0.167	0.001
LSA (mean top three cosine)	0.478	0.474	105.657	0.721	0.001
Age of Acquisition	0.478	0.474	105.677	0.680	0.001
Repeated Content Lemmas	0.478	0.474	105.684	0.667	0.001
Note: DF for all comparison models = (4, 461). Baseline model R syntax = *creativity ~ L2 English Proficiency Level + Text Length + L2 English Proficiency Level:Text Length*. *F* and *p* values correspond to change in R^2 from baseline model.					

Linguistic Features and English Proficiency

Our second research question asked whether linguistic features explained differences in creativity scores while taking L2 English proficiency into account. Early model exploration as well as a series of hierarchical linear regression comparisons suggested that almost all of the linguistic features selected for this study failed to predict any

meaningful amount of variance beyond the effect of L2 proficiency and text length, which combined to explain nearly 50% (Adjusted R^2 = .475) of the variance in the raters' perceptions of creativity, suggesting a relatively strong effect; see Table 4. The interaction between L2 proficiency and text length demonstrates that while text length was a strong, significant predictor of creativity scores, this effect was significantly stronger at lower L2 proficiency levels. Specifically, while texts with a greater number of content word types predicted increased creativity scores for participants across all eight proficiency levels, this effect was much stronger for participants who received lower L2 proficiency scores by the interviewer.

When comparing the difference in creativity scores between the upper bound and the lower bound of text length in Figure 1 (i.e., the minimum and maximum values for number of content word types), this difference attenuates for participants with higher L2 proficiency scores. This suggests that while differences in creativity scores at lower L2 proficiency levels are strongly predicted by the ability to produce more words (and therefore more ideas), this was not the case at the higher L2 proficiency levels. At higher L2 proficiency levels, variation in creativity scores based on total number of content word types was relatively low, suggesting that other features of the texts may have influenced the raters' creativity scores at higher L2 proficiency levels. However, these additional features, if any, were not captured in any of the linguistic features provided by our automatic text analysis tools. Therefore, unlike results reported in the L1 data, it is difficult at this time to draw concrete connections between specific linguistic features and bilingual performance on tests of creativity. It may be the case that additional linguistic features not included in the current study can explain variance in creativity at higher levels of L2 proficiency, providing ample opportunity for future research.

Aside from text length, one index, Vader Positive Sentiment, did result in a significantly better regression model fit, but only by approximately .07% of variance explained, suggesting that this index had a relatively weak effect. Nonetheless, it is still worth considering why this index may have provided a significant amount of additional variance explained. The Vader Positive Sentiment index is a component score derived from formulas specifically designed to measure sentiment in shorter texts, especially those used in social media (Hutto & Gilbert, 2014). The coefficient for the Vader Index was .148 (intercept = 11.881), suggesting a positive relation between positive sentiment and perceptions of creativity. Thus, narratives with more positive vocabulary may have appeared more creative to the raters in this study. Perhaps narratives with more positive language reflects a greater intent by the speakers in the corpus to create a unique story, as compared to narratives that were more factual descriptions of events. It would thus be worthwhile to further consider the role of sentiment in linguistic investigations of creative performance, as this would help identify links between specific types of linguistic knowledge and the cognitive construct of creativity.

Conclusion and Limitations

Previous investigations of bilingual creativity have reported a tendency for bilinguals with greater L2 proficiency to outperform those with lower L2 proficiency on standardized tests of creativity. The results from the current study support these claims while raising further questions. Specifically, we observed that increased levels of L2 proficiency were associated with higher perceptions of creativity, but this effect was moderated by the length of the speech samples. Moreover, while our results identified Vader Positive Sentiment as a significant linguistic predictor of creativity, this (and our other linguistic features) was overshadowed by the strong effect of text length. As a whole, these results suggest that there may be an L2 proficiency threshold for bilingual creativity, in that raters attended to additional linguistic features beyond text length only for speakers with relatively higher levels of L2 proficiency. In the future, it may be helpful to incorporate diversity-based linguistic information based on the prompts in order to control for potential vocabulary differences among the different prompts, which may influence the raters' perception of creativity (Chiru & Rebedea, 2017).

One final consideration is that the L2 English proficiency measure used in the current study was based solely on oral L2 proficiency at the time of the picture description task. Previous research in bilingual creativity has relied on proficiency assessments based on vocabulary knowledge tests as well as participant self-ratings of L2 proficiency and levels of bilingualism, which captures receptive vocabulary knowledge (i.e., reading and listening ability). The JLE L2 proficiency scores, on the other hand, are a measure of productive vocabulary knowledge (i.e., speaking and writing skill), and productive vocabulary size is typically smaller than receptive size (Schmitt, 2008). However, receptive and productive vocabulary knowledge are inextricably linked, suggesting that the JLE oral proficiency score is also a correlate of receptive L2 vocabulary knowledge (Webb, 2008). In all, these findings further highlight the association between bilingualism and the cognitive ability of creativity while providing avenues for future research.

What's Lagging in our Understanding of Interruptions?: Effects of Interruption Lags in Sequential Decision-Making

Abstract

Interruptions are an inevitable part of every day life. Previous research suggests that interruptions can decrease performance and increase errors and response time. Additionally, there is evidence that providing a lag time prior to an interruption can mitigate some of the interruption costs. The goal of this paper is to investigate the effects of interruptions and interruption lags and explore possible strategies to attenuate interruption costs. A novel sequential decision-making paradigm was used, where the difficulty of the task and type of interruption were the two experimental manipulations. The results indicate that there is a potential benefit to including a lag time when presented with interruptions.

Keywords: interruption; interruption lag; decision making

Introduction

Interruptions are a common occurrence in daily life. From a telephone ringing in the middle of a conversation with a friend, to a nurse handing an X-ray to a surgeon in the midst of a procedure, interruptions can happen at any moment and in any situation. The interruption literature dates back to the early 1900's when Zeigarnik (1938) surprisingly found that interrupted tasks were better recalled compared to tasks that were uninterrupted. This is often referred to as the "Zeigarnik effect". However, research within other fields, such as aviation, suggests interruptions can have negative impacts on behavior. For example, Fitts and Jones (1947) explain, "forgetting may occur when something unusual happens to interrupt or momentarily distract the pilot from his normal routine." Although there has been conflicting results when trying to replicate the Zeigarnik effect and countless of studies on interruptions since the 1920s, Gillie and Broadbent (1989) argue it is even more important to research how easily can people resume a task after being interrupted and what makes interruptions disruptive?

To answer these questions, Gillie and Broadbent (1989) had participants complete a complex computer-based adventure game and manipulated the types and duration of interruptions within the task. They found that similarity to the primary task and the complexity of the task lead to disruptive interruptions, but not the length of an interruption or when it occurred (Gillie & Broadbent, 1989). However, it is worth noting that there were only 10 participants in the experiment and this study was completed 30 years ago. In a more recent review of interruptions, Borst, Taatgen, and van Rijn (2015) conclude that there are three main disruptive factors: duration of the interruption, complexity of the interruption, and the moment of the interruption. Research on the effects of interruptions has dramatically increased in recent years, especially in fields where interruptions can lead to serious and sometimes even fatal consequences, such as in medicine (Westbrook, Raban, Walter, & Douglas, 2018; Walter, Li, Dunsmuir, & Westbrook, 2014; Westbrook et al., 2010), aviation (Gontar, Schneider, Schmidt-Moll, Bollin, & Bengler, 2017), and driving (Klauer et al., 2014; Young, Salmon, & Cornelissen, 2013) just to name a few.

Here, we will define interruptions as a break from one task in order to complete another task, and in our experiment, resuming the primary task can only occur once the secondary task is completed. Within the literature of interruption lags, studies have often used paradigms that are inherently complex and only include one interruption (Gillie & Broadbent, 1989; Trafton, Altmann, Brock, & Mintz, 2003; Cane, Cauchard, & Weger, 2012). Therefore, the main aim of the current experiment is to explore strategies to minimize interruption costs in a decision-making task with varying levels of difficulty so that we can easily manipulate the frequency, type, and location of interruptions. This is a novel sequential decision-making task that will be referred to as "The Mazing Race", which will be explained in greater depth later.

Theoretical Framework

Theories for understanding human cognition have been around for decades. Adaptive Control of Thought-Rational (ACT-R) is one cognitive architecture to model human memory that has been gradually developing for years (J. Anderson, Lebiere, Lovett, & Reder, 1998). Derived from ACT-R, the Altmann and Trafton's Goal Activation Model (GAM) theorizes whichever goal is most *active* will govern behavior. This contrasts to the basic "last-in, first-out" structure to model goal behavior, which assumes the *newest* goal directs behavior. Although this specific model will not be implemented in this study, the model is important to understand as it motivates the research question and design.

GAM predicts that people can take time to prepare before goals are suspended or interrupted. Therefore, the model suggests it may be important to give a cue before an interruption. Specifically, the GAM "predicts that interruption lag is critical to the ability to resume an interrupted goal" (Altmann

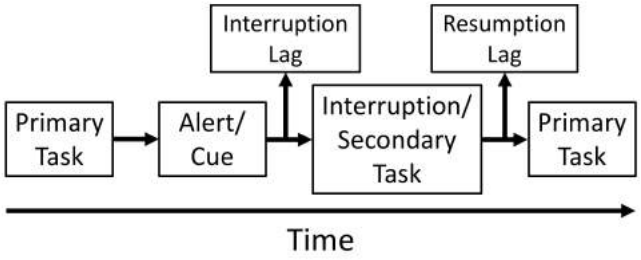

Figure 1: Image modified from Trafton et al. (2003) for a visual representation of the model including interruption and resumption lags.

& Trafton, 2002). Figure 1 illustrates a model to visualize what is happening during an interruption as a function of time. The overall idea of this model is that a person in the middle of completing a primary task is suddenly interrupted with another task, and ultimately has to resume the primary task. Often times there may be an alert, or cue, before the interruption occurs. The interruption lag is the time between the alert and the onset of the interruption. Depending on the context, the duration of the interruption lag may be able to be manipulated. Finally, the resumption lag is the time it takes to resume the primary task once the interruption has ended. This is often the dependent variable in experimental studies investigating interruption lags. One prediction from this model is that the interruption lag gives one time to prepare to resume the primary task after being interrupted.

To further understand this model, we will elaborate on a real-world example alluded to in the introduction. Imagine two people are in the midst of a conversation and suddenly the phone rings. Before the individual goes to answer it, she has the option to quickly end the current conversation, ignore the incoming call, or temporarily pause the conversation. In this scenario, the phone ringing is the alert and choosing to answer the phone would be the interruption to the primary task of the current conversation. If she chooses to pause the conversation, it would be advantageous to take a couple of seconds to remember exactly where the conversation has left off in order to successfully resume the conversation after the call. This is the idea of the interruption lag.

Interruption Lags

Over the past couple of decades, there have been several studies focusing on the effects of interruption lags. However, there are conflicting results with regards to the benefits of interruption lags. On one hand, problem solving tasks (e.g. Tower of London) showed interruption lags lead to faster resumption times compared to no lags (Morgan, Patrick, & Tiley, 2013; Hodgetts & Jones, 2006b, 2006a; Trafton et al., 2003). In fact, Hodgetts and Jones (2006a) found that even a two-second interruption lag can aid resumption on the primary task. Although most research on interruption lags has focused on static contexts, Labonté and colleagues show that a pre-interruption warning can be beneficial in dynamic environments, as well (Labonté, Tremblay, & Vachon, 2019, 2016). On the other hand, there were no benefits to including interruption lags within a reading task (Cane et al., 2012). The authors suggest that the lack of an effect is possibly because interruption lag effects may be dependent on the specific task (e.g. reading task vs. problem solving task).

It is also important to note the complexity of these tasks. For instance, Trafton et al. (2003)'s primary task was a computer game where participants had to keep track of a number of different resources including munitions, fuel, fuel tanks, vehicles, and more. Even the interruption was an involved tactical assessment task lasting 30 seconds. Similarly, the interruption in the reading task was a full minute long. The studies mentioned here investigated the effects of interruption lags in complex primary and secondary tasks. This current study looks to extend the literature by asking what effect, if any, will interruption lags have on a "simpler" task? The "simpler" task will be a novel sequential decision-making task. It is simpler in the sense that participants had to make very quick decisions and the interruptions were relatively short, as well. This paradigm is also novel because the number of interruptions was manipulated, rather than just having one interruption throughout the entire duration of the task. This is arguably a better model of the real world as interruptions are often frequent, unavoidable, and unpredictable.

Method

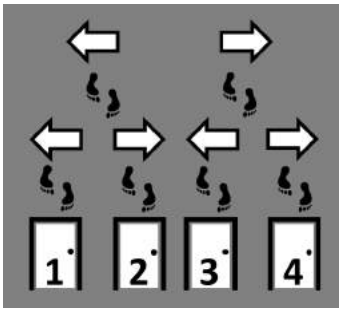
Participants

A total of 64 undergraduate students from the University of New South Wales were recruited to complete the experiment for course credit. Five participants' data were removed from analysis because the programmed crashed, so they were unable to complete the study, leaving 59 participants left for analysis.

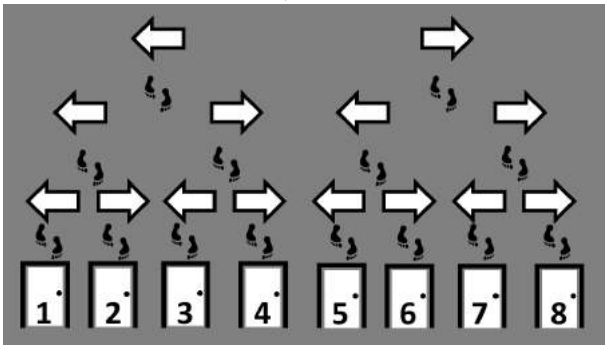
Design

This study was a 3 (difficulty: easy, medium, hard) x 3 (type of interruption: no interruption, interruption, and interruption + lag) fully within-subject design. Participants completed every combination of the conditions once for a total of nine blocks. The Mazing Race was the primary task and the interrupting task was a short-term recognition memory task. The number of interruptions depended on the difficulty level of the block. We were concerned about the difficulty of the task, and so we ensured participants completed the blocks in order of difficulty, from easiest to hardest. Within a set of problems with the same difficulty level, the type of interruption was randomized.

Primary Task: The Mazing Race In The Mazing Race participants had to make a series of decisions to go either "left" or "right" to work their way through a maze to open up doors. Figure 2 shows a visual representation of the underlying structure of the maze. These images were the stimuli used in the experiment and examples of what participants

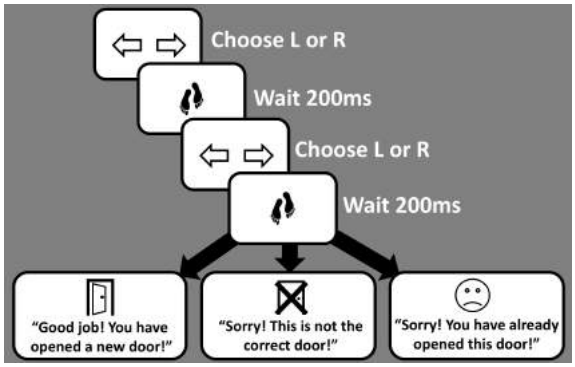


(a) Easy condition

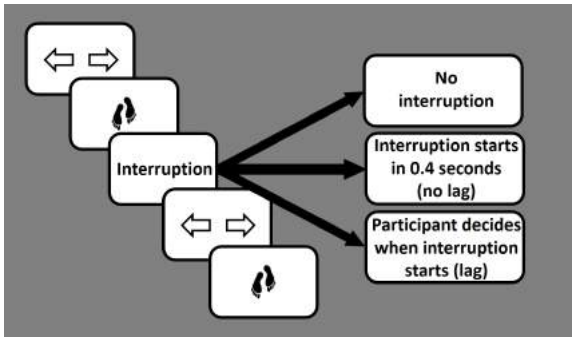


(b) Medium condition

Figure 2: The underlying structure of The Mazing Race for the (a) easy condition and (b) medium condition. The design required participants to open doors in the given order.



(a) Trial outcomes



(b) Interruption types

Figure 3: Schematic representation of the experimental design in the easy condition, depicting the (a) three possible trial outcomes and the (b) interruption types.

saw before each block. This figure illustrates a maze in the easy condition (a) with a total of four doors and a maze in the medium condition (b) with a total of eight doors. Although it is not displayed, the hard condition was of a similar structure, but had one additional decision-making level, resulting in a total of 16 doors. We named it The Mazing Race as it is a race to get to the bottom of every unique path in order to open all of the doors in as few attempts as possible. Once a door was opened, it stayed opened for the remainder of the block. Thus, the main dependent variables were the number of doors successfully opened and the number of trials needed to complete each block. Response times were recorded for further analysis, specifically looking at the response time of every decision (i.e. from when a stimulus is presented until the participant makes a keyboard response).

After participants studied the underlying structure of the maze, they pressed the space bar to start the block. Then, as shown in Figure 3a, two arrows appeared on the screen: one pointing left (L) and one pointing right (R) and participants simply had to choose to go L or R with the respective arrow keys. After every decision, animated footprints appeared for a total of 200ms symbolizing the participant walking down to the next level of the maze, where they made their next decision to go L or R. In the easy condition, for example, after two sequential decisions they reached the bottom of the maze. Every difficulty level had a maximum number of attempts to open all of the doors. In the easy condition it was 8 attempts, medium had 16, and hard had 32. These maximum numbers were included to try to minimize participants' frustration while completing the task.

Participants were required to open the doors in a specific order as shown in Figure 2. The order was always the same: starting by opening the left-most door and systematically working their way to the right-most door. Therefore, on any given attempt to open a door, there was always only one correct response. Feedback was provided every time the participant reached a door (see Figure 3a). If they reached the correct door they received positive feedback saying, "Good job! You have opened the correct door!" If they reached a door that had not already been opened, but was the incorrect door, they received negative feedback saying, "Sorry! This is not the correct door!" Finally, if they opened a door that was already opened, they also received negative feedback saying, "Sorry! You have already opened this door!" To successfully complete an easy block, for example, participants needed to go down the following four paths in this sequence: LL, LR, RL, RR. The block ended when the participant either successfully opened all of the doors or exceeded the maximum number of attempts. The experiment ended when all nine blocks were completed.

Interrupting Task: Recognition Memory Test Past research has shown that similarity and complexity between the

primary and interrupting task are factors that determine if the interruption is disruptive (Borst et al., 2015; Gillie & Broadbent, 1989). Because the main interest was the potential benefits of interruption lags, it was necessary that the interruptions were disruptive. Therefore, a recognition memory task was chosen because we assumed that both the primary and secondary tasks relied on a similar subset of memory-related cognitive processes. Figure 3b illustrates the three types of interruptions: no interruption, interruption, and interruption + lag. Participants were explicitly told what type of interruption to expect before the start of each block.

In our memory task there was a study and a test phase. The stimuli included randomly selected words from a list of 1535 words, where all the words were between three and six letters and one-syllable. This is the same word pool as used in Donkin and Nosofsky (2012). Anticipating that some participants may strategically try to keep count of the number of doors they have opened, numbers (randomly generated between 0-999) were also included in the memory test as a way to interfere with any possible counting. In the test phase, participants were presented with one "old" (i.e. previously studied) item and one "new" (i.e. previously unstudied) item and they were instructed to select the word that they believed to be the old item. During every interruption, there was a total of 10 study items and 10 test pairs. Each study item was randomly selected to be either a word or a number and test pairs could be two words, two numbers, or one of each.

The memory test was programmed to occur once in each set of four trials, where a trial is an attempt of opening a door, in The Mazing Race with a set number of interruptions in each condition. There was only one interruption in the easy condition, up to four in the medium condition, and up to eight in the hard condition. The interruptions were purposefully random and spread out to make it harder for the participant to anticipate when they would be interrupted. Before the memory task began, participants completing an interruption block saw a screen that said: "Start memory test **NOW**" (the task began automatically after 400ms) and in the interruption + lag block they saw a screen that said: "**Think about where you are in the Maze.** Press the space bar to start the memory test". The interruption lag was self-paced, meaning participants decided when to start the memory task. As soon the memory task was completed, participants immediately resumed The Mazing Race at the exact point where they left off and were given no environmental cues about where they were in the maze, which they were told from the start.

Furthermore, after every block, participants were given feedback on their performance for both tasks. For The Mazing Race, they were shown the number of doors they successfully opened and, if there were interruptions, they were shown the percentage of correct answers on the memory test. Lastly, participants were instructed that performance on The Mazing Race and the memory test were equally as important.

Results

We predicted that performance would be best in the no interruption condition and worst in the interruption condition. We expected the interruption + lag condition to fall somewhere between the others, as the lag would provide time to prepare to switch tasks and resume The Mazing Race. As this is a novel paradigm, several different analyses were carried out to try to fully understand the results. We will report the results of both frequentist and Bayesian repeated-measures ANOVAs. The Bayesian anaylses were performed using JASP (JASP Team, 2018), with priors set to their default values within the program. We report Bayes Factors (BF), which express the probability of the data given the alternative hypothesis (H_1) relative to the null hypothesis (H_0). A BF = 1-3 indicates weak evidence for the alternative hypothesis and a $BF > 30$ indicates strong evidence for the alternative hypothesis. Also note that for the purposes of this proceedings paper, due to the large number of comparisons, and exploratory nature of this investigation, we will only present the result of omnibus F-tests as a rough indicator of whether there were differences among conditions as a result of the introduction of interruptions. As such, we will focus on describing the qualitative pattern of the means and attempt to provide a more holistic interpretation of the overall pattern of results.

Before looking at specific dependent variables, Table 1 illustrates results from the interruption task. Participants performed equally well in both the interruption and interruption + lag conditions. Although performance decreased slightly as the primary task got harder, performance was still well above chance in all of the conditions. This suggests that participants were engaged in the secondary task and not using all of their cognitive resources on The Mazing Race.

To measure performance on the task, we first observed the average number of doors participants opened (Figure 4). The dotted lines represent the maximum number of doors in each level of difficulty: four doors in easy, eight doors in medium, and 16 doors in hard. Perfect performance would be to open all the doors in four, eight, and 16 trials, respectively. Looking at the Figure, it doesn't appear that the type of interruption affected the number of doors opened in the easy (BF_{10} = .68; $F(2,116) = 2.85$, $p = 0.06$) or hard (BF_{10} = .12; $F(2,116) = 0.87$, $p = 0.42$) conditions. There may have been an effect of interruptions in the medium condition, but the evidence is

Table 1: Summary Statistics of Interruption Task

	Easy	Medium	Hard
Interruption	0.82 (0.12)	0.79 (0.12)	0.77 (0.13)
Interruption + lag	0.82 (0.14)	0.80 (0.11)	0.77 (0.11)

Average probability of correct responses on the interruption task (memory test) across the different levels of difficulties. Standard deviations are provided in parentheses.

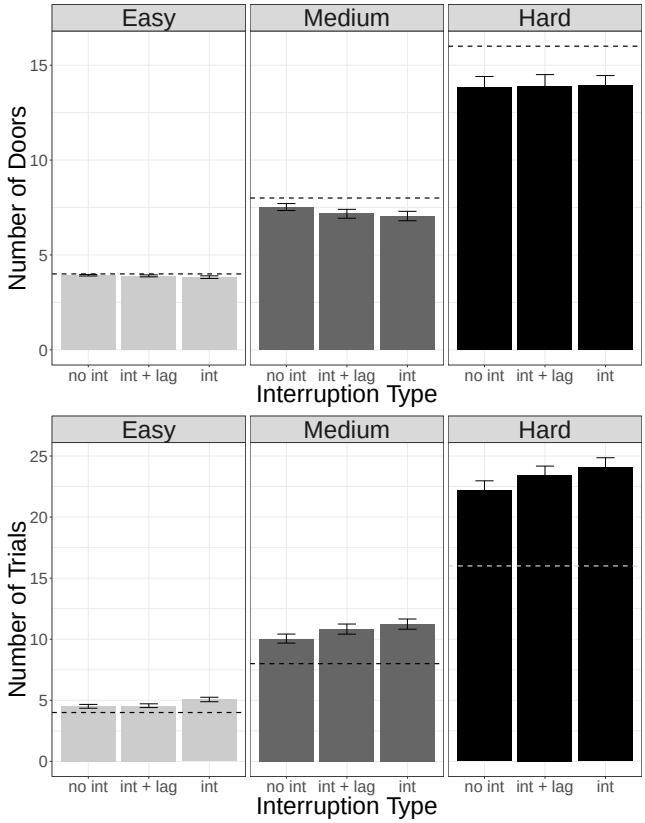


Figure 4: Average number of doors opened (top) and average number of trials needed to successfully complete the maze (bottom) in each condition as a function of interruption type. Dotted lines represent the maximum number of doors. Error bars indicate standard error in this and the subsequent figure.

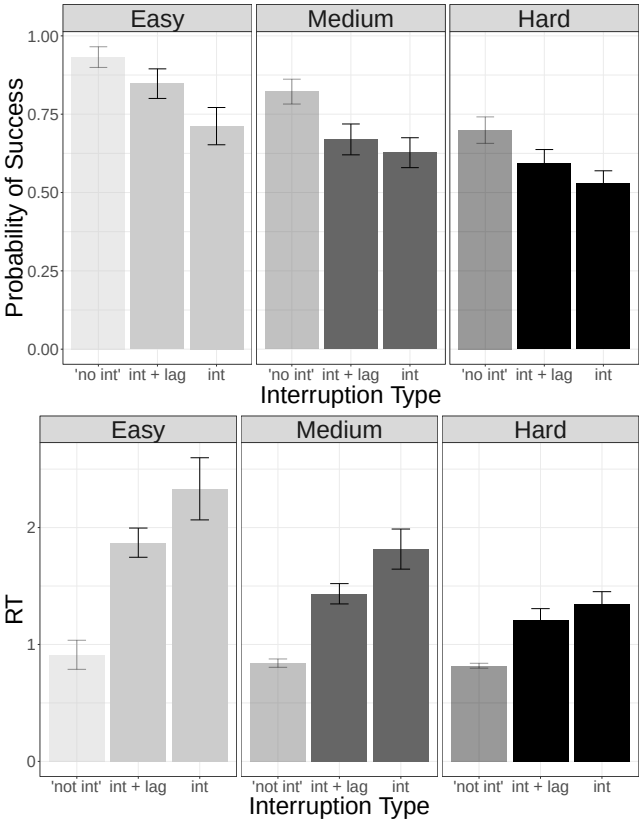

Figure 5: Probability of successfully opening the correct door (top) and median reaction times on trials immediately following interruptions. The "no interruption" condition is a lighter shade to show that it represents a baseline group for comparison even though there was no interruption in these conditions.

inconclusive ($BF_{10} = 1.427$; $F(2,116) = 3.78$, $p = 0.03$). However, it is likely that there were ceiling effects, especially in the easy condition, such that participants were opening all, or close to all, of the doors.

Even if participants successfully opened all of the doors, it is possible that they made more mistakes and needed more trials to open all doors when interrupted. Therefore, we next looked at the average number of trials needed to complete the block (Figure 4). The type of interruption did effect the number of trials in the easy condition ($BF_{10} = 38.22$; $F(2,116) = 7.79$, $p < 0.001$), medium condition ($BF_{10} = 5.93$; $F(2,116) = 5.47$, $p = 0.01$), though the statistical evidence was less clear for the hard condition ($BF_{10} = 1.82$; $F(2,116) = 4.10$, $p = 0.019$). Focusing on the mean scores in all difficulty conditions, we see that performance tends to decrease across interruption type with best performance in no interruption, followed by interruption + lag, with poorest performance in the interruption condition without lag.

Our next analyses examined the probability of successfully opening a door and the average median RT on trials immediately following an interruption (Figure 5). In order to have a baseline condition, we created a no interruption ("no int") condition for these two figures. As a reminder, there was one interruption in the easy condition, two in the medium, and four in the hard. That gives one, two, and four data points per participant in the respective conditions. Therefore, for the no interruption condition, we sampled one, two, and four data points for each respective condition from every participant to represent where an interruption may have occurred. It was predicted that the no interruption condition would have the highest probability of success and the fastest RT, the interruption condition would have the lowest and the slowest, and the interruption and lag would fall somewhere in the middle.

Turning first to the probability of success of opening a door immediately after an interruption, there was an effect of interruption type in all of the conditions: easy ($BF_{10} = 12.60$; $F(2,116) = 5.81$, $p < 0.01$), medium ($BF_{10} = 24.91$; $F(2,116) = 7.13$, $p = 0.001$), and hard ($BF_{10} = 15.11$; $F(2,116) = 6.57$, $p < 0.01$). Looking at the means, we can see there was the biggest difference between "no interruption" and interruption + lag, such that the introduction of the interruption had a relatively large effect on the next trial. In all conditions, however, we do still see a benefit of the lag, with worse performance in the interruption without a lag condition.

Next, we looked at median RTs following interruptions as a way to measure resumption lag. The ANOVA analyses reveal very large effects for easy ($BF_{10} > 100$; $F(2,116) = 22.50$, $p < 0.001$), medium ($BF_{10} > 100$; $F(2, 116) = 34.8$, $p < 0.001$), and hard ($BF_{10} > 100$; $F(2,116) = 28.59$, $p < 0.001$) conditions. Again, we saw a similar pattern when looking at the mean scores. The "no interruption" had the shortest RTs and then a big jump up to interruption + lag, and the interruption conditions had the longest RTs. We will turn to the discussion for further possible interpretations of these results.

Discussion

The aim of this study was to analyze the effects of interruptions and explore the possible benefits of interruption lags in a novel sequential decision making task. While performance was, by no surprise, the best in blocks without interruptions, we did find benefits to having lag time when there was an interruption.

Using the number of doors opened as a dependent variable did not show any large effects of interruption type. Additionally, we did not see the quantitative pattern of data like we saw in the other analyses. However, 49 participants successfully opened every door in all three easy blocks, suggesting performance was at ceiling. This has real world implications, such that if one gets interrupted in the middle of an effortless task, the interruption may not disrupt the primary task at all. Performance, however, did begin to decline when the primary task got harder. In the medium and hard conditions, 39 participants successfully opened all of the doors, with a handful of participants opening less than 50% of the doors.

When looking at the maximum number of trials needed to open all the doors, we did begin to see effects of interruption type. This was the first analysis where a consistent pattern of data emerged. Participants were able to complete the task in the lowest number of trials when there were no interruptions. Performance appeared to decrease in the interruption + lag condition and even more so in the interruption condition. This makes sense as participants were explicitly told to use the interruption time to try to remember their place in the maze.

When interrupted, it often takes time to pick up where you left off. For this reason, we were interested in observing the trials that occurred immediately following interruptions, specifically looking at the probability of success and response time when making the subsequent decision. The probability of success was highest and the average RT was the shortest when examining data from the no interruption condition because participants had nothing from which to be distracted. Additionally, we see a similar trend in the data as previously mentioned, where the interruption lag appears to be improving performance (compared to the interruption condition) in both of these analyses.

Limitations

Observing the effects of interruptions is difficult because it is unreasonable and unrealistic to interrupt participants on every single trial. For that reason, we decided to only include interruptions on $\frac{1}{4}$ of the trials. Therefore, we were left with limited data points for each participant. One solution would be to increase the number of interruptions, but that may be too cumbersome and frustrating for participants. Another solution would be to increase either the number of participants or number of trials per participant. Additionally, participants were required to open the doors in the same order (i.e. left to right) in all the blocks and always completed the blocks in order of difficulty (i.e. easy to hard). Therefore, although the overall RTs are longest in the easy condition and shortest in the hard conditions, this is likely due to practice effects. By the time participants get to the more difficult conditions, they can begin to anticipate their next move resulting in quicker decisions. However, models of volitional action control (Heise, Gerjets, & Westermann, 1997) predict that difficult tasks will protect against distractions. For example, Scheiter, Gerjets, and Heise (2014) and Wirzberger, Bijarsari, and Rey (2017) found that irrelevant interruptions only impaired performance in the easy, and not difficult, conditions of their respective experiments. The competing theories of whether practice effects or volitional control are driving the RT effects can be tested in follow up studies by randomizing the difficulty order of the blocks.

Future Directions

Possible avenues for future research would be to make The Mazing Race more challenging, for example, by randomizing the order of doors to open. Another interesting question is would we see the same pattern of results if the interruption task was different? For example, on one hand, the interruption could be as simple as pushing the space bar every time a cue appears. On the other hand, it is possible that a spatial recognition memory task may be even more disruptive. It is necessary to implement different types of interruptions to see if these results generalize. The relative simplicity and flexibility of The Mazing Race makes it possible to address these questions in follow up studies.

Conclusions

Taken together these findings illustrate the potential benefit to including a lag time when presented with an interruption. Performance increased from interruption < interruption + lag < no interruption across levels of difficulty and across multiple analyses, suggesting there is evidence from this study that interruption lags can reduce some interruption costs. Furthermore, this complements previous research on interruption lags in problem solving tasks (Hodgetts & Jones, 2006a; Trafton et al., 2003). Follow up studies should aim to include more interruptions (if possible) to provide more data points. Additionally, modeling these results could prove invaluable in trying to understand and predict participants' performance and the types of mistakes they make. Interruptions will always be part of our daily lives, so it is not only important to study the effects and costs of interruptions, but also to study possible strategies to minimize those costs.

Abstract

Several studies reported that it is harder to switch from a difficult task to an easy task than vice versa. Previous studies explain this paradoxical effect in terms of differences in task strength, by letting participants switch between different types of tasks. However, these studies failed to isolate the effects of task strength from task identity. Here, we present a series of experiments in which we systematically varied the strength of two tasks independent of their identity. We adapted a computational model of task switching by Yeung and Monsell (2003) to derive predictions about the magnitude of asymmetric switch costs (ASC) as a function of task strength, and compared predictions from the model to behavioral data. Our results reveal that ASC depend on the overall and relative task strength across the two tasks. ASC can therefore flip directions if the strength of two tasks is reversed, irrespective of their identities.

Keywords: task switching; paradoxical switch cost; task-set inertia

Introduction

Humans are remarkably flexible in their ability to switch between different tasks. However, a paradoxical finding in task switching experiments is that participants require more time and exhibit more errors when they switch from a harder task to an easier task than vice versa (Monsell, Yeung, & Azuma, 2000; Yeung & Monsell, 2003). For instance, bilinguials take more time to switch from their first language to their second language compared to switching from their second language to their first language (Meuter & Allport, 1999).

Alport, Styles, and Hsieh (1994) explained such asymmetric switch costs (ASC) in terms of the task-set inertia hypothesis. This postulates that the processes needed to execute a task (the task-set) persist in time, causing interference with the next task, and that switch costs reflect the time needed to resolve this interference. Executing a weak[1] task is assumed to require inhibition of automatic processes from a competing dominant task that would otherwise interfere (e.g. speaking a second language would require inhibition of the first language). According to the task-set inertia hypothesis, this inhibition persists when switching back to a dominant task, yielding high switch costs (Allport & Wylie, 2000). In contrast, switching to a weaker task should result in lower switch costs since the weak task would not require to be inhibited when performing the dominant task.

Building on the task-set inertia hypothesis, Yeung and Monsell (2003) devised a formal model that explains ASC as an interaction between task priming and top-down control. In their model, task priming corresponds to a carry over of the previous task-set, resulting in a facilitation of task repetitions (positive priming) but a delay for task switches (negative priming). Top-down control is assumed to vary as a function of task strength, with the weaker task requiring and receiving more control than the more dominant task. Without top-down control, both tasks would be subject to the same switch cost as they would be governed by the same amount of negative task priming. However, higher amounts of top-down control for the weaker task can compensate the effects of negative task priming, yielding lower switch costs for the weaker task relative to the more dominant task.

These and other accounts identify differences in task strength as a necessary condition for ASC (Alport et al., 1994; Allport & Wylie, 2000; Yeung & Monsell, 2003; Gilbert & Shallice, 2002). These accounts predict that the asymmetry in switch costs between two tasks should reverse if their task strengths reverse. In the example above, switching from a second language to a first language should be easier if the task strength of the first language was decreased relative to the second language. However, to date, there is no empirical support for this prediction as previous studies confounded task strength with task identity (e.g. the first language is always easier than the second language, at least for the duration of the experiment). The inability to manipulate task strength independent of task identity has also prevented researchers from testing the precise constellations of task strength under which ASC arise. One may ask if ASC would arise as soon as two tasks differ significantly in task strength, even if both are considered weak, or dominant? Finally, several studies have failed to observe ASC in error rates (ERs) (Meuter & Allport, 1999; Costa & Santesteban, 2004), or reported effects for reaction times (RTs) only (Mayr & Keele, 2000; Philipp, Gade, & Koch, 2007), failing to address whether participants traded off speed against accuracy.

So far, it is unclear (a) whether an asymmetry in switch costs between two tasks reverses if the task strength of the two tasks is reversed, and (b) whether the magnitude of ASC depends on the strength of the dominant task, in addition to

[1]Here, we refer to a task as weak if it requires higher amounts of cognitive control in order to overcome processing interference from more automatic (dominant) tasks.

the difference in strength between the dominant and the weak task. Here, we examine these questions across five experiments in which we manipulate the strength of two tasks independent of their identity. To account for tradeoffs in speed versus accuracy, we fit a hierarchical drift diffusion model (DDM, Ratcliff, 1978; Wiecki, Sofer, & Frank, 2013) to RTs and error rates. Finally, we compare experiment results to predictions derived from the task switching model by Yeung and Monsell (2003)

Experiments

We examined ASC across five experiments in which participants switched between categorizing the motion and categorizing the color of random-dot kinematograms (RDKs) (Kayser, Erickson, Buchsbaum, & D'Esposito, 2010). We manipulated the strength of each task across experiments by varying the signal to noise ratio of the task-relevant stimulus dimension. For each experiment, we then determined the strength of each task, as well as ASC in the drift rate of the fitted DDM.

Participants

All participants were students from Princeton University and received one hour of course credit. The study was approved by the Institutional Review Board of Princeton University. Participants signed a consent form prior to participation and were debriefed about the purpose of the study at the end of testing. We excluded participants whose performance was below 60% accuracy. Table 1 lists participant information for each experiment.

Table 1: Participants across all experiments.

Exp.	Participants	Age	Excluded
1	76 (37 female)	M = 19.5, SD = 0.56	6
2	25 (13 female)	M = 20.5, SD = 0.96	4
3	76 (42 female)	M = 20.4, SD = 0.54	6
4	33 (18 female)	M = 19.8, SD = 0.71	3
5	33 (17 female)	M = 20.1, SD = 0.63	4

Method

Each stimulus was an RDK that consisted of blue and red moving dots. Some of the dots consistently moved in either an upward or downward direction (independent of their color) while the remaining dots moved in a random direction. Participants switched between a color task, in which they had to indicate the color of the majority of the dots (red or blue), using the response buttons 'K' and 'L' respectively, and a motion task in which they had to indicate the direction of coherent motion (up or down), also using the response buttons 'K' and 'L', respectively. Participants performed each task over a mini-block of four to six trials.

Only the first trial of a mini-block was of interest to our analysis. Thus, in each sequence, we counterbalanced seven factors with respect to the first trial of each mini-block: task (color or motion task), task transition (task switch or task repetition), dot motion (upward or downward), dot color (mostly blue or red) and correct response ('K' or 'L' key). Participants were exposed to a total of 256 mini-blocks, divided into four larger experiment blocks.

Each mini-block was preceded by a task cue that instructed participants which task to perform. In some mini-blocks, participants had to repeat the task that they performed in the previous mini-block (task repetition), whereas in other mini-blocks they had to switch to the other task (task switch). The cue was displayed for 700ms before it disappeared for another 500ms. On each trial of a mini-block, the RDK stimulus was shown for 2000ms, followed by an inter-trial interval of 700ms. Participants were asked to respond while the stimulus was on the screen.

Critically, we varied the difficulty for both tasks across experiments, by changing the signal to noise ratio (coherence) for each task (see Tables 2 & 3). Note that variations in the signal to noise ratio of task-relevant stimulus dimensions can mimic the effect of traditional notions of task strength, such as stimulus-response associations in models of cognitive control (Cohen, Dunbar, & McClelland, 1990; Botvinick, Braver, Barch, Carter, & Cohen, 2001) and task switching (Gilbert & Shallice, 2002; Yeung, Nystrom, Aronson, & Cohen, 2006). Thus, differences in the signal to noise ratio between tasks resemble differences in task strength. We defined the color coherence as the percentage of dots that were displayed in the dominant color. For instance, a color coherence of 60% indicated that 60% percent of the dots were colored in blue while the rest of the dots were colored in red. Similarly, we defined motion coherence as the percentage of dots that moved consistently in one direction as opposed to moving in a random direction. In both tasks, coherence was used as a proxy for task difficulty: the higher the coherence, the easier it was to perform the task (Kayser, Buchsbaum, Erickson, & D'Esposito, 2009). It is important to note that equal values for color coherence and motion coherence do not necessarily yield the same level of performance for both tasks.

We adjusted the coherences of both tasks based on results from prior experiments (Tables 2 & 3). The coherence setting for Experiment 1 was determined based on prior pilot studies, with the intention to make the motion task easier than the color task. As expected, we observed that it was easier for participants to perform the motion task relative to the color task in Experiment 1. To test whether this relationship can be inverted, we lowered the coherence of the motion task and increased the coherence of the color task in Experiment 2. In Experiment 3, we tested whether we can invert the relationship observed in Experiment 1 by just lowering the coherence of the motion task while keeping the coherence of the color task the same as in Experiment 1. This manipulation did not yield ASC in terms of RTs, possibly due to a small difference in task strength. We therefore conducted a fourth Experiment in which we decreased the coherence of the motion task even further (relative to Experiment 3) while keeping the coherence of the color task the same as in Experiment 1. Despite significant differences in task strength in terms of both RTs

and error rates, we still failed to observe ASC in Experiment 4, suggesting that ASC may also depend on the strength of the dominant task (in this case, the color task). We therefore decided to increase the coherence of the color task in Experiment 5 while setting the coherence of the motion task to the same value as in Experiment 1.

Data Analysis

We were specifically interested in the performance costs associated with task switches and therefore focused our analyses on the RTs and error rates associated with the first trial of a miniblock (Rogers & Monsell, 1995). We assessed the effects of task (indexing relative task strength), as well as the interactive effect of task and task transition (indexing ASC) on RTs and error rates using a linear mixed model and logistic mixed model, respectively. We then fit a DDM to RTs and error rates, using the HDDM package (Wiecki et al., 2013). The DDM simulates performance on a task as an accumulation process that integrates information about the stimulus until one of two response thresholds is reached. The rate of evidence accumulation, henceforth referred to as drift rate, can be taken as a proxy for task strength, whereas the threshold indicates the degree to which speed is traded against accuracy (Ratcliff, 1978; Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006; Simen et al., 2009).

Fitting performance with the DDM serves two purposes. First, we quantify behavioral differences in task strength, as well as the asymmetry in switch costs in terms of drift rate, thereby isolating tradeoffs in speed versus accuracy. Second, we can compare performance of human participants to performance of the model. In the behavioral experiment, we manipulated the strength of each task in terms of the signal to noise ratio of the stimulus whereas in the computational model described below, we manipulate the strength of a task in terms of how much a corresponding task processing unit is driven by the stimulus. The DDM parameters collapse across RTs and error rates. Thus, quantifying task performance in terms of drift rate allows us to compare the strength of two tasks in comparable terms, and ASC in terms of the interactive effect between task and task transition on drift.

$$Drift \sim TaskTransition * Task + (1|Subj_i). \quad (1)$$

We fit the DDM using a Monte Carlo Markov Chain of 1000 samples of which the first 300 samples were not considered (burned). Other parameters of the DDM (response threshold, starting point, non-decision time and noise) were fit independent of condition.

Results

Table 2 and Table 3 show effects for RTs and error rates, respectively. In Experiment 1, participants were faster and made fewer errors during the motion task. The interaction between task and task transition was significant, with the dominant motion task yielding higher switch costs in RTs and error rates. The results from Experiment 1 were reversed in Experiment 2, with the motion task exhibiting higher RTs and higher error rates, and a significant interaction between task and task transition for error rates, but not RTs. In Experiment 3, participants responded slower to the motion task, but there was no significant difference in error rates between tasks. Moreover, the interaction between task and task transition was only significant for RTs, but not error rates. RTs and error rates were higher in the motion task in Experiment 4, however, we did not observe a significant interaction between task and task transition for RTs and error rates. Finally, in Experiment 5, we observed a speed accuracy tradeoff for the main effect of task, with the motion task showing higher RTs but lower error rates. A significant interaction between task and trask transition suggests that participants exhibited higher switch costs in terms of both RTs and error rates for the motion task relative to the color task.

Table 2: RT results for main effects of task and ASC.

Exp.	Color Coh.	Motion Coh.	Fixed Effects	β	SD	p

5	80%	60%	ASC*	0.52	0.22	0.018

In addition to the RT and error rate analysis, we fitted the data with a hierarchical drift diffusion model (HDDM), to investigate the effects of task strength and ASC in terms of drift rate. In Experiment 1, the drift rate fitted to the motion task was significantly larger than the drift rate for the color task, (M = 0.34, 95% CI = [0.30, 0.40]), suggesting that the motion task was easier than the color task. Furthermore, the drift rate cost of switching to the easier motion task was higher than the drift rate cost of switching to the color task (M = -0.33, 95% CI = [-0.42, -0.24]). We examined the hypothesis that ASC reverse with the relative strength of two tasks, by comparing ASC of Experiment 1 against ASC in Experiment 2 (with lower coherence of the motion task and higher coherence of the color task). Results indicate that the task effect on drift rate reversed in Experiment 2 (M = -0.53, 95%

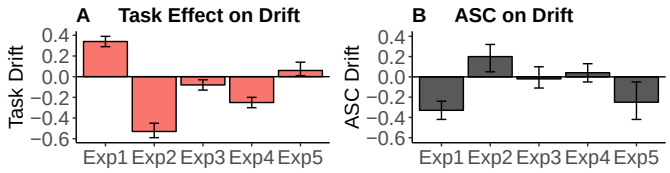

Figure 1: Main effects of task and ASC in terms of drift rate. (A) The main effect of task on drift rate is plotted for each experiment. Positive values indicate that participants accumulated evidence at a higher rate for the motion task relative to the color task (i.e. the strength of the motion task was higher). (B) The ASC effect in terms of drift rates is plotted for each experiment. Positive ASC drift rates indicate that switch costs for the color task were lower than the motion task. Vertical bars indicate 95% confidence intervals.

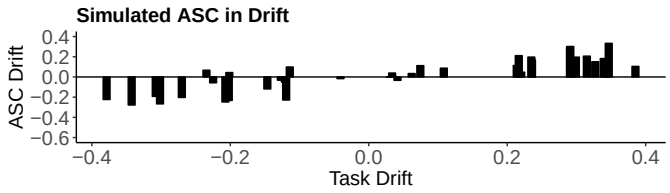

Figure 2: ASC as a function of task effect in drift rate simulated by the model.

CI = [-0.60, -0.46]), suggesting that the color task was easier than the motion task. Moreover, the cost of switching to the motion task was now lower than the cost of switching to the color task, as indicated by a positive interactive effect of task and task transition on drift rate (M = 0.20, 95% *CI* = [0.10, 0.36]). We also compared ASC across Experiments 3-5 to examine whether the magnitude of this effect depends on the task strength of the dominant task. In Experiment 3, we observed no effect of ASC in terms of drift rate (M = -0.02, 95% *CI* = [-0.11, 0.10]), despite significant differences in the task strength of each task (M = -0.08, 95% *CI* = [-0.13, -0.13]). Similarly, in Experiment 4, we observed no drift rate effect of ASC (M = -0.041, 95% *CI* = [-0.05, 0.13]), despite high differences in drift rate between tasks (M = -0.25, 95% *CI* = [-0.30, -0.20]). However, in Experiment 5 where the coherence of both tasks was high, we observed observed ASC (M = -0.25, 95% *CI* = [-0.42, -0.05]) while the difference in drift rate between tasks was relatively small (M = 0.06, 95% *CI* = [0.01, 0.14]).

One concern is that observed differences in drift rates between experiments may arise due to differences in sample size. We therefore performed the same analysis for each experiment on a random sample of 25 participants. Results of this analysis yield the same qualitative effects in drift rates.

Task Switching Model

To test whether our experimental results would be predicted by the model of Yeung and Monsell (2003), we simulated

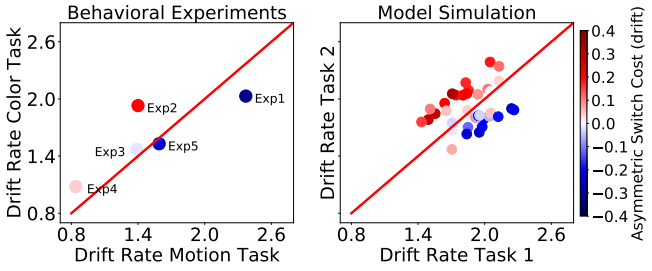

Figure 3: ASC as a function of task drift in the simulated model (left) and 5 behavioral experiments (right). Each colored dot represents a behavioral experiment (left) or a simulation (right) with a different configuration of input strength. Here, we quantified the strength of a task in terms of the drift rate fitted to RTs and error rates for that task. Positive ASC values (red) indicate that switch costs were higher for task 1 relative to task 2, whereas negative values (blue) indicate the opposite. The red line indicates equal strength for both tasks.

ASC as a function of task strength. The model explains the costs of switching between two tasks as a function of their activation. The activation of a task is determined by its strength, the amount of control allocated to a task, as well as task priming. RTs and error rates are generated by two separate equations for response generation and response resolution.

Model Mechanisms

Here, we outline the mechanisms of the model using the notation of Yeung and Monsell (2003). On each trial, the net input for a given task i is determined by a linear combination of four sources of input

$$input_i = strength_i + priming_i + control_i + noise \quad (2)$$

Where $strength_i$ corresponds to the strength of the task[2], $priming_i$ corresponds to inertia from the previously executed task and is set to a constant, $control_i$ is the amount of cognitive control allocated to the task, and *noise* is sampled from a Gaussian distribution with zero mean. The activation of each task is a negatively accelerated function of its net input

$$activation_i = 1 - e^{(-c * input[i])} \quad (3)$$

where c is a scalar that regulates the strength of the net input. Response generation time is computed by first normalizing activation of the two tasks

$$generationrate_i = activation_i / \sum activation \quad (4)$$

and then dividing a threshold by the normalized activation

$$generationtime_i = THRESHOLD / generationrate_i \quad (5)$$

where THRESHOLD is set to 100 in the model. The difference between the generation times for each task determine

[2]Here, the strength of a task is equivalent to the strength of processing weight in a neural network model multiplied by the input signal provided by the stimulus (Cohen et al., 1990; Gilbert & Shallice, 2002)

the time it takes to resolve which task to perform (resolution time). The resolution time depends on the relative time at which response codes for competing tasks are generated, and was computed as follows:

$$resolutiontime = r + f[r - generationtime_j - generationtime_i] \quad (6)$$

where r corresponds to a sample from an ex-Gaussian distribution. Finally, the RT for each task is computed as the sum of generation time, resolution time, and the two constants P and R representing the time taken for perceptual and response-production processes, respectively.

$$ReactionTime_i = P + generationtime_i + resolutiontime_i + R \quad (7)$$

Here, we counted a response as correct if the RT for the currently relevant task was lower than the RT for the currently irrelevant task, and incorrect otherwise [3].

Parameterization

The model parameters were adjusted to yield RT an error rate distributions that matched the behavioral data. The priming factor was set to 0.2 for the current task and set to 0 for the irrelevant task. Noise for the net input was sampled from a Gaussian distribution (μ=0, σ= 0.1) and r was sampled from an ex-Gaussian distribution (μ=200, σ = 240, λ = 150). We fixed c to 0.5 and set perceptual and response-production parameters, P and R, both to 200. In this study, we analyzed switch costs irrespective of stimulus congruency and therefore set f to 0. The priming factor and c were adjusted to receive best ASC fits to the data.

Control for both tasks was first initialized to 0.15, and then adjusted using the stair-casing procedure for each task described by Yeung and Monsell (2003). Each time the model made a correct response the control parameter was decremented by 0.01, and each time the model made an error, the control parameter was incremented by 0.1. The task strength parameter was varied across simulations (see below).

Task Environment

We assessed performance while the model was switching between 64 mini-blocks of two tasks. Each mini-block consisted of four to six trials of the same task. Trial sequences were generated akin to the sequences of the behavioral experiment. We generated the sequence of mini-blocks by counterbalancing which of the two tasks the model is asked to perform, as well as the task transition with respect to the previous mini-block (repetition or switch). Following the analysis procedure of the behavioral experiment, we focused our analyses on RTs and error rates of the first trial of a mini-block (Rogers & Monsell, 1995).

Simulation Procedure

We used the model to generate predictions about ASC as a function of task strength. To do this, we varied the task strength parameters $strength_i$ for both tasks from 0.2 to 0.7 in 0.2 steps across simulations, resulting in 36 parameter configurations. For each parameter configuration, we simulated behavior of the model across 30 task switching sequences. In each trial of a sequence, we set $control_i$ of the relevant task i to the value determined by the adaptation procedure described above while $control_j$ of the irrelevant task $j \neq i$ was set to 0, and fixed all other parameters to their default values. We recorded RTs and error rates for the first trial of each mini-block. We then fitted the drift rate parameter of the DDM separately for each task, as well as for the interaction between task and task transition using the same fitting procedure as described in the Experiment section.

[3] Note, that Yeung and Monsell only analyzed RTs.

Results

Our simulation results indicate that ASC increase with the magnitude of the difference between the strengths of tasks (Fig. 2, 3 & 4). Interestingly, the ASC effect was independent of the absolute magnitude of the task strengths, i.e. the magnitude of the ASC effect remained the same with extremely high or low task strength values measured in terms of main effects on drift rates. However, the range of task drift rates produced by the model did not cover the drift rates obtained from Experiments 1, 3 and 4, preventing a direct comparison. We could only obtain lower task drift rates if the model committed a high amount of errors that did not match human behavior. However, our simulation results suggest that, at least for the range of simulated task strengths, ASC are predicted to depend only on the relative but not the absolute strengths of the two tasks.

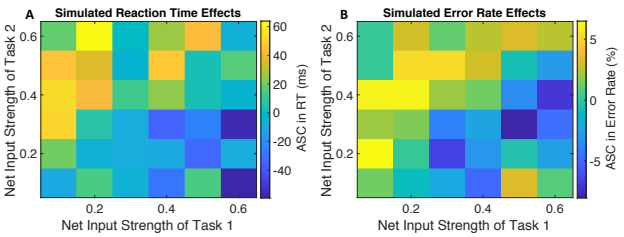

Figure 4: Simulated ASC in RTs and error rates as a function of the input strength for both tasks.

General Discussion and Conclusion

The seemingly paradoxical finding that switching to an easier task is more difficult has been under investigation for the last two decades. Here, we conducted five task switching experiments to systematically investigate ASC as a function of task strength. We manipulated the strength of two tasks, by varying the signal to noise ratio of the corresponding stimulus dimension, and fitted the behavior of human participants with a DDM to quantify (a) the strength of each task and (b) the ASC in terms of changes in the rate of evidence accumulation (drift rate). Our behavioral results indicate that the asymmetry in switch costs between two tasks can indeed reverse if the more dominant task is weakened and the weaker task is strengthened (Experiment 1 and 2). While previous studies

have shown ASC for different tasks, they have typically confounded the difficulty of a task with its identity (Alport et al., 1994; Costa & Santesteban, 2004; Mayr & Keele, 2000; Philipp et al., 2007). Here, we provide empirical support for the hypothesis that ASC can flip if the relative strengths of the two tasks are reversed, even if their identies stay the same. However, our behavioral results suggest that a difference in task strength is not sufficient to yield ASC (Experiment 3-5). That is, we only observed ASC if (a) tasks differed in terms of their strength and (b) the dominant task was relatively easy.

We contrasted human behavior against predictions of a task switching model by Yeung and Monsell (2003) which provides a mechanistic account of this effect in terms of the dynamics of task set priming and top-down control. As in the behavioral experiments, we quantified the strength of each task, as well as the signed magnitude of ASC in terms of drift rate, by fitting the DDM to simulated performance. Our simulation results match the observation that the asymmetry in switch costs should reverse if the strength of two tasks inverses. However, in contrast to participants, the model does not seem to be sensitive to the overall strength of both tasks.

An exaustive analysis of ASC as a function of task strength can help to inform future models of task switching. While most task switching models do not address ASC (Meiran, 1996; Logan & Bundesen, 2003; Brown, Reynolds, & Braver, 2007; Altmann & Gray, 2008), the connectionist model by Gilbert and Shallice (2002) explains ASC, similar to Yeung and Monsell (2003), in terms of differences in top-down input for both tasks: The easier task yields higher switch costs because a stronger top-down input needed to perform a difficult task persists when switching to the easier task. It is worth noting that both models provide a different explanation than Alport et al. (1994). Allport and colleagues suggest that the easier task is associated with higher switch costs because it needed to be suppressed in order to perform the difficult task. In any case, the dependence of ASC on the absolute strength for both tasks presents an interesting challenge for existing and future models of task switching.

Our study provides an important step towards understanding ASC in that it highlights the importance of absolute task strength. However, it does not explain ASC in terms of the factors that contribute to the strength of a task. Here, we operationalized task strength in terms of drift rate that we fitted from RTs and error rates for each task. While this metric allowed us to compare predictions of the model (with respect to task strength) with behavioral performance, it confounds the effects of task automaticity and top-down control on performance. That is, the measured strength of a task may be high, either because it has a high automaticity or because the task receives a high amount of cognitive control. Recent theories of control allocation suggest that the latter can be manipulated by incentivizing accuracy on task (Shenhav, Botvinick, & Cohen, 2013; Musslick, Shenhav, Botvinick, & Cohen, 2015; Botvinick & Braver, 2015). For instance, Umemoto and Holroyd (2015) associated one of two tasks with a higher reward, and observed that participants exhibited lower switch costs when switching to the more rewarded task. Prior modeling work suggests that such incentive-driven differences in switch costs can be attributed differences in allocation of top-down control as opposed to differences in task automaticity (Musslick et al., 2015). Future empirical studies may be able to disentangle the contribution of controlled and automatic processing to ASC, e.g. by manipulating the amount of reward participants receive for a given task.

While task strength appears to play an important role in the explanation of ASC, there are other factors to consider. Yeung and Monsell (2003) found that a delayed onset of the task-irrelevant stimulus (high stimulus onset asynchrony, SOA) could either reduce or reverse the effect of ASC. Moreover, the authors observed no ASC if participants responded with different key presses to each task. These findings identify interference between tasks as a necessary condition for ASC. The results presented here indicate that such interference may not occur when both of the tasks are difficult to perform, even if one of the tasks is much easier than the other.

Go with Plan A: Backup Plans Help the Powerful but Distract the Powerless

Leila Straub
ETH Zurich, Zurich, Switzerland

Petra C. Schmid
ETH Zurich, Zrich, Switzerland

Abstract

Backup plans represent a safety net that can help ensure goal attainment. However, managing backup plans during goal pursuit can also deflect attention away from the initial plan. We examined how individuals sense of power, which is said to facilitate goal pursuit, affects the extent to which one gets distracted by backup plans. Results from four studies showed that when a backup plan was activated, greater sense of power was associated with lower self-reported distraction and better performance. Studies 2 and 3 further revealed mediating effects of distraction between sense of power and performance. Greater sense of power was associated with less distraction, which in turn was related to better performance. Our findings suggest that when pursuing goals, individuals experiencing high power may be better at allocating their limited cognitive resources to the initial plan.

Ain't that a shame: An exploration into "academic" shame and STEM learning

Anonymous CogSci submission

Abstract

The current study explored the impact that "academic" shame had on learning of the human circulatory system. Participants were randomly assigned to one of two conditions: a shame induction condition or a control condition (no shame induction). Results revealed that the shame induction manipulation was related to higher levels of state shame. Additionally, it was discovered that by and large "in the moment" shame and having a proneness to experiencing shame dampened down any subsequent learning. Implications to education and future research are discussed.

Keywords: shame; cognition; learning; STEM; emotions

Theoretical Framework

Although there are many ways to define shame, for the purposes of this study, shame is an acutely painful affective state that is brought on by a failure to meet internally set rules, ideals, goals, or standards (Turner, Husman, & Schallert, 2002). A gap currently exists in the literature regarding a quantitative exploration of shame. Of the research that has been conducted, much has been qualitative in nature and not focused on "academic" shame (i.e., shame affiliated with learning and education). One possible reason for the underdeveloped exploration of this construct is due to the difficulty in studying it. More specifically, research has shown that individuals may deny their feelings of shame, they tend to self-isolate when they feel shame, and they may be unwilling or unable to express themselves when they feel shame. In fact, one's difficulty in communicating a shameful experience may be a distinctive characteristic of shame (Turner, 2014; Babcock & Sabini, 1990, Lunde, 1958).

Although research has suggested the *difficulties* in studying shame, the difficulty does not detract from the *importance* of studying shame. Tangney and Dearing (2002) suggested that, "Guilt, and especially shame ... are powerful, ubiquitous emotions that come into play across most important areas of life." (p. 8). Contemporary research has shown that experiences of shame can have a "negative impact on interpersonal behavior and functioning" (Tangney & Dearing, 2002, p. 5). Within the context of education, a number of educational psychologists have asserted that feeling shame can interfere with motivation, and negatively impact students' academic goals and achievement (Pekrun, Frenzel, Goetz, & Perry, 2007; Weiner, 1986). Indeed, once students experience shame, their ability to become cognitively engaged may be hindered, they may lose motivation for studying, and, they may feel reluctant to attend class (Turner, Husman, & Schallert, 2002).

Given the importance of gaining a better understanding of this self-conscious emotion, the current study explored the impact that "academic" shame had on learning of the human circulatory system with the hope that we can better understand students' experiences of this emotion.

Current Study

Materials

Test of self-conscious affect The TOSCA-3 (Tangney & Dearing, 2002) was developed as a tool to measure guilt-proneness, shame-proneness, proneness to externalization, and proneness to unconcern. The TOSCA-3 consists of 15 scenario-based situations that test takers may encounter in their day to day lives. Following each scenario, test takers are asked to rate the likelihood of reacting to each of the options on a five-point scale.

Pretest/posttest To assess deep conceptual understanding of the functioning of the human circulatory system, three separate tests were developed in the authors' research laboratory. One test consisted of ten multiple choice questions that were related to the human circulatory system. For example, *"the process of circulation includes which of the following: a) the intake of metabolic materials b) the convergence of metabolic materials throughout the organism c) the return of harmful by products to the environment* ***d) all of the above****".* A second test consisted of 20 matching questions in which the participants had to correctly identify the different components of the human heart. A third and final test consisted of 13 matching questions where the participants had to correctly label the proper functioning of the different parts of the human circulatory system. For example*, "which part of the human circulatory system carries blood away from the heart?" (answer: arteries).*

Self-regulated learning-self report survey (SRL-SRS) The SRL-SRS is intended to measure self-regulation as a relatively stable attribute in multiple learning domains and is based on Zimmerman's self-regulated learning theory. It is comprised of six subscales: planning, self-monitoring, evaluation, reflection, effort, and self-efficacy (Toering, Elferink-Gemser, Jonker, van Heuvelen, & Visscher, 2012).

Casual dimension scale-II The CDS-II consists of 12 closed ended 9-point Likert scale items designed to assess causal attributions related to achievement outcomes. The CDS-II measures attribution across the following four areas: locus of causality (e.g., the cause of your performance reflects an aspect of yourself), external control (e.g., the

cause of your performance is under the power of other people), stability (e.g., the cause of your performance is permanent), and personal control (e.g., the cause of your performance is something you can regulate) (McAuley, Duncan, & Russell, 1992).

Experiential shame scale According to Turner (2014), the Experiential Shame Scale (ESS) is "an opaque measure of physical, emotional, and social markers of shame experiences...developed to address the difficulties of assessing state shame." The ESS consists of eleven questions in which the test taker indicates the number that best describes how they feel right now when comparing two opposite word states. For example, "Physically, I feel [Very Warm 1--2--3--4--5--6--7 Very Cool]".

Participants

Participants consisted of 40 students from a private liberal arts university located in the southern United States. Volunteers fulfilled a course requirement in their general psychology class for their participation.

Procedure

Before entering the lab, participants were randomly assigned to either the experimental (i.e., shame induction) group or the control group. After completing the informed consent, participants were given as much time as needed to complete the TOSCA-3. They then completed the three circulatory system tests. Following completion of the pretests, participants then were asked to fill out the SRL-SRS.

Before beginning the ACT practice problems, participants were read the following instructions: "During this portion of the study you will be asked to complete a series of problems. **These are problems that, as a college student,** should not be extremely challenging for you. In order to recreate a scenario that would match an actual testing environment, you will have 30 minutes to complete the test. After you submit the test, instructions will appear on the screen that will let you know the next steps that you will need to take in this study. Please let the experimenter know if you have any questions at this time. Thank you again for your participation!" The bolded portion in the instructions is the only difference between what is read to participants in the control group and experimental group (i.e., experimental group receives the bolded statement). For the experimental (i.e., shame induction) group, after finishing the ACT, a text box appeared that stated "Your combined score on the test was: 40%. The average (school name; removed for blind reviews) student scored 90%. Please let the experimenter know your score so that it can be catalogued." The control group received the following feedback once they had completed the ACT practice problems: "You have now completed this portion of the study. Please let the experimenter know you are ready to proceed."

Immediately following the completion of the ACT practice problems, participants were asked to complete the Experiential Shame Scale in order to measure state shame (i.e., "in the moment shame"). Participants then filled out the Causal Dimension Scale-II and began interacting with a hypermedia encyclopedia (this served as our instructional delivery to assess the impact of shame on learning). Before interacting with the encyclopedia, they were read a set of instructions by the experimenter which told the learner that their job was to spend 30 minutes learning all they could about the human circulatory system. Participants were required to use the full 30 minutes before moving on from this part of the study. Following completion of the encyclopedia, participants were given the circulatory system posttests, were debriefed, and were then allowed to leave.

Results

Participants in the shame induction condition (M = 4.5) scored significantly higher on the ESS than participants in the control condition (M = 3.6), t (38) = 2.876, p = .007, d = .91. See Figure 1.

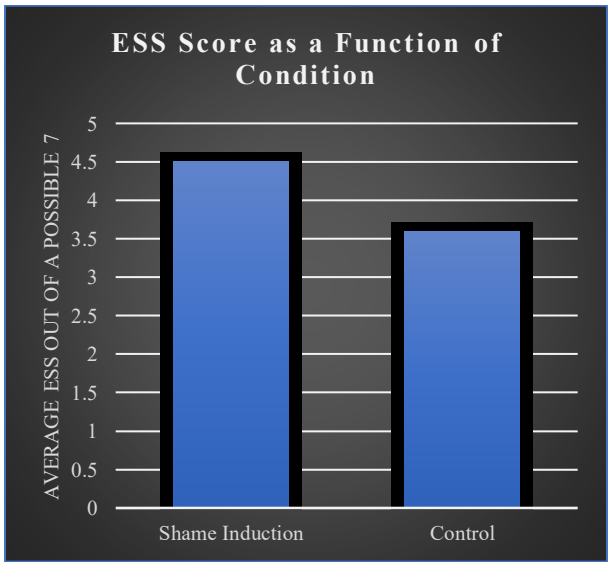

Figure 1: Average shame score as a function of condition.

Initial results revealed that participants in the control condition (M = 1.5) learned significantly more from pretest to posttest compared to participants in the shame induction condition (M = .50), F (1, 38) = 3.188, p = .04 (one-tailed) on the multiple-choice dependent measure. See Figure 2.

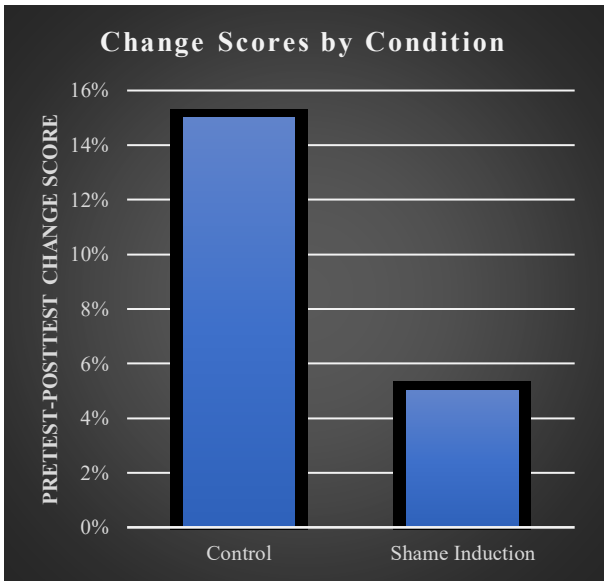

Figure 2: Average learning gain as a function of condition.

A significant main effect was found between the variables "shame proneness" with change scores as the dependent measures. More specifically, change scores on the matching test revealed that participants with a low proneness to shame (M = 5.4) learned significantly more than participants with a high proneness to shame (M = 2.1), p = .000. Additionally, when looking at all tests combined, participant with a low proneness to shame (M = 12.94) learned significantly more than participants with a high proneness to shame (M = 7.34), p =.002. See Figure 3.

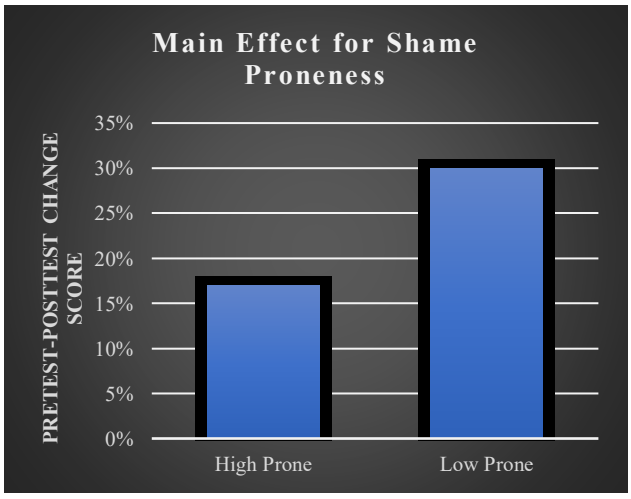

Figure 3: Average learning gain as a function of shame proneness.

Significant interactions were discovered between condition and shame proneness. Participants in the shame induction condition with a high proneness to shame (M = 2.18) learned significantly less than participants in the shame induction condition with a low proneness to shame (M = 6.5), p = .001 (Matching Test).

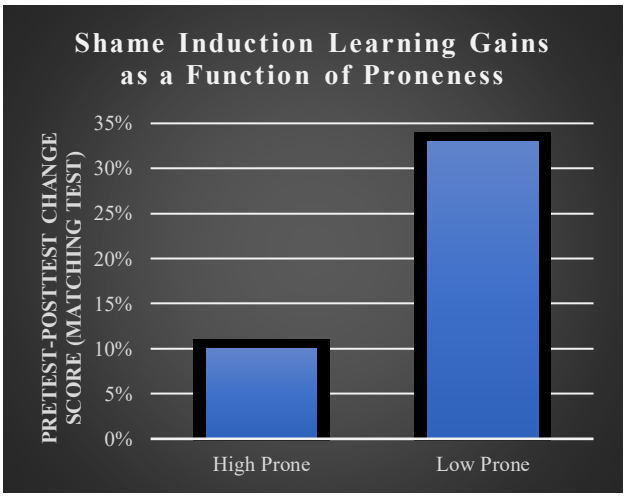

Figure 4: Average matching test learning gain for shame induction condition as a function of proneness.

Similarly, participants in the shame induction condition with a high proneness to shame (M = 3.82) learned significantly less than participants in the control condition with a low proneness to shame (M = 7.8), p = .05 (Labeling Test).

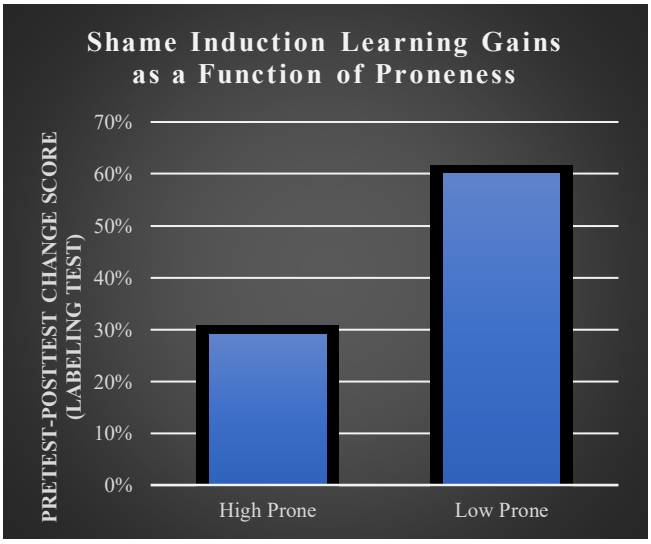

Figure 5: Average labeling test learning gain for shame induction condition as a function of proneness.

Additionally, participants in the control condition with a low proneness to shame (M = 4.3) learned significantly more than participants in the control condition with a high proneness to shame (M = 2.0), p = .036 (Matching Test Only).

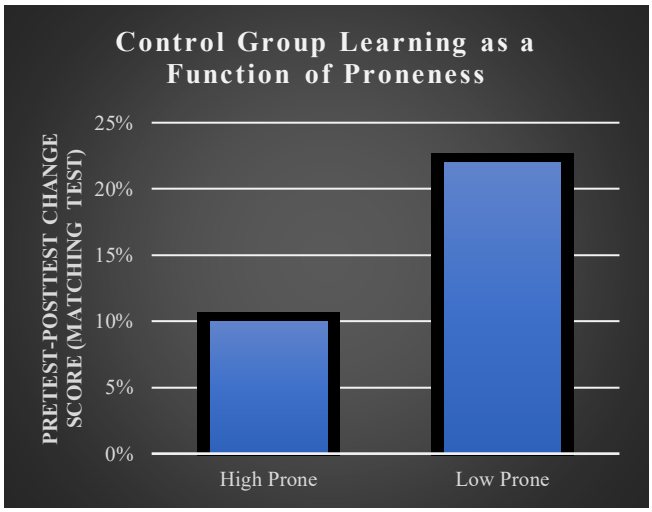

Figure 6: Average matching test learning gain for control condition as a function of proneness.

When looking at the change scores of all tests combined, participants in the shame induction condition with a high proneness to shame (M = 8.2) learned significantly less than participants in the shame induction with a low proneness to shame (M = 10.9), p = .002.

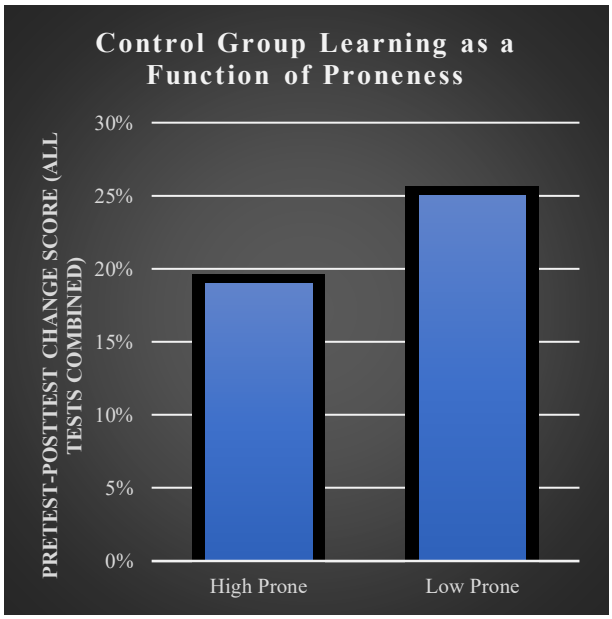

Figure 7: Average learning gains across all tests for control condition as a function of proneness.

Discussion

The results from the current study demonstrated that it is possible to have a systematic quantitative exploration of the self-conscious emotion shame. More specifically, those participants randomly assigned to the shame induction condition had higher instances of "in the moment" shame (as measured by the ESS) compared to those in the control condition. The methodology and findings are consistent with previous research that has found that feelings of shame are significantly positively correlated with feelings of shock (Turner, Husman, & Schallert, 2002).

Furthermore, as can be seen from these preliminary results, by and large, "in the moment" shame and shame proneness appear to be detrimental to the learning of complex science topics (i.e., human circulatory system). Participants randomly assigned to the shame induction condition learned significantly less about the circulatory system compared to participants in the control condition. Furthermore, a main effect was found showing that those with a high proneness to shame learned significantly less about the circulatory system compared to participants with a low proneness to shame. Finally, several significant interactions were discovered that revealed the detrimental impact of shame on learning. As mentioned earlier, this finding is in line with previous findings that have shown that feeling shame can interfere with motivation, and negatively impact students' academic goals and achievement (Pekrun, Frenzel, Goetz, & Perry, 2007; Weiner, 1986). Furthermore, once students experience shame, their ability to become cognitively engaged may be hindered, they may lose motivation for studying, and, they may feel reluctant to attend class (Turner, Husman, & Schallert, 2002).

What if a teacher was able to figure out which subset of students were actually experiencing shame and were able to be proactive to the potential negative consequences? Mitigating shame-consequences by understanding the who- and when-indicators of shame experiences, could facilitate teachers' ability to provide motivational interventions. A better understanding of the when and how of shame may be especially important given that individuals may deny their feelings, and may be unwilling or unable to express themselves, particularly if they self-isolate. In other words, as of now, we have no reliable way (other than perhaps self-report measures) to determine who is experiencing shame. Thus, intervention is near impossible without perceiving reliable indicators.

Abstract

Notably, while English tends to prefer shorter before longer complements (*explained to us a very clear effect*), Japanese displays the opposite tendency. Far less cross-linguistic work has investigated possible differences in the ordering of nouns within conjunctions ("binomials'), although a corpus study suggests that the same factors predict binomial ordering in Japanese and English. To investigate the issue experimentally, we report Japanese and English speakers' productions of names of the members of couples that they knew personally. Results confirm that conceptual accessibility is the most important factor in the ordering of familiar name binomials in both languages. That is, both groups tended to name the member they felt closer to first. Length (syllables/mora) was not a significant predictor in either language. Differences in the preferred order of verbs' complements are then attributable to other factors, possibly a very general preference to minimize the average distance between semantically related elements.

Keywords: accessibility; binomials; Japanese; English; word order

Introduction

Accessibility refers to the speed and accuracy with which concepts are activated in memory. When English speakers produce utterances, more accessible and shorter grammatical phrases tend to be produced before less accessible, longer phrases (Bock 1982, 1987; Levelt 1989; Bock & Levelt 1994; McDonald, Bock & Kelly 1993; Bock & Warren 1985; Carroll 1958; Tomlin 1995; Downing & Noonan 1995). This has been argued to allow for more efficient processing insofar as it reduces the need to hold accessible phrases in working memory while less accessible phrases are retrieved and produced first (Ferreira and Dell 2000; Branigan and Feleki 1999; Prat-Sala and Branigan 2000; Ferreira & Yoshita 2003; Kempen & Harbusch 2004).

The factors that have been evoked in discussions of accessibility are quite diverse. They include animacy (McDonald, Bock, & Kelly 1993; Ferreira 1994; Prat-Sala & Branigan 2000; Christianson & Ferreira 2005); givenness in discourse Ferreira & Yoshita 2003; Prat-Sala and Branigan 2000); prototypicality (Onishi, Murphy, and Bock 2008); and basic level status (Lohmann & Takada 2014).

Several of these factors can be quite difficult to tease apart. For example, animacy and discourse-givenness tend to be correlated because people--or agentive entities more generally--are the most common topics of conversation. Moreover, discourse-givenness correlates strongly with length, since previously introduced entities are commonly referred to using pronouns, which are short, and in many languages, discourse-given arguments need not be expressed at all (Ariel 1988; Byrne & Davidson, 1985; McDonald et al., 1993; Narasimhan & Dimroth, 2008).

Yet there is good reason to try to distinguish or control for animacy and discourse-givenness in investigations of length and conceptual accessibility. Importantly, certain factors that result in a shorter-earlier tendency in English (Arnold, Wasow, Losongco, & Grinstrom, 2000; Arnold, 2003; Gries, 1999; Stallings, MacDonald, & O'Seaghdha, 1998; Stallings & MacDonald, 2011; Wasow, 2002) produce the *opposite* order in Japanese (Chang, 2009; Hakuta, 1981; Yamashita & Chang, 2001). For instance, in English, particle placement, the dative-alternation and "heavy NP shift" all prefer particularly long complements to be uttered later in the string, while in Japanese especially long complements tend to be produced earlier (Dryer 2000; Hawkins 1994, 2004; Gibson 1998; Yamashita and Chang, 2001).

The first study to experimentally demonstrate a preference for longer-earlier in Japanese was Yamashita and Chang (2001). They interpreted this finding in a way that attempted to preserve the idea that *all* speakers prefer to express more accessible entities first, by invoking a distinction between formal complexity and cognitive accessibility. They suggested that longer phrases should be considered more semantically or conceptually accessible, even though they are more complex. This raised the following possibility, as described by Jaeger and Norcliffe (2009:876): "Japanese speakers [may be] more sensitive to conveying meaning (putting enriched material earlier), while English speakers prefer to sequence forms (putting easier to produce, e.g., shorter, words earlier, (Yamashita and Chang 2001, 2006)."

The current study tests the possible distinction between conceptual accessibility and length—here, the number of syllables or mora—on how English and Japanese speakers produce the names of familiar couples. If Japanese speakers are influenced more by conceptual accessibility and less affected by length when compared to English speakers, it would provide evidence that a distinction between conceptual accessibility and length underlies the difference between English and Japanese' word order preferences. We refer to

this hypothesis in what follows as the Conceptual Accessibility vs. Formal Accessibility hypothesis (CA v. FA).

Hawkins (1994, 2004) suggested an alternative explanation for the shorter-earlier preference Japanese and the longer-earlier preference in English. He argued that both Japanese and English display a preference to minimize the average distance between a verb and its non-subject complements. His "minimal distance" proposal is satisfied in Japanese and other verb final languages by positioning longer complements before shorter complements (<longer> <short >V). English and other VO languages obey the same preference by expressing short complements *before* longer complements (V<short> <longer>). But if Hawkins' proposal accounts for the shorter-earlier preference in VO and the longer-earlier preference in OV, it raises the question as to whether there *also* exists an accessible-early preference in Japanese, English and other languages.

We address these important issues by considering the preferred word order in both Japanese and English, given a case that clearly involves conceptual accessibility. This allows us to determine whether speakers of both languages prefer to order more conceptually accessible terms earlier (or both prefer to order them later). The idea that the difference between shorter-earlier English and longer-earlier Japanese is due to a Japanese preference for conceptually-accessible-earlier and an English preference for formally-accessible-earlier would predict that Japanese speakers should weigh conceptual accessibility more strongly than length, while English be more strongly affected by length than conceptual accessibility.

We report experimental results which compared the ordering of "binomial" conjunctions (<noun> and <noun>) by speakers of English and speakers of Japanese. Specifically, we investigate the ordering of the names of couples that are personally known to participants (e.g., *Jessie and Gary*). We hypothesized that the person the speaker feels a closer connection to will be named before the other member of the couple in both languages. We recognize that feelings of emotional closeness are hard to decompose, but at the same time, we take it as self-evident that if semantic accessibility is to be a meaningful construct at all, our mental representation of an individual whom we feel closer to should, *ceteris paribus*, be more semantically accessible than our mental representation of someone we feel comparatively less close to. We recognize that if one member of the couple is already under discussion, then all things are not equal. Therefore discourse-givenness is controlled for in the current experiment: participants simply generate the names of couples that they know with no additional context provided. Thus, if, in both Japanese and in English, the name mentioned first tends to be the name of the member of the couple whom the participant feels a greater personal attachment to, it will be evidence that *both* languages prefer to order more cognitively accessible words first.

There already exists a good deal of work on how English speakers order binomial phrases, but with rare exceptions described below, comparative work on the construction is exceedingly rare. Moreover, studies of English binomials have offered a wide range of often quite specific predictors of ordering but have only rarely invoked accessibility explicitly. For instance, Cooper and Ross (1975) suggested 19 factors which included the first element of a binomial being more "Here, Now, Adult, Male, Positive, singular, Living, Friendly, Solid, Agentive, Powerful, at Home, and Patriotic" (pg. 67).

This classic study led to a number of refinements. For example, Benor and Levy (2006) quantified a model that included 20 constraints related to aspects of lexical semantics, phonetics, and frequency. Morgan and Levy (2016) reduced this list to the following seven factors (in order of effect size): iconic sequencing (e.g., early before later), perceptual markedness (which encompassed the majority of factors proposed by Cooper & Ross), formal markedness, power, final stress, length, and frequency. These weighted constraints produced a model that predicted the preferred order in a large corpus of natural speech with 77% accuracy. Notably absent from these discussions was mention of a possible role for accessibility. Onishi et al. (2008), a rare study that did explicitly evoke accessibility as a key factor in English binomial order, introduced yet another predictor: more prototypical members of categories tended to be produced before less-prototypical members.

Importantly, Morgan & Levy (2016) also demonstrated that experience with specific binomial expressions influences the way familiar binomials are expressed. Specifically, they found that the frequency of familiar binomials correlated with reading time when binomials were ordered in the familiar way, and frequency correlated negatively when the two nouns were read in reverse order. Morgan & Levy proposed that the generative factors they proposed influenced the ordering of *novel* combinations of words. While a large number of binomial expressions are familiar, it is equally important to ask how conventional binomials ("freezes") come to be ordered in the particular ways they are (Mollin, 2014). To this end, an early cross-linguistic study of English, Russian and German by Fenk-Oczlon (1989) found that the relative frequency of words determined the ordering of 400 frozen binomial expressions with 84% accuracy; however, Lohmann & Takada (2014) found frequency to be much less influential.

Lohmann & Takada (2014) provides an important precedent for the current work, as they compare results from corpus analyses of binomial expressions in Japanese and English texts. This study included a number of potential predictors including power (including male and "importance"), iconicity (early before later), frequency, discourse-givenness, length (in syllables or mora), and conceptual accessibility. Conceptual accessibility, in this study, was treated as an umbrella category that included animacy, concreteness, prototypicality, basic level, proximal and self before other. In this work, which likely included a number of "frozen" binomials since it was based on corpus data, significant effects were found for length, power,

iconicity, discourse-givenness and accessibility but not frequency in both languages. The Lohmann & Takada work explicitly omitted conjoined proper names from their analyses. But by considering personal names that are known to the participants, the current work is able to index cognitive accessibility with a single factor, closeness. In addition, the ordering of names of familiar couples in our experimental context avoids potential confounds of animacy and givenness, as well as avoiding freezes that are influenced by the language at large. Possibly relevant factors of length and gender are included in the preregistered analyses.

There are two other key precedents for the current study. Like the current study, Wright et al. (2005) also considered the ordering of "Name and Name" phrases. Critically, however, that study differed from the current one in that the experimenters provided names without referents. Therefore, participants had no opportunity to rely on personal experience with the people involved. The study found a bias to order male before female names and shorter before longer names, two factors that have been proposed for English binomials generally, but which are not necessarily related to cognitive accessibility, the key factor of interest in the current work.

A precedent for considering "psychological closeness" to be relevant to binomial order comes from Iliev & Smirnova (2014). This work hypothesized that "psychological closeness of the speaker to one of the poles in the word pair" should predict order with the closer entity positioned earlier (pg. 210). Unlike the current study, all proper names were excluded from analysis. Instead, in one study, websites about cars, politics, religion were analyzed. Results demonstrated that sites sponsored by Honda, for example, were more likely to mention *Honda* before its competitors; liberal leaning websites were more likely to mention *liberal* before *conservative,* and to a lesser extent, websites about Islam showed a tendency to mention *Muslim* before *Christian*. A second study focused on gender and results were more equivocal. The authors hypothesized that male authors should be more likely to order male terms before female, while female authors might show the reverse tendency. Notably, however, male terms were ordered before female terms 93% of the time by male authors and 90% of the time by female authors. The strong skewing toward male-first, also found in previous work, may partially be due to the fact that many relevant phrases are conventionally frozen in English (e.g., *men and women; husband and wife*). A final study was experimental rather than based on corpus data; it elicited various binomials from participants by asking for the top two colleges in Chicago, the two main political parties in the US, the traditional two genders and so on. Participants showed a tendency to name their university first (Northwestern, 67%), and liberal students were more likely to name *Democrat* before *Republican* than were conservative students. Echoing theirs and others' corpus work, an overwhelming majority of respondents produced *male* before *female* (91%), although of the participants who produced *female* first, 80% were women.

An analysis of how participants order the names of familiar couples satisfies several desiderata. It allows us to avoid expressions that are conventional in the language at large, which are recognized to be subject to many general influences as documented in other work. Names are particularly well-suited as an index of cognitive accessibility because a name selects an individual rather than a category: We might know several people named *Gary*, but when we talk about *Gary and Jessie* we have particular individuals in mind, and our representation of Gary, Jessie and their names are dependent our own particular experiences. The experimental context enables us to control for animacy and discourse-givenness, while keeping the generation of names similar to that of natural production. Finally, by comparing Japanese and English, we can determine whether either or both languages tend to order more conceptual accessible names earlier.

Method

Participants

60 native speakers of English living in the US and 60 native speakers of Japanese living in Japan were recruited on Amazon Mechanical Turk as participants and moderately compensated for their time.

Procedure

Participants first answered questions about their gender and native language. They were then asked to name 3 sets of important couples in their life. They entered the name of each member of the couple in blank boxes. For the Japanese survey, participants were also asked to provide the phonetic spelling for each name. The rest of the survey asked whether or not participants were related to either or both of members of each couple, who they felt they were closer to, and the gender of each member of the couple. For these questions, the order of names that had been given were randomized for each participant.

Response coding & model development

To analyze the data, we followed the model of ordering preference for binomial expression introduced in previous work by Levy and colleagues (Benor & Levy 2006; Morgan & Levy 2016). The model predicts the likelihood that the ordering preference for a given pair is consistent with various planned fixed effects. First, each pair was coded in an essentially arbitrary way, specifically whether or not the names were ordered alphabetically. This was used as the outcome variable. Next, for each response, each fixed effect was assigned 1 if the factor predicted the alphabetical order and 0 if it predicted a non-alphabetical order. For example, if the participant indicated that they were closer to Gary than Jessie, closeness would receive a 1 because both alphabetical order and closeness predicted the same order, *Gary and Jessie*. If they had indicated that they were closer to Jessie than Gary, then closeness would receive a 0 because the alphabetical order (*Gary and Jessie*) does not match the closeness preference (*Jessie and Gary*). Note that we are not

testing whether or not there is a preference for alphabetical order. Rather, we use alphabetical order as a basis to get a binary code to compare with the order the participant provided.

To see if the length of names affected their ordering, we counted the number of syllables in each name for English and for Japanese, the number of morae, a more appropriate measure of length in that language (Otake, Hatano, & Mehler, 1993). We then calculated the difference in number of syllables/morae between each pair of names. We assigned this number a positive score if alphabetical order and ordering based on longer-before-short matched (the longer name was earlier in the alphabet) and a negative score when they did not.

Results

Before presenting the results of the model, we present the raw percentages of responses in the pooled data for each coded factor in Table 1. The person whom the participant reported feeling closer to was named first 65% of the time in Japanese and 77% of the time in English.

Cognitive accessibility (closeness) (%)		Gender (%)		Length (%)	
JAPANESE					
1st	65	M-F	56	Long-Short	31
2nd	35	F-M	30	Short-Long	21
		Same	14	Same	48
ENGLISH					
1st	77	M-F	54	Long-Short	33
2nd	23	F-M	43	Short-Long	40
		Same	3	Same	27

Table 1. % of responses for each fixed effect for Japanese (top) and English (bottom). Percentages rounded to the closest integer.

We first created models for each language independently. For this we used a multilevel model with closeness, gender, and length as fixed effects, random intercepts for subject, and alphabetical order as the outcome (Barr, Levy, Scheepers, & Tily 2013), using the lmerTest library (R Development Core Team 2008).

For the English data, the model revealed a significant effect of closeness (β = -0.52, t = -7.31, $p < 0.0001$); the tendency to order males first was not significant, (β = -0.32, t = -1.45, p = 0.15) and neither was a tendency to order shorter before longer names (β = -0.002, t = 0.10, p = 0.9).

The model for the Japanese data also revealed a significant effect of closeness (β = -0.29, t = -4.19, $p < 0.0001$) and no effect of length (β = 0.04, t = 0.90, p = 0.37). Unlike the English data, a marginal effect of gender was found with male names being more likely to appear before female names (β = -0.23, t = 1.98, p = 0.05).

In order to better quantify the importance of each of these effects, we used a leave-one-out method in which we compared a model without each effect to the full model. For both English and Japanese, conceptual accessibility (as operationalized as closeness) significantly improved the model (English, $\chi^2 = 46.02$, $p < 0.0001$; Japanese, $\chi^2 = 16.79$, $p < 0.0001$). Length did not improve either model (English, $\chi^2 = 0.01$, $p = 0.92$; Japanese, $\chi^2 = 0.69$, $p = 0.41$). Gender significantly improved the model only for Japanese (χ^2 = 13.30, $p = 0.001$), and not for English ($\chi^2 = 3.72$, $p = 0.16$). While there seems to be a difference in importance of gender in Japanese and English (or rather Japan and US), all analyses indicate that conceptual accessibility is the most important predictor of binomial expression of proper names.

In order to compare the effect size of conceptual accessibility (closeness) in the two languages, we looked at the interaction of closeness and language using the combined data. For this we used a multilevel model with gender and length as independent fixed effects, closeness and language as interacting fixed effects, random intercepts for subject, and alphabetical order as the outcome. The model found a significant effect of closeness (β = -0.53, t = 7.05, $p <$ 0.0001), and a significant interaction of closeness and language (β = 0.25, t = 2.53, p = 0.01), suggesting that closeness is a larger effect for English than Japanese.

Discussion

The ordering of the names of familiar couples was found to be strongly predicted by which member of the couple the speaker felt closer to. Taking personal closeness as an index of cognitive accessibility, we find that cognitive accessibility was the strongest predictor of name ordering in both English and Japanese, operating in the same direction in both languages: more cognitive accessible names tended to be produced first. This effect was stronger in English than in Japanese, although it is possible that the difference in effect size was due to the fact that a gender effect (male-before-female) was only evident in Japanese. That is, given that gender accounted for some of the variance, it is not surprising that the only other significant effect (cognitive accessibility) accounted for somewhat less in Japanese.

The lack of male-before-female bias in the current English data is intriguing, given that a male-before-female bias has been consistently found in prior corpus work (Cooper & Ross 1975; Lohmann & Takada 2014), and notably, on work involving on non-referential proper names (Wright, Hay, & Bent 2005). The reason a male-first bias exists at all deserves more discussion than we can offer here. Insofar as it is rooted in cultural sexism, it may be relevant that personal contact is recognized to reduce this and other forms of prejudice

(Pettigrew & Tropp, 2006). Japanese society obeys more stereotypical gender norms than the US (Bresnahan, Inoue & Kagawa, 2006; Saito, 2007), which might lead to a weak effect of male-before-female bias in Japanese.

Length was not a significant factor in English or Japanese, nor was there an interaction. And this lack of significance was apparent regardless of whether we treated length as a continuous or binary value. We note that it is possible that the lack of an interaction was due to a lack of power, since the names of each couple were commonly equal in length. That is, 27% of the couple names in English were of equal number of syllables and 48% the two names had the same number of morae in Japanese. Intriguingly, if we consider only the combinations of names that did differ in length, the trends in Japanese and English numerically pattern in opposite directions. Specifically, the ratio of shorter-first in English was roughly 4:3, while in Japanese, the ratio of *Longer*-First was roughly 3:2. Iliev & Smirnova (2014) had found evidence of shorter-first in binomals in both languages, but they had found the effect to be 3x as large in English as Japanese. Thus it is possible that a shorter-first bias only exists in English binomials. Future work with a larger sample may be necessary to confirm this trend.

Let us return to the striking difference in preferred order of especially long complements in English and Japanese. Previous work had appealed to a distinction between conceptual accessibility and lexical accessibility, suggesting that longer phrases are "semantically richer" and that "This semantic richness increases the overall accessibility of the phrase in the conceptual arena" (Chang & Yamashita 2001:B53). Shorter phrases were recognized to be more accessible in the formal (lexical) domain. The difference between Japanese and English then, was that "In English, weight-based shifts [word order variation] seem to be less sensitive to conceptual factors." However, in the current work, we have seen that if anything, English shows a *stronger* conceptually-accessible-early bias than Japanese does.

The current work allows that cognitive and formal/lexical accessibility need not be mutually dissociable. Clearly, certain episodic memories, smells, or images may be more or less cognitively accessible, depending on context and encoding. So clearly conceptual accessibility cannot be reduced to formal or lexical accessibility. But it is reasonable to assume that lexical (or formal) accessibility is simply a type of cognitive accessibility.

Our results are consistent with Hawkin's (1994; 2004) proposal that languages prefer to minimize the distance between the verb and its (non-subject) complements. This ordering is beneficial to listeners since the interpretation of a verb often critically depends on its co-occurring complements. This is clear in English, for instance, in the contrasts between, e.g., *hitting on an idea; hitting on someone; hitting someone up for something*; *hitting a place vs. a person vs. a goal.* See also Chang (2009) for interesting discussion how the minimal distance idea may emerge over the course of learning. In fact, the minimal-distance preference has been generalized to other kinds of semantic dependency relations and validated across a number of languages (Choi, 2007 for Korean; Faghiri & Samvelian 2014 for Farsi[1]; Gildea & Temperley 2010 for English and German; Liu, 2008 for 15 languages; and Futrell et al., 2015 for 20 languages).

The present work finds that both English and Japanese show a preference to produce more conceptually accessible terms first. Prior work has established that languages also generally appear to prefer to minimize the distance between a verb and its arguments. While these types of processing biases may differ in their strength across languages, the present work supports the idea that language processing systems emerge in much the same way in speakers of different languages. This is perhaps to be expected insofar as language processing is shaped by constraints on memory, learning and interpretability.

Conclusion

To conclude, results in both English and Japanese confirmed that the order of names of couples, personally familiar to a participant, were most strongly predicted by which member of the couple the participant felt a closer personal attachment to. By investigating the ordering of the names of familiar couples, animacy and discourse-givenness were controlled for. Investigating the names of couples known to participants was also advantageous because the ordering is not expected to be affected by language-wide conventions. Results did not reveal length to be a significant factor, and gender only played a (relatively small) role in the Japanese data. Therefore, we submit that feelings of personal closeness serve as a useful and relatively direct index of cognitive accessibility.

Thus, the present work provides evidence that cognitive accessibility plays a similar strong role in word order in both Japanese and English. This undermines the possibility that the reverse ordering preferences in Japanese and English clauses is a result of cognitive accessibility influencing the two languages in different ways. Instead, the Japanese

[1] Hawkins had argued for a more specific proposal, namely that the *heads* of dependents should be as close as possible to their external head. This proposal motivates the idea that verb final languages tend to have *post*positions, while verb-medial languages tend to have *pre*positions. However, Faghiri & Samvelian (2014) find that Farsi speakers prefer longer-early, parallel to Japanese. But while Farsi is an SOV language like Japanese, it has prepositions rather than postpositions. Therefore as Farghiri & Samvelian (2014) observe, the longer-early preference in Farsi cannot be explained in terms of a preference to minimize the distance between a verb and the *head* of its complement, since when a PP is is long, the long-early preference actually lengthens the distance between the V and P: <[**P** long>$_{IO}$ <short>$_{DO}$ **V**. Nonetheless, Farsi is consistent with the idea that languages and speakers prefer to reduce the average distance between semantically related units (Gildea & Temperley, 2010).

ordering preference for grammatical phrases (longer-early) must be due to some other factor, quite possibly a preference to indicate a verb's arguments as close to the verb as possible (Hawkins 1994, 2004). The current study demonstrates that, *ceteris paribus*, speakers of both Japanese and English prefer to produce more cognitively accessible words early (Arnold et al. 2000; Ferreira & Dell 2000).

Neural dynamic concepts for intentional systems

Jan Tekülve (jan.tekuelve@ini.rub.de)

Gregor Schöner (gregor.schoener@ini.rub.de)
Institut für Neuroinformatik, Ruhr-Universität Bochum
44780 Bochum, Germany

Abstract

How may intentionality, the capacity of mental states to be about the world, emerge from neural processes? We propose a set of theoretical concepts that enable a simulated agent to have intentional states as it perceives, acts, memorizes, plans, and builds beliefs about a simulated environment. The concepts are framed within Dynamic Field Theory (Schöner et al., 2015), a mathematical language for neural processes models at the level of networks of neural populations. Inspired by Searle's analysis of the two directions of fit of intentional states (Searle, 1980), we recognize that process models of intentional states must detect the match of the world to the mind (for "action" intentions) or the match of the mind to the world (for "perceptual" intentions). Neural representations of Searle's condition of satisfaction implement these detection decisions through dynamic instabilities that are instrumental in enabling autonomous switches among intentional states.

Keywords: Dynamical systems modeling; Mathematical modeling; Neural networks; Intelligent agents; Cognitive Architectures

Introduction

How are neural processes organized to create coherent, complex cognitive function? For instance, how are sequences of actions and processes of active perception generated to orient actions at objects to achieve a desired outcome? How may the nervous system switch between actions and mental states that are driven by current sensory information and actions or mental states that are driven by memory and knowledge?

Philosophers of mind have framed related questions in terms of the notion of *intentionality*: How may an organism with its nervous system generate intentional states that are about objects in the world? How may an organism act to change the world according to its intentional states? The logical structure of this problem has been analyzed in depth by John Searle (Searle, 1980). He postulates that intentional states come in two directions of fit (DoF), the *world-to-mind* direction of fit, in which an intentional state's content represents a desired state of the world, capturing the intuitive "action" flavor of intention. The *mind-to-world* DoF comprises states in which the state's content matches circumstances in the world, a "perceptual" flavor of intention. Each intentional state can be described through its *condition of satisfaction* (CoS), which determines whether the fit between mind and world is achieved. Searle has conjugated these two forms of intentionality through three layers of psychological modes: *intention-in-action* (IiA) and *perception* are intentional states directly linked to the motor or sensory systems. *Prior intention* and *memory* are intentional states with a more indirect form of linkages, in which additional steps are needed to act out or bring about the intentional state. *Beliefs* and *desires* are more abstract forms of intentionality, typically thought to take propositional forms, with an inherent generalization beyond the immediately accessible perceptual or motor experience.

We come to these questions from the theoretical framework of Dynamic Field Theory (DFT) (Schöner et al., 2015), a mathematical language for neural processes models at the level of networks of neural populations. Here, we take inspiration from Searle's concepts to address the neural processes required to autonomously switch between intentional states in these six psychological modes. A key idea has been that there must be neural processes that explicitly represent a CoS and whose activation controls the transitions from one intentional state to another (Sandamirskaya & Schöner, 2010). Specifically, for world-to-mind intentional states, activation of the neural representation of the CoS signals the successful achievement of an intentional state that leads to its deactivation and opens the system to switch to a subsequent intentional state. In mind-to-world intentional states, it is the representation of the content of the intention itself that forms the CoS, which is activated when a detection decision is made and remains activated as long as the intentional state persists.

In this paper we develop this idea into a systematic account of how intentional states can be organized to autonomously generate goal- and object-oriented behavior. We simulate a rudimentary toy scenario, in which an agent explores its simple environment containing colored objects and buckets of paint. The agent may move towards objects and direct an effector to them, either taking up paint (for a bucket) or painting the object (for the colored objects). The agent detects objects, may attentionally select objects, may build scene memories, generate sequences of actions to paint particular objects with a particular paint, and learn and exploit beliefs about which paint applied to which surface generates which outcome. Simple desires (to seek particular outcomes of painting acts) drive the agents goal-oriented and exploratory behaviors. The scenario is chosen such that the amount of time each action or mental operation takes varies, and that during that time the agent is exposed to other perceptions or sensory states that could distract from its current intention. The inherent stability of its intentional states and the capacity to

release these states from stability under the right conditions is thus probed in this scenario.

Dynamic Field Theory

Dynamic Field Theory (DFT) (Schöner et al., 2015) is a theoretical framework for understanding perception, motor behavior, and cognition based on neural principles.The activity in neural populations is modeled by activation fields, $u(x,t)$, spanned across the metric dimensions, x, to which the population is tuned. The neural dynamics of the activation fields,

$$\tau\dot{u}(x,t) = -u(x,t) + h + s(x,t) + \int \omega(x-x')\sigma(u(x',t))dx$$

describes the time-continuous evolution of neural activation on the time scale τ. Activation $u(x)$ below the sigmoidal threshold σ relaxes to the stable solution $h+s(x)$, defined by the field's resting level h and its localized inputs $s(x)$. Field sites, where activation strength surpasses the threshold level, will engage in lateral interaction defined by the field's kernel $\omega(x-x')$, which is locally excitatory and inhibitory over longer distances $x-x'$. This leads to the formation of self-stabilized peaks of supra-threshold activation, which are the unit of representation in DFT (see figure 1).

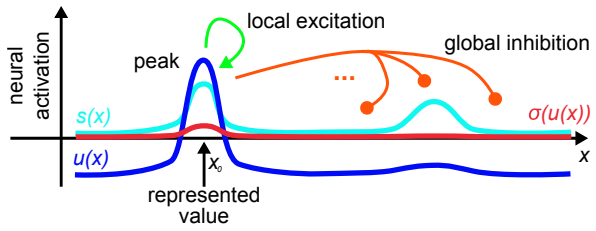

Figure 1: A dynamic neural field spanned across the metric-dimension x representing value x_0 through a supra-threshold activation peak.

Depending on the individual strength of excitatory and inhibitory interaction, fields may allow the formation of multiple peaks (self-stabilized), single peaks (selective) or they may sustain peaks once localized input is removed (self-sustained). Multi-dimensional fields may represent conjunctions of feature dimensions, for example, the conjunction of color and space. Zero-dimensional fields are dynamic neural nodes that represent categorical states.

Two fields u_{src} and u_{tar} may be coupled by adding a field's output $\sigma(u_{\text{src}})$ to the other field's rate of change $\dot{u}_{\text{tar}}$, weighted with a homogeneous connection kernel $\omega_{\text{src,tar}}$. Such projections may preserve the dimensionality of the fields, or may expand or contract the field dimensionality (Zibner & Faubel, 2015). *Dimensionality expansions* may take the form of ridges (or tubes, or slices), in which input along one or several of the receiving field's dimension is constant. *Dimensionality contractions* typically entail integrating along the contracted dimension. Dynamic neural nodes that project homogeneously onto a field by expansion are called *boost nodes*. They may alter the dynamic regime in the target field and induce the formation or vanishing of peaks. Within field architectures such boost nodes may effectively modulate the flow of activation by enabling or disabling particular branches of an architecture to create units of representation. *Concept nodes* project a specific pattern on a higher dimensional field to elicit a peak representing the concept, e.g. a blue-concept node activates neurons tuned to blue hue in a field spanned across the color dimension.

The transition from a stable sub-threshold solution to a new supra-threshold activation pattern marks a discrete event in the presence of time-continuous input variations and is labelled *detection instability*. In the context of intentional states the detection instability is utilized to determine a state's condition of satisfaction, the discrete point in time where a successful match between world and mind representations is achieved.

In the world-to-mind DoF a *matching field* (CoS field) receives sub-threshold input from an *intention-field* representing the desired world-state and sub-threshold input from a *perception-field* representing the current world-state. Due to the resting level h in relation to the strengths of both field inputs, a supra-threshold peak will only form in the matching-field, if both input patterns overlap sufficiently, thus signaling the states CoS through a detection instability. Representation of a world-to-mind CoS is thus independent from the planned timing of the underlying action and signals its termination on a perceptual basis. The formation of a CoS may thus be used to terminate the action and activate the next action in a planned sequence (Richter, Sandamirskaya, & Schöner, 2012).

In the mind-to-world DoF the CoS is determined through the formation of a peak in a field that is connected to sensor or memory substrates. The detection instability may be the result of salient input alone or of the combination of sensor/memory input and top-down attention input from within the neural architecture. Representations of a mind-to-world CoS are made available to the rest of the architecture and may be used in further cognitive processing, e.g. determining a world-to-mind CoS.

Transforming Searles logical analysis of intentional states into a process account has led us to a number of new insights. One is a difference in the time structure of world-to-mind vs. mind-to-world intentional states. World-to-mind intentional states are active before the corresponding state of the world has been achieved and are deactivated once the CoS detects a match between the expected and the sensed state of the world. Mind-to-world intentional states, in contrast, often persist beyond the detection of a match, which is an essential characteristic of memories and beliefs. But what if memories or beliefs (and even percepts) are false? Then they must be deactivated. This is controlled by a condition of dissatisfaction (CoD), which detects a mismatch between current sensory or internal information and an intentional state. Upon activation, a CoD inhibits that intentional state. The CoD responds to evidence against the intentional state, not to the mere absence

of evidence supporting the intentional state.

Model/Scenario

We illustrate how intentional states can be organized to generate autonomous goal- and object-oriented behavior in a minimal scenario requiring Searle's six major psychological modes. The scenario contains a simulated agent engaged in an artificial painting task controlled by a dynamic field architecture connected to the robots sensorimotor surface (see figure 2 for a sketch).

Mind-to-World States

Intentional states of the mind-to-world DoF are the prerequisite to engage in meaningful actions in a given environment as any action at least aims to achieve a perceivable outcome.

Perception The virtual environment contains cuboids of different height and color, which are arranged in an array along a single dimension facing the robotic agent. The agent's visual perception fields are therefore spanned across horizontal retinal space and the two feature dimensions height and color. A selective spatial attention mechanism causes peaks to form in the same spatial location in the *space/color* and *space/height* perception fields, representing a perception of the particular height and color features at that particular location (see Grieben et al. (2018) for details on the attentional selection). To detect successful interaction with the world, the agent perceives changes in the environment through a two-layer transient detector that forms peaks in response to sudden changes in visual input (see Berger et al. (2012) for details).

To monitor its own actions the agent requires self-perception of the task-dependent "body parts", which includes an estimate of the agent's position in the world. A simulated sensor provides input to a one-dimensional *current position* field, as the agent's movement is restricted to driving in parallel to the cuboid array. Arm movement is restricted to two Cartesian dimensions, lateral and forward translation, which leads to a two-dimensional representation of the current end effector position in the *proprioception* field. The painting device is located at the robot's end effector and can either be filled with color or not. This categorical perceptual state is represented through a neural node that is activated if the device is filled.

Attention directed towards particular self-perceptions is modeled through a homogeneous resting level boost, which causes the sub-threshold sensor information to form a peak

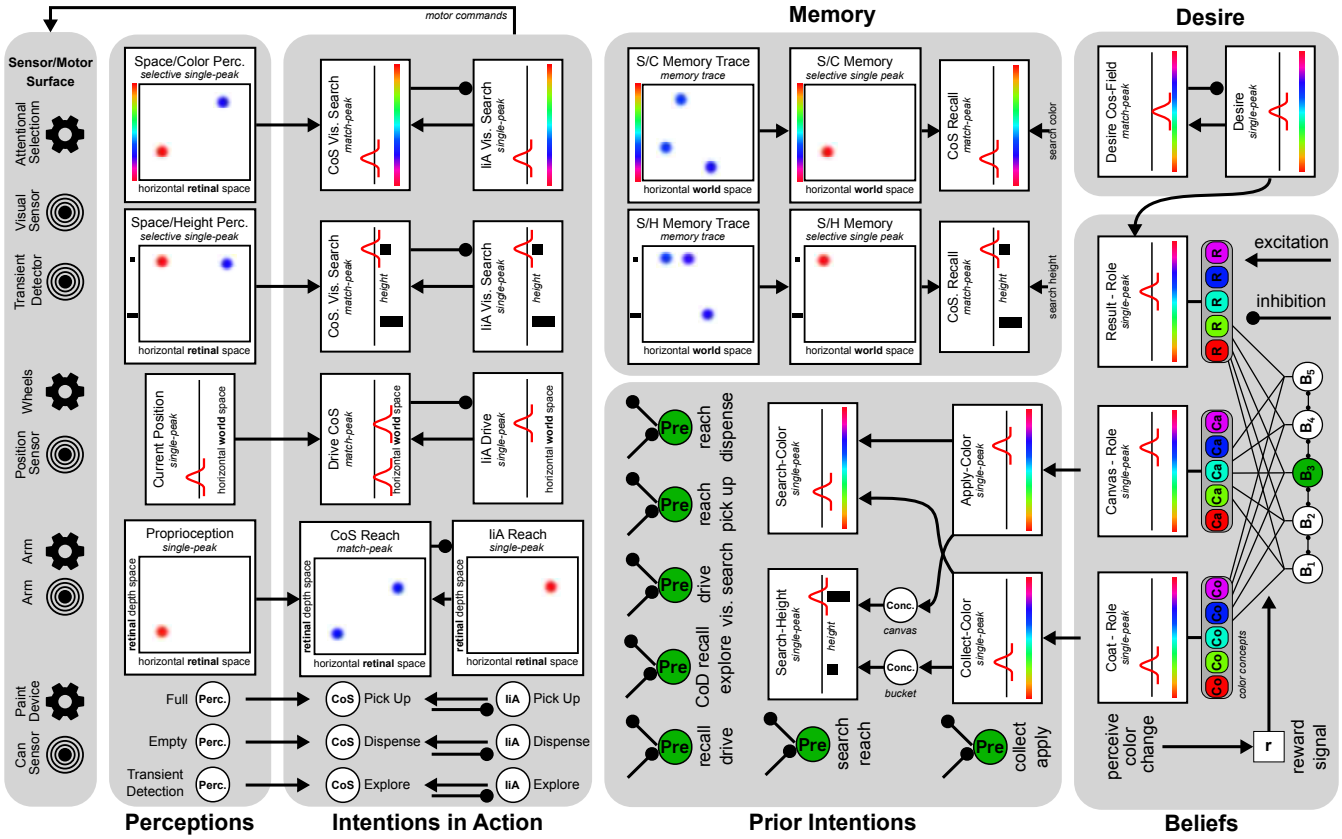

Figure 2: Schematic overview of the dynamic fields and nodes representing the agent's intentional states grouped according to their psychological modes. For clarity's sake only the most relevant connections are shown and parts of the architecture relevant to autonomous learning and exploration are hidden. Prior intentions are depicted as precondition nodes with labels describing the inhibiting CoS followed by the inhibited IiA.

in the respective perception field. Neural interaction in perception fields is strong enough to prevent the destabilization of perceptions through noise, but retains its input coupling such that a continuous change in input induces a drift in peak position.

Memory To allow the agent to engage in more sophisticated actions that are not purely based on current perceptions, the agent stores past perceptions of cuboids in memory. Each visual perception of the agent leaves a slowly decaying two-dimensional memory-trace spanned across world-space and feature, modeling a memory process that is subject to interference (Erlhagen & Schöner, 2002). The trace is forwarded as sub-threshold activation to a space/feature *memory* field analog to the visual perception fields. Memory states represented as peaks in the memory field may emerge through either spatial or feature cues overlapping with the memory trace substrate.

Self-sustained fields retaining task-relevant information, such as the recently collected color, represent working memory, which is functionally closer to the mode of perception than memory, as self-sustained peaks resemble lasting perception representations and do not need an additional detection mechanism to form.

Belief Meaningful interaction with the world also relies on general knowledge or beliefs about the world represented in propositional form. In the toy scenario, beliefs are about relations between the three color concepts: the color of a canvas, the color of the paint, and the color that results from coating the canvas with the paint. Each painting action contributes to the formation of a belief about that relation. The relation is represented through a neural node with reciprocal connections to three color concept nodes, each linked to a different *color role* field. An activated belief state is represented through a supra-threshold belief node that leads to the formation of three peaks, each in one self-sustaining color role field, which provide working memory representations to guide the painting process. The color concept nodes ensure a degree of generalization, as different shades of hue activate the same concept node, while the activation of the concept node activates the mean hue value of the particular color.

A belief is activated when color nodes in either of the three roles become active, to which the belief has learned synaptic connections. For instance, a belief linking the red point on a blue canvas to a yellow result may become activated, if the result color node yellow is activated by a corresponding desire. Inhibitory coupling among belief nodes ensures that only a single belief may be activated at any time. The belief with most matching color role input will typically win the competition and can then be used to guide action. If an active color role does not match the learned projections of any belief, no belief is activated.

The learning of new beliefs is organized by a neural dynamic architecture inspired by Adaptive Resonance Theory (Carpenter & Grossberg, 2016) illustrated in Figure 3. It associates color concepts in the three roles coating, canvas and result color with a single belief node. Such learning steps occur whenever the transient detector registers a change of color during a painting action. This happens under two possible conditions. In one case, a belief has previously been activated that predicts the expected color change. If that prediction is confirmed, a Hebbian learning mechanism consolidates the connectivity. If that prediction is not confirmed, the CoD is activated, and the belief is inhibited. This leaves the system without any activated belief. That second case, no activated belief, may also arise because there was no matching belief to begin with. In this case, a belief note is recruited for learning the new association between coating, canvas, and resulting color. This happens through a homogeneous boost of all belief nodes. Only a previously uncommitted belief node has a chance to become activated, because each belief node is inhibited by a dedicated "commit node" that represents that this belief node is committed to a particular belief it has learned.

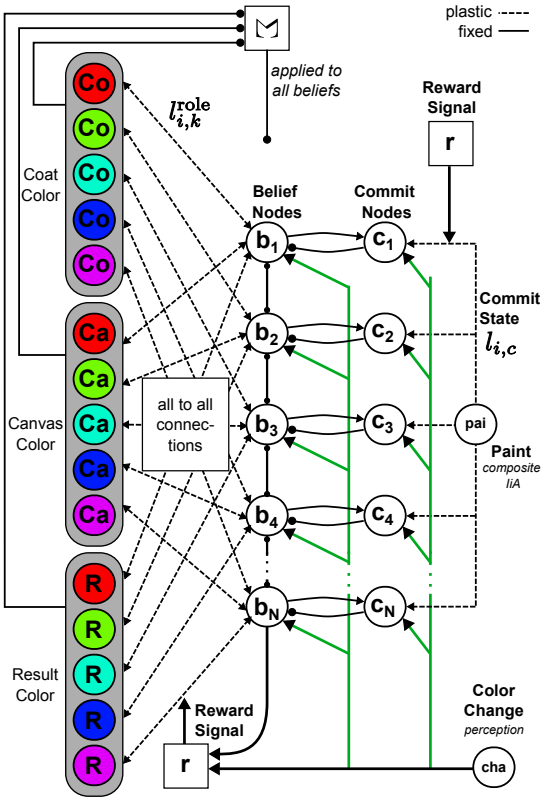

Figure 3: Detailed sketch of the belief learning architecture shown in Figure 2.

The actual learning processes is modulated by a transient reward signal, $r(t)$, that is generated in the presence of an active belief node and a detected color change in the scene. The reward modulated Hebbian learning rule adapts the connections, $l^{\text{role}}_{i,k}$, between belief nodes, b_i, and color-role concept nodes, u^{role}_k (where k is color and role $\in \{$*coat, canvas, result*$\}$):

$$\dot{l}^{\text{role}}_{i,k} = \eta\, r(t)\, \sigma(b_i)\sigma(u^{\text{role}}_k).$$

The learning rate, η, is chosen such that a new belief is learned within a single transient epoch of reward in a form of one-shot learning. For a more detailed analysis of the mechanisms of autonomous learning see (Tekülve & Schöner, 2019).

World-to-Mind States

Intentional states of the world-to-mind DoF are instrumental in bringing about a desired state of affairs in the world, which includes the agent's own body. All world-to-mind states share the representation through the pair of intention and CoS (or match) field. Outgoing connections from the intention field specify the actions driven by a supra-threshold activation peak, while the outgoing inhibitory connection from the CoS field terminates the action once the desired state is detected.

Intention in Action The painting scenario provides several elementary actions that may take a variable amount of time and thus require a representation of a CoS to verify their successful execution. *Reaching* to a particular location in the visual array is realized through a neural field architecture for generating arm movements (see Zibner et al. (2015)). Its duration depends on the relative distance between the agent and the target location. The target location is defined through spatial input from the visual perception fields, which classify reaching as an object oriented action.

Moving to a particular position in the world is motivated through memory instead of perception. The *drive* IiA field thus receives its spatial input from peaks formed in the space/feature memory fields. In absence of a particular target location the agent may also move to either direction until a previously unattended cuboid is perceived. The *explore* IiA realizes this behavior and its CoS is represented through a binary neural node receiving excitatory input from the visual transient detector. The actions explore, *pick up* and *dispense* represent a family of IiAs, where the desired world state is categorical and represented through the activation of a neural node.

Another family of IiAs is represented by the actions *visual search*, *recall* and *activate belief*, which treat the current state of the neural system as part of the world and try to induce particular states of the mind-to-world DoF. Visual search guides the attentional system to achieve a perceptual state matching an intended feature cue, while recall tries to achieve a memory state matching an intended feature cue and activate belief intends to activate a belief node that matches certain color-roles.

Prior Intention Most goal directed actions comprise a sequence of actions such as the painting task in this scenario which requires: Searching for a "color bucket" (high cuboid), collecting color from it, searching for a "canvas" (small cuboid) and applying the collected color on it. Those actions themselves may be described as sequences of more elementary actions, e.g. searching comprises the sequence of recalling a cuboid's position, driving to the position and visually searching for the cuboid, while collecting and applying comprise reaching followed by picking up or dispensing color.

Such a sequence of actions (or composite IiA) is realized through an intention-field that simultaneously activates all IiAs involved in the sequence and an inhibiting precondition node for each IiA. The combination of activating and specifying the input of an IiA, while simultaneously inhibiting it, represents a prior intention. The prior intention turns into an IiA once the precondition node is destabilized by the CoS of a preceding IiA which releases the IiA-field from inhibition (Richter et al. (2012)). These CoS fields may sustain activation in a working memory representation of the current stage within a sequence.

The CoS of a composite IiA is activated through a subset of CoS representations of comprising IiAs determining the successful completion of the composite IiA's goal. This will inhibit the composites IiAs intention field and subsequently destabilize all working memory representations of the comprising IiAs, thus allowing the same sequence of actions to be activated again, which is required in the scenario as searching for a cuboid is part of both collecting and applying color.

Prior intentions may also represent alternative action plans that may occur when a precondition node is destabilized by a CoD, for example, due to failing to recall a specific cuboid.

Desire The agent's desire to observe the change of a cube's color into a desired color is the drive for all actions it executes. The desire specifies the agent's prior intentions of collecting and applying color through the activation of a belief that matches the desired result color. The *desire CoS* is activated through a match between a changing color detected by the visual transient detector and the desired color, which leads to a subsequent inhibition of the desire returning the field architecture to its initial state.

Results

Figure 4 shows activation snapshots of selected fields displaying the formation of CoS peaks during a successful painting sequence. In snapshot $\mathbf{t_1}$ the desire to paint a cube yellow feeds into the result-role field (left column), which triggers a detection instability in belief node B_4 leading to a complete belief representation through the emergence of peaks in the canvas and coat role fields (right column). The coat color leads to an activation of the collect IiA to retrieve blue color and a prior intention to apply the color to a purple canvas, which is represented through a sub-threshold peak in the apply IiA field.

At $\mathbf{t_2}$ the IiA collect activates the "bucket" concept, a high cuboid, which is forwarded as a recall cue to the space/color and space/height memory fields respectively. The collect color also forms the prior-intention to visually search for blue color (left column). The color/height cue leads to the emergence of a single memory peak at the location of the blue/high cuboid, which is read out across space and leads to the formation of a peak in the IiA drive (right column).

The left column of snapshot $\mathbf{t_3}$ shows the IiA drive-field

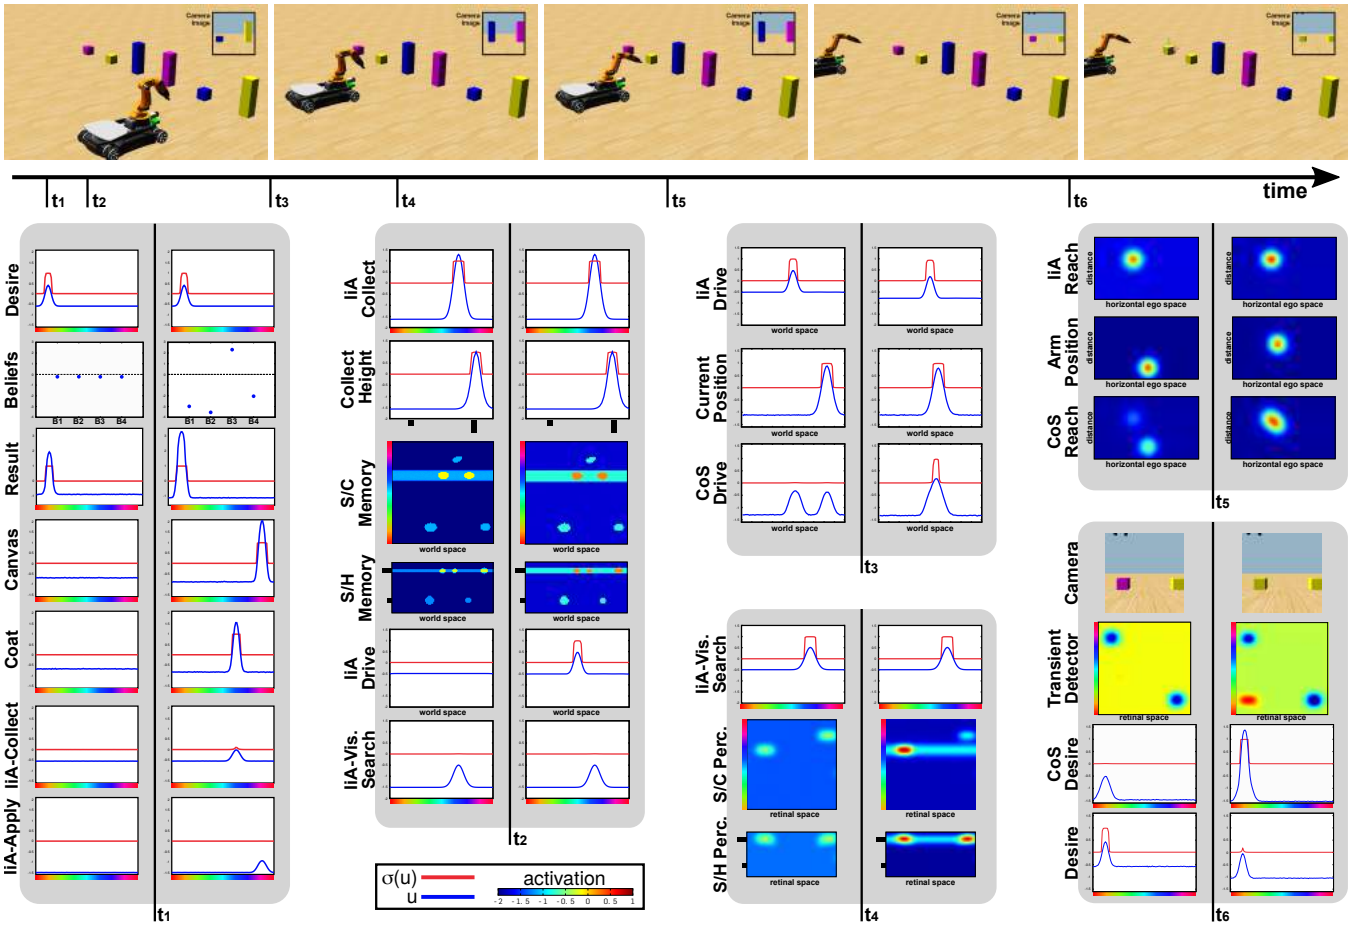

Figure 4: Activation snapshots of selected fields displaying the formation of CoS peaks during a successful painting sequence.

representing the desired goal in the center of the world space, which does not match the currently perceived position. Once movement causes a match between desired and perceived position, a peak emerges in the CoS field causing the termination of the drive IiA (right column).

The detection instability in the drive CoS leads to an autonomous transition to the visual search IiA, which is released from inhibition through the precondition node at $\mathbf{t_4}$ (left column). Ridges of searched color and height are induced in the perception fields causing the emergence of supra-threshold peaks at overlapping positions. (right column).

A match of height and color is detected through the visual search CoS (not shown), which leads to an autonomous transition to the reaching IiA at $\mathbf{t_5}$ by forming a peak at the perceived retinal position in the two dimensional reach IiA field (left column). The reaching IiA is destabilized after a successful arm movement leads to detection instability in the reach CoS-field due to an overlap between proprioception of the eef and the reach goal position (right column).

Snapshot $\mathbf{t_6}$ shows the detection of a color change in the visual scene by the transient detector after the agent successfully collected the color and dispensed it on the purple cube (left column). Activation of the dispense IiA (not shown) changes the color of the purple cube to yellow, which forms a supra-threshold in the transient detector at the conjunction of left and yellow. The color of the perceived change matches with the desired color and leads to the emergence of a peak in the desire CoS which causes a subsequent destabilizing of the desire to paint a cube yellow (right column).

Discussion

We present a neural dynamic architecture that endows a robotic agent with the capability to generate intentional states of the six major psychological modes. Self-stabilized peaks of activation within neural populations determine the content of an intentional state while the state's psychological mode is determined by how the neural population is positioned within a neural dynamic architecture. The CoS of intentional states is modeled through the detection-instability of dynamic neural fields with the DoF determining under which circumstances the instability emerges.

The architecture is demonstrated in a toy scenario, where the agent seeks particular perceptual states (desires), and uses beliefs about contingencies of which paint transforms which color into which new color, to plan sequences of action (prior intentions) based on its current scene representation (mem-

ory). The agent follows these plans by driving towards objects and interacting with them (intention-in-action), if they visually match specified feature combinations (perception). Beliefs about the three different color roles are learned autonomously during each painting sequence.

Similar goals are pursued by Schrodt and colleagues (Schrodt & Butz, 2016; Schrodt et al., 2017), who learn production rules within a cognitive architecture. That work is framed within a probabilistic approach, which is partially embedded in neural networks. Our methods to achieve autonomous sequencing overlap with techniques developed in (Kazerounian & Grossberg, 2014). Globally speaking, we pursue similar aims as the research program of cognitive architectures (Anderson, 1996). Our emphasis is to be pervasively consistent with neural principles, generating the sequence of processing steps autonomously from neural dynamics alone. Although the functions fulfilled by portions of the neural dynamics can be described using concepts of information processing, the system is simply a set of integro-differential equations that generate time courses of activation. These integro-differential equations capture the time-continuous evolution of activation in populations of cortical and subcortical neurons (Erlhagen, Bastian, Jancke, Riehle, & Schöner, 1999). It remains a challenge to provide direct neural support for a complex model like ours (see (Wijeakumar, Ambrose, Spencer, & Curtu, 2017) for an outline of how that may happen). Empirical support for a model like ours may also be sought in the form of behavioral signatures of the neural dynamics, an approach that has been successful for past DFT models. The highly integrative nature of the model makes this difficult, but perhaps not impossible.

Future modeling tasks include scaling the demonstrated principles to more complex task-environments, elaborating the simplistic account for desires, and addressing how believed propositions may be both true and false.

In conclusion, we have explored the requirements on neural processes that arise when embodied cognitive systems are endowed with intentional states of the two directions of fit and the six psychological modes that provide a foundation for intentionality.

Abstract

It is well known that people tend to anthropomorphize in interpretations and explanations of the behavior of robots and other interactive artifacts. Scientific discussions of this phenomenon tend to confuse the overlapping notions of folk psychology, theory of mind, and the intentional stance. We provide a clarification of the terminology, outline different research questions, and propose a methodology for making progress in studying the intentional stance toward robots empirically.

Keywords: human-robot interaction; social cognition; intentional stance; theory of mind; folk psychology; false-belief task

Introduction

The use of folk psychology in interpersonal interactions has been described as "practically indispensable" (Dennett, 1989, p. 342), and its predictive power has been proclaimed to be "beyond rational dispute" (Fodor, 1987, p. 6). The emergence of interactive technologies, such as computers and robots, has sparked interest in the role of folk psychology in human interactions with these systems. For example, John McCarthy stated: "It is perhaps never logically required even for humans, but expressing reasonably briefly what is actually known about the state of a machine in a particular situation may require ascribing mental qualities or qualities isomorphic to them" (McCarthy, 1979, p. 2). The usefulness of folk psychology however does not extend to interaction with all artifacts, and it does not necessarily extend to all kinds of interactions with robots. Although the prevalence of folk-psychological interpretation of robot behavior might be considered as being beyond dispute, its predictive power – i.e., the *usefulness* of taking the intentional stance toward robots – remains largely unassessed.

Researchers from diverse fields have explored people's folk-psychological theories about emerging robotic technologies, such as humanoid robots and autonomous vehicles. For example, Krach et al. (2008) and Chaminade et al. (2012) explored the neural activity of persons engaged in interactive games with robots. Waytz et al. (2014) showed that people's ascriptions of mental states to an autonomous vehicle affected their willingness to trust it. Thellman et al. (2017), Petrovych et al. (2018), and de Graaf and Malle (2018, 2019) investigated whether people judge distinctively human behaviors as intentional when exhibited by robots. Terada et al. (2007) asked people directly about whether they adopted the intentional stance toward a robot. Marchesi et al. (2018) developed a questionnaire-based method specifically for assessing whether people adopt the intentional stance toward robots. These studies all provide insight into people's folk-psychological theories about robots. However, none of them assessed how such theories affect people's predictions of behavior to shed light on the usefulness of taking the intentional stance in interactions with robots.

Moreover, research that has so far explicitly addressed the intentional stance toward robots in many cases conflated the intentional stance with overlapping but different notions, such as folk psychology and theory of mind. In particular, the question whether it is useful for people to predict robot behavior by attributing it to mental states (what we in the present paper will call "the intentional stance question") tends to be confounded with whether robots have minds ("the reality question"), whether people think that robots have minds ("the belief question"), and what kinds of mental states people ascribe to robots ("the attribution question"). For example, Chaminade et al. (2012, p. 8) claimed that participants in their experiments did not adopt the intentional stance when interacting with a robot as opposed to a person based on having "[manipulated] participants' belief about the intentional nature of their opponent" (thereby confounding the attribution question with the belief question). Wykowska et al. (2015, p. 768) stated that "it seems indeed very important to know whether the observed entity is an agent with a mind, and thus, whether the entity's behavior provides some social meaningful content" (confounding the attribution question with the reality question). Wiese et al. (2012, p. 2) stated that "adopting the intentional stance is based on a decision as to whether or not an observed agent is capable of having intentions" (confounding the intentional stance question with the belief question).

In view of these confusions, we aim to provide a clarification of the terminology and different research questions related to the folk psychology about robots in general and the intentional stance toward robots in particular. We also discuss in more detail how (not) to approach research questions specifically targeted at the intentional stance toward robots.

Basic Terminology

We here review Griffin and Baron-Cohen's (2002) distinction between *folk psychology*, *theory of mind*, and *the intentional*

stance and relate these overlapping but different notions to the literature surrounding the role of folk psychology in interactions with robots.

Folk psychology about robots

The notion of folk psychology (also known as belief-desire psychology, naïve or intuitive psychology, or commonsense psychology) broadly encompasses all mind-related theories that people have about themselves and others (Griffin & Baron-Cohen, 2002). This includes views about intentional, content-bearing, representational states (beliefs, desires, intentions, hunches, etc.) as well as phenomenal states (e.g., undirected anxieties, feelings and pain), traits, dispositions, and empirical generalizations such as that *people who are tired are generally irritable*, or – as in the context of folk psychology about robots – the cultural platitude that *robots do not have minds* (Fiala et al., 2014).

Research on people's folk-psychological theories about robots in general (as opposed to specific robots) has been pursued in part because of the societal (e.g., political, legal, or ethical) consequences that such theories might have. For example, European citizens' views on and acceptance of emerging robotic technologies, and their use in different areas of society, have been monitored in extensive surveys by the European Commission (2012, 2015). Ethically motivated research has targeted robot abuse, killer robots, robots in elderly care, child-robot interaction, and sex robots (for an overview, see Lin et al., 2014).

Theory of (robot) mind

Theory of mind refers more narrowly to the ability to attribute the behavior of *specific* others or oneself to underlying mental states, in particular intentional states, such as beliefs and desires, that are perceived to have a causal role in behavior (Griffin & Baron-Cohen, 2002).

People's views about the mental attributes of specific robots are frequently probed for the purpose of evaluating human-robot interactions. Examples of such measures are the Godspeed Questionnaire Series (Bartneck et al., 2009) and the Robotic Social Attributes scale (Carpinella et al., 2017). To the best of our knowledge, these measures have so far not been used in conjunction with measures of people's ability to predict the behavior of specific robots in the context of human-robot interaction research.

The intentional stance toward robots

The intentional stance refers to the *use* of intentional constructs (the beliefs, desires, intentions, etc., that are part of people's folk-psychological theories) as an interpretative strategy or framework to predict the behavior of specific others (Griffin & Baron-Cohen, 2002)[1]. The intentional stance is sometimes mistakenly equated with folk psychology. Dennett (1991) describes the intentional stance as "the craft" of folk psychology and distinguishes it from "the theory" itself. The intentional stance concerns what people *do* with folk psychology (i.e., predict and explain behavior using intentional constructs); folk psychology, in Dennett's view, refers to how we talk about what we do.

Although there seems to be a general consensus in the literature concerning the meaning of "intentionality" as denoting the distinguishing characteristic of certain mental phenomena of being "about" or "directed at" something as an object (Brentano, 1874/2012), some authors have treated it as a biological property (e.g., Searle, 1980; Varela, 1997; Ziemke, 2016) whereas others have refrained from doing so (e.g., Dennett, 1989; McCarthy, 1979). It is also important to recognize that intentionality is a separate notion from having certain intentions. Intentionality is a property of a specific set of mental states, namely intentional mental states. This set includes intentions, but also beliefs, desires, hopes, fears, hunches, and so on. Searle (2008, pp. 85–86) noted that the English translation of the German words for intentionality and intention, "Intentionalität" and "Absicht", are confusingly similar, stating that "we have to keep in mind that in English intending is just one form of intentionality among many".

In some cases, adopting the intentional stance toward an object is a useful strategy for predicting its behavior; in other cases, it is not. Dennett introduced the notion of an *intentional system* to denote objects that are "usefully and voluminously predictable from the intentional stance" (Dennett, 2009, p. 339). Humans are the most obvious example of intentional systems because human behavior is generally successfully predicted from the intentional stance but not from other modes of interpretation. The label "intentional system" is not restricted to humans, but it also does not extend to all non-human objects. Although a person might predict that a thermostat will raise the room temperature in the morning because it *wants* to keep it at 73 degrees and *knows* that it has fallen during the night, the use of such folk-psychological interpretations does not add predictive value *above and beyond* the corresponding non-psychological interpretation. In the words of John McCarthy (1979, p. 11), "ascribing beliefs to simple thermostats is unnecessary for the study of thermostats, because their operation can be well understood without it". In contrast, the moves of a chess-playing computer are, according to Dennett (1971), practically inaccessible to prediction from any other interpretative mode than the intentional stance.

It is reasonable to conjecture, given the complex behavior and social situatedness (Lindblom & Ziemke, 2003) of emerging robotic technologies, that taking the intentional stance might turn out to be crucial in many cases of human-robot interaction (Hellström & Bensch, 2018; Schellen & Wykowska, 2019; Thill & Ziemke, 2017; Vernon et al.,

[1] As noted by Griffin and Baron-Cohen (2002), the intentional stance theory (also known as intentional systems theory; Dennett, 2009) is both Dennett's take on the role of folk psychology in social interactions and on what intentional states really are. These two components can be considered separately (as in this paper); for example, one might agree with Dennett's claims about the role of the intentional stance in social interaction without subscribing to his views about the reality of ascribed mental states.

2016). However, although there is a growing body of evidence that people take the intentional stance toward robots, the usefulness of doing so remains largely unassessed. Hence, the central question in the context of the intentional stance toward robots is the extent to which the behavior of robots is usefully predicted from the intentional stance. The usefulness of the intentional stance toward robots presumably depends on a number of unknown factors, possibly related to the person interacting with the robot, the interaction context, and the robot in question. Answers to the intentional stance question might thus range from "the intentional stance is a practically dispensable mode of interpretation for predicting robot behavior" (cf. thermostat) to "the intentional stance is practically indispensable for predicting robot behavior" (cf. chess-playing computer), depending on these factors. Research into the usefulness of taking the intentional stance toward robots may also reveal unique social cognitive challenges associated with taking the intentional stance specifically toward robots (e.g., compare inferring what a robot vs. a person can perceive in a given situation in order to predict it's behavior), some of which may be universally present in human-robot interactions.

Four Distinct Research Questions

We have attempted to clarify some of the basic terminology surrounding the intentional stance toward robots. We also identified the central question about the intentional stance toward robots as concerning its usefulness for predicting robot behavior. We now move on to distinguish this question from three overlapping but separate research questions that appear frequently in the literature surrounding the intentional stance toward robots.

The reality question: Do robots have minds?

Questions such as "Do robots have minds?" and "Can machines think?" concern the nature or reality of the mental states of robots and other machines. We here collectively refer to such questions as different formulations of *the reality question*. The reality question is clearly independent from people's beliefs about it, and presumably also from people's disposition to predict and explain robot behavior based on mental state ascriptions (and the potential usefulness of doing so). While it seems plausible that ontological "discoveries" about the minds of robots may have a significant impact on how people relate to and interact with robots, there is no apparent reason to believe that they would affect people's predictions of robot behavior in interactions. What matters for the purpose of predicting behavior, it seems, is how people conceptualize behavior, and not the correspondence of those conceptualizations to reality. For example, Heider (1958, p. 5) noted: "If a person believes that the lines in his palm foretell his future, this belief must be taken into account in explaining certain of his actions". Hence, the reality question is conceptually distinct from questions regarding people's attributions and beliefs about the mental states of robots.

The belief question: Do people think that robots have minds?

People's views on the reality of the mental states of robots are part of folk psychology. As stated in the previous section, it is difficult to foresee how (if at all) such considerations affect people's predictions of robot behavior, regardless if they spring from collective scientific discovery or personal belief. Clearly, a person might attribute the behavior of a robot to mental states without necessarily committing to any ontological position about the reality of those mental states. Indeed, people commonly ascribe mental states to cartoon characters and animated geometric figures (Heider & Simmel, 1944). When, for example, we see Donald Duck angrily chasing chipmunks Chip and Dale because they are stealing his popcorn, we know that Donald, Chip, and Dale do not really have mental states, but we attribute their behavior to mental states nevertheless (Ziemke et al., 2015). As stated by Airenti (2018, p. 10), "anthropomorphism is independent of the beliefs that people may have about the nature and features of the entities that are anthropomorphized". There is to our knowledge no evidence that people's beliefs about the reality of the mental states of robots – or of cartoon characters, thermostats, or fellow humans – affect their disposition or ability to predict behavior. It does not seem to matter, for the purpose of predicting the behavior of an agent, whether the person interpreting the behavior of the agent in question believes that the agent *really* has mental states. *The belief question*, therefore, must be treated as distinct from questions concerning people's ascriptions of mental states to robots as well as the reality question.

The attribution question: What kinds of mental states do people ascribe to robots?

There is now an abundance of evidence that people commonly predict and explain the behavior of robots based on attributing it to underlying intentional states. The assumption that they do is arguably even built into many of the methods that are used to evaluate social human-robot interactions, whereby researchers explicitly ask people to evaluate mental properties of robots. The if-question in "Do people take the intentional stance toward robots?" has thus already been answered in the affirmative. Considerably less is known about what we for the present purposes call *the attribution question*, namely what kinds of mental states people ascribe to robots. The lack of knowledge about the attribution question does not stem from a lack of research effort but, at least in part, from issues in the methodology adopted to tackle the attribution question.

There is so far little agreement about what kinds of mental states people ascribe to robots. Gray, Gray and Wegner (2007) found that people tend to attribute the behavior of robots to mental states related to agency (e.g., memory, planning, and thought) but not subjective experience (e.g., fear, pain, and pleasure). Sytsma and Machery (2010) found, in contrast, that people refrain from attributing subjective states

that have hedonic value for the subject, that is, valenced states (e.g., feeling pain and anger) as opposed to unvalenced states (e.g., smelling a banana or seeing red). Buckwalter and Phelan (2013) further showed that people's tendency to attribute (or not) experiential or valenced states depends on the described function of the robot. Fiala et al. (2014) found that respondents in their experiments – when allowed to choose between different ways of describing the capabilities of a robot (e.g., the robot "identified the location of the box" vs. "knew the location of the box") – preferred not to attribute mental states at all. The authors noted that responses to questions about the mental states of robots are influenced by a wide variety of factors, including the apparent function of the robot, the way in which the question is asked, and cultural platitudes about robots.

In sum, it seems problematic to identify what kinds of mental states people ascribe to robots by asking them directly. Part of the problem, we believe, is that such questions are ambiguously open to interpretation as regarding the reality of the mental states of robots. As pointed out previously, people tend to predict and explain robot behavior with reference to mental states without reflecting on the reality of those states. Thus, when asked directly, a person might deny that a robot has a mind, despite having previously attributed mind to it upon being asked to describe its behavior (Fussell et al., 2008).

The intentional stance question: Is it useful for people to predict robot behavior by attributing it to mental states?

The usefulness of predicting robot behavior by attributing it to mental states is not a pre-given. *The intentional stance question* is therefore distinct from the attribution question. The ability to predict behavior based on the intentional stance is also, as evidenced by studies on mental state attribution from Heider and Simmel (1944) and onwards, independent from the reality of the attributed mental states and from people's beliefs about them.

Although the prevalence of people taking the intentional stance toward robots might be considered as beyond dispute, its predictive power – that is, the usefulness of doing so – remains largely unassessed. Hence, the central question in the context of the intentional stance toward robots is to what extent the behavior of robots is usefully predicted from the intentional stance. Other questions of potential interest concern causes of predictive (mis)judgment from the intentional stance toward robots, how misjudgment can be reduced, and potential effects of taking the intentional stance toward robots on human cognition (e.g., cognitive load).

Measures of the Intentional Stance

If one wants to investigate whether the intentional stance is useful as an interpretative framework for predicting robot behavior, then one must, at the very least, measure people's predictions of behavior and ensure that those predictions stem from specific attributed mental states. Very few previous studies concerned with the intentional stance toward robots employed such measures (one exception is Sciutti et al., 2013). In this section, we review established experimental paradigms in interpersonal psychology that accomplish measuring effects of mental state attribution on behavior prediction, namely explicit and implicit false-belief tasks and anticipatory gaze tasks.

Explicit measures

The standard false-belief task (sometimes referred to as the "Sally–Anne test" or the location-change false-belief test) was outlined by Dennett (1978) in a commentary to Premack and Woodruff's seminal paper "Does the chimpanzee have a theory of mind?". This was later turned into an experimental paradigm in which a human study participant must attribute a false belief to an agent in order to predict its behavior (Wimmer & Perner, 1983). In the experiment, the participant is made aware that an agent observes a certain state-of-affairs x. Then, in the absence of the agent the participant witnesses an unexpected change in the state-of-affairs from x to y. The participant now knows that y is the case and also knows that the agent still (falsely) believes that x is the case. After this, the participant is asked to predict how the agent will behave in some circumstance, given its false belief about the state-of-affairs. If the participant fails to predict the behavior of the agent, this can be directly attributed to a failure of the participant to ascribe a false belief to the agent. Frith and Frith (1999, p. 1692) commented on the strength of the false-belief task: "To predict what a person will do on the basis of a true belief is not a sufficiently stringent test [of the ability to take the intentional stance], since here the belief coincides with reality, and it's hard to tell whether the action is governed by physical reality or mental state. In everyday life, beliefs rather than reality determine what people do, and false beliefs play an important role".

False-belief tasks have primarily been used to test for the possession of a theory of mind (e.g., Baron-Cohen, Leslie & Frith, 1985). However, they can also be used to explore the relative difficulty of reasoning about others' beliefs (Bloom & German, 2000). We argue that the false-belief task is a suitable paradigm for assessing the usefulness of the intentional stance toward robots because it enables measuring the extent to which a person's mental state ascriptions to a specific robot are conducive to predicting its behavior. Hence, false-belief tasks would be used in the context of human-robot interaction studies not to test for a person's *possession* of a theory of a specific robot's mind but for the successful or unsuccessful *use* of such theories in interactions with robots.

Concerns have been raised previously in the theory of mind literature about whether the explicit formulation of false-belief questions might impute folk-psychological theory to the task participant or affect his or her disposition to ascribe mental states. In some false-belief experiments, participants were asked questions, such as "Where does the agent *believe/think* that the object is now?", which explicitly suggest that the agent possesses beliefs or thoughts. Other experi-

ments used questions such as "Where will the agent look for the object?" which implicitly suggest the possession of beliefs or thoughts. However, an extensive meta-study of theory of mind research on children showed that the type of question (e.g., explicit vs. implicit statements of belief) provided to participants did not significantly affect participants' success in the false-belief task (Wellman, Cross & Watson, 2001). This finding can be taken as supporting the view expressed by Dennett that "whether one calls what one ascribes to the computer beliefs or belief-analogues or information complexes or Intentional whatnots makes no difference to the nature of the calculation one makes on the basis of the ascription" (Dennett, 1971, p. 91). Regardless of this meta-analytic finding, researchers concerned with the risk of imputing folk-psychological theories about robots to study participants, in the context of false-belief tasks, can employ implicit intentional stance measures. In the following section we review two such measures: implicit false-belief tasks and goal-directed anticipatory gaze tasks.

Implicit measures

Implicit false-belief tasks employ non-verbal measures to assess people's behavior predictions (for an overview, see Schneider & Slaughter, 2015). Using implicit measures, the intentional stance can be investigated by recording anticipatory gaze behavior (Clements & Perner, 1994) or reaction times (Kovács, Téglás & Endress, 2010), even without instructions to predict behavior or providing questions about the mental states of agents (Kovács, Téglás & Endress, 2010; Schneider et al., 2012). Implicit measures also provide an opportunity to investigate the potential effort involved in tracking the beliefs of robots whose sensory perspectives significantly differ from the human case.

Goal-directed anticipatory gaze tasks represent another way to measure the intentional stance toward robots. Using an anticipatory gaze paradigm, Sciutti et al. (2013) showed that people shift their gaze toward perceived "goals states" of robot actions prior to the execution of the actions themselves. One limitation of this paradigm is that it is not always possible to infer which gaze behaviors are anticipatory gazes (and therefore reflect goal ascriptions) and which are not. As such, goal-directed anticipatory gaze measures might not be as strong a measure of the intentional stance as false-belief tasks. Nevertheless, studying goal ascription through anticipatory gaze measures might be suitable as a complement to studying belief ascription using false-belief tasks.

Conclusion

We have attempted to clarify the difference between three overlapping concepts that are used (in many cases confusedly) in the literature surrounding the intentional stance toward robots: folk psychology, theory of mind, and the intentional stance. The central question in research on the intentional stance toward robots was identified as the extent to which the intentional stance is a useful (and potentially even indispensable) interpretative strategy or framework for predicting behavior in interactions with robots. We argued that this question is distinct from questions regarding the reality of the mental states of robots, people's beliefs about the mental states of robots, and what kinds of mental states people ascribe to robots. We also established a "methodological criterion" for investigating the usefulness of the intentional stance toward robots: the measurement of people's predictions of robot behavior and reliable inference that those predictions stem from specific attributed mental states. Last, but not least, we identified explicit and implicit false-belief tasks and anticipatory gaze tasks as fulfilling these criteria, thereby constituting a promising experimental paradigm for future empirical investigations of the intentional stance toward robots.

The ability to infer the intentional states (beliefs, desires, etc.) of robots is presumably in many cases crucial to the successful prediction of robot behavior and, consequently, to well-functioning and socially acceptable human-robot interaction (Hellström & Bensch, 2018; Schellen & Wykowska, 2019; Thill & Ziemke, 2017; Vernon et al., 2016). However, continuously tracking changes in the intentional states of robots as interactions unfold represents a potentially difficult and demanding challenge to humans: robots have different "perspectives" on or sensorimotor couplings with the world than humans. Consider the task of simultaneously navigating interactions with three different types of robots in a crowded environment (e.g., a busy street): the first robot can detect objects behind humanly opaque structures such as walls, vehicles, or humans; the second robot cannot see through glass; and the third robot is sensory-equivalent to most humans. How do humans fare in an interaction scenario like this? We propose that taking the intentional stance toward robots must in some cases be more difficult (in terms of predictive accuracy) and demanding (e.g., in terms of cognitive load; Sweller, 1988) than taking the intentional stance toward humans, and view this as a hypothesis worthwhile exploring in the context of human-robot interaction research. In particular, we speculate that people employ a reasoning heuristic which can be described as "anthropocentric anchoring and adjustment", consistent with the accounts in Epley et al. (2004) and Nickerson (1999) but where people adopt the perspective of specific robots by serially adjusting from their own (human) perspective.

Another question relevant to the intentional stance toward robots is the extent to which its usefulness or predictive power can be improved by providing information about the capabilities and limitations of robots prior to interactions. People base their estimations of the knowledge of robots partly on their assumptions about people (Kiesler, 2005). People's knowledge estimations of robots have been shown to be affected by the physical attributes of robots (Powers & Kiesler, 2006) and information about the robot given beforehand, such as robot gender (Powers et al., 2005) or country of origin (Lee et al., 2005). However, it has to our knowledge not yet been investigated whether providing information or manipulating

social cues can improve the accuracy with which people predict the behavior of a robot. Would prior knowledge about the sensory capabilities of the three types of robots in the example above help people interact with them? This is another question worthwhile exploring in studying the intentional stance toward robots.

We believe that cognitive science has important contributions to make in the continued exploration of the role of folk psychology in human interaction with robots, especially in the development of appropriate methodological approaches to investigating the intentional stance toward robots. As suggested in this paper and elsewhere, the intentional stance can be a confusing concept (Griffin & Baron-Cohen, 2002) and a difficult phenomenon to measure, perhaps especially in the context of interactions with robots (Schellen & Wykowska, 2019). In the folk psychology about robots, robots might not have *real* minds but have *attributed* minds nevertheless, and as for the science of mind, the jury is still out regarding the extent to which mind possession and mind attribution go hand-in-hand in the case of robots (cf. Dennett, 1989; Fodor, 1987; Searle, 1980). We therefore hope that the conceptual clarifications and methodological proposals presented here will pave the way for fruitful research on the intentional stance toward robots.

Acknowledgments

Articulatory features of phonemes pattern to iconic meanings: evidence from cross-linguistic ideophones

Abstract

Iconic words are known to exhibit an imitative relationship between a word and its referent. Many studies have worked to pinpoint sound-to-meaning correspondences for ideophones from different languages. The correspondence patterns show similarities across languages, but what makes such language-specific correspondences universal, as iconicity claims to be, remains unclear. This could be due to a lack of consensus on how to describe and test the perceptuo-motor affordances that make an iconic word feel imitative to speakers. We created and analyzed a database of 1,888 ideophones across 13 languages, and found that 5 articulatory properties, physiologically accessible to all spoken language users, pattern according to semantic features of ideophones. Our findings pave the way for future research to utilize articulatory properties as a means to test and explain how iconicity is encoded in spoken language.

Keywords: iconicity; ideophones; systematicity; sound symbolism; phonology; semantics

Introduction

Iconicity in spoken language can be summed up as the relation of a linguistic form (or sound) to its meaning (Hinton, Nichols, & Ohala, 1994). One fundamental example is onomatopoeia, as in the English *woof woof* for the sound of a dog bark or *vroom vroom* for the reving a car engine. Sound mapping to meaning in an imitative way is also called sound symbolism. An implicit assumption underlying the term sound symbolism is that phonemes, or clusters of phonemes, map onto meaning below word or morpheme level thus acting as affordances which together allow the sound symbolic word to take on meaning. For example, the /ŋ/ in English /diŋ.doŋ/ seems to be characteristic of the reverberating echo of a bell tolling, while the alternating /i/ and /o/ seems characteristic of movement or a fluctuation in pitch as the bell tolls. While various studies have worked to elicit sub-phonemic sound-to-meaning correspondences (Aryani, 2018; Blasi, Wichmann, Hammarström, Stadler, & Christiansen, 2016; De Carolis, Marsico, & Coupé, 2017; Kawahara, Noto, & Kumagai, 2018; Shih, Ackerman, Hermalin, Inkelas, & Kavitskaya, 2018; Kwon & Round, 2015; Ofori, 2009; Hamano, 1998; Maduka, 1988; Oswalt, 1994; Akita, Imai, Saji, Kantartzis, & Kita, 2013; Ayalew, 2013; McCune, 1985; Assaneo, Nichols, & Trevisan, 2011; Strickland, J, Schlenker, & Geraci, 2017), the underlying mechanisms of such correspondences are unclear. To begin rectifying the issue of what exactly makes a sound symbolic word iconic, and so the field of iconicity can move toward a unified understanding of what affordances in the spoken modality should be classified as iconic, this paper attempts to reveal the gestural affordances underpinning imitative words, i.e., ideophones. Ideophones are marked words which depict sensory meaning and belong to an open lexical class (Dingemanse, 2012, in press). Recent studies have likened ideophones to oral gestures considering that they co-occur with other visual forms of communication so frequently in spontaneous speech (Dingemanse, 2015; Hatton, 2016; Mihas, 2013; Dingemanse, 2013; Nuckolls et al., 2000). This speaks to the importance of analyzing (articulatory) movement in order to understand how ideophones mean what they mean. Ideophones have been shown to be easily learnable by speakers from different language backgrounds, which may also speak to their imitative, gestural nature encoded despite language-specific differences such as phonotactics, phonological inventory, or lexical associations (Lockwood, Hagoort, & Dingemanse, 2016; Dingemanse, Schuerman, Reinisch, Tufvesson, & Mitterer, 2016; Iwasaki, Vinson, & Vigliocco, 2007a, 2007b). Thus, ideophones are an ideal testing ground for how articulatory properties pattern to meaning. Vocal imitations and onomatopoeia created spontaneously by participants in experimental settings have been shown to exhibit sound-meaning correspondences which can be attributed to patterns of oral articulation (Assaneo et al., 2011; Taitz et al., 2018). This leads us to our investigative focus on the articulatory gestures of consonants in imitative words. In a methodological vein similar to Blasi et al. (2016), this study looks at whether articulatory feature (e.g., plosive, fricative, nasal, velar, labial) is more or less found in certain semantic domain (e.g., telic events, human vocal sounds, motion, appearance) following cross-linguistic descriptions of ideophone meaning (Dingemanse, 2012; Hamano, 1998; Van Hoey, 2018; Nuckolls, Swanson, Sun, Rice, & Ludlow, 2017). However, unlike Blasi et al. (2016) who focused on identifying sound-to-meaning mappings in arbitrary words, this study focuses on words which are explicitly iconic in nature. If an oral articulation is more attested in one semantic domain of ideophones than another this could explain why some phonosemantic mappings might be perceived as imitative and therefore iconic of a given percept. Such mappings are therefore explainable as perceptuo-motor affordances grounded in gestural means, e.g., total closure of plosive articulation, affords the semantic category of telic events and their percept coming to an abrupt stop. We created a database of ideophones from 13 languages (in total, 1888 ideophones) to carry out our investigation on how articulatory properties of consonants pattern with ideophone meaning.

Background

Phonosemantics

Sub-phonemic sound-to-meaning mappings have been proposed for a number of languages (Maduka, 1988; Waugh, 1994; Hamano, 1998; Oswalt, 1994; Assaneo et al., 2011; Akita et al., 2013; Ayalew, 2013; Kwon & Round, 2015; Blasi et al., 2016). The general assumption is loosely encapsulated by a broad hypothesis that every phoneme is meaning-bearing, and that this meaning is rooted in its articulation (Diffloth, 1979, 1994; Hamano, 1998; Dingemanse, 2018). Though this study does not assume all phonemes to be meaning bearing in all contexts, we do subscribe to the notion that the meaning of a phonosemantic mapping for iconic word should be rooted in its articulation following previous studies (Diffloth, 1979, 1994; Oda, 2001; Assaneo et al., 2011; Taitz et al., 2018; Strickland et al., 2017).

Ideophone Database

Database

Currently there is no cross-linguistic database dedicated solely to ideophone inventories. We created a database of 13 languages[1] which were selected with the aim of being as typologically diverse as possible despite the limited number of linguistic descriptions for ideophone inventories in the world[2]). The languages are as follows with their number of ideophones in brackets: Manyika Shona (Niger-Congo) [112] , Uyghur (Turkic) [49], Manchu (Tungusic) [91], Chaoyang Southern Min (Sino-Tibetan) [248], Ma'ai Zhuang (Kra-Dai) [232], Kam (Kra-Dai) [223], Akan (Niger-Congo) [190] , Kisi (Niger-Congo) [98], Kuhane (Niger-Congo) [64], Pastaza Quichua (Quechuan) [283] , Upper Necaxa Totonac (Totozoquean) [146], Temne (Niger-Congo) [76] , Yakkha (Sino-Tibetan) [76]. Due to their depictive nature, and the various methods of elicitation, the ideophone inventory numbers reported above are not absolute, but instead reflect a general picture about the semantic "visibility" of ideophones per language. This is in line with a claim recently put forth by Dingemanse (Dingemanse, in press) that ideophones form an open class, speaking to the creative potential for newly coined ideophones.

Total number of ideophones was 1,888. Ideophones were entered into the database with their orthography (if available), International Phonetic Alphabet (IPA) transcription, and reported translation. A phonetically trained transcriber provided IPA transcription of words when original resources do not provide IPA transcriptions. To analyze the phonetic properties of words, the transcriber also provided with place (labial, coronal, dorsal, pharyngeal, laryngeal), manner (sonorant, continuant, nasal, lateral, delayed release), and laryngeal features (voice, spread glottis, constricted glottis) of consonants for each ideophone. An independent transcriber checked the validity of the transcriptions as well as featural descriptions of ideophones. Ideophones were then coded for semantic features following criteria below (Table 1).

Table 1: Semantic features

Semantic Feature	Description of [+] feature
[+/- animal]	vocalization made by animals
[+/- appearance]	depicts visual information, i.e., how something looks or degrees of visibility
[+/- friction]	depicts rubbing together or rough contact of surfaces (not necessarily active movement), i.e., grinding, rustling, sharpening, hacking up phlegm, tearing cloth
[+/- human]	vocalization made by people, i.e., laughter, crying, talking
[+/- loud]	auditory information of inherently high amplitude, i.e., explosion, screaming, shattering
[+/- motion]	depicts active (the act of X) movement, i.e., walking, chopping, splashing, sneaking, flapping, water boiling, bumping, spitting, firecrackers exploding
[+/- sound]	depicts auditory information (the sound of X)
[+/- telic]	depicts an event which reaches completion
[+/- wind]	depicts movement of air, i.e., blowing, coughing, gales

Semantic Features

Feature were created to correspond to Dingemanse (2012) implicational hierarchy of ideophones which lists the following semantic categories: sound <movement <visual patterns <other sensory perceptions <cognitive states. Additional categories were created based on observations of what ideophones depict cross-linguistically (Hamano, 1998; Hinton, Nichols, & Ohala, 2006; Van Hoey, 2018; Nuckolls et al., 2017). It is important to note that semantic features are not mutually exclusive. An ideophone may be coded for multiple. For example, the Chaoyang ideophone /hu.hu/ wind blowing was coded with [+sound] (because this ideophone depicts an auditory percept), [-telic] (because this ideophone does not involve a perceived endpoint of an event), [+wind] (because this ideophone involves a percept created by the movement of air), and [-motion] (because this ideophone is not depictive of an action plus its resulting sound or manner thereof). In total 18 features in Table 1 were considered.

Articulatory Features

We categorized place, manner and laryngeal features in our phonetic transcriptions of ideophones into 7 groups (see Table 2), based on how the articulators (lips, tongue) and airflow are

[1](Franck, 2014; Gerner, 2005; Beck, 2008; Schackow, 2016; Kanu, 2008; Childs, 1988; Ofori, 2009; Nuckolls et al., 2017; Xiao, 2015; Wang & Tang, 2014; Mathangwane & Ndana, 2014; ?, ?)

[2]Ma'ai Zhuang ideophones were collected during ongoing fieldwork.

Table 2: Articulatory features

Articulatory Feature	Description
[+labial]	usage of one or both lips
[+tongue resting]	tongue is in resting/neutral position and not raised
[+tongue root]	usage of back of tongue (dorsum)
[+airflow]	air is forced out through a narrow channel in the mouth, i.e., fricatives
[+velum] (nasal)	velum is lowered and air escapes through the nasal passage
[+oral contact]	lips and/or tongue make constriction
[+vocal folds]	vibration of the vocal folds

involved in their production[3].

While some features can be subsumed by another, such as [+labial] by [+oral contact], which is relevant to both the lips and the tongue, the decision to test a more specific feature is to keep distinctive place features that are frequently contrastive among ideophones; for example, in Chaoyang, we have [+labial] [+oral contact] ideophone /pu.pu/ meaning rapid movement and [-labial] [+oral contact] ideophones /tsu.tsu/ whispering. Likewise, in Pastaza Quichua we have [+labial] [+oral contact] /pɑw/ manner of being turned downward and [-labial] [+oral contact] /kw/ sound of stepping on dry leaves. We also include [+tongue root], which is specific to a particular part of an articulator given their frequent contrastiveness among ideophones. For example, in Akan we have [+tongue root] /kuu/ call of a large bird and [-tongue root] /tuu/ manner of hitting with the fist. The reason we created encompassing features, i.e., [+oral contact] or [+tongue resting], was so that general manner of the consonant is described regardless of place in the oral tract. There are 14 articulatory features when counting the negative counterparts of Table 2. If properties of iconicity are truly universal, then we predict that the universally accessible properties captured by our articulatory features should bear the explanatory power for what perceptuo-motor affordances underpin iconicity and its notions of (analogical) depiction.

We coded semantic and articulatory features in Table 1 and 2 for all consonants found in the ideophones in our database using binary features. Our coding did not consider syllable structures or semantic hierarchy of ideophones, treating all consonants in all ideophones equally. We measured the ratio of each semantic feature given each articulatory feature to see if a semantic feature is more likely to co-occur specifically with certain articulatory features. We used chi-squared tests to see if the distributions of a binary articulatory feature differ between two samples: ideophones that have the semantic feature **X** and those that do not in a given language. The ratios then entered into a Wilcoxon's sign rank test.

[3][+airflow] applies to IPA symbols /ɸ β f v θ ð s z ʃʒ ʂ ʐ ç ʝ x ɣ χ ʁ ħ ʕ h ɦ/. [+tongue root] IPA = /j c ɟ k g ɲ ŋ ç ʝ x ɣ j ɯ ʎ ʟ/. [+labial] IPA = / p b m ʙ ɸ β ɱ v ʋ f ɓ w/. [+velum] IPA = /m ɱ n ɳ ŋ ɴ/. [+oral contact] IPA = /p b m ʙ ɸ β ɱ v ʋ ʋ f θ ð t d n r ɾ z ɮ ɹ l s ɬ ʃ ʒ ɖ ɳ ɽ ʐ ʂ ɻ c ɟ ɲ ç ʝ j ʎ k ŋ x ɣɯ ʟ ɓ ɗ ʄ w/. [+tongue resting] IPA = / t ħ ʕ p b m ʙ β ɸ ɱ v ʋ f ʋ/.

Hypotheses

We have made 4 preliminary hypotheses based on observations from the phonosemantic literature. These observations are grounded in perceptuo-motor analogy but have yet to be tested for ideophone inventories across languages. (1) Stop consonants, characterized by total occlusion of airflow, i.e., [-airflow], have been observed for ideophones indicating complete, i.e., [+telic], events or events with abrupt endings (Diffloth, 1979; Hinton et al., 2006; Hamano, 1998; Alpher, 1994; Taitz et al., 2018; Strickland et al., 2017). (2) Fricatives, i.e., [+airflow], have been associated to wind or friction between two objects (Diffloth, 1979; Oswalt, 1994; Hinton et al., 2006; Ofori, 2009; Taitz et al., 2018). Improvised vocal imitations have shown that (3) labial consonants, i.e., [+labial], are associated with the sounds resulting from motion, i.e., [+motion], (4) while dorsal consonants, i.e., [+tongue root], are associated with movement itself (Taitz et al., 2018) i.e., [+motion] in our feature set.

Analysis

We analysed every semantic feature (32) against every articulatory gesture feature (16), and removed all the pairs when there were two or more languages that did not have ideophones with either the semantic feature, or the articulatory gesture considered (n=213). In total, we analysed 299 pairs of semantic features and articulatory gestures. When evaluating the significance of a mapping between an articulatory gesture and a semantic feature, we compared it against all ideophones that did not have the semantic feature. To do this, we compared on an individual-language basis the distributions of a binary articulatory feature in two samples: ideophones that have the semantic feature **X** (e.g. "human vocal" vs "not human vocal") and those that do not in a given language. We are thus testing for differences in distributions of a binary feature. We first compare these ratios for each individual language. Because the sample sizes were quite low in some comparisons (5-6 samples for e.g. the "human vocal" category in some languages), we use the chi-squared test. To test whether mappings of articulatory gesture to meaning were consistent across languages, we pooled the data from across languages. We decided not to run tests on all the agreggated ideophones across languages, as this would have been biased by the differences in sample sizes across languages. Instead, we compared the ratios from the previous analysis done at the individual language level. There were many maximum ratios (i.e. languages where all words have a given feature). We thus used a wilcoxon's sign rank test, since it is a non-parametric test and does not assume the data to be normal like e.g. a paired Student's t-test.

Table 3: Articulatory feature to semantic feature mappings significant across 13 languages.

#	Articulatory Feature	Semantic Feature	Correlation across all languages (Wilcoxon's test p-values)	Number of individual languages,with significant chi-squared ($p<0.05$)
1	-airflow	+telic	0.0015	7
2	+airflow	+wind	0.0015	6
3	-airflow	+motion	0.0019	4
4	+airflow	+friction	0.0024	4
5	+labial	+motion	0.0107	4
6	-vocal folds	+telic	0.0121	4
7	-tongue resting	+telic	0.0159	4

Results

Out of 299 combinations of articulatory to semantic features, 69 combinations were significant across languages according to Wilcoxon signed rank tests. To be conservative, we used the results of the single-language chi-squared tests as a threshold for reporting Wilcoxon signed rank tests across languages. Specifically, Wilcoxon tests reported here are only those that apply to combinations which were significant ($p < 0.05$) for 4 or more languages on an individual basis. 7 articulatory feature and semantic feature, shown in Table 3, were above this threshold. The correlations in Table 3 are ordered according to the number of languages who had a significant articulatory to semantic feature correlation. The correlation of [-airflow] to [+telic] and [+airflow] to [+wind] are our most robust articulatory feature to semantic feature mapping ($z = 0.00, p = 0.0015$) across all languages, and are significant (χ^2,$p < 0.05$) for 7 and 6 languages on an individual-basis respectively. The correlation of [-airflow] to [+motion] is significant across all languages (Wilcoxon, $p = 0.0019$).

Discussion

Our results overall show that certain articulatory properties map to semantic features of ideophones from 13 languages. More specifically, our results show that phonosemantic mappings as proposed in the ideophone literature (see **Hypotheses** section, hypotheses 1-3) are supported, while [+/-tongue root] was not significant for [+/- motion] as claimed by hypothesis (4). Table 3 shows that five modes of articulation create robust cross-linguistic patterns with regards to imitative meaning. These five modes are: tongue movement, lip movement, airflow, velum lowering (nasal airflow), and vocal fold vibration. This suggests that the imitative nature of ideophones is begotten from perceptuo-motor analogies afforded by such articulatory properties. That is to say, imitative words to an extent derive their imitative meaning through their articulation, implying that articulatory properties of speech are a potential route for explaining the iconic nature of words, such as ideophones. By extension, words of contested iconic nature could thus be deemed more or less iconic depending on whether their articulatory properties support such a claim, For example, if *gl-* of *glisten*, *glimmer*, *glint* was to be proven iconic and therefore imitative, an analogy supported by articulatory features would be required to argue for its purported meaning of luminescence.

If iconicity is imitative due to perceptuo-motor analogy (Dingemanse, Blasi, Lupyan, Christiansen, & Monaghan, 2015) (relations made between sensory percepts and movements), then articulatory properties should likewise map to semantic features for reasons grounded in perceptuo-motor analogy. In Table 4, we propose the perceptuo-motor analogies that allow these articulatory properties to pattern with their semantic features and are in turn embedded in a given ideophone on a sub-phonemic level.

There are few things worth noting regarding the overlap of semantic features. First is that the articulatory feature [+airflow] corresponds to semantic features [+friction] and [+wind] but not motion, i.e., [+air flow] corresponds to [-motion]. This does not imply that [+friction] ideophones are not coded for movement related meaning (as friction must imply some kind of movement). Rather, this implies ideophones which are no to do with motion[4], and are thus beyond motion on Dingemanse (2012) semantic hierarchy for ideophones, involve [+airflow]. With that in mind, the finding that [+labial] corresponds to [+motion] would imply that some (not necessarily complete) occlusion of airflow made by contact with the articulators, is involved in the perceptuo-motor analogy of [+motion]. However, here we would argue that it is the movement of the articulators, not the blockage of air, which affords this perceptuo-motor analogy of movement. This is because [+labial] allows for labio- and labiodental fricatives which of course are consonants coded as [+airflow]. This is further supported by the fact that [-tongue resting], i.e., tongue movement rather than lip movement, also corresponds with [+telic]. Implying that the tongue is used to occlude air in the oral tract to give us the correspondence of [-airflow] to [+telic].

Another observation regarding the overlap of features is that the semantic feature [+telic] is associated with articulatory features [-vocal folds], and [-airflow]. Bear in mind that our feature airflow does not encompass nasal consonants, i.e., air escaping through the nose. We did not find the relation of [+velum] to [+telic] to be significant overall using our Wilcoxon signed rank test (p=0.0869) and thus it is unreported in Table 4. However our chi-squared tests showed it to

[4]There are very few ideophones in our database which are [+motion] but [-sound]. If ideophones are [+motion] they are almost always [+sound], implying that the sound is resultative of the motion and somehow semantically entails it. For example, an ideophone for the sound of footsteps would be [+sound] and [+motion]. The reverse however is not true. For example, the sound of a cow or the sound of wind blowing is [+sound] but [-motion].

Table 4: Analogical justifications for articulatory feature and semantic feature correspondences across 13 languages.

#	Articulation	Corresponds	Justification (≈ analogical to)
1	-airflow	+telic	airflow occlusion ≈ cessation of an event
2	+airflow	+wind	continual airflow ≈ air movement
3	-airflow	+motion	movement of articulators to obstruct airflow ≈ movement depiction
4	+airflow	+friction	airflow sibilance ≈ sibilance of friction and/or ≈ rubbing of two surfaces
5	+labial	+motion	movement of lips ≈ motion depiction
6	-vocal folds	+telic	lack of vocal fold vibration ≈ cessation of an event
7	-tongue resting	+telic	active tongue movement to create [-airflow] articulation ≈ cessation of an event

be significant ($p < 0.05$) in 5 languages on an individual basis (Chaoyang, Akan, Kam, Maai, and Manyika Shona). Though not as robust as other findings, taken together with the other [+telic] associations, this [+velum] to [+telic] pattern would suggest that unvoiced stops are likely associated with telicity, nasal consonants are an exception. This implies that the occlusion created by nasal consonants (air blocked from entering the oral cavity) is just as important as the occlusion of air from escaping the oral cavity for [+telic] ideophones. We can propose that it is the articulatory gesture of blocking of air, an articulatory property common to [+velum] and [-airflow] consonants, that affords the perceptuo-motor analogy of [+telic]. Vocal fold vibration is inherent to nasals. However, as our results show, [-vocal folds] is significantly associated to [+telic] ideophones. This implies that the [-airflow] consonants are those that are unvoiced. Based on the articulatory similarities between [-airflow] and [+velum] consonants, we might also propose that the voicing inherent to nasals is not as important for perceptuo-motor analogy of [+telic] as the occlusion of air. Overall, our results also show for some languages certain articulatory properties pattern with semantic features while others do not. Therefore some perceptuo-motor analogies could be language specific. These language-specific results may have come about for a number of reasons. Firstly, phoneme inventories differ across languages so it is inevitable that some languages make use of certain articulatory features less than others, e.g., voicing. Crucially, we did not take predictable phonotactic processes into account when entering the ideophones into our database. Phonotactic processes could result in the addition or deletion of certain segments in order to satisfy language-specific phonological rules and thus potentially obscuring and/or skewing the articulatory features present for imitative purposes only. Controlling for said phonotactic processes requires in-depth analysis per language (Thompson & Do, in press). We would like to emphasize, however, that our main goal here was to see if there were any cross-linguistic articulatory-semantic patterns despite the presence of language-specific phonotactic patterns. The significance of eight articulatory-semantic feature mappings show that this is possible.

Future directions of research could look into how syllable structure affects the patterning of articulatory features with semantic features. For example, stop consonants, characterized as [-airflow] in our study, might be more attested in codas of ideophones depicting telic events, since the coda is the final segment of a syllable and is thus considered imitative of an events endpoint (Hinton et al., 1994; Strickland et al., 2017). Articulatory properties of vowels are also an obvious direction for future studies, especially given what has been gleaned from the rich literature on *kiki-bouba* studies (Lockwood & Dingemanse, 2015), as well as recent acoustic work on vocal imitations (Perlman & Lupyan, 2018). Given that we only report correlations between individual articulatory features and individual semantic features, future tests could look at how features cluster together, e.g., [+labial] [-airflow] or [+telic] [+motion]. Experimental research could test the results of our study by seeing whether (1) articulatory feature and semantic feature patterns are easily learnable for novel words or ideophones, (2) speakers refer to these articulatory features or perhaps exaggerate them when explaining the meaning of ideophones, as with Dingemanse (2015)'s study on folk definitions of Siwu ideophones. Finally, our study unifies iconicity in the spoken and visual modalities, since both rely on movement to make imitative meanings.

Inductive Biases Constrain Cumulative Cultural Evolution

Bill Thompson (billdthompson@berkeley.edu)

Departments of Psychology and Computer Science, Princeton University

Abstract

Cumulative cultural evolution is a distinctively human form of information-processing that endows our societies with improbable and efficient technologies. But how objective is this process? A widely held conjecture is that human cognitive biases can constrain cumulative cultural evolution, and therefore shape our discoveries. We present a Bayesian analysis of a simple form of cumulative cultural evolution. This model allows us to formulate and test the theoretical conjecture in an experimental setting. Across a series of behavioural experiments, we show that people's inductive biases constrain a population's ability to discover counter-intuitive virtual technologies in a simple search problem. Our analysis highlights formal relationships between cumulative cultural evolution, Bayesian inference, and stochastic optimization.

Keywords: cumulative cultural evolution; inductive biases; optimization; computation; Bayes; cultural evolution;

Introduction

We are surrounded by bizarre and complex objects that vastly improve our lives. To our recent ancestors, many of the tools and technologies we rely on today were inconceivable, yet the same innovations will soon seem primitive to our descendants. The capacity for cumulative discovery is a uniquely human form of information processing on a breath-taking scale – but how objective is this process? Is technological evolution an unbiased search for optimal solutions to the problems we face? Or is it shaped by the same representational constraints and biases that limit individuals?

This question has been widely discussed in the context of *cultural evolution* (Mesoudi, 2016). Most theories of cultural evolution agree on the conjecture that in some circumstances, human cognitive biases must constrain cumulative cultural evolution (Morin, 2016; Acerbi & Mesoudi, 2015; Claidière, Scott-Phillips, & Sperber, 2014). This hypothesis has been widely debated and examined in formal models (Claidière & Sperber, 2007; Boyd & Richerson, 1985; Henrich & Boyd, 2002; Griffiths, Kalish, & Lewandowsky, 2008), but it has never been tested experimentally. In part, testing this hypothesis has been challenging because it is difficult to quantify an appropriate set of expectations in an experimental setting (Miton & Charbonneau, 2018).

In this paper, we develop a mathematical model of cumulative cultural evolution that allows us to formulate these expectations precisely. Our model is derived from a Bayesian analysis of individual cognition. The model makes quantitative predictions about the circumstances under which inductive biases are likely to stifle discovery. To test these predictions, we adapt a widely studied experimental paradigm in which participants design and transmit a simple artificial technology: virtual arrowheads. Our strategy is to first characterise participants' inductive biases in this context using serial reproduction chain experiments. On the basis of these estimates, we conduct a series of arrowhead-design experiments which differ only in the extent to which task reward structure contradicts participants' biases. In the process of formalizing our predictions, we identify a formal relationship between cumulative cultural evolution and stochastic optimization.

Background

Cumulative Cultural Evolution

Unlike other species, every generation of humans builds on the insights and actions of their ancestors (Henrich, 2015). When an Apple engineer develops iPhone security updates, she makes use of cognitive resources expended by Turing almost a century before. In this sense, people alive today extend the computations initiated by people who faced similar problems in the past. What kind of process allows us to effectively pool computational resources with strangers over seemingly unbounded timescales? Computation over generations depends on a proclivity to learn from the people around us and the artefacts they create. When this kind of learning is repeated over time, a stochastic process is induced. This process is called *cultural transmission* (Boyd & Richerson, 1985). In some species, cultural transmission leads to cumulative innovation. This special case is known as *cumulative culture* (Mesoudi & Thornton, 2018) and is surprisingly rare (Whiten, Caldwell, & Mesoudi, 2016).

Discovering Technologies

There are many forms of cumulative culture, but one simple example has been heavily studied: refinement of technologies towards consistent functional objectives. Outside of the laboratory, examples of this process are easy to find: motorcycles today are faster, more efficient, more reliable, safer, and longer-lasting than the motorcycles people rode during the second World War. In an experimental setting, small-scale analogues of this process have been studied in several domains. For instance, Caldwell and Millen (2008) showed that micro-societies of experimental participants discover cumulatively more effective ways to design a tall-standing tower

of spaghetti. In these experiments, later participants observed the designs of earlier participants, and created taller and taller spaghetti towers as a result. Similar findings have been reported in lineages of participants designing simple knots (Muthukrishna, Shulman, Vasilescu, & Henrich, 2014), paper aeroplanes (Caldwell & Millen, 2008), rice baskets (Zwirner & Thornton, 2015), and fishing nets (Derex, Beugin, Godelle, & Raymond, 2013), for example.

Inductive Biases in Cumulative Culture

Cumulative cultural evolution can be recreated and manipulated in the laboratory. However, it remains unclear whether the products of these processes are shaped by biases in the way people think, or whether inductive biases and representational constraints are effectively washed out over time. This has been difficult to establish empirically, in part because it is often challenging to quantify the influence of people's inductive biases. Recent reviews have noted that experimental tasks often feature unconstrained or difficult to quantify design spaces (Miton & Charbonneau, 2018), and that there is a need for a better understanding of the information-processing dynamics that link cognition and cultural evolution (Mesoudi & Thornton, 2018; Heyes, 2018). Mathematical analyses have repeatedly identified the potential for human biases to shape cumulative cultural evolution (Claidière & Sperber, 2007; Boyd & Richerson, 1985; Griffiths et al., 2008). However, extending abstract models to an experimental setting remains a challenge. Here, we introduce a formal model that is closely related to these theories of culture, but derived from a Bayesian analysis of cognition, and therefore directly applicable in an experimental context. Our analysis extends prior Bayesian models of cultural evolution (Griffiths & Kalish, 2007; Navarro, Perfors, Kary, Brown, & Donkin, 2018) to the cumulative case. The model we introduce allows us to specify formal predictions about the circumstances in which inductive biases constrain cumulative cultural evolution, and test those predictions experimentally.

Model: Optimization by Cumulative Culture

Our analysis applies to settings in which the design features of a technology can be described in terms of (n) continuous valued parameters $\Theta^t \in \mathbb{R}^n$. This setting offers a natural connection to prior experimental work, in which participants modify design features such as length, height, width, angles, crossing points, mass, or hue.

Induction of a Design

Each new individual estimates these design features from artefacts produced by the previous generation. If this estimation procedure can be given a formulation as Bayesian inference, then an individual's estimate $\hat{\Theta}$ can be decomposed into a trade-off between two quantities: noisy empirical observation of the true design features Θ; and inductive biases imposed by cognition. Inductive biases can expressed as a prior distribution $p(\Theta)$. Using this framework, $\hat{\Theta}^t$ can be treated as a random variable distributed according to the posterior distribution implied by a Bayesian model of learning.

Innovation

After estimating the existing design, each participant attempts an innovation. Assume a $f\colon \Theta \to \mathbb{R}$ is a function that reflects the utility of a technology with respect to it's design features. In the literature on cultural evolution, this quantity would sometimes be referred to as a *fitness* landscape. We will make the assumption that individuals are capable of bounded, local innovation. This is appropriate to scenarios in which innovation is largely driven by an ability to identify similar but improved variants of whatever already exists, through limited experimentation with minor design variations for example. Local information about f can be naturally expressed as its gradient with respect to design features, evaluated at Θ^t. We denote this quantity $\nabla_f = \nabla_\Theta f(\Theta^t)$.

Diffusion Chains

These assumptions formalize a simple theory of cumulative culture as repeated cycles of observation, induction, and local innovation, leading to the expression:

$$\Theta^{t+1} = \Theta^t - \alpha\nabla_f - (\Theta^t - \hat{\Theta}^t)\,, \tag{1}$$

where $t \in 1,\ldots,T$ denotes a specific generation in a transmission chain. This equation describes a single step of a transmission chain in terms of the relationship between an existing technology (Θ^t), its utility (f), its status with respect to human cognitive constraints and the fidelity of transmission ($\Theta^t - \hat{\Theta}^t$), and an innovation rate (α). We examine the properties of this general model under some simplifying assumptions.

Assumption 1: Gaussian Prior & Observation Noise Assume individual learning can be modelled as probabilistic inference in a Gaussian model: observations of an existing design are noisy, and this noise can be approximated by Gaussian corruption of the true design features; inductive biases can be approximated by a Gaussian distribution.

Assumption 2: Independent Features Individual design features $\theta_i \in \Theta$ can be treated independently. This is a limiting assumption, but nonetheless appropriate to many relevant contexts. If μ_i is the prior expectation, the posterior expectation is:

$$\mathbb{E}\left[\hat{\theta}_i^t\right] = \lambda_i\mu_i + (1-\lambda_i)\theta_i^t \tag{2}$$

where $\lambda_i = \sigma_i^2/(\sigma_i^2+\delta_i^2)$ reflects the relative variance of the prior (δ_i^2) and observation noise (σ_i^2) – in other words, the strength of an inductive bias $p(\theta_i)$ relative to the fidelity of transmission.

Chain Dynamics

The expected change at each generation can be written:

$$\mathbb{E}\left[\theta_i^{t+1} - \theta_i^t\right] = \lambda_i(\mu_i - \theta_i^t) - \alpha\nabla_f\,. \tag{3}$$

which implies no further accumulation in expectation when $\nabla_f = \nabla_f^*$, where $\nabla_f^* \equiv (\mu_i - \theta_i^t)(\lambda_i/\alpha)$. This cultural process will halt if the potential for local innovation drops below a threshold determined by: the distance of the current design from the prior expectation ($\mu_i - \theta$), relative to a willingness to explore (α), weighted by the balance of prior and empirical leniencies in learning (δ_i^2/σ_i^2).

Assumption 3: Quadratic Utility Landscape The fate of the process is closely tied to the utility landscape in which it is operating. A simple but broad class of cases can be captured by the assumption that there is an optimal design Θ^*, and that f can be locally approximated by a quadratic surface with the optimum design at its minimum / maximum. In this regime, utility decreases with squared distance from the optimum at a rate proportional to a parameter a. A utility landscape that can be described in this manner has gradients $\nabla_f = a(\theta - \theta_i^*)$. A transmission process acting on a utility landscape of this form will halt in expectation if it reaches $\theta_i^t = \phi_i^*$:

$$\phi_i^* = \lambda_i^* \mu_i + (1 - \lambda_i^*)\theta_i^* \tag{4}$$

which is a linear combination of the prior mean μ_i and the optimum design θ_i^* with mixing proportions:

$$\lambda_i^* = \sigma_i^2/(\sigma_i^2 + \alpha a s) \tag{5}$$

where $s = \delta_i^2 + \sigma_i^2$. Equations (4) and (5) represent our main theoretical result. Our analysis predicts that the outcome of a transmission chain is a compromise between the inductive biases of individuals and the optimal design. When these conflict, the balance of the compromise is quantifiable from the relationships between: transmission fidelity (σ_i^2), strength of inductive bias (δ_i^2), an exploration rate (α), and the slope of the utility landscape (a). The weighting factor $0 \leq \lambda_i \leq 1$ interpolates between cultural evolutionary processes that are constrained by inductive biases ($\lambda \to 1$) and therefore dragged back toward the prior $p(\theta_i)$, and processes that are dominated by information contained in the the utility landscape ($\lambda \to 0$), and therefore destined to discover an objective optimum.

Biased Computation by Cumulative Culture

One way to interpret this finding is as a description of the computation that is being implemented by the *process* we have analysed – the computation implemented by a chain of individuals. Two analogies motivate this interpretation. First, equation (5) has the same form as equation (4). At each generation, an individual person performs a computation that we formalized as a sample from the posterior distribution in a Bayesian model of inference. This computation is biased and *local*: the expectation is a linear combination of the individual's inductive bias and the *currently existing* design θ^t. However, the chain *as a whole* can be understood to implement a biased but *global* computation: equation (5) describes the expectation of a posterior distribution computed by the same kind of learner after observing (a noisy realisation of) the *optimal* design θ^*. Second, in the Gaussian case, equation (1) can be rewritten as:

$$\theta_i^{t+1} = \theta_i^t - \alpha \nabla_f - \lambda_i(\theta_i^t - \mu_i) + \varepsilon_i^t \tag{6}$$

which is a form of stochastic gradient descent with regularisation. Stochastic optimization and Bayesian inference are known to be related (Mandt, Hoffman, & Blei, 2017). This highlights a common interpretation of cognitive and cultural processes – they are both forms of information processing. This cultural process solves an optimization problem subject to regularisation by human inductive biases. In the remainder of this paper, we test this prediction.

Experiment: Discovering Virtual Technologies

We adapted an experimental paradigm that has been widely used to study the influence of social learning on cumulative culture (Mesoudi, Chang, Murray, & Lu, 2015). The experimental task involves designing a virtual arrowhead. The arrowhead has a number of attributes (e.g. length, width) that can be modified and achieves a score when deployed on a virtual hunt. The score reflects the number of calories of food earned by the arrowhead. Participants' goal was simply to test and redesign a single arrowhead they inherited, in an attempt to increase its score. This paradigm allowed us to construct a low-dimensional search problem in which we hypothesised that task-naive participants would display biased expectations. Athough there is signfificant discussion surrounding the definition of cumulative cultural evolution, a central requirement is that over time, it's products must"enhance some measure of performance...[through]...sequential improvements..." (Mesoudi & Thornton, 2018). In our experiment, unconstrained cumulative cultural evolution would correspond to the chains of participants sequentially designing arrowheads that achieve higher scores until the maximum score is achieved.

Method

Stimuli The experiment was presented as a website. Participants designed a virtual arrowhead using two HTML range sliders which modified its width and length. Figure 1 shows the design space. During experimental trials, the screen was split into left (25% screen width) and right (75% screen width) panels. The left panel displayed the participant's estimate of the arrowhead they inherited in reduced proportions that nonetheless preserved the design. Underneath was a depiction of two range-sliders positioned in accordance with the arrowhead's attributes, and text indicating the number of calories that the arrowhead earned. The main panel (Right) displayed an arrowhead in the center, pointing downwards. Two range-sliders were located beneath the arrowhead. Moving a range-slider modified either the length or the width of the arrowhead dynamically. Both dimensions of the arrowhead could take values ranging between 50 and 150 pixels.

Arrowhead scores were determined by a quadratic function of the form $f(\theta_i) = \frac{1}{2}a(\theta_i - \theta_i^*)^2 + c$, where θ_i^* is the

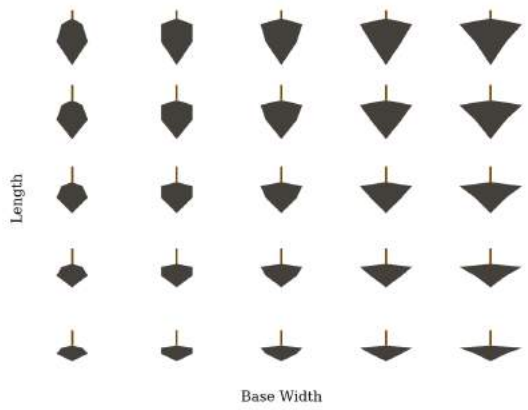

Figure 1: Regularly sampled virtual arrowheads in a design space implied by the ability to modify two features – length and base width.

optimum value for feature θ_i. We chose to use this family of functions because it constructs a smooth utility landscape with a single optimum. Previous work has focused on conditions that allow populations to search effectively through more complex landscapes with both local and global optima (Acerbi, Tennie, & Mesoudi, 2016). In contrast, our analysis focuses on a problem that should be relatively easy to solve optimally if people's inductive biases do no constrain cultural evolution. Quadratic functions are also the class of landscapes we examined in our theoretical analysis.

Within the family of quadratic landscapes, we required a function which was: smooth over the full range; did not return negative scores; had an optimum (maximum) score that lies within a semantically reasonable range given the framing of the task. To meet these requirements, we set $\alpha = -30$ and $c = 10000$ for all experiments and divided the result by 100. Given our settings of θ_i^* (see below), the maximum available score was 1000 calories. Calories decreased away from θ_i^* at a rate given by $\nabla_f = -\frac{3}{10}(\theta_i' - \theta_i^*)$. To award a score, we computed f for both arrowhead features (length and base width) and awarded the mean.

Procedure Participants were informed that: they would go on a virtual hunt; their task was to design a virtual arrowhead that will earn as many calories of food as possible on the hunt; a bonus payment would be made in proportion to the number of calories their arrowhead earned. After consenting to the experiment, participants completed an Information Trial (IT), during which they observed the arrowhead they had inherited (first generation participants inherited an arrowhead with a randomly sampled design). This arrowhead was displayed in the center of the right panel for 3000 milliseconds. Participants then recreated the arrowhead as accurately as possible. Participants then proceeded to the first Modification Trial (MT). The participant's estimate of the arrowhead design was displayed as the arrowhead they inherited in the left panel. Participants completed four MTs. During each MT, $\hat{\theta}_i'$ was displayed in the left panel. At the beginning of an MT, no arrowhead was displayed in the right panel, and the positions of the range-sliders were randomised. Participants could not proceed to the next trial until at least one range-slider had been modified. Upon modifying any of the rage-sliders positions, the arrowhead was redrawn. Modifications were limited to a range of ± 30 pixels around $\hat{\theta}_i'$. This enforced a weak restriction on the innovations participants could make in accordance with our theoretical model. There was no limit to the number of times participants could modify the range-sliders in a given MT. Once satisfied, participants could click Submit to obtain feedback – the number of calories earned by the current arrowhead design. Arrowheads evaluated during previous MTs were displayed (in reduced proportions) in the left panel, in trial order. After completing four MTs, participants were informed that their opportunity to test arrowheads was complete and proceeded to the test trial (TT). Participants were reminded that the arrowhead they designed during this trial would determine a bonus payment. TT was identical to MT in all other respects.

Participants Participants ($n = 1000$) were recruited online using Amazon's Mechanical Turk. The experimental protocol was approved by the University of California, Berkeley's Committee for the Protection of human Subjects. Participants were paid \$0.50 to complete the experiment, and awarded a performance-based bonus of up to \$0.50. Most participants completed the experiment in less than three minutes. Data from any participants who completed the experiment in less than 20 seconds were rejected.

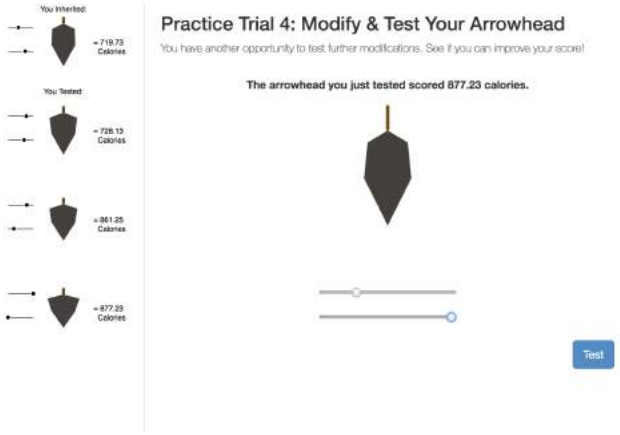

Figure 2: Participant view of the experiment. Screenshot shows the fourth Modification Trial. At this point in the expreriment, the participant has completed the Information trial (and recreated their inherited arrowhead, shown first in the left panel) and three Modification Trials (the arrowheads tested by the particiant so far and their scores are shown in the left panel).

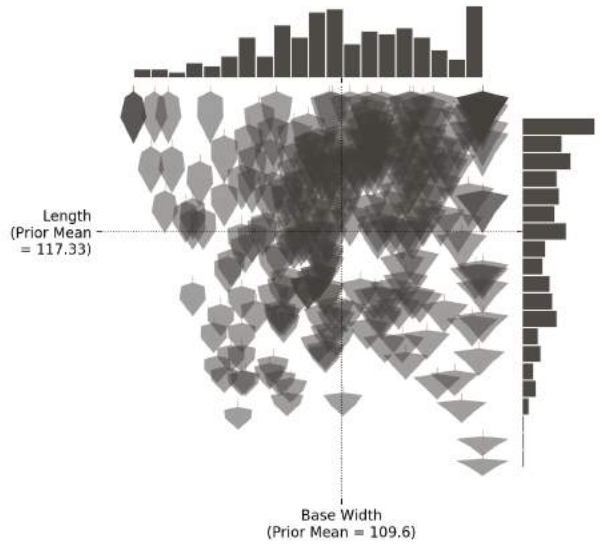

Figure 3: All arrowheads produced by participants at generation 3 or later in 20 serial reproduction chains of 10 generations each. A sample based approximation to participants' inductive biases, $p(\theta)$.

Results

Reproduction Chains We first ran a simpler experiment using the same stimuli. This experiment used *serial reproduction chains* to characterise participants' inductive biases in our stimulus set. In these chains, each participant completed an IT, but did not proceed to MT and TT. Each participant observed the arrowhead designed by the previous participant, and was asked to reproduce it as accurately as possible. Previous mathematical (Griffiths & Kalish, 2007) and experimental (Griffiths et al., 2008; Xu & Griffiths, 2010) research has established that serial reproduction chains characterise participants' inductive biases. Figure 3 shows the distribution of arrowheads produced by all participants at generation 3 or later (in all our analyses, the first two generations of a chain are excluded as *burn-in* generations to minimise the effects of random initial conditions), across 20 serial reproduction chains of 10 generations each. This collection of arrowheads can be understood as a sample-based approximation to the prior distribution $p(\Theta)$. The empirical mean of this distribution is $\hat{\mu}_{width} = 111, \hat{\mu}_{length} = 118$. People favoured arrowheads that are relatively long and relatively wide.

Optimization Chains In light of participants' inductive biases, we conducted four experiments. We treat these as separate experiments rather than experimental conditions because they were carried out sequentially. Each experiment (20 chains of 10 generations) featured a utility landscape with a differently located optimum but the same calorie gradient surface. Our prediction was that differently located optimums would lead to differential discovery of those designs, and differential task success (number of calories). Our mathematical analysis identified the distance between the optimum arrowhead and the mean of the prior distribution $p(\theta)$ as the crucial predictive quantity: optimal arrowheads that are farther from the prior distribution should be harder to find because they are less intuitive. Figure 4 shows our results. Experiment 1 ($\theta^*_{width} = 115, \theta^*_{length} = 115$) was designed to be most consistent with people's inductive biases. In this experiment, the arrowheads people designed scored well (mean calories $M = 948$, $SD = 46$). Experiment 4 was least consistent with people's biases, contradicting people's expectations in both dimensions. Success in the task suffered as a result ($M = 794$, $SD = 183$). Experiments 2 ($\theta^*_{width} = 75, \theta^*_{length} = 115$, $M = 912$, $SD = 98$) and 3 ($\theta^*_{width} = 115, \theta^*_{length} = 75$, $M = 845$, $SD = 132$) were designed to contrast with people's biases in one of the two dimensions – width and length respectively.

We combined data from all four experiments and computed the difference between the optimum arrowhead and the mean of the prior distribution. The main prediction of our formal model (equation 4) can be rearranged into a linear model of the form $\phi^*_i = \hat{\mu}_i + \beta(\theta^*_i - \hat{\mu}_i)$. This allowed us to perform an ordinary least squares regression analysis of this model in our experimental data. The prediction was upheld. Accounting for the mean of the prior distribution ($\hat{\beta} = 1.0, p < .001$) and the difference between the mean of the prior and the optimum design ($\hat{\beta} = 0.42, p < .001$) accounted 96% of the variance in the features of the arrowheads people produced ($R^2 = 0.962$). We also analysed task success, and found significant differences in the distribution of arrowhead scores in all pairwise comparisons of our four experiments (at $\alpha = .05$). Only the comparison between experiments 3 and 4 ($t(197) = 3.2, p = 0.0017$) was not significant at $\alpha = .001$. Figure 4 (b) shows how task success reduced over the four experiments. Finally, we computed the predictions of our mathematical model under the inferred mixing proportions λ explicitly. Figure 4 (c) shows these predictions.

Conclusion

We introduced a simple formal theory of cumulative cultural evolution. We used this theory to predict how the inductive biases of individuals would constrain a cultural process. We tested this prediction in a series behavioural experiments. We found that discovery of an optimal virtual technology in a simple search problem was impeded by people's inductive biases. These results reinforce a theoretical conjecture that had previously not been studied empirically. Our analysis highlighted formal connections between cumulative cultural evolution, Bayesian inference, and stochastic optimization. Our results suggest a more general insight: identifying the algorithm that is implemented by a cultural process can allow us to characterise the computation it performs, yielding a cognitive interpretation of the process in information-processing terms. Our results showed that computation by cumulative culture can be biased. This naturally raises the question: under what circumstances is computation by culture *unbiased*?

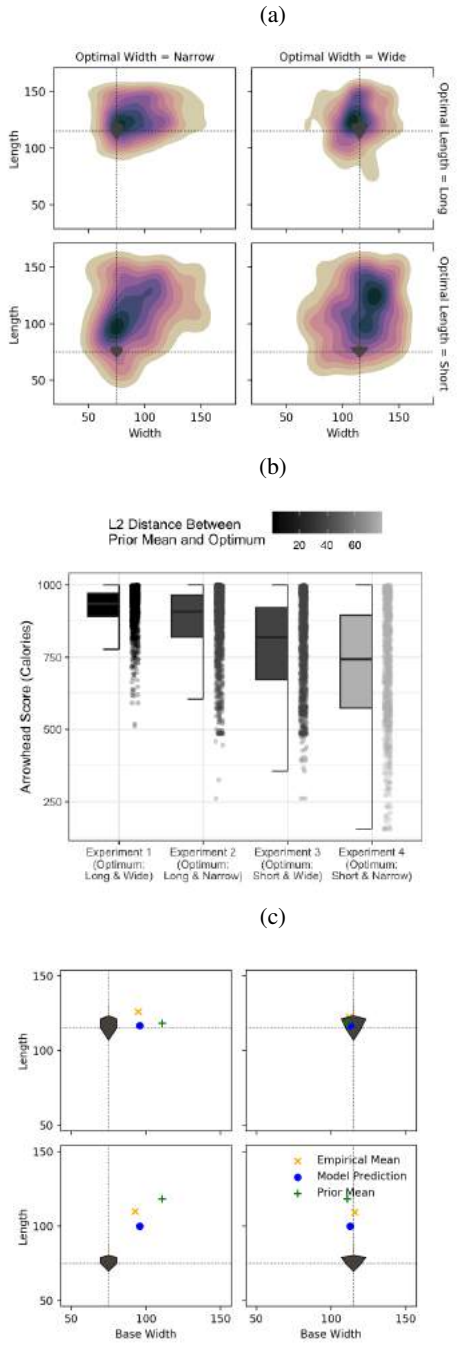

Figure 4: Results of all optimization experiments. Above (a): kernel density estimates of the distribution of arrowheads produced by all participants at generation 3 or later. Dotted lines show the location of the optimum arrowhead in design space. Middle (b): The distribution of scores obtained by the arrowheads produced by participants at generation 3 or later in all optimization chains. The Euclidean distance between the optimum arrowhead and the mean of the prior distribution predicts task success (No. calories). Below (c): Mean arrowhead design produced by all participants at generation 3 or later in all optimization chains (yellow cross), alongside the mean design predicted by our mathematical model (after fitting λ to experimental data, blue circles), the empirical mean of the prior distribution ($\hat{\mu}$, green plus), and the experiment-specific optimum design (black arrowhead).

Abstract

Constrained by results from classic behavioral experiments we provide a neural-level cognitive architecture for modeling behavior in working memory tasks. We propose a canonical microcircuit that can be used as a building block for working memory, decision making and cognitive control. The controller controls gates to route the flow of information between the working memory and the evidence accumulator and sets parameters of the circuits. We show that this type of cognitive architecture can account for results in behavioral experiments such as judgment of recency, probe recognition and delayed-match-to-sample. In addition, the neural dynamics generated by the cognitive architecture provides a good match with neurophysiological data from rodents and monkeys. For instance, it generates cells tuned to a particular amount of elapsed time (time cells), to a particular position in space (place cells) and to a particular amount of accumulated evidence.

Keywords: Cognitive architecture; Neural-level modeling; Working memory; Cognitive control; Decision making; Judgment of recency; Probe recognition; Delayed-match-to-sample

Introduction

Behavioral experiments provide important insights into human memory and decision making. Building neural systems that can describe these processes is essential for our understanding of cognition.

Here we propose a neural-level architecture that can model behavior in different working memory based cognitive tasks. The proposed architecture is composed of biologically plausible artificial neurons characterized with instantaneous firing rate and with the ability to: 1) gate information from one set of neurons to the other (Hasselmo & Stern, 2018; Bhandari & Badre, 2018; Sherfey, Ardid, Miller, Hasselmo, & Kopell, 2019) and 2) modulate the firing rate of other neurons via gain modulation (Salinias & Sejnowski, 2001). The architecture is based on a canonical microcircuit that represents continuous variables via supported dimensions (Shankar & Howard, 2012; Howard et al., 2014). The microcircuit is implemented as a two-layer neural network. The same microcircuit prototype is used for maintaining a compressed memory timeline, evidence accumulation and for controlling the flow of actions in a behavioral task. Here we demonstrate that this architecture can be used for modeling behavioral responses and neural activity in a variety of working memory tasks.

A neural architecture for cognitive modeling

We sketch a neural cognitive architecture and apply it to three distinct working memory tasks. The architecture is composed of multiple instances of a canonical microcircuit (Figure 1). This microcircuit represents vector-valued functions over variables. These functions can be examined through attentional gain field and then used to produce a vector-valued output. We first discuss the properties of the microcircuit.

Function representation in the Laplace domain

The microcircuit consists of two layers. The first layer approximates the Laplace transform of $\mathbf{f}(t)$ (a vector across the input space) via set of neurons which can be described as leaky integrators $\mathbf{F}(t,s)$, with a spectrum of rate constants s. Each neuron in $\mathbf{F}(t,s)$ receives the input and has a unique rate constant:

$$\frac{d\mathbf{F}(t,s)}{dt} = \alpha(t)\left[\pm s\mathbf{F}(t,s) + \mathbf{f}(t)\right], \qquad (1)$$

where $\alpha(t)$ is an external signal that modulates the dynamics of the leaky integrators. If $\alpha(t)$ is constant, $\mathbf{F}(t,s)$ codes the Laplace transform of $\mathbf{f}(t)$ leading up to the present. It can be shown that if $\alpha(t) = dx/dt$, $\mathbf{F}(t,s)$ is the Laplace transform with respect to x (Howard et al., 2014). We assume that the probability of observing a neuron with rate constant s goes down like $1/s$. This implements a logarithmic compression of the function representation.

The second layer $\tilde{\mathbf{f}}(t,\overset{*}{x})$ computes the inverse of the Laplace transform using the Post approximation. It is implemented as a linear combination of nodes in $\mathbf{F}(t,s)$: $\tilde{\mathbf{f}}(t,\overset{*}{x}) = \mathbf{L}_k^{-1}\mathbf{F}(t,s)$. The operator $\mathbf{L}_k^{-1}$ approximates kth derivative with respect to s. Because $\mathbf{L}_k^{-1}$ approximates the inverse Laplace transform, $\tilde{\mathbf{f}}(t,\overset{*}{x})$ provides an approximation of the transformed function. It turns out (Shankar & Howard, 2012) that the width of the activity of each unit in $\tilde{\mathbf{f}}(t,\overset{*}{x})$ depends linearly on its value of $\overset{*}{x}$ with a Weber fraction that is determined by the value of k.

Accessing the function

The representation described above stores working memory as a vector-valued approximation of a function over an internal variable. We assume that this entire function cannot be accessed all at once, but that one can compute vector-valued integrals weighted by attentional gain over the function. The microcircuit includes an attentional gain function $\mathbf{G}(\overset{*}{x})$ that is

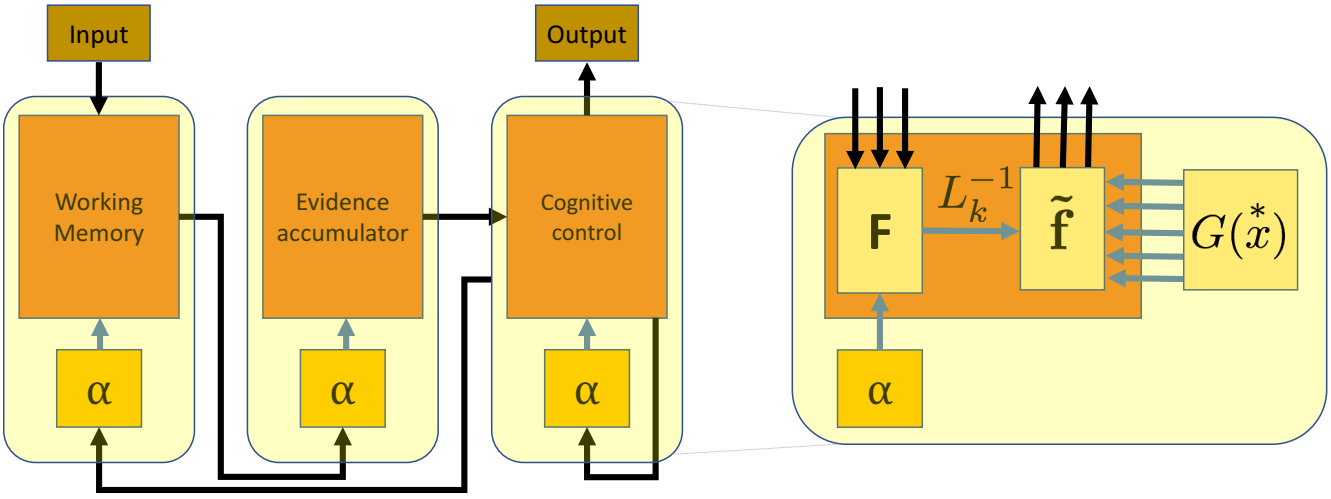

Figure 1: **A schematic of a neural-level circuit that can be used to model different behavioral tasks. This circuit was used to implement all the tasks described here.** The diagram on the left-hand side displays a configuration of the circuit composed of three blocks: working memory, evidence accumulator and cognitive control. The cognitive control block executes a sequence of actions. While a particular action is executed (e.g. waiting for a probe) the sequence is paused by setting its own α to 0. To move to the next action α is set to ± 1. Some actions will access working memory and feed the memory output to the evidence accumulator (e.g. to compare the probe with the content of memory). Output of the evidence accumulator is sent to the cognitive control block where it is used to trigger an appropriate action (e.g. press the left button). Each of the three blocks on the left-hand side is implemented with the microcircuit shown on the right-hand side. The microcircuit takes a vector input (fed into $\mathbf{F}(t,\overset{*}{x})$) and outputs a vector of the same size (through $\tilde{\mathbf{f}}(t,\overset{*}{x})$) selected by the attentional gain field $\mathbf{G}(\overset{*}{x})$ (multiple arrows from $\mathbf{G}(\overset{*}{x})$ represent that it can select different $\overset{*}{x}$ from $\tilde{\mathbf{f}}(t,\overset{*}{x})$). Depending on the initialization and inputs, this multipurpose microcircuit can run a predefined sequence in a self-modulating manner (by modulating its own α), store a compressed memory representation through sequential activation in $\tilde{\mathbf{f}}(t,\overset{*}{x})$ or encode functions of variables (e.g. accumulated evidence) for which a temporal derivative is available.

externally controllable. The output of the microcircuit at any moment is:

$$\mathbf{O}(t) = \sum_{i=1}^{N} \mathbf{G}(\overset{*}{x}_i)\tilde{\mathbf{f}}(t,\overset{*}{x}_i), \tag{2}$$

where N is the number of values of $\overset{*}{x}$ used to implement the function approximation $\tilde{\mathbf{f}}$. In models used here we restrict $\mathbf{G}(\overset{*}{x})$ to be unimodal across $\overset{*}{x}$. Attentional gain field can be made narrow and then activated sequentially, allowing a scan of the function representation or it can be made broad to sum across the $\overset{*}{x}$. This enables one to construct cognitive models based on scanning (e.g., Hacker, 1980) or to construct global matching models (e.g., Donkin & Nosofsky, 2012).

Working memory: Functions of time

When $\alpha(t)$ is constant, $\tilde{\mathbf{f}}$ maintains an estimate of $\mathbf{f}(t)$ as a function of time leading up to the present and we write $\tilde{\mathbf{f}}(t,\overset{*}{\tau})$. If the input stimulus was a delta function at one point in the past, the units in $\tilde{\mathbf{f}}(t,\overset{*}{\tau})$ activate sequentially with temporal tuning curves that are broader and less dense as the stimulus becomes more temporally remote (Figure 2A). Neurons with such properties, called time cells, have been observed in mammalian hippocampus (MacDonald, Lepage, Eden, & Eichenbaum, 2011) and prefrontal cortex (Tiganj, Kim, Jung, & Howard, 2017). Furthermore, different stimuli trigger different sequences of cells (Tiganj et al., 2018), Figure 2B. Taken together at any time t, $\tilde{\mathbf{f}}(t,\overset{*}{\tau})$ can be understood as a compressed memory timeline of the past. The application of the Laplace transform in maintaining working memory in neural and cognitive modeling has been extensively studied (e.g., Shankar & Howard, 2012; Howard, Shankar, Aue, & Criss, 2015).

Evidence accumulation: Functions of net evidence

In simple evidence accumulation models, the decision variable is the sum of instantaneous evidence available during the decision-making process. In these models, a decision is executed when the decision variable reaches a threshold. By setting $\alpha(t)$ to the amount of instantaneous evidence for one alternative, we can construct the Laplace transform of the net amount of decision variable since an initialization signal was sent via the input $f(t)$. If no new evidence has been observed at a particular moment then $\frac{dF(t,s)}{dt} = 0$, thus all the units remain active with sustained firing rate. Large amount of evidence will, on the other hand, mean a fast rate of decay. Inverting the transform results in a set of cells with receptive fields along a "decision axis" (Howard, Luzardo, & Tiganj, 2018) consistent with recent findings from mouse recordings (Morcos & Harvey, 2016).

Cognitive control: Functions of planned actions

The program flow control activates a sequence of actions necessary for completion of a behavioral task. For instance, a typical behavioral task may consist of actions such as attend-

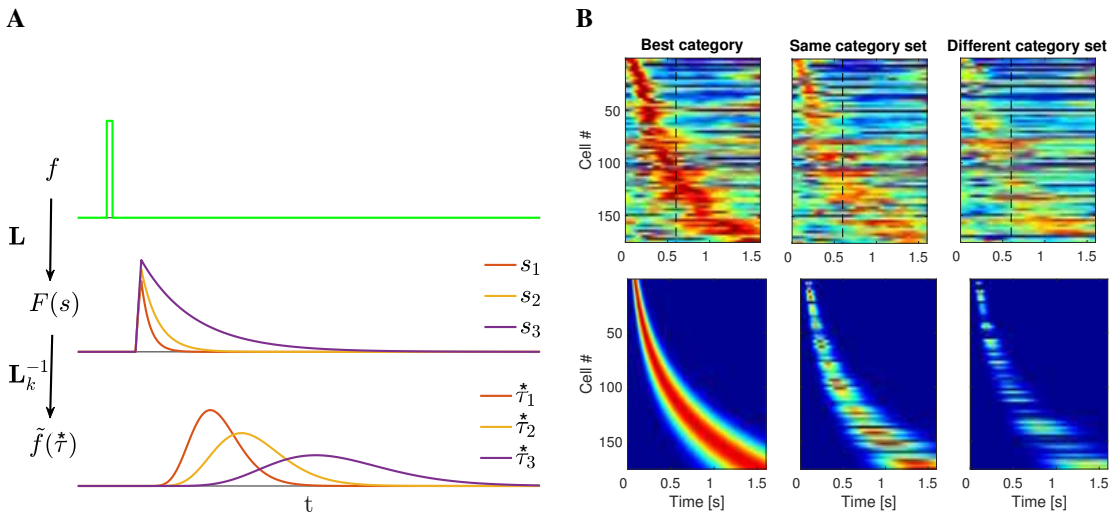

Figure 2: **A scale-invariant compressed memory representation through an integral transform and its inverse: model and neural data**

A. A response of the network to a delta-function input. Activity of only three nodes in each of the two layers is shown. Nodes in $\tilde{f}(\overset{*}{\tau})$ activate sequentially following the presentation of input stimulus f. The width of the activation of each node scales with the peak time determined by the corresponding $\overset{*}{\tau}$, making the memory scale-invariant. Logarithmic spacing of the $\overset{*}{\tau}$ makes the memory representation compressed. **B.** Top: During DMS task sequentially activated cells in monkey lPFC encode time conjunctively with stimulus identity (firing rate encodes visual similarity of the stimuli - stimuli in "Best category" were visually more similar to stimuli in the "Same category set" than to stimuli in the "Different category set"). The three heatmaps show neural activity during the stimulus presentation (first 0.6 s) and the delay period (following 1 s) averaged across trials. (Taken from Tiganj et al. (2018)). Bottom: Activity of the units in the working memory block of the architecture resembles the neural data.

ing to stimuli, detecting the probe, accumulating evidence and taking an appropriate action depending on which of the available choices accumulated more evidence. These operations require the ability to route information to and from the working memory and evidence accumulation modules. For instance, in order to compare a probe to the content of memory, one might route the output of the working memory unit, filtered by a probe stimulus, to the $\alpha(t)$ of an evidence accumulation unit. Because various operations take place in series, we can understand them as a function of future planned actions. Rather than past stimuli, the vectors in $\mathbf{F}(t,s)$ and $\tilde{\mathbf{f}}(t,\overset{*}{\tau})$ can be understood as operations that affect other units (each action has a corresponding two-layer network turning $\mathbf{F}(t,s)$ and $\tilde{\mathbf{f}}(t,\overset{*}{\tau})$ into vectors across the action space).

Different cognitive models correspond to different initial states in $\mathbf{F}(t,s)$ and $\tilde{\mathbf{f}}(t,\overset{*}{\tau})$. The actions will be executed sequentially by setting $\alpha(t) < 0$, winding the planned future closer and closer to the present. For instance, if the first step of a behavioral task is to wait for a probe, then that action will set the controller's $\alpha(t)$ to 0 until the probe is detected. Once the probe is detected, $\alpha(t)$ will be set to a default value of -1 so the neurons in the first layer will grow exponentially and the sequence loaded in $\tilde{\mathbf{f}}(t,\overset{*}{\tau})$ will continue evolving.

Integrating microcircuits into cognitive models

The three blocks described above: working memory, evidence accumulation and cognitive control are all constructed from the same microcircuit (Figure 1 right-hand side). Each circuit has an input, α and output. To demonstrate the utility of this approach, we connected the three blocks such that the program control block gates information from the working memory block to the evidence accumulation block and monitors its output (Figure 1 left-hand side).

Results

We demonstrate performance of the proposed architecture on three classical behavioral tasks: Judgment of Recency (JOR), probe recognition and Delayed-Match-to-Sample (DMS). We compare the results of the model with behavioral data (for JOR and probe recognition) and neural data (for DMS). Critically, even though these three tasks have very different demands, the neural hardware for the models is identical. The only difference is in the initial state of the program block. After initialization, each model runs autonomously and is self-contained.

Judgment of Recency: Sequential scanning of the memory timeline

In JOR subjects are presented with a random list of stimuli (e.g. letters or words) one at a time, and then probed with two stimuli from the list and asked which of the two stimuli was presented more recently. The classical finding is that the time it takes subjects to respond depends on the recency of the more recent probe, but not the recency of the less recent probe (Figure 4A) (Hacker, 1980; Singh & Howard, 2017). This result is consistent with a self-terminating backward scan along a temporally organized memory representation, suggesting

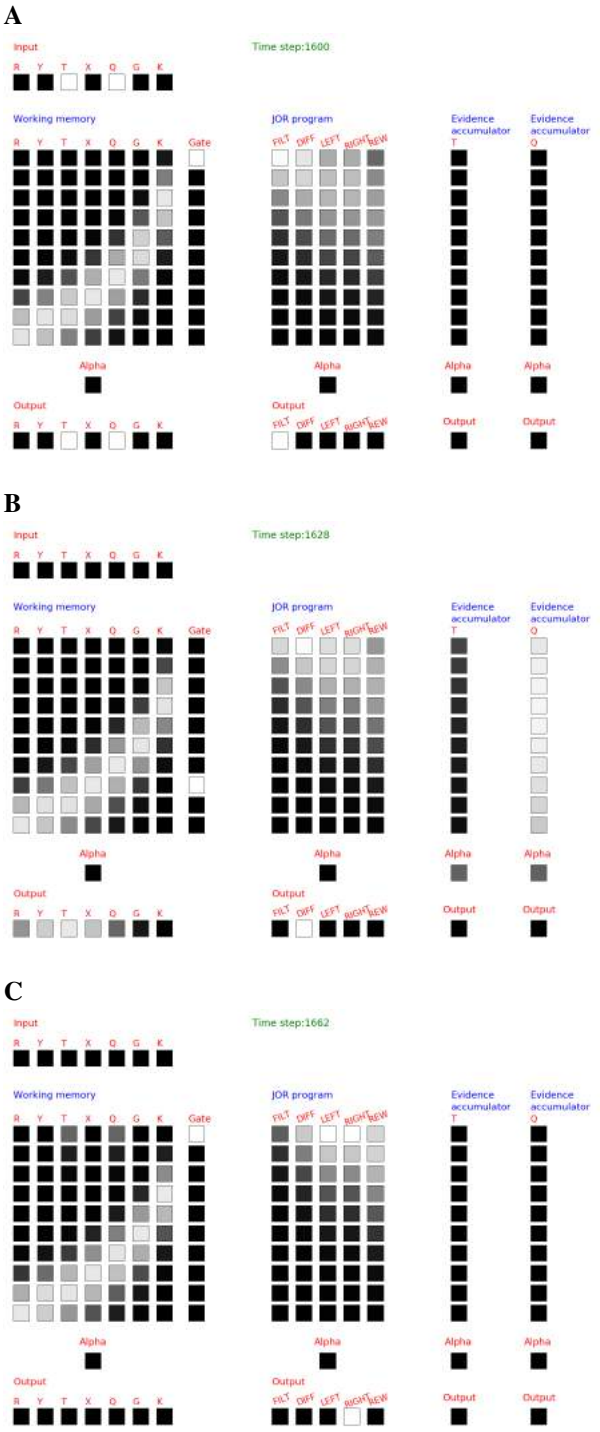

Figure 3: **Example of a JOR task implemented with the proposed architecture.** The implementation is done with microcircuits that correspond to those in Figure 1. Each square corresponds to a single neuron. Squares in the middle layer of each panel correspond to single neurons from $\tilde{\mathbf{f}}(t, \overset{*}{x})$ (neurons from $\mathbf{F}(t,s)$ are not shown). Shading reflects the activity of the neuron at a given time step; darker shading means less activity. **A.** At this time step all the seven items from the test list have been presented and they are stored in the sequentially activated memory. The two probe items T and Q are at the input. **B.** The program (cognitive control) block sequentially gates the information from the working memory into the α neuron of the evidence accumulator (DIFF action in the program block), causing sequential activation in the accumulator. **C.** After the evidence accumulator reaches the threshold, program control continues execution by activating an appropriate action (in this case RIGHT).

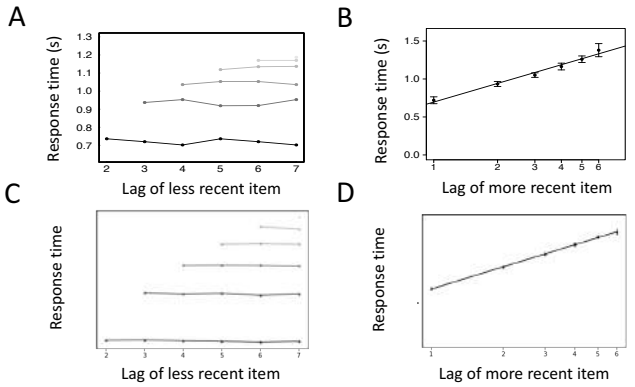

Figure 4: **The model captures behavioral results in the JOR task. A.** In JOR, median response time for correct responses depends strongly on the recency of the more recent probe but not the recency of the less recent probe. Shade of the line denotes lag of the more recent item, with the most recent item shown in black and the most distant item shown in the lightest shade of gray. (From Singh and Howard (2017).) **B.** In JOR, median response time varies sublinearly with recency (x-axis is log-spaced). **C.,D.** Results of the model corresponding to **A** and **B** respectively.

that subjects maintain working memory as a temporally organized, scannable representation. Moreover, the response time is a sublinear function of the lag (Figure 4B) (Singh & Howard, 2017), suggesting that the working memory representation is log-compressed, as proposed by earlier modeling work (Howard et al., 2015; Brown, Neath, & Chater, 2007).

In the model of JOR, the first action was to wait for the probe item to appear (Figure 3A). After that, the gain field over $\overset{*}{\tau}$ was set to scan the memory representation sequentially from more recent towards more distant past. At each step, the value found in the memory was used to drive two evidence accumulators, one independent accumulator for each probe item (Figure 3B). Once one of the two evidence accumulators reached a threshold, the program executed an appropriate action (left or right choice, Figure 3C). Variability in the response times was obtained by adding Gaussian noise to the evidence accumulation process.

Results in Figure 4C indicate that the model captures well the aspect of the data that suggests sequential scanning (Figure 4A): response time depends on the lag of the more recent probe item and does not depend on the lag of the more distant probe item. In addition, the model is consistent with the data regarding compression of the memory representation (Figure 4B - data, Figure 4D - model): the response time grows with the lag of the more recent item.

Old-new probe recognition: Global matching model using the memory timeline

Similarly to JOR, in old-new probe recognition task subjects are presented with a random list of stimuli one at a time. After the list is presented subjects are probed with a single probe that was or was not an item from the list. Subjects choose either *Old* or *New* to indicate their memory. The well-established behavioral results indicate that the response time

increases and accuracy decreases with increasing lag of the probe item (Figure 5A). In other words, if the probe item was further in the past (had larger lag) subjects will take longer to respond and their accuracy will be lower than if the probe was presented less far in the past. Models based on global matching, such as EBRW have managed to capture subjects accuracy and response times (Donkin & Nosofsky, 2012; Nosofsky, Little, Donkin, & Fific, 2011).

Our implementation of probe recognition was similar to JOR, but with several important differences. The main difference between the two tasks was in the way the memory was accessed. Unlike in the implementation of JOR where $G(\overset{*}{x})$ was a delta function resulting in serial scanning, in probe recognition task $G(\overset{*}{x})$ was uniform. This means that the entire memory representation was accessed simultaneously, rather than sequentially scanned. This type of memory access falls under the umbrella of global matching models which includes e.g. EBRW, SAM, Minerva and TODAM (Raaijmakers & Shiffrin, 1980; Murdock, 1982; Hintzman, 1988; Nosofsky et al., 2011).

Figure 5B shows model performance in probe recognition. The two qualitative features observed in the data were captured with the model: response time increased and accuracy decreased as the lag of the probe item increased. Overall, the result of the model resembles the data reported by Donkin and Nosofsky (2012).

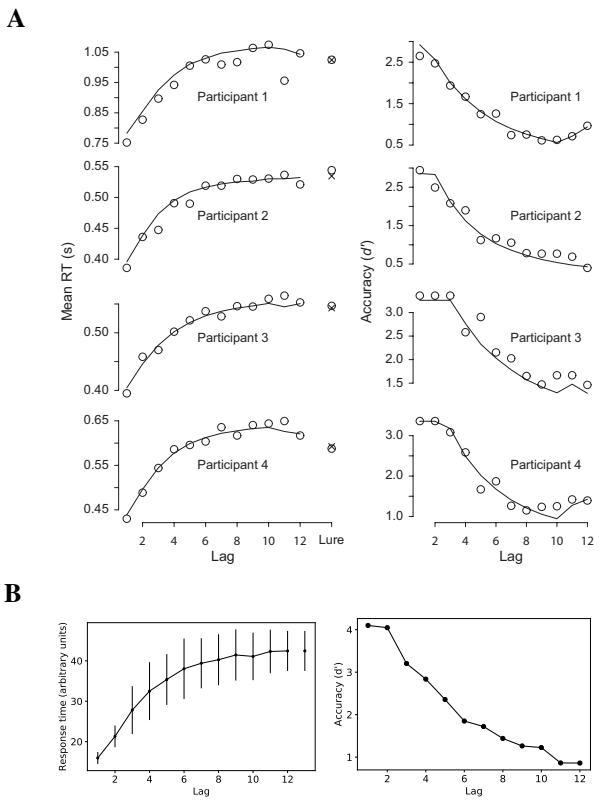

Figure 5: **The model captures behavioral results in the probe recognition task. A.** In probe recognition response times increase and accuracy decreases as the lag of a probe item increases. Circles correspond to data points and solid line is a fit obtained with EBRW model. Taken from (Donkin & Nosofsky, 2012). **B.** Results of the model capture qualitative properties of the data. Response times are shown with standard deviation.

Delayed-Match-to-Sample: Comparing model neurons to empirical evidence for conjunctive coding of what and when

In DMS subjects are presented with a sample stimulus followed by a delay interval, followed by a test stimulus. The action that subjects need to take (e.g. pressing a left or right button) depends on whether the two stimuli were the same or different. We modeled the task with the same components as the JOR task. The only differences were in 1) how the probe item was set (in DMS the second stimulus is by construction the probe, while in JOR the probe is marked by presenting two stimuli at the same time) and 2) what parts of the working memory were gated to the evidence accumulator (in DMS one accumulator accumulated evidence for presence of the probe item in the memory and the other accumulator accumulated evidence that any other item was found in the memory, while in JOR each of the two probe items had its own evidence accumulator). While simple in terms of behavior, DMS task is often done on animals while recording activity of individual neurons. Neural recordings during the delay period of this task show evidence for existence of stimulus-selective sequentially activated cells (Tiganj et al., 2018) that correspond well to the neural activity produced by the sequential memory used here (Figure 2B).

Conclusions

Here we provided an architecture that is based on realistic neural data and that can account for non-trivial behavior. In particular, the behavioral results of JOR task are consistent with the hypothesis that the subjects are scanning along a compressed timeline. The same architecture was used to model DMS task, resulting in neural representation of working memory that closely corresponds to the neural data. Finally, we have also captured qualitative properties observed in probe recognition task by applying an approach analogous to global matching models, but implemented on a neural-level.

Critically, implementation of all three tasks uses the same neural hardware, differing only in the initial condition of the controller. This work is complementary with ongoing efforts of building cognitive architectures such as ACT-R (Anderson, Matessa, & Lebiere, 1997) and SOAR (Laird, 2012). The distinction of the present work is in its attempt to build such architecture with neuron-like units, similar to Spaun (Eliasmith et al., 2012), but with a different type of neural representation. The present work commits to a specific type of representation: variables are represented as supported dimensions via neural tuning curves, tuned to a particular amount of elapsed time, accumulated evidence or a position in a sequence.

Semantic influences on episodic memory distortions

Abstract

Semantic knowledge can facilitate or distort new memories, depending on their alignment. We aimed to quantify distortions in memory by examining how category membership biases new encoding. Across two experiments, participants encoded and retrieved image-location associations on a 2D grid. The locations of images were manipulated so that most members of a category (e.g. birds) were clustered near each other, but some were in random locations. Memory for an item's location was more precise when it was near members of the same category. Furthermore, typical category members' retrieved locations were more biased towards their semantic neighbors, relative to atypical members. This demonstrates that the organization of semantic knowledge can explain bias in new memories.

Keywords: episodic memory; semantic memory; category membership; typicality; distortion

Introduction

Episodic and semantic memory are commonly studied as distinct cognitive phenomena, the former defined as memory for 'personal experiences and their temporal relations' and the latter as memory for the 'meaning of words, concepts, and classification of concepts' (Tulving, 1972). While this distinction has led to important characterizations of both memory systems, it also oversimplifies the complexity in memories that comprise both episodic and semantic elements. In other words, it neglects the critical notion that new experiences are made up of re-combinations of objects, places, and people for which we already have semantic knowledge. We aimed to probe interactions between the two systems by quantifying how semantic knowledge distorts new episodic learning.

Research on schemas, a type of semantic knowledge defined as a structure of associated information (Bartlett, 1932; Ghosh & Gilboa, 2014), sheds some light on how prior knowledge influences new episodic memory formation. The benefit of prior knowledge for episodic memory is widely documented (Bransford & Johnson, 1972; Alba & Hasher, 1983). Similarly, the presence of prior knowledge accelerates the integration of novel words into existing memory networks (Coutanche & Thompson-Schill, 2014). However, new encoding can also be biased by prior knowledge, resulting in false memories or confabulation (Warren, Jones, Duff, & Tranel, 2014; Webb, Turney, & Dennis, 2016). Taken together, these findings suggest that whether prior knowledge helps or hinders encoding depends on the match between the old and new information.

One weakness of this work is that the operationalization of prior knowledge often ignores its rich, hierarchical structure (Collins & Loftus, 1975). In such a structure, concepts vary in the similarity of their features, giving rise to categories. Typical category members are defined as items that share the greatest number of features with other members, and thus are the best examples of that category (Rosch, Mervis, Gray, Johnson, & Boyes-Braem, 1976). As a result, typical items are thought to be more strongly associated with category neighbors, relative to atypical items. The consequences of these strong associations are well documented: typical items are more quickly categorized, more efficiently recognized, and less resistant to disruption by brain damage (Patterson, 2007). Furthermore, the features of typical items are more often attributed to category neighbors (Osherson, Smith, Wilkie, López, & Shafir, 1990; Rips, 1975). As an example, if a typical item, rather than an atypical item, is accompanied by a shock, participants are more likely to anticipate shocks with other category members (Dunsmoor & Murphy, 2014). Examining how new memories are formed in the context of this structure may lead to a better understanding of the interactions between episodic and semantic memory.

One promising approach to examining such interactions is by considering retrieval as a construction of different sources of information. According to this view, retrieval is not a veridical recapitulation of past events, but instead an imperfect recombination of event-specific details and other knowledge (Addis, Pan, Vu, Laiser, & Schacter, 2009). Because episodic memories are often noisy and incomplete, successful remembering is thought to combine these partial representations with knowledge from prior experiences (Huttenlocher, Hedges, & Vevea, 2000). Integrating prior knowledge with episodic memories can thus be thought of as a way to improve the 'signal' of a memory. Yet, it also introduces systematic errors if there are discrepancies between a new memory and prior knowledge. For example, exposure to semantically related words (e.g., sour, candy, sugar) often produces a false memory for a non-studied word (sweet; Roediger & McDermott, 1995). Such errors are also captured with continuous measures of bias; for example, memory for the color of shapes is biased towards canonical hues (Persaud & Hemmer, 2014), and estimates of the size of fruits and vegetables are biased by both their superordinate and subordinate mean sizes (Hemmer & Steyvers, 2009). However, it is unknown whether other

properties of semantic knowledge, like category typicality, exert similar distortions on new encoding.

We aimed to quantify distortions in episodic memories due to prior knowledge by examining how differences in category typicality bias new memories for item-location associations. In two experiments conducted on Amazon Mechanical Turk (AMT), participants encoded and retrieved image-location associations on a 2D grid. Critically, the locations associated with each image were determined by semantic relatedness ratings, such that most members of the same category (e.g. birds) were located near each other, but some typical and atypical members were located elsewhere. With this design, participants could learn that items from a certain category tended to be located in a certain area as they encoded item-specific locations.

We used a continuous retrieval measure to disentangle biases driven by semantic knowledge from errors due to forgetting. Critically, these two measures varied independently such that memory for an item could be biased towards or away from category neighbors regardless of its precision. In both experiments, we used these measures to test two predictions. First, we predicted more precise memory for items located near category members, relative to those located farther away, which would replicate past observations that new memories can benefit from prior knowledge if they are aligned. Second, for those typical and atypical items located far from category neighbors, we predicted that their *direction* of error would be different, such that retrieval of typical items would be more biased towards category neighbors relative to atypical items. Such a bias would reflect stronger associations between typical category members and their category neighbors. We did not have strong predictions about precision by typicality, except for the critical notion that any observed differences in bias would be independent of differences in precision.

Experiment 1: Stimulus Development

In the first experiment, we developed a data-driven approach to create item-location associations for the memory task. Specifically, we used semantic relatedness ratings from a separate set of participants to define the images' locations and sort them according to their typicality.

Method

Participants 24 participants (23 – 49 years old, 9 female) completed semantic relatedness judgments. The University of Pennsylvania Institutional Review Board (IRB) approved all consent procedures.

Materials Stimuli comprised 70 100x100-pixel color images on white backgrounds (35 animals, 35 objects). Based on pilot data, we selected images with equivalently high recognition across these two superordinate categories.

Odd-Man-Out Procedure On each trial, participants were presented with three images from a superordinate category and were instructed to click on the image that was least similar to the other two. Once an image was chosen, the images faded away and three new images were displayed after a 200-ms interval. Participants were encouraged to respond in 2 – 4 seconds. They were instructed to make their decisions based on many factors, like whether animals belonged to the same family or shared similar habitats, and whether objects served a similar purpose or tended to be in similar locations. Based on prior piloting, participants completed a random sample of 2,620 combinations per superordinate category, of the 6,545 possible combinations (choose 3 of 35). The trials were divided into 20 separate batches, expected to take 12 - 15 minutes each, and participants were given 1 week to complete them. Of the 35 invited to participate, 24 completed it and 3 were excluded.

The responses were used to create similarity matrices for each participant and superordinate category. Starting with a 35 x 35 matrix of zeros, for every trial on which an odd image was chosen, the value for the other two increased by 1. The summed values across all trials were then divided by the number of times the two images appeared in the same trial. Cells in the matrix thus ranged from 0 to 1, with higher values corresponding to greater similarity between the items. We computed split-half correlations as a test-retest reliability measure for each participant (group mean r = .60, SD = .24). The reliability of the 3 excluded participants was >3 SD lower than the group mean (all r's < .04). Matrices from the 21 remaining participants were averaged into a separate matrix for animals and for objects.

Image-Location Associations Each image was paired with a spatial location on a white 600x1200-pixel rectangle with gray gridlines forming a 50x50-pixel grid. The locations were determined by applying multidimensional scaling (MDS) to the similarity matrices from the odd-man-out procedure. Each matrix was projected into two dimensions, where the x and y coordinates of an item determined its location on the grid. Thus the locations of items represented participants' 2D organization of animals and objects.

We then used k-means clustering of these projections to determine the categories within animals and objects that were captured in the 2D locations. The animal and object locations were separately entered into 10 k-means clustering algorithms with 1 to 10 clusters. The optimal number of clusters was chosen by plotting the sum of within-cluster squared error as a function of the number of clusters used in the algorithm. The 'bend' in this elbow plot signifies the fewest number of clusters that minimize the distance between items in the same cluster. This procedure revealed 3 animal categories (birds, mammals, and sea creatures) and 3 object categories (kitchen, tools/personal care, and office). These clusters were used to identify typical and atypical category members. The center of each cluster was defined as the average x and y coordinate of its constituent items. Then the items were sorted by their distance to its center. The closest 20% were labeled 'typical' and the furthest 20% 'atypical'.

Experiment 1: Memory Task

The item-location associations developed in the prior section were used in an episodic memory task. We probed whether the precision of participants' location memory was related to the consistency between an item's spatial location and the locations of its category neighbors, and whether bias was influenced by its category typicality.

Method

Participants There were 25 participants in the experimental group (21 - 65 years old, 9 female) and 35 in the control group (20 - 61 years old, 16 female). The University of Pennsylvania IRB approved all consent procedures.

Materials See Stimulus Development section.

Image-Location Associations The locations paired from each image were derived from semantic relatedness judgments such that category neighbors were clustered together (see Stimulus Development). The locations of the typical and atypical items were manipulated to be inconsistent with the semantic relatedness ratings. Specifically, they were randomly assigned locations closer to one of the other two cluster centers from the same superordinate category (Figure 1A). In total, 42 images were associated with locations consistent with the ratings ('consistent'), and 28 were associated with a random location ('inconsistent). Of the inconsistent items, 14 were typical and 14 were atypical category members. The projections for animals and objects were arranged side-by-side, randomized for each participant (Figure 3A).

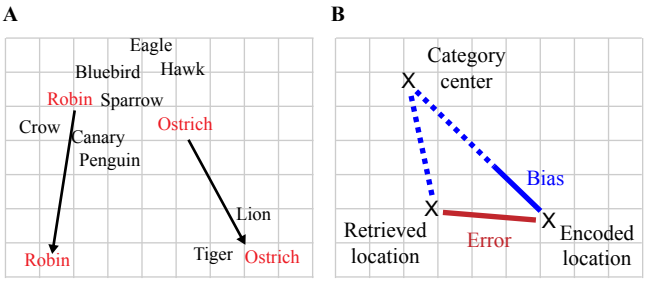

Figure 1 (A) Consistency and typicality for 'birds'. Black indicates 'consistent' and red indicates 'inconsistent' items. Inconsistent items were either typical or atypical category members. (B) Retrieval measures for an item biased towards its category neighbors. Solid red line indicates error. Solid blue line indicates bias.

In the control group, all image-location pairings were randomly shuffled within superordinate category. This group viewed the same locations as the experimental group, but the images assigned to the locations did not cluster by category. In other words, the locations that had originally been associated with (in)consistent or (a)typical images could be associated with any image in that superordinate category, rendering these conditions meaningless.

Memory Procedure The memory experiment comprised an encoding phase and a retrieval phase, separated by a 5-minute break. On each encoding trial, participants viewed an image beneath the grid and a red dot corresponding to that image's location. They were instructed to drag the image onto the dot, click the mouse button once it was positioned over the dot, and memorize its location for a later memory test. Images were presented three times, in three rounds of encoding separated by 1-min breaks. The retrieval task was identical to encoding, but with no dot. Participants were instructed to drag the image to its associated location. The trial order was randomized[1].

Statistical Analyses Two dependent measures were established to quantify error and bias for each image (Figure 1B). Error was defined as the distance between an image's encoded and retrieved location, where greater values indicate less precision. Bias was defined as the relative difference in distance between an item's cluster center and its encoded versus retrieved location: (encoded – center) – (retrieved – center). Thus, values > 0 indicate that retrieval was biased *towards* the cluster center, and < 0 indicate bias *away* from the cluster center. Both measures were averaged across trials by consistency with the relatedness ratings (consistent vs. inconsistent) and by typicality (atypical vs. typical) and entered into two-tailed paired t-tests and repeated measures ANOVAs.

Results

Error We computed a group (experimental, control) x consistency (consistent, inconsistent) ANOVA to examine if memory precision was modulated by the consistency of item locations with those of other category members. This revealed a main effect of group, $F_{(1,58)} = 7.04$, $p = .01$, and consistency, $F_{(1,58)} = 8.46$, $p = .005$. These effects were qualified by an interaction, $F_{(1,58)} = 5.82$, $p = .02$ (Figure 2A), driven by less error for consistent items relative to inconsistent items in the experimental group, $t_{(24)} = 4.11$, $p < .001$, but not the control group, $t_{(34)} = 0.63$, $p = .54$.

We next asked whether, among the inconsistent items, there were differences in precision by typicality. A group x typicality (typical, atypical) ANOVA revealed a main effect of group, $F_{(1,58)} = 4.16$, $p = .046$, but no reliable effect of, or interaction with, typicality (both F's < 2.03, p's > 0.16).

Bias We next asked whether the direction of error differed for typical versus atypical category members. We computed a group x typicality ANOVA amongst the inconsistent items, with bias as the dependent variable (Figure 2B). We found a main effect of group, $F_{(1,58)} = 9.89$, $p = .003$ and typicality, $F_{(1,58)} = 5.46$, $p = .02$, and a group x typicality

[1]Due to a bug, the trial order and locations of the inconsistent items were randomized identically in all participants. Findings from this cohort are reported in this proceeding. After finding the error, we ran a replication experiment (N = 35) where both were randomized individually. All findings were successfully replicated.

interaction, $F_{(1,58)} = 14.12$, $p < .001$. This interaction was driven by greater bias towards category neighbors for typical items relative to atypical items in the experimental group, $t_{(24)} = 6.76$, $p < .001$, but not the control group, $t_{(34)} = 0.55$, $p = .59$.

As predicted, typical items were retrieved as closer to their category neighbors relative to atypical items. It could be the case, however, that this bias was driven by an unrelated difference in how typical and atypical items' locations were retrieved – one possibility is that typical items were retrieved more centrally in the display. To test this possibility, we computed each item's average bias towards the two other clusters in the superordinate category and entered it into a group x typicality ANOVA. There was no main effect of or interaction with typicality (both F's < .34, both p's > .56). This suggests that retrieval of typical items was specifically biased towards category neighbors.

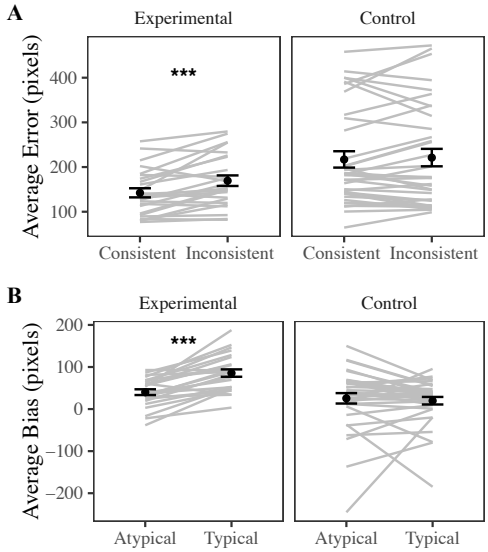

Figure 2 Experiment 1 results. (A) Average error by consistency. (B) Average bias by category typicality. Condition labels in the control group indicate the locations to which (in)consistent and (a)typical items had been assigned in the experimental group; these locations were randomly assigned images in the control group. Lines indicate participants. Error bars signify standard error of the mean (SEM). *** $p < .001$.

Discussion

We found that participants' retrieval was more precise for items located near category neighbors, replicating prior observations of enhancements in memories that are consistent with prior knowledge. Furthermore, of the items that were located far from category neighbors, typical items were more biased towards their category neighbors relative to atypical items, despite no reliable differences in precision. Together, these results suggest that differences in typicality govern the extent of distortion in new memories.

Experiment 2: Stimulus Development

In Experiment 1, we developed data-driven methods to sort items by category typicality and assign them to spatial locations based on their semantic relatedness. We next developed a conceptual replication, using different stimuli, to investigate whether we would observe the same effects with more standard procedures to define category membership and typicality.

Method

Participants 216 participants (27 per category) completed an item ranking procedure. The University of Pennsylvania IRB approved all consent procedures. Demographics were not collected due to experimenter error.

Materials Stimuli comprised 160 100x100-pixel color images on white backgrounds (80 animals, 80 objects). These superordinate categories were divided into 4 categories with 20 images each: birds, insects, sea creatures, mammals, clothes, furniture, kitchen, and office. The categories were selected from prior studies investigating categorization norms (Deyne et al., 2008; Uyeda & Mandler, 1980).

Ranking Procedure We modified a validated item ranking task (Djalal, Ameel, & Storms, 2016) to sort category members by their typicality. Extensive instructions with examples were given to ensure participants understood the sorting procedure. For each category, participants viewed 20 images in a box labeled 'Sort these'. Underneath, there were two empty boxes labeled 'Typical' and 'Atypical'. Participants were instructed to drag 10 images into each box. They were allowed to drag images freely across the three boxes in any order. This resulted in a row of 10 images per box. Then, within each box, participants sorted the 10 images on a scale ranging from most (a)typical to less (a)typical. Arrows and labels in the two boxes indicated the direction that images were to be sorted. The resulting spatial positions in the two boxes were concatenated into a ranked list of category typicality and averaged across participants.

Experiment 2: Memory Task

Results from the ranking task were used in Experiment 2 to define category membership and typicality for a memory task identical to that of Experiment 1. We also aimed to rule out the possibility that memory was more precise for consistent items because they were more densely clustered, increasing the likelihood of guessing the correct location.

Method

Participants 35 participants were in the experimental group (22 - 70 years old, 14 female) and 35 in the control group (24 - 72 years old, 16 female). The University of Pennsylvania IRB approved all consent procedures.

Materials See Stimulus Development section.

Image-Location Associations To generate items' locations, the memory grid was divided into halves with animals on one side and objects on the other, randomized across participants. Each side was divided into four quadrants. Within each quadrant, items from one of the four categories were spaced roughly uniformly apart, resulting in an even distribution of items across the grid (Figure 3B).

As in Experiment 1, some items were assigned locations away from category neighbors. The 15% most typical and 15% most atypical items were swapped across categories, where each quadrant had an equal number of typical and atypical items from the other three quadrants from the same superordinate category. In total, 112 images were located in the quadrant consistent with their category ('consistent'), and 48 in a different quadrant ('inconsistent). Of the 48 inconsistent items, 24 were typical and 24 were atypical category members. In the control group, images were randomly assigned to locations within each superordinate category, identically to the procedure in Experiment 1.

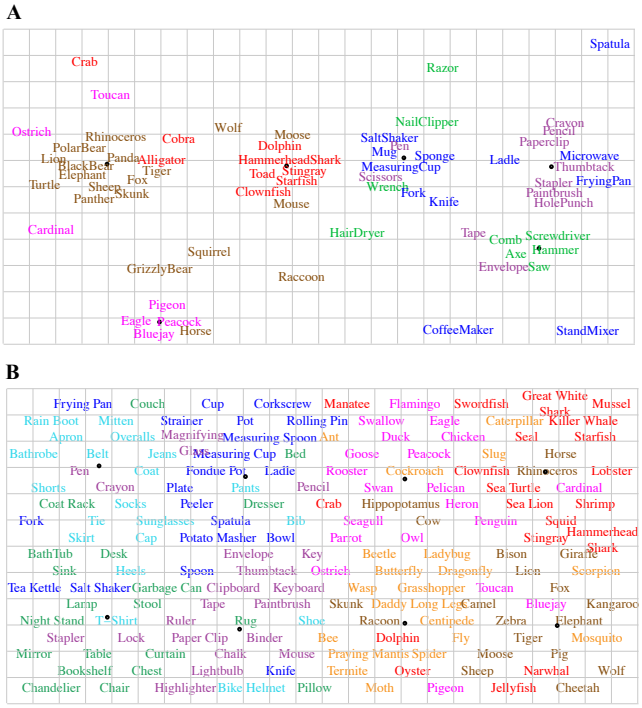

Figure 3 Example memory displays for Experiment 1 (A) and Experiment 2 (B). Each word represents the location of its corresponding image. Colors indicate categories. Black dots indicate a category's cluster center. Each image-location association was presented and tested one at a time.

Memory Procedure The timing and instructions were identical to those of Experiment 1, with an additional confidence measure that will not be discussed.

Statistical Analyses The analyses were identical to those in Experiment 1.

Results

Error We computed a group (experimental, control) x consistency (consistent, inconsistent) ANOVA and found a main effect of consistency, $F_{(1,68)} = 38.63$, $p < .001$, but not of group, $F_{(1,68)} = 0.01$, $p = .91$. Critically, there was also a group x consistency interaction, $F_{(1,68)} = 35.33$, $p < .001$ (Figure 4A). This interaction was driven by less error for consistent items relative to inconsistent items in the experimental group, $t_{(34)} = 7.35$, $p < .001$, but not the control group, $t_{(34)} = 0.24$, $p = .81$. As in Experiment 1, memory precision was modulated by the consistency of an item's location with those of its category neighbors.

We next asked whether, among the inconsistent items, there were differences in error by typicality. A group x typicality (typical, atypical) ANOVA revealed no main effect of group, $F_{(1,68)} = 1.24$, $p = .27$. Interestingly, in contrast to Experiment 1, we found a main effect of typicality, $F_{(1,68)} = 9.65$, $p = .003$, qualified by a group x typicality interaction, $F_{(1,68)} = 5.77$, $p = 0.02$. This interaction was driven by increased error for typical items relative to atypical items in the experimental group, $t_{(34)} = 3.43$, $p = .002$, but not the control group, $t_{(34)} = 0.59$, $p = .56$.

Bias We next focused on differences in bias by typicality and computed a group x typicality ANOVA amongst inconsistent items. We found no reliable main effect of group, $F_{(1,68)} = 1.47$, $p = .23$ and a trending effect of typicality, $F_{(1,68)} = 3.10$, $p = .08$. There was a reliable group x typicality interaction, $F_{(1,68)} = 5.91$, $p = .02$ (Figure 4B). This interaction was driven by greater bias for typical items relative to atypical items in the experimental group, $t_{(34)} = 2.56$, $p = .01$, but not the control group, $t_{(34)} = 0.58$, $p = .56$, replicating the observed difference in bias by typicality in Experiment 1.

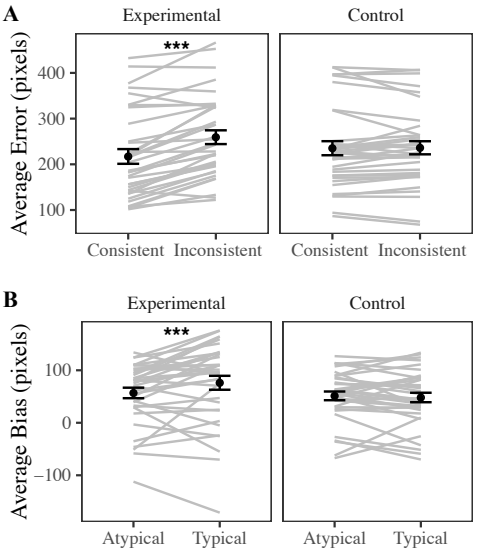

Figure 4 Experiment 2 results. (A) Average error by consistency. (B) Average bias by category typicality. Lines indicate participants. Error bars signify SEM. *** $p < .001$.

General Discussion

Across two experiments, we found that manipulating the match with prior semantic knowledge – by leveraging differences in category typicality – can influence the precision and distortion of new memories. Participants were able to learn associations between an image's category membership and its location on a grid, and this knowledge enhanced their memory of the locations of specific items. Precision of this memory was greater if the items clustered near others from the same category. For items that were located away from category neighbors, participants made systematic errors: typical category members were retrieved closer to category neighbors than atypical category members. These results were observed in two experiments despite differences in the number and type of categories, method of determining typicality, and mapping between category membership and spatial location.

Our findings that consistent items were more precise than inconsistent items (in both experiments), and that precision was greater in the experimental group (in Experiment 1 only), are consistent with a large and diverse body of work showing that prior knowledge facilitates memory for related stimuli (Alba & Hasher, 1983). Our findings extend these results by showing that prior knowledge can improve encoding of new, unrelated features of an item. In our experiment, participants mapped items onto spatial locations on a grid. These locations were not intrinsically related to the items (e.g., nothing about the concept of a 'spatula' implies that it should be located on the top right corner of a grid). However, by associating these locations with the semantic organization of the items, participants treated location as a new 'feature' of items that was explained well by their category membership. Thus, prior knowledge can help to organize the encoding of unrelated contextual details.

When locations did not match expectations, participants' memory was prone to systematic biases. In both experiments, retrieval of typical category members was more biased towards category neighbors relative to retrieval of the atypical category members. While it is well known that memory can be easily distorted (Loftus & Palmer, 1974; Roediger & McDermott, 1995), much of this past work is focused on discrete differences in memory retrieval (e.g. was a word recalled or not). Using continuous reports allows retrieval to be broken down into item-specific error and systematic influences of a particular category or structure (Huttenlocher, Hedges, & Duncan, 1991; Hemmer & Steyvers, 2009; Persaud & Hemmer, 2014). This prior work also demonstrates that new encoding can be biased towards similar stimuli, for example, that memory for the color of an object is biased towards a canonical color. We extended this work by showing that semantic knowledge can exert a stronger or weaker influence on new encoding depending on semantic properties like the typicality of category members, and that such bias can operate independently of memory precision.

What can these biases tell us about how category members are organized; specifically, why is memory for typical members more biased towards neighbors? One possibility is that typical items are more strongly 'pulled' by neighboring items on account of their stronger associations. This interpretation would mirror observations that participants are more likely to cluster the recall of typical items relative to atypical items (Bousfield, Cohen, & Whitmarsh, 1958). Alternatively, because typical items are more similar to other category members, it may be easier to confuse their locations with other item locations that happen to be near the cluster center. This explanation is not specific to category membership but could be applied to any set of memoranda that vary in similarity. Yet another possibility is that because typical items are the closest match to their category, they are more efficiently encoded, but at a cost to in-depth processing of their novel details (Sweegers, Coleman, van Poppel, Cox, & Talamini, 2015) – like their associated location. As we cannot adjudicate between these interpretations with the present design, we have developed follow-up experiments to examine these alternatives.

In summary, we have presented an investigation of the biases that semantic knowledge exerts on episodic encoding. This work demonstrates that semantic knowledge and episodic memory are closely intertwined and offers an opportunity to better understand the interactions between the two systems.

Abstract

It is well-known that in free recall participants tend to recall words presented close together in time in sequence, reflecting a form of temporal binding in memory. This contiguity effect is robust, having been observed across many different experimental manipulations. In order to explore a potential boundary on the contiguity effect, participants performed a free recall task in which items were presented at rates ranging from 2 Hz to 8 Hz. Participants were still able to recall items even at the fastest presentation rate, though accuracy decreased. Importantly, the contiguity effect flattened as presentation rates increased. These findings illuminate possible constraints on the temporal encoding of episodic memories.

Keywords: Free recall, lag-CRP, contiguity effect

Introduction

Cognitive neuroscientists have hypothesized that the successful retrieval of an episodic memory is accompanied by a "jump back in time," a recovery of the previous memory's spatiotemporal context (Tulving, 1983). In free recall studies, this recovery manifests as the contiguity effect, wherein following the successful recall of an item, the next item to be recalled is more likely to be a close temporal neighbor than a more distant one (Kahana, 1996). This distance is measured as lag, a directed distance between items in a study list. For example, in the list "absence, hollow, pupil, river, darling", the lag from absence to river is $+3$, while the lag from darling to pupil is -2. In free recall studies the contiguity effect is typically asymmetric, such that forward transitions are more likely to take place than backward transitions of the same distance. This effect is robust, appearing across a variety of methodological manipulations (Kahana, 2012; Healey & Kahana, 2014). For instance, the contiguity effect is observed with more or less the same properties for lists of different modalities (Kahana, 1996), when rehearsal is discouraged (Howard & Kahana, 1999), and when words are widely separated in time (Howard, Youker, & Venkatadass, 2008; Unsworth, 2008). Healey and Kahana (2014) noted that the contiguity effect was observed for every individual participant in a free recall study of 126 subjects. Thus far, dramatic effects on the contiguity effect in free recall have primarily been observed comparing patient populations; older adults and memory disordered individuals show impaired contiguity effects (Kahana, Howard, Zaromb, & Wingfield, 2002; Palombo, Di Lascio, Howard, & Verfaellie, 2019).

Beyond the contiguity effect, free recall contains many other well-explored patterns of behavior. Individuals exhibit a strong recency effect during immediate free recall tests (Glanzer & Cunitz, 1966). In addition, participants exhibit a primacy effect such that items at the beginning of a studied list are more likely to be recalled (B. B. Murdock, 1962). Both primacy and recency effects are observed in the initiation of free recall, and are both also robustly observed in the probability of first recall, a measure of the serial position curve considering only the first recall (Hogan, 1975; Laming, 1999). The relative strength of primacy and recency is not constant however (B. B. Murdock, 1962). For example, Davelaar, Goshen-Gottstein, Ashkenazi, Haarmann, and Usher (2005) found that presentation rates affect the relative strength of primacy and recency, with primacy becoming more prevalent as the presentation rate is increased.

The ubiquity of the contiguity effect in free recall presents something of a challenge for models of memory encoding—if nothing affects the contiguity effect, it makes it more difficult to understand how it comes about. Conversely, if we knew boundary conditions on the contiguity effect it would perhaps shed light on the processes supporting the binding of experiences presented close together in time. In this study we explore the effects of increasing presentation rates on the contiguity effect. If the contiguity effect is disrupted at a particular rate, that suggests the time scale over which the encoding processes necessary for temporal binding take place.

Considerations from the ERP literature and rapid serial visual presentation (RSVP) literature inform the time scale over which contiguity might be disrupted. A to-be-remembered stimulus typically evokes a P300 waveform approximately 500 ms in duration that is thought to represent the updating of memory representations, even when the stimulus duration itself is on the order of 2 seconds (Donchin, 1981). At presentation rates approaching 10 Hz, there is evidence that individual list items are no longer processed as discrete items, and instead are merged into a single extended cognitive event. For example, individual items in 10 Hz lists receive very low hit rates in an immediate recognition test even

when the stimuli are never-before-seen natural images (Potter & Levy, 1969). This poor performance is in stark contrast to the excellent recognition memory for long series of images at slower rates of presentation (Standing, 1973; Brady, Konkle, Alvarez, & Oliva, 2008). However despite this lack of memorability, it is also clear that each item in a 10 Hz stream is processed to some degree, since it is possible to detect specific target items with high probability (Potter, 1976). If the processing of individual items in a list undergoes a qualitative change as the presentation rate is increased to the point at which the representations blend together, then the CRP, primacy effect, and recency effect may be altered. For example, the CRP effect may depend on the ability to place individual items into a discrete temporal representation, and thus it may disappear with faster presentation rates. The probability of first recall could also be altered, since a long-running stream of rapidly presented items imposes a sequential cost on subsequent items due to encoding interference from previous items (Wyble, Bowman, & Nieuwenstein, 2009).

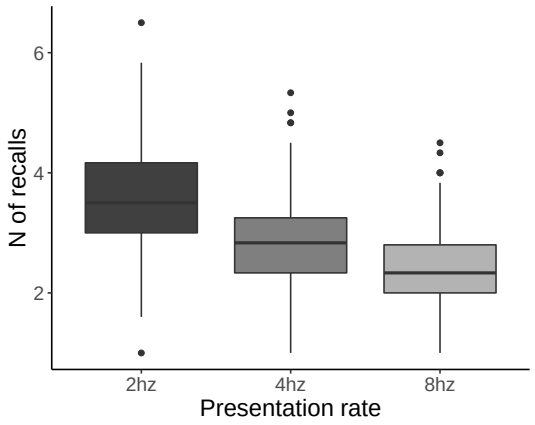

Figure 1: A boxplot of median number of words recalled per trial across participants and presentation rates, with interquartile range, 95% confidence intervals and outliers. Participants recalled fewer words as presentation rate increased.

Methods

Participants

Three hundred and thirty undergraduates from Syracuse University participated in this study. Participants were excluded if they failed to recall a correct word in at least one trial ($n = 15$), and if they did not perform all three conditions ($n = 7$). Data from 308 participants were used in subsequent analyses.

Procedure

Participants took part in 18 trials. Each trial consisted of 20 words from the Toronto Noun Pool (Friendly, Franklin, Hoffman, & Rubin, 1982). Words were visually displayed at three presentations rates: 2 Hz, 4 Hz, and 8 Hz. Participants completed six trials in each condition. Trial order was randomized. Before the start of a trial, participants viewed a bar that discretely rotated at the same rate that words would be presented to help orient them to the upcoming trial (e.g., before a 2 Hz trial the bar would move twice every second). Following the presentation of the list, participants were prompted to verbally recall as many words as possible from the list. Responses were recorded and later parsed using a semi-automatic speech parsing algorithm.

Analysis

We first examined whether presentation rate affected the average number of valid recalls in a trial. This was done with a repeated measures ANOVA. Post-hoc paired permutations (5000 iterations) and Cohen's D effect sizes on mean recalls were then performed to determine significant differences. Serial position curves (SPC) were computed to show the overall probability of a word being recalled based on its position in the list for each participant. We examined whether the recency and primacy effects changed as a function of presentation rate. We performed a paired permutation test in order to predict the difference in the probability of recall for the first and last items in the list (i.e., probability for position 20 minus probability for position 1).

The probability of first recall (PFR) was calculated by dividing the number of times each serial position was recalled first by the total number of first recalls. We then averaged these probabilities across participants per condition. Finally, we calculated the conditional response probability (CRP) for each lag by dividing the number of correct recall transitions at a given lag by the total number of possible correct transitions at that lag. In order to control for serial position effects, which differed across conditions, we restricted the lag-CRP analysis to transitions within the middle of the list where probability of recall was approximately equal across presentation rates. In order to test for differences in the CRP at each lag across conditions, we performed a number of mixed-effects logistic regressions. We estimated the CRP as a function of the interaction between the following fixed-effects predictors: absolute lag, its direction (backwards or forwards from the previously recalled item), and presentation rate. We report Z- and T-scored coefficients for all mixed-effects models.

Results

To anticipate the results, memory performance was reduced at faster presentation rates. We replicated previous findings with respect to changes in the serial position curve at fast presentation rates. Critically, the contiguity effect, even measured at serial positions that avoided contributions from primacy and recency, was severely disrupted at fast presentation rates.

As Presentation Rate Increases, Fewer Words are Recalled

As shown in Figure 1, the total number of words recalled decreased as presentation rates increased (2 Hz: mean = 3.54, SD = 0.85; 4 Hz: mean = 2.86, SD = 0.662; 8 Hz: mean = 2.41, SD = 0.62; ANOVA: $F(2,614) = 309.2, p < 0.001$).

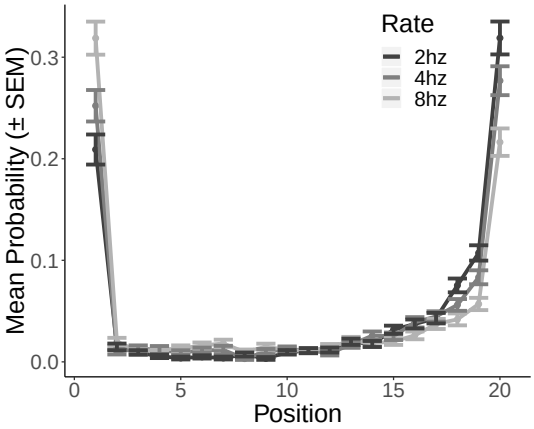

Figure 2: Probability of first recall. Participants tended to begin recall by naming an item from the beginning or end of the list. As presentation rates increased, the probability of initiating recall at the end of the list decreased, and the probability of initiating recall with at the beginning of the list increased.

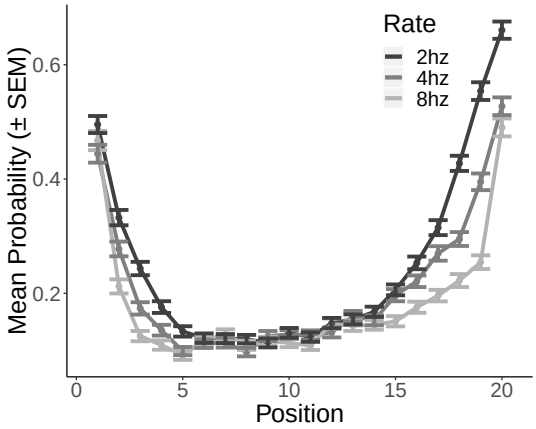

Figure 3: Probability of recall as a function of position in study list. Participants showed the highest level of performance for items at the beginning and end of the list. As presentation rate increased, participants showed a tendency to have a lower recency effect in comparison to the primacy effect.

Post-hoc paired permutations confirmed these results, showing that the presentation rate of 2 Hz yielded significantly higher number of recalls than 4 Hz ($p < 0.001$, Cohen's D $= 0.9$) and 8 Hz ($p < 0.001$, Cohen's D $= 1.5$), and that 4 Hz produced significantly more recalls than 8 Hz ($p < 0.001$, Cohen's D $= 0.69$). This result is consistent with previous findings that faster presentation rates decrease the number of words recalled in a free recall task (B. B. Murdock Jr, 1960).

Increasing Presentation Rates Increases the Primacy Effect and Decreases the Recency Effect

Participants were more likely to begin recall by reporting a word at the beginning or end of the list (Figure 2). As the presentation rate increased, participants initiated recall less frequently at the end of the list and more frequently at the beginning of the list. This was confirmed by paired permutation tests which indicated that the probability of beginning a recall with the first item in a studied list was greater at 8 Hz than both 4 Hz ($p < 0.001$, Cohen's $D = 0.24$) and 2 Hz ($p < 0.001$, Cohen's $D = 0.43$), and greater for 4 Hz than 2 Hz ($p < 0.001$, Cohen's $D = 0.18$). Conversely, the probability of first recalling the last item in a list was greater for 2 Hz than both 4 Hz ($p = 0.002$, Cohen's $D = 0.16$) and 8 Hz ($p < 0.001$, Cohen's $D = 0.40$), and higher for 4 Hz than 8 Hz ($p < 0.001$, Cohen's $D = 0.25$).

As shown in Figure 3, participants showed a higher rate of recalling words from the beginning and end of a list compared to words in the middle (Figure 3). Consistent with previous findings, increasing presentation rates resulted in lower recall for the final item in the list. This was as confirmed by a paired permutation test which found that the probability of recalling the last item in a list was greater for 2 Hz than both 4 Hz ($p < 0.001$, Cohen's $D = 0.50$) and 8 Hz ($p < 0.001$, Cohen's $D = 0.65$), and greater for 4 Hz than 8 Hz ($p = 0.01$, Cohen's $D = 0.15$). In contrast to the PFR, increasing presentation rates did not improve the overall probability of recalling the first item in a list. Rather, it was found that the probability of recalling the first item of a list was greater at 2 Hz than 4 Hz ($p = 0.008$, Cohen's $D = 0.17$), and otherwise there were no significant difference (all $p > 0.05$).

The Contiguity Effect Flattens At Higher Presentation Rates

Figure 4 shows the number of transitions between each serial position in each of the three conditions. The primacy and recency effects can be readily distinguished, as is the tendency to make remote transitions to the beginning of the list. The contiguity effect can be seen as a slightly darker shade along the diagonal; the forward asymmetry appears as a darker shade just above the diagonal. As expected, the contiguity effect appeared to decrease as presentation rate increased. Because primacy and recency effects are a confound in identifying the contiguity effect we calculated the lag-CRP using only transitions that came from items from the middle of the list (serial positions 7-13).

Figure 5 displays the average probability of transitioning from a recalled word to a word at a given lag (with lag 0 corresponding to the diagonal of the matrices in Figure 4), and appears to show a reduction in the temporal contiguity effect as the presentation rate increases. We performed a mixed effect logistic regression to estimate the probability of recall based on absolute lag for each presentation rate separately. This showed that distance from the previously-recalled item significantly decreased the probability of recall for 2 Hz ($z = -9.74, p < 0.001$) and 4 Hz ($z = -4.93, p < 0.001$), but not for 8 Hz ($z = -0.70, p = 0.48$). We then computed another mixed effects logistic regression to test the interaction between absolute lag, its direction (backwards or for-

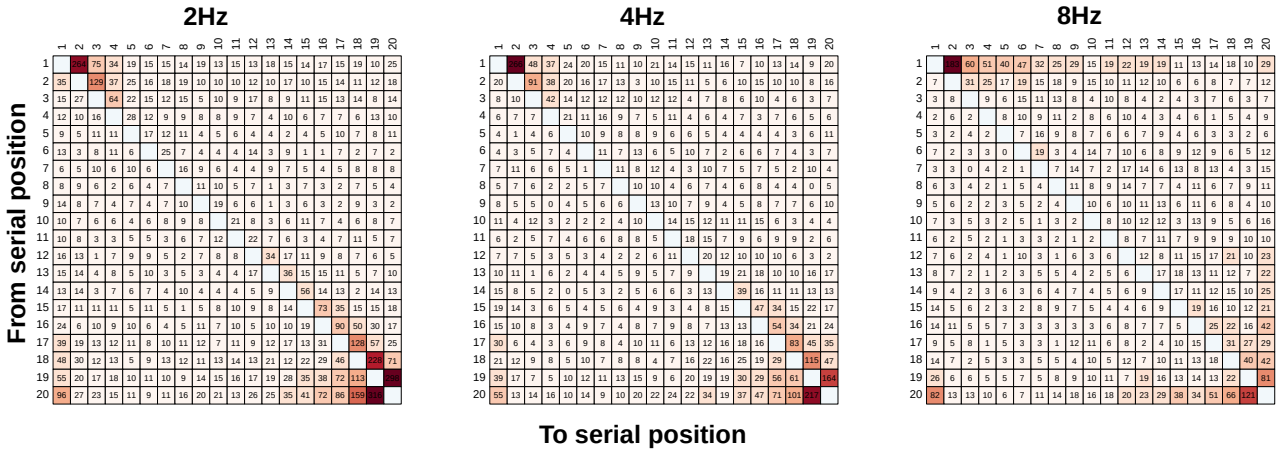

Figure 4: Matrices showing the number of total valid recall transitions between any two study list positions for each presentation rate separately. Colors and numbers correspond to the number of such recalls summed across participants. Transitions between extreme positions in study lists correspond to primacy and recency effects, which persist across rates. In contrast, the likelihood of recalling nearby items (i.e., close to the diagonal) appears to decrease as presentation rate increases.

wards from the previously recalled item), and the presentation rate. This analysis showed that transitions in the forward direction were more probable than backward transitions ($z = 4.18, p < 0.001$); transitions at more distant lags were less probable ($z = -4.83, p < 0.001$); probabilities were higher for 2 Hz compared to 4 Hz ($z = -2.28, p = 0.02$) and 8 Hz ($z = -3.63, p < 0.001$); the effect of absolute lag was stronger for forward transitions than backwards transitions ($z = -2.71, p < 0.01$), and the effect of lag was stronger for 2 Hz compared to 4 Hz ($z = 2.11, p = 0.03$) and 8 Hz ($z = 3.12, p < 0.01$). All other interactions showed no significant effects (all $p > 0.05$). These results show that increasing the presentation rate of studied words decreases the contiguity effect.

Discussion

Remembering past events is associated with a jump back in time, manifesting in a higher probability for temporally contiguous elements to be subsequently recalled. In this study, we investigated whether higher presentation rates would negatively impact the temporal contiguity effect. Many of our results were consistent with previous free recall studies. For instance, the average number of words recalled per list decreased as the presentation rate increased. Also, as the presentation rate increased, the recency effect was diminished. While the primacy effect increased in looking at the probability of first recall, there was not a clear effect on the overall probability of recalling the first item. The novel contribution of this paper is the finding that the temporal contiguity effect was disrupted by fast presentation rates, most notably in the 8 Hz condition. These findings suggest that encoding processes taking place on the order of 125 to 250 ms are im-

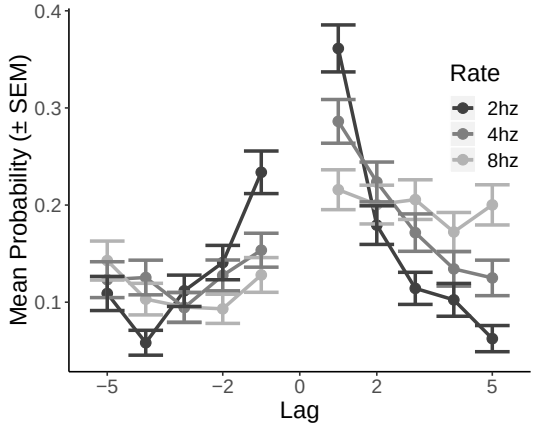

Figure 5: Lag-CRP for transitions restricted to serial positions 7-13 to avoid confounds with primacy and recency effects. As presentation rates increase, the contiguity effect weakens but remains asymmetric. At 8 Hz there is no positive evidence for a contiguity effect.

portant for binding items to their temporal context.

Our results pose questions about the relation of presentation rate and neural coding. Medial temporal lobe theta (3-8 Hz) is related to successful encoding in free recall, particularly when binding elements temporally (Nyhus & Curran, 2010; Sederberg, Kahana, Howard, Donner, & Madsen, 2003). In addition, Guderian, Schott, Richardson-Klavehn, and Düzel (2009) have shown that prediction of successfully-recalled items relies on theta frequency. While presentation rates of 2 Hz and 4 Hz are mostly contained within this frequency band, 8 Hz lies at the upper bound of human theta. It is possible that presening eight words per second outpaces encoding processes that depend on theta (Hasselmo, Bodelón, & Wyble, 2002), thus explaining why lag-CRPs become weaker for this presentation speed. Examination of encoding and retrieval periods using EEG and ECoG could help address this issue in the future.

The Disappearing "Advantages of Abstract Examples in Learning Math"

Dragan Trninic, Manu Kapur, Tanmay Sinha

ETH Zürich

Abstract

When introducing a novel mathematical idea, should we present learners with abstract or concrete examples of this idea? Considerable efforts have been made over the last decade to settle this question in favor of either abstract or concrete representations. We contribute to this discussion through a critical replication and extension of a well-known study in this area. Whereas the target article argues for the general superiority of abstract representations, we demonstrate that seemingly minor modifications of the study design indicate otherwise. Our results suggest that the previously reported "advantage of abstract examples" manifested not because abstract examples are advantageous in general, but because the earlier studies utilized concrete examples that are pedagogically suboptimal.

Keywords: mathematics education; examples; abstract versus concrete; transfer of learning; replication

Introduction

The use of abstract or concrete representations during mathematics and science instruction has been called a "longstanding controversy" (Fyfe, McNeil, Son, & Goldstone, 2014), and with good reason. Conceptually, we might argue that concrete representations have the advantage of connecting to students' existing knowledge. On the other hand, abstract representations have the advantage of eliminating potentially extraneous perceptual elements. But the elimination of these "extraneous" elements may also reduce the degree to which students can ground a particular representation in their prior knowledge. An advantage of abstract representations is thus at odds with an advantage of concrete representations. Which is better? A review of literature suggests that the answer depends on who asks the question: both pro-concrete and pro-abstract advocates are able to cite research where concrete or abstract representations are more, or less, effective (see, e.g., Koedinger, Alibali, & Nathan, 2008; Schalk, Saalbach, & Stern 2016, for examples).

In this paper, we contribute to the debate through a replication and extension of a well-known and unique study in this area, in particular the central experiment discussed in Kaminski, Sloutsky, and Heckler (2008), "The Advantage of Abstract Examples in Learning Math."

Compared to other papers on the topic, Kaminski et al. is unique in that it makes a universal argument in favor of abstract representations. In particular, the authors argue that "Instantiating an abstract concept in a concrete, contextualized manner… obstructs knowledge transfer. At the same time, learning a generic instantiation allows for transfer" (p. 455). In their study, abstract representations are *in general* superior to concrete representations.

Being a rare mathematics education article published in *Science*, the study caught the attention of not only other scholars, but found recognition in the popular media circuit as well. In a *New York Times* science column, Chang (2008) praised the article, criticized other education researchers for failing to conduct proper research (i.e., "randomized, controlled experiments") and made an even stronger recommendation: "let the apples, oranges and locomotives stay in the real world and… focus on abstract equations." Similar articles appeared in *Le Monde*, *De Standaard*, and elsewhere.

Various elements of the study were criticized over the next few years (see De Bock, Deprez, Dooren, Roelens, & Verschaffel, 2011, for a summary). These criticisms frequently took the form of conceptual disagreements published in math education journals. Despite these conceptual critiques, or perhaps because of them, Kaminski et al. remains steadily cited over the last decade.

The core of the present text is an empirical argument for a more critical re-interpretation of Kaminski et al. In our critical iteration of the experiment, we made relatively minor modifications to the design that nonetheless appear to have had a large impact on the results. We also extended the design to include additional transfer domains, including transfer to a formal mathematical context. The accelerated development of formal knowledge is, after all, a key motivation behind using examples in a math classroom. Our results do not support the hypothesized advantage of abstract examples; on the contrary, they favor the concrete example.

In order to contextualize our own critical replication and extension, we first discuss the central experiment reported by Kaminski et al. (2008), as well as De Bock et al.'s (2011) replication, the first to empirically challenge the original.

Kaminski, Sloutsky, and Heckler (2008)

Kaminski et al. reported a number of experiments drawn from Kaminski's (2006) dissertation. In this paper, we focus on the central experiment, as it forms the foundation of their argument. Here we summarize this experiment, and refer the

reader to Kaminski et al. online supplemental materials for a more extensive description.[1]

The experiment consisted of two phases. In the learning phase, undergraduate students (Ohio, USA) were introduced to a mathematical concept, that of an abstract group of order 3 via rules and examples of these rules. (Briefly, an abstract group of order 3 is a set of three elements and a binary operation that satisfies certain abstract rules—closure, associativity, identity, and inverse. As a consequence of these rules, all mathematical groups of order 3 are isomorphic to each other.) The manipulated variable in the study was whether students were introduced to this mathematical concept via more concrete or more abstract representations.

In the concrete representations condition, participants were provided with three icons of a cup—1/3 full, 2/3 full, and 3/3 full—and rules for combining these cups. In the abstract representations condition, participants were provided with three generic shapes—a flag, a square, and a circle—and rules for combining these shapes. Unbeknownst to the participants, adherence to these rules (in either condition) is mathematically equivalent to operating in an abstract group of order 3.

At the end of the learning phase, a multiple-choice test was administered. The second phase—transfer phase—began immediately after completing this test. There, participants were presented with new, seemingly arbitrary icons of real-world objects (e.g., a vase). Unlike in the learning phase, participants received no explicit training in the transfer domain; they were, however, told that these icons combine in ways structurally identical to the rules they just learned, and provided four examples. Then they answered a series of questions structurally identical to the ones they encountered in the learning phase. The training and the tests were accomplished individually via a computer terminal.

Table 1: Average scores (SD), as a percentage. **A** indicates that the learning phase was conducted with abstract instantiations, **C** with concrete ones.

Condition	Learning	Transfer
A (N = 18)	80 (13.7)	76 (21.6)
C (N = 20)	76 (17.8)	44 (16.0)

See Table 1, above, for a descriptive summary of their results. For now, we note that the "abstract representations" learning condition drastically outperformed the concrete condition on the transfer test: 76% to 44%. This difference is remarkable, all the more so as there were apparently no differences in learning scores or learning times.

[1] The experiments presented are easier to grasp visually. See http://www.sciencemag.org/cgi/content/full/320/5875/454/DC1

De Bock et al. (2011)

In their replication of Kaminski et al., De Bock et al. argued that the transfer domain used by Kaminski et al. is better interpreted as an "abstract transfer" (a terminology we will also use), because it satisfies Kaminski et al.'s own definition of an abstract instantiation. De Bock et al. made the reasonable prediction that, while learning with abstract instantiations may transfer better to an abstract domain, concrete instantiations may transfer better to a concrete domain.

To test this hypothesis, undergraduate students (Belgium) were randomly assigned to one of four conditions:

- AA, abstract learning then abstract transfer
- AC, abstract learning then concrete transfer
- CA, concrete learning then abstract transfer
- CC, concrete learning then concrete transfer.

That is, De Bock et al. kept the two-phase format of the original study, but expanded it to include a transfer to a more concrete domain.

For abstract and concrete learning, and abstract transfer, De Bock et al. used identical materials to Kaminski et al. For concrete transfer, they repurposed one of the alternate concrete learning conditions in the original study—that of a pizza divided in thirds.

Table 2: Average scores (SD), as a percentage. See text, above, for a description of the four conditions.

Condition	Learning	Transfer
AA (N = 23)	71 (16.3)	75 (15.8)
AC (N = 30)	64 (14.6)	73 (17.5)
CA (N = 28)	77 (12.1)	50 (17.9)
CC (N = 24)	76 (14.6)	84 (10.0)

See Table 2, above, for a descriptive summary. In brief, the results confirmed the original findings, as well as De Bock's own hypothesis. In their words: "if transfer to a new abstract domain is targeted, abstract instantiations are indeed more advantageous than concrete instantiations" (p. 120). They continue, "However… the opposite holds as well: Transfer to a new concrete domain is more enhanced by a concrete learning domain than by an abstract one" (p. 120). While not contradicting the original study, De Bock et al. demonstrated that there is more there than meets the eye.

Present Study

We questioned whether the observed "advantage of abstract examples" was due—at least in part—to certain pedagogically suboptimal aspects of the design, which we detail below. To the best of our knowledge, neither De Bock et al., nor anyone else using Kaminski et al.'s materials (e.g., Kaminski, Sloutsky, & Hecker, 2013; McNeil & Fyfe, 2012), attempted to *improve* the materials (as a teacher might). In addition to these pedagogical modification, we also extended the study beyond the original transfer task, as detailed below.

Design modifications and justifications

We identified two aspects of the original materials for improvement. First, the concrete representations used in the main study—those of 1/3, 2/3, and 3/3 liquid-filled cups[2]—caught our attention. The cover story for this instantiation involved combining two or more cups, and trying to determine the "left-over." For instance, 2/3 + 2/3 = 1/3 left-over. Why did Kaminski et al. use the full cup (3/3) as the identity element? The authors presumably used this scheme because it matches our everyday intuition that 1/3 + 2/3 = 3/3. There are at least two issues with this. First, it leads to unintuitive calculations, such as 3/3 + 3/3 = 3/3. More critically, 1/3 + 2/3 = 3/3 is precisely the wrong intuition for mod 3 arithmetic (arithmetic of groups of order 3), because *there* 1 + 2 does not equal 3, but 0.

To us, this suggested that Kaminski's study was not optimized for learning in the concrete condition. An introductory example, we hold, should align not mismatch the superficial concrete elements with the target mathematical structure. Consequently, the concrete representations of cups filled with varying quantities of liquid were modified from 1/3, 2/3, and a full cup (3/3) to 1/3, 2/3 and an empty cup (0/3). This leads to initially surprising but more structurally appropriate 1/3 + 2/3 = 0/3.

Our second concern had to do with the "cover stories" for each of the instantiations. Across these, participants were put into drastically different roles, some believable, others not. These cover stories are as follows (drawn from Kaminski et al. supplementary materials, and Kaminski, 2006):

Abstract instantiation: an archeologist trying to make sense of symbolic combinations left by an ancient civilization.

Concrete (main): an employee at a detergent company calculating the left-over after quantities of liquid are combined.

Concrete (alternative): a pizzeria owner discussing the chef who systemically and persistently burns predetermined portions of every pizza.

Concrete (alternative): an employee at a tennis ball factory dealing with malfunctioning machines producing incorrect quantities of balls.

Transfer: an anthropologist trying to understand a "children's game from another country."

While university students are surely capable of handling nonsense cover stories, such as the one where "the cook systematically burns a portion of each group order," we had concerns about their uneven, varying quality. Specifically, we felt that—pedagogically speaking—the concrete instantiations cover stories were poor in quality, while the generic and transfer narratives impressed us as reasonable. We conjectured that this matters, because a "reasonable" story may be more likely to connect to and activate relevant prior knowledge *without* also being overly distracting. In contrast, a cover story concerning a pizzeria where "the cook systematically burns a portion of each group order" is at odds with any prior knowledge one might have concerning pizzerias, cooking, or business profitability.

A closely related concern has to do with our general sense that the framing of the generic instantiation (an archeological discovery) and the transfer instantiation (a game from another country) had more to do with each other than the concrete instantiations (all of which had to do with odd work).

In response, we made the following modification to the study: every cover story was changed to "a children's game from another country." We generally accept that children play all kinds of games, and recognize that games can involve more concrete instantiations (e.g., combining cups of liquid), or more abstract instantiations (e.g., combining symbols). In other words, this particular cover story was chosen because it naturally accommodates concrete as well as abstract representations.

Because the students in our study would be asked to solve multiple transfer tests rather than one, a compromise was made to remove 4 items from the multiple-choice tests (same 4 from each test); this reduced the number of items on each of the tests from 24 to 20. Specifically, the items removed were 5, 8, 13, and 17 from the original abstract learning instantiation, and all the corresponding items from the other tests. (Of those, items 5 and 8 were chosen for elimination because they were basic and replicated across other questions. Items 13 and 17 were chosen because they used noticeably more text than the other items, a pattern we worried would become apparent across the phases.)

In addition to these modifications to the original study, we extended the study by introducing two additional transfer phases. Similar to De Bock et al.'s study, and for the same reason, we employed a concrete transfer task structurally identical to the original abstract transfer task. While De Bock et al. repurposed the alternative pizza concrete instantiation for this phase, we repurposed the tennis ball factory concrete instantiation.

Finally, we introduced a formal transfer phase, a group of order 5 and consisting of 0, 1, 2, 3, and 4. That is, addition mod 5, formally presented, where 2 + 2 = 4, yet 4 + 2 = 1, 4 + 3 = 2, and so on. We introduced this transfer test to evaluate a particular claim by Kaminski et al., namely that abstract representations lead to superior transfer because they support

[2] Again, we invite the reader to consult the supplementary online materials from the original study. These can be found at: http://www.sciencemag.org/cgi/content/full/320/5875/454/DC1

a deeper understanding of underlying mathematics. But, if students indeed developed a "deep understanding" of groups (or, at least, modular arithmetic), then it stands to reason that they should be able to transfer this knowledge to a formal instantiation of a group of order 5, which shares many similarities with a group of order 3. In this phase, just as in the other transfer phases, participants were not explicitly instructed on the rules, but provided with a few examples and told that the rules of this system are similar to the rules of the previous systems. This phase contained only 11 multiple choice items, focusing on deeper understanding of underlying principles, for example each element having an inverse.

Method

Undergraduate students attending a public university in Switzerland were randomly assigned to one of the (concrete or abstract) learning conditions (38 each; a priori power analysis informed by the original studies indicated that this number was sufficient).[3] Students majoring in mathematics or a computer science field were excluded. Training included explicit training in the rules, with accompanying examples (as in the original study). After this learning phase was completed, participants completed three more transfer phases in the following order: abstract, concrete, and formal. Transfer phases did not include explicit training, but did provide a few examples and inform participants that the rules are "the same" as in the previous tasks (again, as in the original study). To (partially) account for order effects, half the participants in each condition instead completed the phases in the following order: learning, concrete, abstract, formal (formal transfer was always last). No order effects were observed, and the orders are combined for this analysis.

As an illustration, this is what the cover stories and representations looked like for each phase:

Learning, abstract:
In another country, children play a game that involves three symbols: ,  , and  .

Learning, concrete:
In another country, children play a game by combining cups with different quantities of water:  ,  , and  .

Transfer, abstract:
In another country, children play a game that involves these three objects:

 (a ladybug)

 (a vase)

 (and a book).

Transfer, concrete:
In another country, children play a game that involves these three objects:

 - a container with two tennis balls

 - a container with one tennis ball

 - a container with zero tennis balls.

The final phase, formal transfer, did not use a cover story. There, participants were told that they will work with "a number system" and provided with examples of that system.

As in the original study and De Bock's replication, the study was completed individually, on a computer terminal, and there were no breaks during the study. The majority of participants completed the study within an hour, with no one taking more than 75 minutes. The study was conducted by assistants blind to the study expectations.

Reliability analysis for the learning, abstract transfer, concrete transfer, and formal transfer tests yielded McDonald's ω of 0.893, 0.857, 0.888, and 0.856, respectively.

Analysis

No participants were excluded from our analysis. The significance of this is addressed in the Discussion.

For inferential tests (JASP, 2018), Mann-Whitney U test was used as the data were not normally distributed. As is commonplace in education research, we report Cohen's *d*; however, we prioritize the rank-biserial correlation r_B as a more appropriate, unbiased effect size measure.

Results

Table 3, below, provides descriptive statistics for the present study. There were no significant differences in time for completion.

Table 3: Average scores (SD), as a percentage. **A** indicates that the learning phase was conducted with abstract instantiations, **C** with concrete ones. (Note that "Transfer Abstract" in this study corresponds to "Transfer" in previous studies reported in Table 1 and Table 2.)

	Learning	Transfer Abstract	Transfer Concrete	Transfer Formal
A (N = 38)	70 (24.8)	78 (18.3)	90 (14.3)	70 (24.9)
C (N = 38)	95 (12.1)	73 (25.9)	95 (10.7)	78 (27.7)

Comparing concrete to abstract learning conditions, we found a significant difference between the learning scores in

[3] A third condition, a modification of the abstract learning instantiation, was also investigated in the study. As it has no bearing on our current discussion, it is omitted from the analysis.

favor of the concrete learning condition, Mann-Whitney U = 1167.5, $p < .001$, rank-biserial correlation $r_B = 0.617$ with 95% CI [.429, .754] (Cohen's $d = 1.276$). On abstract transfer, we found no difference on performance, U = 701.5, $p = 0.835$, and a very small effect size, $r_B = -0.028$ with 95% CI [-.282, .229] (Cohen's $d = -0.176$). On concrete transfer, we found evidence in favor of the concrete condition, U = 913.5, $p = .033$, and a small-to-moderate effect, $r_B = 0.265$ with 95% CI [.010, .488] (Cohen's $d = 0.396$). Finally, formal transfer favored the concrete condition, but this difference was not significant, U = 877, $p = .103$, $r_B = 0.215$ with 95% CI [-.043, .446] (Cohen's $d = 0.304$).

To check for the influence of outliers, we excluded all participants who scored more than two standard deviations from the mean on any of the tests (same criterion used by Kaminski et al. and de Bock et al.). Three participants were excluded from each condition. Two results were affected. First, the difference on concrete transfer changed from significant to trending in favor of the concrete learning condition, U = 758.5, $p = .064$. Second, the differences on formal transfer reached significance, U = 777, $p = .048$, and a small-to-moderate effect in favor of the concrete learning condition, $r_B = 0.269$ with 95% CI [0.003, 0.499] (Cohen's $d = 0.408$).

Discussion

We aimed to critically replicate and extend an influential study that argued for the advantage of abstract representations in learning mathematics. We made two modification to the original study: (1) using an icon of an empty cup rather than a full cup in the concrete learning condition, and (2) keeping the "cover stories" similar to each other across the tasks. These modifications were made with the intent of removing pedagogically suboptimal elements present in the original design. We also extended the study by included a more concrete transfer task and a formal transfer task. Overall, our results put into question the previously reported advantage of abstract examples.

Whereas Kaminski et al. found no difference in the learning scores, and De Bock's study found a small difference in favor of the concrete instantiation, we found a significant and very large effect in favor of the concrete instantiation. How is it that the concrete instantiation condition in our study performed much higher than participants in the original, and even De Bock's study, on *both* learning and abstract transfer? In the original study, concrete learning to abstract transfer showed 44%, compared to 76% for abstract learning to abstract transfer. In De Bock's study, students fared slightly better, at 50% vs. 75%. In the present study: 73% vs. 78%.

We briefly entertained the (surely self-satisfying) notion that our students are more capable. However, this explanation is unlikely, because our students scored comparatively similar on the other comparable tests, for example across the *abstract* learning condition to abstract transfer (Kaminski: 80%, De Bock: 75%, present study: 78%). This suggests that the concrete instantiation condition performed better because of the changes made to the original materials. But those changes, as detailed earlier, were minor. Of these, we conjecture that using an empty cup rather than a full one may have made the largest difference, as this modification better aligned the concrete representation with the underlying mathematical notion.

As with De Bock et al., we found evidence in favor of the concrete instantiation on the concrete transfer test, although in our case this evidence was not robust.

Furthermore, once outliers were removed, we found evidence in favor of concrete instantiations on the formal transfer test, as well.

An additional point on data analysis may be worth considering. When analyzing our data, we chose to conduct analysis on all the participants, and again after removing those participants scoring more than two standard deviations from the mean. In contrast, the results reported by Kaminski et al. and De Bock et al. (the later following the former), were performed *after* eliminating participants who scored below chance on the learning test, for "failing to learn" (as well as removing the outliers, as we did). This is an unusual method of removing participants in an educational study, and one not conceptually justified in previous articles. Note that it biases the results in favor of students who found the materials useful in the first place. This is an artificial restriction—imagine a mathematics professor evaluating her teaching but refusing to consider those students who "failed to learn" from her lectures, as determined by a learning test immediately following the lecture.

In our data, this "failure to learn" elimination favored the abstract learning condition, because only in that condition did the students score below chance on the learning test. It did not favor it enough to impact the results, but it suggests that this particular elimination introduces bias in favor of the abstract instantiation. This does not explain the drastic differences between our results and those of previous studies, but it raises a question as to why this particular method was employed in the first place. After all, we researchers are unlikely to eliminate data that favors our predictions.

Limitations

Because our design makes not one but multiple modifications to the original study, further work is needed to identify the impact of each modification, as well as to investigate the potential mechanisms through which these modifications influence the learning process.

Summary and Implications

We made a relatively minor change to the concrete learning instantiation in Kaminski et al., in addition to making the various "cover stories" similar to each other. In turn, we observed results that contradict Kaminski et al., and partially support De Bock et al.

Overall, our findings suggest that, if only one instantiation is to be used, and *for these types of tasks*:

Concrete representations facilitate the initial learning of a mathematical concept better than abstract representations of the same idea.

On an abstract transfer, there is no notable advantage between learning via concrete or abstract representations.

On a concrete transfer, learning via concrete representations is preferable, although this difference is relatively small.

When transferring to a formal domain, learning via concrete representations may be preferable, although this difference is, again, relatively small.

Can the current study make any pedagogical recommendations? De Bock et al. (2011) and Jones (2009) caution, and we concur, that brief interventions of this sort should not be applied directly and uncritically to mathematics classrooms. Seen from that perspective, this study claims no more than the following: concrete instantiations may be more or less useful, depending on their quality and context. To be clear, we do not advocate concrete examples as universally advantageous. We agree with Lampinen and McClelland (2018), who argue that it is not the static qualities of "abstractness" or "concreteness" that are likely to impact learning; rather, learning depends on the *interactive* aspects of the learning environment (see Abrahamson & Trninic, 2015). As such, the existence of universally "ideal" learning examples seems unlikely.

The scholarly value of this study lies instead in its contrast to previous work, which found a significant and large effect in favor of the abstract learning instantiation. Our results provide an alternative explanation for those earlier findings. The "advantages of abstract examples" of Kaminski et al. did not manifest because "abstract examples" are better in general. It was because, in that particular design, the concrete learning condition was suboptimal.

Abstract

Ambiguity pervades language. One prevalent kind of ambiguity is *indirect requests*. For example, "My office is really hot" could be intended not only as a complaint about the temperature, but as a request to turn on the AC. How do comprehenders determine whether a speaker is making a request? We ask whether the *prosody* of an utterance provides information about a speaker's intentions. In a behavioral experiment, we find that human listeners can identify which of two utterances a speaker intended as a request, suggesting that speakers *can* produce discriminable cues. We then show that the acoustic features associated with an utterance allow a classifier to detect the original intent of an utterance (74% accuracy). Finally, we ask which of these features predict listener accuracy on the behavioral experiment.

Keywords: indirect requests; prosody; language production; language comprehension; inference

Introduction

People often make requests indirectly. For example, "Can you open that window?" is literally a question about the hearer's ability to open the window, but is often intended instead as an implied request for the hearer to open the window. Some indirect requests use a highly conventionalized form (in this example, "**Can you** X?"). But other indirect requests are less conventional, such as "My office is really hot." Indirect requests have been a topic of active research for decades in psycholinguistics (Gibbs, 1979), philosophy (Searle, 1990), cognitive psychology (Holtgraves, 1994), and natural language processing (Perrault & Allen, 1980; Williams et al, 2018) for several reasons. First, they're exceedingly frequent. One study eliciting requests from participants found that over 80% were indirect in some way (Gibbs, 1981). Second, successfully comprehending indirect requests requires the hearer to make inferences about the speaker's intent, using linguistic and other contextual knowledge, potentially involving diverse cognitive systems, which can pose challenges to computational implementations of language comprehension (Briggs, Williams, & Scheutz, 2017). But it still remains to be determined what information human comprehenders use to recover the intended interpretation of a potential indirect request.

Previous work suggests that successfully understanding indirect requests requires the integration of extra-linguistic contextual information. For *conventional* indirect requests, comprehenders can use the form of the utterance as a partial cue to its meaning. Consequently, conventional indirect requests are thought to be easier to understand (Gibbs, 1981), and in some cases the *request* interpretation may even be the default (Gibbs, 1986). But even conventional indirect requests can pose a challenge: the conventionality of a particular form is still dependent on context (Gibbs, 1986), and canonical forms can even lead listeners to *misidentify* intended questions as requests (e.g. "Can you play tennis?"), as has been reported for individuals with anterior aphasia and right-hemisphere brain damage (Hirst, LeDoux, & Stein, 1984).

Less conventional indirect requests, such as "My office is really hot", require the hearer to infer both the speech act (e.g. is it a request?) as well as the intended substance of the request, and are thus thought to incur higher processing costs than their literal, non-request counterparts (Tromp, Hagoort, and Meyer, 2016), as well as more conventional indirect requests (Gibbs, 1981). Successful disambiguation of these utterances may benefit from co-speech gesture and eye gaze (Kelly et al, 1999), as well as a representation of what is mutually known across interlocutors (Gibbs, 1987; Trott & Bergen, 2018).

Finally, indirect requests have proven challenging for machine language understanding. Wizard-of-Oz style experiments show that human speakers continue to use indirect requests when speaking to robots (Briggs, Williams, & Scheutz, 2017), even when those robots demonstrably cannot understand them (Williams et al, 2018). Current state-of-the-art solutions (Briggs, Williams, & Scheutz, 2017) use rules relating utterance forms to contexts to probabilistically derive the intended interpretation of ambiguous utterances like "Can you knock down the red tower?" While these solutions work well for established utterance-context mappings, they could still benefit from an increased understanding of precisely which disambiguating

information is available (e.g. paralinguistic or extralinguistic cues), and which is actively exploited by human comprehenders.

Specifically unexplored to date as a candidate source of disambiguating information, is **prosody**: the intonational, rhythmic, and tonal properties of how an utterance is spoken or signed.

Prosodic Cues for Disambiguation

Previous work on other kinds of linguistic ambiguity has already demonstrated that prosodic cues can provide disambiguating information about a speaker's intent.

For one, prosodic features such as *pitch* and *pause duration* can act as "parsing instructions" for listeners. Using speech synthesis, Beach (1991) modified the pitch and duration of critical regions of sentences involving temporary ambiguity (e.g. whether a noun phrase was functioning as a sentential complement or direct object), and found that participants were able to identify the intended parse without listening to the entire utterance. Similarly, Price et al (1991) found that FM radio newscasters, naïve to the purposes of the experiment, produced marked prosodic cues that aided listeners' comprehension of parenthetical statements, apposition, and prepositional phrase attachment ambiguities. This boost in comprehension may even occur before the ambiguity is encountered, as suggested by differences in the visual scan patterns of listeners tasked with determining which object a speaker was referring to (Snedeker & Trueswell, 2003). Nonetheless, there are still substantial debates about the conditions under which *speakers* reliably produce such cues—some studies (Allbritton et al, 1996; Snedeker & Trueswell, 2003) have found that discriminating prosodic cues disappear in the presence of sufficiently disambiguating contextual information, while others (Schafer et al, 2000; Speer et al, 2011) have found that they persist, and have argued that the failure to find such cues is due to limitations on the elicitation paradigms used (e.g. being non-interactive or having low stakes). Regardless, the evidence shows that when such cues *are* available, listeners improve at identifying the intended syntactic parse—pointing to a clear role for prosodic features in syntactic disambiguation.

There is also a growing body of evidence that prosody helps a comprehender decipher a speaker's pragmatic intentions. Early work (Shriberg et al, 1998) found that including prosodic features from conversational speech (including duration, pause, F0, energy, and speech rate) improved a classifier's ability to categorize utterances by Dialogue Act, above and beyond a model equipped with only statistical word-level features. While these results do not indicate that *human* comprehenders infer a speaker's intentions on the basis of prosodic-level features, they do suggest that such features are, in principle, useful. More recently, Hellbernd & Sammler (2016) asked whether trained human speakers could produce cues that identified the intended speech act of one-word utterances—e.g. producing the word "beer" as a Warning, Criticism, or Suggestion. In a behavioral task, human listeners successfully identified the speaker's intended speech act for 82% of words (and 73% of non-words). The authors also trained a machine learning classifier to categorize speech act using prosodic features (duration, mean intensity, harmonics-to-noise ratio, mean fundamental frequency, and pitch rise), obtaining 92% accuracy for words (and 93% for non-words).

Additional evidence that people use prosody to disambiguate comes from research on irony detection. Listeners were able to identify the presence (or absence) of irony in spontaneously-produced speech from radio shows when presented in auditory, but not written, format (Bryant & Fox Tree, 2002), suggesting that success was at least partially dependent on information contained in the speech signal (though see Bryant & Fox Tree (2005) for further discussion of whether these prosodic features are *global* or *local*, and whether they are uniquely characteristic of irony in particular). More recent studies (Deliens et al, 2018) have confirmed that prosodic features aid in the detection of irony; however, listeners appear to exhibit a speed/accuracy trade-off in the integration of prosodic vs. contextual congruity cues, respectively.

Finally, beyond the level of individual speech acts, prosodic features have been shown to improve the detection of a speaker's attitudinal stance (Pell et al, 2018; Ward et al, 2017; Ward et al, 2018). Features such as speech rate and pitch can also influence judgments about the perceived *politeness* of a speech act, including requests (Caballero et al, 2018), though as has been pointed out, the information conveyed by a given prosodic feature is not necessarily independent from the social-interactional context in which that feature is observed (Wichmann, 2000; Culpeper, Bousfield, & Wichmann, 2003).

Together, these findings indicate that speakers are capable of producing signals whose prosodic features provide information about the intended syntactic parse or pragmatic interpretation. Critically, these signals are reliable enough to be detectable—and useful—to both human and machine comprehenders.

However, the role of prosodic features in signaling the intended interpretation of potential indirect requests is currently unexplored. Do speakers and hearers use prosody to overcome the pragmatic ambiguity intrinsic to the most common way to make requests? We addressed this in the current work through three core questions. First, *can* speakers produce reliable cues to indicate to human listeners whether or not they are making a request? Second, *which* cues do speakers actually produce? And third, are these the same cues that listeners seem to use?

Note that all critical data, as well as the code to reproduce the analyses described below, can be found online at: https://github.com/seantrott/prosody_indirect_requests.

Experiment: Listener Judgments of Intent

In a behavioral experiment, we asked whether speakers can produce reliably discriminable prosodic cues. Specifically,

we asked whether these prosodic cues reliably aid human *listeners* in discriminating the speaker's pragmatic intent. On each trial, participants were given two recordings of the same utterance by the same speaker (e.g. "Can you open that window?", or "My soup is cold"), and were asked to select which of the two utterances was intended as a request. If speakers can produce detectable, reliable cues, then participants should be able to identify which utterance was produced as a request; but if speakers cannot produce such cues, or if the cues they produce are not usable by human listeners, then participants should perform at chance.

Methods

Participants 78 participants, all native English speakers, were recruited from Amazon Mechanical Turk. We aimed to recruit 80 participants, but Mechanical Turk under-sampled to 78 participants. The mean age of our participants was 37 (SD=11), ranging from 20 to 69. 30 identified as female, 45 as male, 2 as non-binary, and 1 declined to answer. Each participant was paid $2 for participating, and the experiment took on average 24 minutes to complete.

Materials We recorded five English speakers (2 male, 3 female). Speakers were given 12 utterances to produce (6 conventional indirect requests of the form "Can you X?", and 6 non-conventional indirect requests of the form "My X is Y"), and were instructed to say each utterance twice—once as a request, and once as a literal question or statement. They were allowed to read over the utterances before speaking. The experiment was implemented using JsPsych (de Leeuw, 2015).

Procedure After completing an audio check, participants were instructed that they would listen to a series of paired utterances. They were told that one member of each pair was always intended as a request, and the other member was not. Their task was to indicate which was the request by selecting one of two buttons (either "First" or "Second", corresponding to the first or second utterance presented).

On each trial, participants heard two utterances, containing the same words and produced by the same speaker, with 1 second of silence following each utterance. The order of the utterances (e.g. whether the request or non-request version came first) was counterbalanced within-speaker using a weighted randomization scheme (e.g. for each *speaker-block*, 6 trials contained the request version first, and 6 contained the non-request version first). After listening to both versions, participants indicated which one they thought was intended as a request via button-press.

Each participant performed 60 trials (12 utterance pairs for each of the 5 speakers), blocked by *speaker*. The order of the trials within each *speaker-block* was randomized, as was the order of *speaker-blocks*.

Results

All statistical analyses were performed in R (R Core Team, 2017), using the *lme4* package (Bates et al, 2015). Random effects structure was determined by beginning with the maximal model, then reducing as needed for model convergence (Barr et al, 2013).

Our first question was whether participants could successfully determine which utterance was intended as the request. To test this, we built a generalized linear mixed effects model, with *response* (First or Second) as the dependent variable, and *correct answer* (First or Second) as a fixed effect, as well as random slopes for the effect of *correct answer* for both subjects and items (as well as random intercepts for both). We compared this full model to a reduced model omitting the fixed effect of *correct answer*, and found that the full model explained significantly more variance [$X^2(1)=24.97$, $p=5.8*10^{-7}$]. In other words, participants were able to discriminate request and non-request utterances at a rate above chance.

We were also interested in which characteristics predicted accuracy on particular items—were participants better at identifying pragmatic intent for certain *forms* (conventional vs. non-conventional), or for certain *speakers*? We used nested model comparisons, with *correct* (Yes or No) as a dependent variable, by-item random slopes for *speaker*, by-subject random slopes for *form*, and random intercepts for both items and subjects, to determine whether *form*, *speaker*, and their interaction explained independent sources of variance in participant accuracy. A model with fixed effects for both *form* and *speaker* explained more variance than a model with *form* alone [$X^2(4)=11.5$, $p=.02$], as well as a model with *speaker* alone [$X^2(1)=5.2$, $p=.02$]. Adding an interaction between *form* and *speaker* explained additional variance [$X^2(4)=14.1$, $p=.007$]. In other words, certain speakers produced more discriminable signals overall, and *conventional* requests were generally easier to identify than non-conventional requests, except in the case of one speaker, "S2" (see *Figure 1*).

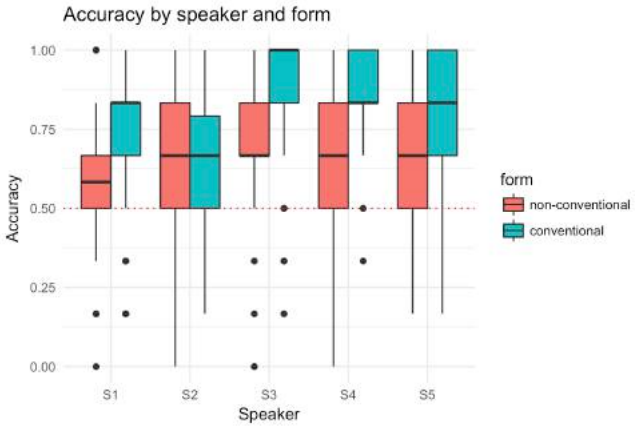

Figure 1: Human accuracy was above chance for all speakers and forms. Accuracy was higher for some speakers (e.g. S3, S4) and some forms (e.g. conventional requests). Dotted red line signifies chance (50%).

One possibility is that participants improved in accuracy over the course of the experiment, perhaps learning which prosodic features signaled intent. We compared a model

with *correct* (Yes/No) as a dependent variable, *Order* (1-60) as a fixed effect, and random intercepts for subjects and items, to a model omitting the fixed effect of *Order*, and found that the full model did not explain significantly more variance [$X^2(1)=.7$, $p=.4$]. Thus, there is no evidence that participants improved over the course of experiment. However, it is also possible that participants improved within each *speaker-block*, but that this adaptation did not carry over across blocks. To test this, we replaced *Order* with *Order-within-block* (1-12) as a fixed effect; a model including *Order-within-block* explained marginally more variance than a model omitting this term [$X^2(1)=3.1$, $p=.08$]. This explanatory power was independent from the variability explained by *speaker*, as determined by comparison of a model including fixed effects of both *speaker* and *Order-within-block* to a model with only *speaker* [$X^2(1)=3.3$, $p=.07$]. Adding an interaction between these factors did not increase explanatory power [$X^2(4)=3.3$, $p=.5$]. This provides weak evidence for within-block adaptation or learning, but requires further analysis and experimentation.

Analysis of Acoustic Features

Listener judgments of pragmatic intent in the behavioral experiment described above demonstrated that speakers produced signals that increased communicative success. However, this analysis does not indicate *which* acoustic features predict a speaker's intended pragmatic interpretation. Here, we asked whether seven acoustic features reliably predicted a speaker's *intent*. Predictive power was assessed in two ways. First, we asked about the explanatory power of each variable in turn using nested model comparisons. Second, we used leave-one-out cross-validation to determine how the combination of *all* features improved the ability of a classifier to identify *intent*.

Data Processing

For each of the 120 recordings (5 speakers producing 12 utterances with two versions each), we used Parselmouth (Jadoul et al, 2018), a Python interface to Praat, to extract the following acoustic features: mean F0, range F0 (max F0 – min F0), standard deviation of F0, duration (number of voiced frames), mean intensity, standard deviation of intensity, and slope of F0 (slope of regressing *F0 ~ time*). We then *z-scored* each of these variables with respect to each speaker's mean and SD, to account for considerable variability in speakers overall.

Results

First, we asked how much independent variance was explained by each feature in turn, comparing a full model (including all seven features) to a model omitting only the feature under consideration. In each case, the full model included *intent* (Request vs. Non-Request) as a dependent variable, fixed effects for each of the seven acoustic features, and random intercepts for each utterance. We adjusted for multiple comparisons using Holm-Bonferroni corrections (Holm, 1979). In each case, a positive coefficient represents a higher likelihood of a *Non-Request*, while a negative coefficient represents a higher likelihood of a *Request*.

For a logistic regression model predicting *intent* of all items (e.g. both *conventional* and *non-conventional* utterances), model fit was improved by including *mean intensity* [$X^2(1)=8.7$, $p=.003$, $p_{adj}=.02$] and *SD intensity* [$X^2(1)=7.8$, $p=.005$, $p_{adj}=.03$]. Higher-intensity utterances were more likely to be Requests [$\beta=-.69$, $SE=.25$, $p=.006$], as were utterances were with greater variation in intensity [$\beta=-1.1$, $SE=.4$, $p=.01$]. No other acoustic features significantly improved model fit after correcting for multiple comparisons.

Because human listener accuracy differed significantly as a function of *form* (see the behavioral experiment), it is possible that distinct prosodic features predict intent for *conventional* and *non-conventional* requests. Thus, we ran the same analysis as above twice: once on only *conventional* and once on only *non-conventional* requests.

For a model predicting *intent* of only *conventional* requests, model fit was improved by including *F0 slope* [$X^2(1)=7.8$, $p=.005$, $p_{adj}=.03$], *SD intensity* [$X^2(1)=7.7$, $p=.005$, $p_{adj}=.03$], and *F0 duration* [$X^2(1)=8.8$, $p=.003$, $p_{adj}=.02$]. More positive slopes were associated with Non-Requests, e.g. literal questions [$\beta=1.1$, $SE=.5$, $p=.01$], as were longer utterances [$\beta=1.1$, $SE=.4$, $p=.01$] and less variation in intensity [$\beta=-1.1$, $SE=.4$, $p=.01$].

For a model predicting *intent* of only *non-conventional* requests, model fit was significantly improved by including *F0 duration* [$X^2(1)=19.6$, $p=9.7*10^{-6}$, $p_{adj}=.00004$], with longer utterances having a higher probability of being Requests [$\beta=-2.5$, $SE=.94$, $p=.008$].

In sum, we identified several acoustic features that predict pragmatic intent. Overall, intent was predicted by *mean intensity* and *SD intensity*. For *conventional* requests in particular, intent was predicted by *F0 slope*, *F0 duration*, and *SD intensity*; for *non-conventional* requests, intent was predicted by *F0 duration*. These results suggest that those features *could*, in principle, be used to identify the intent of an ambiguous utterance.

To determine whether the combination of all seven acoustic features could improve a classifier's ability to detect *intent*, we used leave-one-out cross-validation (LOOCV). A model including all seven acoustic features (as well as their interactions with *form*) accurately predicted *intent* on 74% of the held-out items, a rate substantially above chance (50%).

Predicting Accuracy from Acoustic Features

By regressing pragmatic intent against extracted acoustic features, we isolated multiple features that appear to indicate intent of either conventionally or non-conventionally formatted utterances: F0 slope, F0 duration, mean intensity, and SD intensity. However, this does not entail that listeners actively exploit differences in these features to infer intent. It could be that these features are *statistically* reliable, but

not *psychologically* valid. Which, if any, of these features actually benefit listeners?

One way to test this is to ask: do by-item *differences* in any of the acoustic features explain independent sources of variance in listener *accuracy*, above and beyond the full model specified above in the behavioral experiment (containing an interaction between *form* and *speaker*)? If larger differences from a given dimension (e.g. *F0 slope*) consistently predict accuracy, this suggests that listeners are actively benefitting from those differences, and are thus consistently sampling and deploying information about that particular dimension.

Data Processing

For each utterance pair, we computed the *difference* of each z-scored feature between the Request version and the Non-request version. Thus, a positive value for *F0 slope difference* indicates that the Request version had a larger slope than the Non-request version, while a negative value indicates that the Non-request version had a larger slope. We repeated this procedure for each acoustic feature.

Results

We asked about the informativeness of each acoustic feature (as well as its interaction with *form*) using nested model comparisons. The explanatory power of a given variable was determined by comparing a model including that term to a model without it. We adjusted for multiple comparisons using Holm-Bonferroni corrections (Holm, 1979).

The full model included the terms from the maximal model specified in the behavioral experiment, with *correct* (Yes/No) as a dependent variable, an interaction between *form* and *speaker*, fixed effects for both *form* and *speaker*, and random intercepts for subjects and items. It also included each of the seven acoustic features, as well as their interaction with *form*.

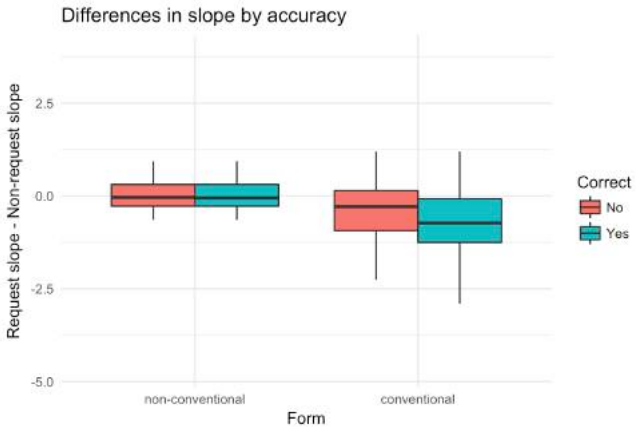

Figure 2: Differences in z-scored F0 slope by *form* and *accuracy*. Conventional items with a larger difference between the Request and Non-Request version (specifically, where the slope on the *Non-Request* version was more positive than the slope on the *Request* version) were more likely to be answered correctly.

Model fit was significantly improved by the interaction between *F0 slope difference* and *form* [$X^2(1)=16.98$, $p=3.78*10^{-4}$, $p_{adj}=.0005$], but was not significantly improved by *F0 slope difference* alone ($p_{adj}>.1$). The direction of this interaction is illustrated in *Figure 2*: accuracy on non-conventional items was not significantly impacted by the difference in *F0 slope* between the Request and Non-Request differences, whereas a larger difference for conventional items predicted more accurate responses. Specifically, conventional items on which the Non-Request version had a more positive slope than the Request version (and thus their difference was more *negative*) were more likely to be answered correctly [$\beta=-.4$, SE=.1, $p=5.5*10^{-5}$].

Model fit was also improved by the interaction between *mean F0* and *form* [$X^2(1)=10.6$, p=.001, $p_{adj}=.01$], as well as the main effect of *mean F0* [$X^2(1)=15.03$, p=.0001, $p_{adj}=.001$]. Specifically, conventional items on which the Request version had a lower *mean F0* than the Non-Request version were more likely to be answered correctly [$\beta=-.47$, SE=.14, p=.001]. Because these comparisons included a term for *F0 slope*, this does not appear to be due simply to conventional Non-Request items exhibiting a sharper final rise (e.g. more positive slope). Differences in *mean F0* explained independent sources of variance from *F0 slope*.

A model including an interaction between *mean intensity* and *form* did not explain more variance than a model omitting that term, but the fixed effect of *mean intensity* did improve model fit [$X^2(1)=9.7$, p=.002, $p_{adj}=.02$]. Specifically, items on which the Request version had a higher overall *mean intensity* than the Non-Request version were marginally more likely to be answered correctly [$\beta=.1$, SE=.05, p=.06].

Model fit was also improved by the interaction between *SD intensity* and *form* [$X^2(1)=7.12$, p=.008, $p_{adj}=02$], though not the fixed effect of *SD intensity* alone ($p_{adj}>.1$). Conventional items on which the Request version exhibited greater variation in intensity than the Non-Request version were more likely to be answered correctly [$\beta=.29$, SE= .11, p=.007].

In summary, four of the acoustic features we extracted predicted listener accuracy—*F0 slope*, *mean F0*, *mean intensity*, and *SD intensity*. *F0 slope* appeared to be useful primarily for conventional requests (with more positive slopes indicating the literal, Non-Request interpretation). *Mean F0* was helpful for both, though again, appeared to be particularly predictive of accuracy on the conventional items (with higher mean F0 on the Non-Request versions predicting higher accuracy). *Mean intensity* was predictive of accuracy on both kinds of items; items on which the Request version exhibited higher overall intensity than the Non-Request version were more likely to be answered correctly. Finally, *SD intensity* was particularly helpful for conventional items—Request versions with more variability in intensity than their Non-Request counterpart were more likely to be correctly identified.

General Discussion

Human listeners were able to discriminate the pragmatic intent of potential indirect requests, indicating that speakers *can* produce discriminable cues, at least when made aware of an utterance's different interpretations. We extracted seven acoustic features from each recorded utterance, and found that four of these features were predictive of listener accuracy in the behavioral experiment: F0 slope, mean F0, mean intensity, and SD intensity. Specifically, larger differences in each of these features were associated with more accurate responses; some were primarily helpful for conventional items (F0 slope, SD intensity, mean F0), while others were helpful for both (mean intensity).

Additionally, using leave-one-out cross-validation, a machine learning classifier trained on these features (and their interaction with utterance *form*) successfully identified the *intent* of potential request utterances 74% of the time (where chance is 50%). Thus, prosodic features are not only useful to human comprehenders attempting to discriminate a speaker's pragmatic intent—they are also informative to machines, suggesting that they could perhaps be integrated into existing natural language understanding architectures (Briggs et al, 2017).

Open questions remain. First, we noted a weak effect of *Order-within-block*, but not *Order* overall, on accuracy. That is, there is no evidence that listeners improved over the course of the entire experiment, but they might have improved while listening to each speaker. If true, this provides weak evidence for *adaptation* to each speaker, which may not successfully carry over across speakers. The effect was marginally significant. Since it arose during exploratory data analysis, it requires further investigation.

Second, a limitation of the behavioral experiment is that participants were asked to explicitly discriminate between two versions of the same utterance (e.g. "which was the request?"), rather than *classifying* an individual utterance (e.g. "is that a request?"). The latter design is clearly more applicable to real-world scenarios, in which comprehenders do not have immediate access to alternative versions of an utterance. We are designing a new set of studies to ask whether comprehenders can identify whether a given utterance was intended as a request, and whether the same acoustic features—e.g. F0 slope, mean intensity, etc.—predict their response. This task design will also allow more direct comparison to the classifier's results, so that we can determine whether the classifier is using similar features (and making similar errors) as human comprehenders.

Third, a long-standing question in the literature on prosody and pragmatic intent is whether particular prosodic features convey direct information about the intended speech act, or whether they function primarily as contrastive markers, which invite the listener to perform additional inference. For example, prosodic features may not directly convey sarcastic intent, but rather prompt listeners to integrate other multimodal, contextual information to recognize irony (Attardo, Eisterhold, Hay, & Poggi, 2003; Bryant & Fox Tree, 2005). Our experiment was not designed to adjudicate between these two possibilities, but our results do suggest that the answer is nuanced, and likely falls somewhere in between. Certain features, such as *F0 slope*, were predictive only of accuracy for conventional forms (E.g. "Can you open that window?"), and thus might be more aptly described as "marking" a deviation from the default interpretation of modal interrogatives as requests (Gibbs, 1986). But other features, such as *mean intensity*, predicted accuracy across forms; in both cases, items with higher intensity on the Request version (vs. the Non-Request version) were more likely to be answered correctly.

Finally, perhaps the most obvious question is whether, or under what conditions, these kinds of prosodic cues would actually be produced. Speakers in our experiment were made aware of the two interpretations of each utterance, and were explicitly asked to produce utterances consistent with those interpretations. While our results indicate that speakers *can* produce discriminable cues, they do not demonstrate that speakers actually *do*. A similar issue arises in the study of prosodic cues for syntactic disambiguation—some (Allbritton, 1996; Snedeker & Trueswell, 2003) have found that these cues are no longer present when the utterance is produced in a disambiguating context, while others (Schafer et al, 2000; Schafer et al, 2005) have argued that the cues are produced regardless of how much information is provided by the context. Thus, the question becomes: are the discriminable prosodic features we observed automatically and conventionally associated with pragmatic intent, or are they deployed strategically for a particular audience in a particular context?

Acknowledgments

We thank Rachel Ostrand for her helpful advice on the modeling of acoustic features. We are also grateful to both the speakers and the participants, and to the reviewers for their suggestions.

To Catch a Snitch: Brain potentials reveal knowledge-based variability in the functional organization of (fictional) world knowledge during reading

Abstract

People vary in what they know, yet models of language processing do not take this variability into account. We harnessed the temporal sensitivity of event-related brain potentials alongside individual differences in Harry Potter (HP) knowledge to investigate the extent to which the availability and timing of information relevant for real-time word comprehension are influenced by variation in degree of domain knowledge. We manipulated meaningful (category, event) relationships between sentence contexts about HP stories and critical words (endings), assessed via behavioral ratings and by measuring similarity of word embeddings derived from a high-dimensional semantic model trained on HP texts. Individuals' ratings were sensitive to these relationships according to the degree of their domain knowledge. During reading, N400 amplitudes (neural measures of semantic retrieval) also reflected this variability, suggesting the degree to which information relevant for word understanding is available during real-time sentence processing varies as a function of individuals' domain knowledge.

Keywords: language processing, ERPs, knowledge, individual differences

Introduction

Across cognitive systems, world knowledge allows individuals to organize raw sensation into meaningful experiences. Understanding language is no exception—words cue world knowledge which can be rapidly brought to mind in real time (e.g., Hagoort et al., 2004), incrementally and sometimes even predictively (reviewed in Altmann & Mirković, 2009; Kutas, DeLong, & Smith, 2011). A more precise description of how this occurs—including which types of knowledge, their organization, and the timing of their use—requires a closer look at knowledge availability in real time. It is, however, experimentally challenging to capture the specifics of an individual's world knowledge with standard laboratory procedures.

Troyer and Kutas (2018; Troyer, Urbach, & Kutas, under review) provided a potential solution by focusing on a restricted domain of knowledge with the requisite properties for online language processing studies, including a large, rich set of verbal descriptions, wherein college-aged young adults differed in their degree of knowledge—the fictional world of Harry Potter (HP) by J.K. Rowling. Troyer & Kutas (2018) recorded EEG while participants with varying degrees of knowledge about HP read sentences that described general topics, followed by sentences that described events from the HP stories; sentences ended either in contextually supported or unsupported words. Across participants, and for both sentence types, the effect of contextual support was present on N400 amplitudes—a brain potential sensitive to factors impacting the ease of retrieval from semantic memory, with larger reductions in N400 (i.e., more positive-going potentials) associated with greater ease of retrieval (reviewed in Kutas & Federmeier, 2000). But critically, participants' degree of HP knowledge influenced the size of this effect only for the sentences about HP. More specifically, individuals' HP knowledge was correlated with N400 amplitudes to contextually supported, but not to unsupported, words. These results empirically demonstrate that the rapid influence of written sentence context, known to modulate N400 brain potentials, is a function of each individual's knowledge.

These findings are not surprising given the vast literature showing that people rapidly make use of a variety of word and world knowledge as they understand words in real time, such as orthographic neighborhood density (Laszlo & Federmeier, 2009), word frequency (Van Petten & Kutas, 1990), and non-linguistic knowledge including the organization of categories in semantic memory (Federmeier & Kutas, 1999), facts about the world (Hagoort et al., 2004), generalized event knowledge (Metusalem et al., 2012), personal preferences (Coronel & Federmeier, 2016), and fictional characters (Filik & Leuthold, 2013). It stands to reason that the structure and organization of individuals' knowledge would have consequences for the availability, contents, and timecourse of bringing to mind these varied sources of knowledge in real time.

One way to ask whether and, if so, when people bring different types of information to mind as they read sentences is to probe them with words that are linguistically anomalous, yet systematically related to the sentence context and/or a likely upcoming, linguistically licensed word. This related anomaly paradigm has been fruitfully employed to investigate the influence of the functional organization of semantic memory on sentence processing. For example, in sentence contexts setting up an expectation for the word *pines*, categorically related words (e.g., another type of tree, *palms*) elicited reduced N400 amplitudes compared to words from a different category (e.g., *tulips*), but which were larger than those to the expected word (Federmeier & Kutas, 1999, 2002). In a different study, where individuals read short paragraphs about common events (e.g., playing football) that set up linguistic expectations for a word (e.g., *touchdown*), unexpected and linguistically unlicensed words related to the event being described (e.g., *helmet*) also elicited reduced N400 amplitudes compared to unrelated words (e.g., *license*) (Metusalem et al., 2012). It is worth noting that the "related anomaly" in Federmeier & Kutas shared many features with an expected word whereas in Metusalem et al. the related anomaly was related in one or more of several ways to the generalized event being described in the context, but not did not share features with the linguistically expected word. Nonetheless, the related anomaly ERP effects in both studies had a similar timecourse and scalp topography, maximal around 400 ms over centro-parietal recording sites,

suggesting that people made quick use of both types of related information during real-time sentence processing.

The availability of related/relevant information stored in semantic memory during real-time language processing must, at least to some degree, be modulated by each individual's degree of domain knowledge. Indeed, the literature on expert knowledge proposes that the functional organization of information around themes, events, and categories is likely to depend on individuals' degree of expertise (reviewed in Ericsson et al., 2006). To investigate the extent to which variation in domain knowledge influences the nature and timing of the availability of knowledge stored in long-term memory during real-time sentence processing, we probed semantic memory using a related anomaly paradigm incorporating sentences describing the narrative world of Harry Potter.

Using freely available materials (including Wikipedia and HP fan sites) along with the text of the HP book series by J.K. Rowling, the first author created a set of 156 sentence pairs that accurately described events and entities from the series. Each sentence context ended either in (a) a contextually Supported (and linguistically expected) word; (b) a word which was factually incorrect and Unrelated to the context and to the supported word; and (c) a word which was factually incorrect but which was Related in one of two ways to the context and/or contextually supported word. For half of the materials, the related words were taken from the same category as the linguistically expected word, as in Federmeier & Kutas (1999). For the remaining materials, the related word was related in some way to the episode/event being described by the preceding sentence context, as in Metusalem et al. (2012). Based on the previous findings, we expected that both types of relationships would lead to N400 related anomaly effects which might be similarly influenced by the degree of individuals' domain knowledge. Three lists were constructed such that each sentence frame and each critical word appeared only once per list (examples provided in Table 1).

In order to verify that the words we deemed related via category or event to contextually supported words were indeed more closely related than the unrelated ending, we conducted a series of experiments to examine these relationships. First, we trained a high-dimensional semantics/language model directly on the text of the HP book series; we then asked whether the word embeddings learned by the model reflected the manipulation in our materials (e.g., with Supported-Related word embeddings being closer in semantic space than Supported-Unrelated word embeddings). Next, we conducted two experiments asking participants of varying degrees of HP knowledge to rate critical words from our materials for their similarity and relatedness, respectively. Finally, with these measures in hand, we conducted an EEG/ERP study to ask to what extent and when domain knowledge impacts the availability of contextually supported as well as contextually unsupported yet functionally (categorically, event-based) related knowledge during written sentence comprehension.

Experiment 1: Word embeddings

We trained a word2vec model (Mikolov et al., 2013a,b) on the text from the HP book series. This model uses a neural net to learn word embeddings (vectors) in high-dimensional semantic space from word co-occurrences in the input. The semantic "contents" of such embeddings can reflect various aspects of meaning, including category and event-based relationships (reviewed in Lenci, 2018). We could then use these embeddings to quantify relative similarities/differences between word pairs (or average vectors computed over sequences of words).

Methods

Word2vec model. We trained a word2vec model (distribution by D. Yaginuma, https://github.com/dav/word2vec) on the text from the seven books of the HP series, taken from the official electronic publication (https://usd.shop.pottermore.com)—a total of 1,125,854 words, with a vocabulary size of 8,046 words (subject to the constraint of each word appearing at least 5 times in the HP books). We used the continuous bag-of-words (CBOW) architecture, which learns to predict a word based on its context—in our case, a window of 10 words on either side. Each word from the HP books was modeled as a point (i.e., vector) in a 200-dimensional space.

Word-word similarity Using this model, we extracted word embeddings for critical words from each of our experimental conditions (Supported, Related, and Unrelated). For each

Table 1. Sample HP sentence materials.

Sentence frame	Supported	Related	Unrelated	Related Anomaly Type
Sybill Trelawney is a Hogwarts Professor. She teaches	*Divination*	*Transfiguration*	*basilisk*	**Category**
In Quidditch, games are usually won in one way. This is when the seeker catches the	*Snitch*	*Bludger*	*dragon*	**Category**
Harry has a patronus. It takes the form of a	*stag*	*dementor*	*Sectumsempra*	**Event**
When Harry is one year old, Hagrid brings him to the Dursleys'. For transportation, he uses a borrowed	*motorcycle*	*Sirius*	*Vow*	**Event**

item (156 total), we then computed the cosine similarity (angular distance) between the word embeddings for Supported-Related and Supported-Unrelated pairs of critical words. We expected that the similarity for the Supported word-Related word pair would be greater Supported word-Unrelated word pair.

Sentence context-word similarity We also extracted word embeddings for each word (where possible) of our sentence pair frames/contexts. To create a single embedding (i.e., vector) for each item's sentential context, we took the average of all its words' vectors. We then computed the cosine distance between this aggregate context vector and the vector for each ending type (Supported, Related, Unrelated). We expected this distance would be greatest for the Context-Supported pair, followed by Context-Related and finally Context-Unrelated.

Results

As expected, we found that word embeddings—derived from a corpus of the HP novels' text—for Supported words were more similar to Related words than to Unrelated words (Fig. 1a). This pattern held for both category- and event-related item subsets, though it was somewhat larger within category-related items ($p < .01$). Also as expected, average word embeddings for sentential contexts were most similar to Supported words, followed by Related and Unrelated words (Fig. 1b). This pattern held both for category- and event-related item subsets. These findings show that the high-dimensional semantic space learned by the word2vec model captured systematic, meaningful differences in the relationships between the sentence context and the Supported, Related, and Unrelated endings.

Experiments 2a-b: Ratings studies

To further assess the manipulation in the HP sentences, and to examine the extent to which the manipulation was dependent on HP knowledge, we conducted two behavioral studies, asking participants to rate critical word-pairs (Supported-Related and Supported-Unrelated) on similarity (Exp. 2a) or relatedness (Exp. 2b). These criteria were chosen specifically to examine the two types of relationships we targeted in our HP sentence materials, namely categorical relationships (words share many similar features) and event relationships (words are related via an event/episode from the HP books). In addition, these experiments allowed us to assess the ratings of similarity/relatedness as a function of individuals' degree of HP knowledge. We expected that individuals with greater knowledge would be more sensitive to our experimental manipulations—i.e., that more knowledgeable individuals would indicate relatively greater similarity/relatedness for Supported-Related than for Supported-Unrelated word pairs.

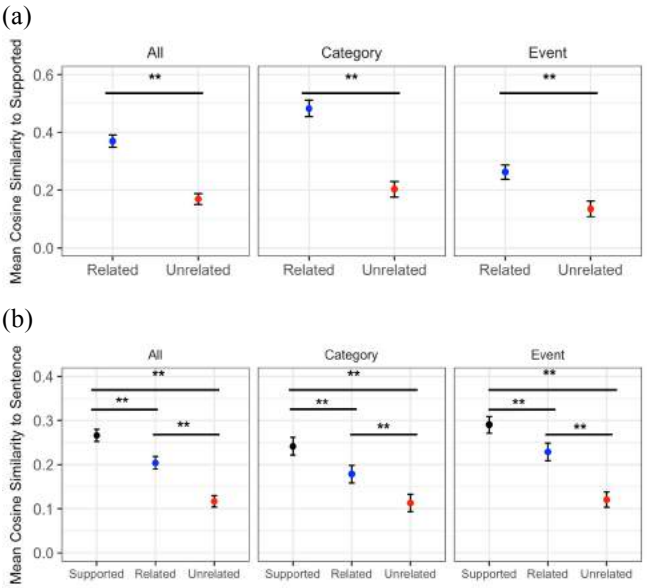

Fig. 1. (a) Across items and within each subset (Category-related, Event-related), mean cosine similarity for Supported & Related endings is greater than for Supported & Unrelated (all ps < .01). (b) For all 156 items (and within each subset) there was a significant three-way difference between cosine similarity of averaged word embeddings for sentences and Supported < Related < Unrelated endings.

Methods

Participants 24 participants completed similarity ratings; 25 different participants completed relatedness ratings. All participants were UCSD students; they received partial course credit as compensation.

Procedure For the similarity ratings experiment, participants were asked to consider word-pairs in the context of the Harry Potter stories and to judge their similarity in meaning using a scale ranging from 1 ("not similar at all") to 7 ("nearly the same meaning"). They were given the following guide to judging similarity of word meanings:

(1) Do the two word meanings behave similarly (e.g., do they perform the same actions)?
(2) Do the two word meanings share physical / sensory properties (e.g., do they look, taste, smell, sound or feel similarly)?
(3) Do the two word meanings share many functional properties (e.g., are they used in similar ways, or do they serve a similar purpose)?
(4) Do the two word meanings share any other properties and/or features in common?

For the relatedness ratings experiment, instructions were similar, except participants were asked to judge words on how *related* they were using a scale ranging from 1 ("not related at all") to 7 ("very closely related)". They were given

the following guide to judge whether the pairs were meaningfully related:

(1) How likely are the words to show up within the same context (that is, in/around the same part of the HP stories)?
(2) How important does one word seem to be for understanding the meaning of the other?
(3) Are the two words related via some theme, topic, event, or episode/scenario in the HP stories?
(4) Are the two words related via any other relationship?

Participants in Exp. 2a-b also completed a 10-question trivia quiz assessing their HP knowledge and a questionnaire about their HP experience.

Results

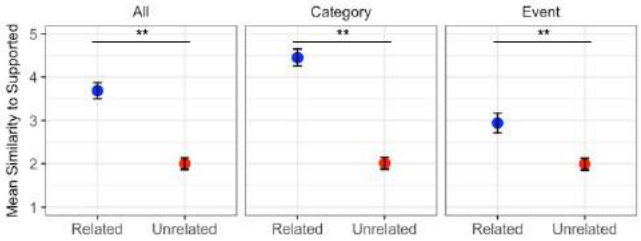
As expected, mean similarity ratings for Supported-Related word pairs were greater than those for Supported-Unrelated word pairs (Fig. 2a). This pattern was similar for both the category- and event-related item subsets, but was larger for the category-related subset, which might be expected based on greater similarity due to feature overlap between members of the same category (compared to words related via an event or episode).. Also as expected, HP knowledge was positively correlated with the size of the effect (i.e., similarity for Supported-Related word pairs minus similarity for Supported-Unrelated word pairs) at $r = .51$, $p < .05$.

In addition, mean relatedness ratings for Supported-Related word pairs were greater than those for Supported-Unrelated word pairs (Fig. 2b). This pattern was similar for both the category- and event-related item subsets. Also as expected, HP knowledge was positively correlated with the size of the effect (i.e., relatedness for Supported-Related word pairs minus relatedness for Supported-Unrelated word pairs) at $r = .68$, $p < .001$.

We also examined the correlation between the word2vec cosine similarity measures (Exp. 1) and the similarity and relatedness ratings for Supported-Related and Supported-Unrelated word pairs, respectively (Exp. 2). Cosine similarity was positively correlated with both similarity ($r = .43$, $p < .0001$) and relatedness ($r = .26$, $p < .01$) ratings for the Supported-Related word pairs, but not for the Supported-Unrelated word pairs (n.s.).

These results empirically indicate that our Supported sentence endings were indeed more similar/related to our Related, compared to Unrelated, endings. Moreover, that the size of these effects was positively correlated with HP knowledge further supports the notion that sensitivity to the relatedness manipulation depends on knowledge specific to the HP book series. Next we describe an ERP/EEG study designed to investigate the extent to which individual differences in domain knowledge influence the availability of information relevant for word processing—i.e., information cued by categorically / event related words—during real-time sentence processing.

(a)



(b)

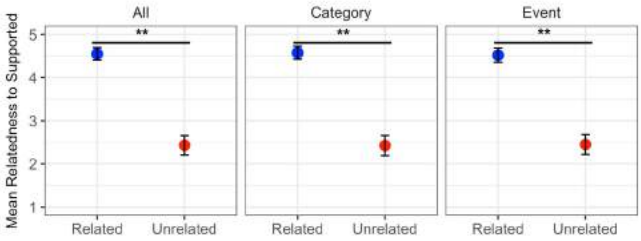


Fig. 2. (a) Across items and within each subset (Category-related, Event-related), similarity ratings for Supported & Related endings are greater than Supported & Unrelated (all ps < .01); this effect was larger for the category-related subset of items compared to the event-related subset ($p < .0001$). (b) Across items and within each subset, relatedness ratings for Supported & Related endings are greater than Supported & Unrelated (all ps < .001).

Experiments 3a-b: ERP studies

In Experiment 3, we asked whether certain aspects of the functional organization of semantic memory—namely organization of words/concepts via categories (wherein members share many similarities/features) and event/episode relationships—would be available to comprehenders as they read sentences about a fictional domain. We were particularly interested in whether the availability of not just the contextually supported information, but also the contextually unsupported, related information would be a function of the degree of individuals' domain knowledge.

To this end, participants of varying degrees of HP knowledge read 156 sentence pairs about the fictional world of HP while we recorded EEG (Experiment 3b). Sentences ended in a critical word that was either Supported, Related, or Unrelated (HP sentence materials described above). Three lists were then constructed so that every participant read each sentence frame and each critical word only once. That is, even though the same critical word appeared in other conditions on other lists, it never appeared in the critical position more than once in the same list. All but three words appeared as critical words in two or all three conditions. We expected that for individuals knowledgeable about HP, we would see a three-way difference in the amplitude of N400 potentials to the critical words, with the largest amplitude for Unrelated, the most reduced amplitude for Supported, and an intermediate amplitude for Related. We also expected that

N400 amplitude to Supported words would be positively correlated with HP knowledge (replicating Troyer & Kutas, 2018 and Troyer, Urbach, & Kutas, 2018). Moreover, we expected that N400 amplitude to Related words would be positively correlated with HP knowledge, consistent with the real-time use of differential functional organization of long-term memory as a function of degree of domain knowledge. For visualization of ERPs, we present subgroups of participants based on a median split on HP knowledge.

To demonstrate (a) that individuals spanning a range of HP knowledge scores could elicit N400 effects, more generally, and (b) that the relationship between HP knowledge and N400 effects was specific to sentences about HP, we also recorded EEG while the same participants read sentences about general topics (Experiment 3a). Due to time constraints, we included only 40 such sentences, half of which ended in a contextually Supported word / the best completion (determined by an offline cloze norming task in which participants provided completions to sentence frames) and the other half of which ended in a contextually Unsupported word (a plausible word that was low-cloze).

Methods

Participants 48 students from the UCSD community participated in the EEG study (Experiments 3a-b).

Experimental procedures Participants were instructed to silently read sentences for comprehension, first about general topics (Experiment 3a) and then about Harry Potter (Experiment 3b). In each experiment, the whole first sentence appeared in the center of the screen. When ready, participants pressed a button to move on to the second sentence, which was presented one word at a time in the center of the screen with a 500 ms SOA (200 ms on, 300 ms off). Following the ERP study, participants completed a 10-question HP trivia quiz and a questionnaire about their HP experience.

In addition, we collected several other measures of individual differences to better understand group differences among participants (see Troyer & Kutas, 2018, for more details). We combined measures of general print/reading experience (media and reading habits questionnaire, author and magazine recognition tests; Stanovich & West, 1989) for an aggregate reading experience score, and we also collected a measure of general knowledge (trivia quiz developed from freely available materials), and verbal working memory (sentence span, Daneman & Carpenter 1980). Finally, we administered a debriefing questionnaire.

ERP recording and data analysis The electro-encephalogram (EEG) was recorded from 26 tin electrodes geodesically arranged in an ElectroCap, with impedances kept below 5 KΩ. Recordings were referenced online to the left mastoid and re-referenced offline to an average of the left and right mastoids. EEG was recorded by Grass bio-amplifiers with a bandpass of .01-100 Hz at a sampling rate of 250 Hz. Trials contaminated by artifacts (e.g., eye movements or blinks) were not included in analyses.

Grand average ERPs to sentence-final words were computed across all 26 recording sites for each experiment and by Ending Type (3a: Supported / Unsupported; 3b: Supported / Related / Unrelated). For statistical analyses, we used linear mixed effects models and focused on a region of interest (ROI) where N400 effects are typically largest, including an average of 8 centro-parietally distributed channels (MiCe, LMCe, RMCe, MiPa, LDPa, RDPa, LMOc, and RMOc) in a canonical N400 time period (250-500 ms) relative to a 200 ms pre-stimulus baseline.

Results

ERPs from our centro-parietal ROI are shown in Fig. 3. ERPs to critical words are characterized by N1 and P2 sensory components. Across all participants, the P2 is followed by a relative negativity (N400), which is most reduced for Supported words compared to Unsupported (Control) and Unrelated/Related (HP) words.

Experiment 3a: Control sentences. Our primary aim in analyzing the control experiment was to ask (a) whether individuals, irrespective of their degree (or depth) of HP knowledge, would elicit standard N400 effects to contextually supported vs. unsupported words in sentences about general topics and (b) to determine whether HP knowledge influenced the size of this effect. We predicted that HP knowledge would have a specific influence on sentences about HP, but not on the size of the effect for control sentences. Our results confirmed this prediction. We observed main effects of ending type (Supported < Unsupported; $p < .0001$) and HP knowledge (individuals with greater HP knowledge tended to yield overall somewhat more positive-going N400 potentials; $p < .01$), but critically, no interaction between ending type and HP knowledge. That is, the size of individuals' N400 reduction to contextually supported, compared to unsupported, words did not differ as a function of individuals' degree of HP knowledge.

Experiment 3b: HP sentences. We expected that HP knowledge would modulate N400 amplitude to contextually supported words in sentences about HP, as in previous studies. In addition, we asked whether HP knowledge would also modulate N400 amplitude to contextually unsupported, but related, words in HP sentences. We observed a reliable interaction between HP knowledge and ending type ($p < .05$) and followed up using planned comparisons examining (a) the Unrelated vs. Supported endings and (b) the Unrelated vs. Related endings, finding that HP knowledge interacted with ending type in both cases (both ps < .05). Follow-up analyses revealed that HP knowledge was correlated with N400 amplitudes to Supported words (Pearson's $r = .57$, $p < .0001$) and Related words (Pearson's $r = .47$, $p < .001$), but not to Unrelated words (n.s.).

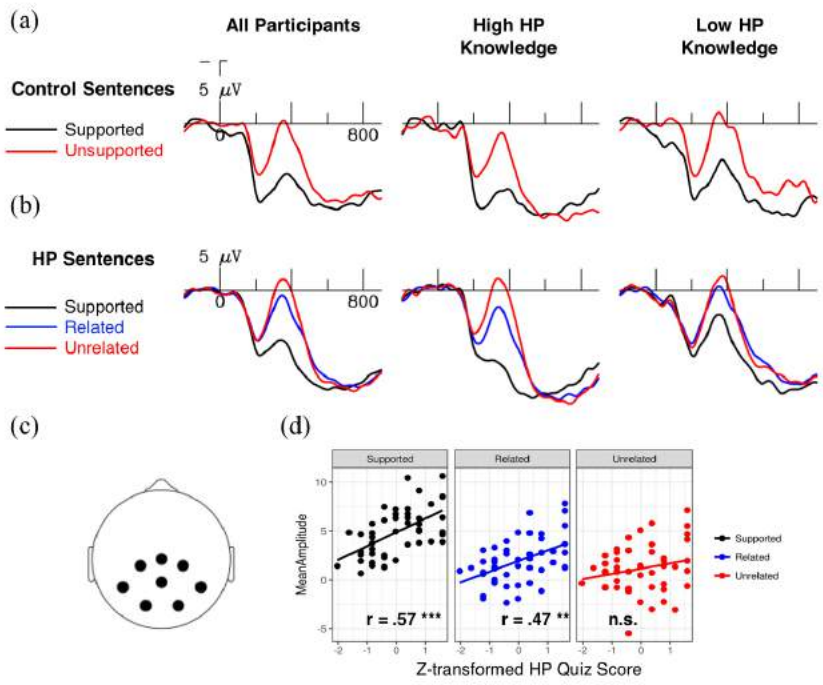

Fig 3. ERPs are plotted to critical words from Control (a) and HP (b) sentences for an ROI based on an average of 8 centro-parietal channels (c). For Control sentences, across all participants, Supported words elicited a reduced N400 compared to Unsupported words; there was no interaction between ending type and degree of HP knowledge. For HP sentences, across all participants, Supported words showed reduced N400 amplitude compared to Unrelated words, with Related words eliciting an intermediate N400. Reductions in N400 amplitude for both Supported and Related words were largest for individuals with high HP knowledge and smallest for individuals with low HP knowledge. (d) N400 amplitude is plotted against HP knowledge; the correlation between the two was strong for Supported and moderate for Related words, but was not significant for Unrelated words.

Due to some differences present in similarity metrics for category- vs. related-anomaly subgroups of items (Exp. 1-2), we also tested whether there were systematic differences in the N400 response between subgroups of materials. However, linear mixed effects models revealed no interaction of ending and related anomaly type on N400 potentials nor any interaction between these predictors and HP knowledge.

To rule out the possibility that other existing individual differences (namely reading experience, general knowledge, and verbal working memory scores) could better account for the observed variability in N400 ERPs, we tested a model that incorporated fixed effects of ending type, HP domain knowledge, general knowledge scores, reading span scores, and aggregate reading experience scores along with interaction terms for each individual differences measure with ending type. We compared this model and a similar model that did not incorporate interaction terms with any individual differences measures (except for the HP domain knowledge-by-ending type interaction term), and found that the more complex model did not explain additional variance.

Discussion

We asked whether, when, and to what extent individuals' degree of domain knowledge of the fictional world of HP would reliably influence the availability of meaningfully relevant information during written language comprehension, even when it was linguistically unexpected. To that end, we assessed a set of materials in which sentence contexts set up expectations for contextually supported words, along with sentence endings that were contextually unsupported, but were meaningfully related or unrelated to the sentence contexts and/or to the supported endings. In a word-by-word reading ERP study, we probed the extent to which real-time access to the same sentence endings was modulated by domain knowledge.

Importantly, individuals' degree of HP knowledge did not influence the size of the contextual support effect for Control sentences about general topics. Replicating Troyer & Kutas (2018), we found that N400 reduction to supported words was strongly predicted by degree of domain knowledge. Moreover, we observed a similar pattern for critical words that were contextually unsupported, yet related to the sentence context and/or supported word.

These results suggest that variation in knowledge—even of a fictional narrative world—influences what knowledge is retrieved in real time, which we believe is likely to reflect the way that knowledge is functionally organized. Our results further suggest that having relatively more knowledge, and thereby more organization around categories and/or events, allows for quick availability of this relevant organization during real-time reading. That is, knowledgeable individuals can quickly (pre)-activate relevant featural and/or thematic (as in the event-related subset of items) information—the very knowledge that is needed to make sense of words in real time. Moreover, individuals' degree of knowledge seems to predict the likelihood with which and/or extent to which such information becomes available for use. These methods and findings invite new research using knowledge-based individual differences to better understand how language processing interfaces with knowledge in real time. For example, future work could combine subject-level domain knowledge and sentence-and-word-level similarity and/or relatedness measures (e.g., based on computational models (Exp. 1) or human judgments (Exp 2.)) to investigate their joint influences at the individual trial level.

Environmental Regularities Shape Semantic Organization throughout Development

Abstract

Our knowledge of the world is an organized lexico-semantic network in which concepts can be linked by relations, such as "taxonomic" relations between members of the same stable category (e.g., *cat* and *sheep*), or association between entities that occur together or in the same context (e.g., *sock* and *foot*). Prior research has focused on the emergence of knowledge about taxonomic relations, whereas association has received little attention. The goal of the present research was to investigate how semantic organization development is shaped by both taxonomic relatedness and associations based on co-occurrence between labels for concepts in language. Using a Cued Recall paradigm, we found a substantial influence of co-occurrence in both 4-5-year-olds and adults, whereas taxonomic relatedness only influenced adults. These results demonstrate a critical and persistent influence of co-occurrence associations on semantic organization. We discuss these findings in relation to theories of semantic development.

Keywords: semantic development; semantic organization; categories

Introduction

Our knowledge about the world is fundamental to many of the cognitive feats we accomplish on an everyday basis, including applying what we know to new situations, retrieving knowledge from memory, and incorporating new information into existing knowledge (Bower, Clark, Lesgold, & Winzenz, 1969; Heit, 2000; Tse, Langston, Kakeyama et al., 2007). These feats are possible due to the organization of our knowledge into an interconnected lexico-semantic network of related concepts (Cree & Armstrong, 2012; McClelland & Rogers, 2003). For example, our knowledge of dogs is often connected to our knowledge of other similar animals (e.g., cats), as well as to our knowledge about the contexts in which dogs appear, such as with leashes and doghouses.

Although the fact that our concepts are organized is hardly controversial (e.g., McClelland & Rogers, 2003), the processes that drive the development of semantic organization are a topic of considerable debate. To date, this debate has focused on how connections between concepts from the same stable, "taxonomic" category (e.g., *animals*, *foods*) are formed, in spite of the fact that they may be difficult to observe: Members of the same (especially superordinate) taxonomic category do not necessarily look similar, or occur together. Some have proposed that semantic development begins with easy to observe relations that are then used to bootstrap taxonomic knowledge (Lucariello, Kyratzis, & Nelson, 1992). Alternately, others have proposed that we are endowed with early-emerging biases towards learning taxonomic relations (e.g., Gelman & Markman, 1986).

The goal of this research is to investigate another possibility: That easy to observe relations – specifically, co-occurrence – play a fundamental role in shaping knowledge organization from early in development through adulthood. In this paper, we first review traditional theoretical accounts that have focused on taxonomic relations, then highlight key findings suggestive of a role for co-occurrence that these accounts fail to capture, and an alternate perspective that we test in the present experiment.

Traditional Accounts of Semantic Development

Most extant accounts of the development of semantic organization have focused on how semantic knowledge becomes organized according to membership in taxonomic categories, such as *foods*. According to some accounts, referred to here as *restructuring* accounts, taxonomic relations are the endpoint of development. Critical to these accounts is the idea that the order in which relations between concepts are acquired is dictated by how observable they are. For example, it is easy to observe that cups have the same shape, or reliably co-occur with juice or milk, whereas membership in the same superordinate taxonomic category is more difficult (if not impossible) to observe. Restructuring accounts propose that early organization is shaped by information readily available in the environment, and that taxonomic knowledge comes to replace this (more rudimentary) organization.

An early restructuring account was proposed by Inhelder and Piaget (1964), in which the transition to taxonomic organization is driven by experiences that highlight the inadequacy of earlier modes of organization (although the mechanisms by which this transition occurs are not clear). Another, more specified restructuring account is Nelson and Lucariello's (1992) slot-filler account, which highlights environmental input in which some members of the same taxonomic category play the same role in the same context, such as some members of the taxonomic category of *foods* (e.g., eggs and bacon) reliably *being eaten* in a *breakfast* context. According to this account, young children are sensitive to these regularities, such that semantic knowledge is first organized into contextually-constrained taxonomic groups, which are gradually integrated together as children recognize when entities play the same role in different contexts (e.g., foods *being eaten* in different meal contexts).

According to another set of accounts, referred to here as *taxonomic bias* accounts, taxonomic relations predominate semantic organization from early in development due to early-emerging (possibly innate) biases towards learning which entities are members of the same taxonomic category. These biases include beliefs that entities in the world belong to taxonomic categories, and that labels are indicative of category membership (e.g., Gelman & Coley, 1990). A role for other types of environmental input, such as the regularity with which entities co-occur, is not specified.

A final type of account reviewed here, which we refer to as *featural learning*, posits that the development of semantic organization is driven by detecting clusters of features

whose appearance in entities is reliably correlated, and which are often associated with taxonomic category membership (Rosch, 1975). For example, membership in the category of *birds* is associated with possessing *wings*, *feathers*, and a *beak*. Featural learning accounts propose that sensitivity to these correlations yields taxonomic organization (e.g., McClelland & Rogers, 2003). In contrast with taxonomic bias accounts, featural learning accounts argue in favor of the gradual emergence of taxonomic organization over the course of development. However, featural learning accounts do not consider spatial or temporal co-occurrence of items in the world (or language) as contributors to semantic organization.

Environmental Regularities Overlooked by Traditional Theoretical Accounts

Of the influential accounts reviewed in the previous section, only some restructuring accounts posit any role in semantic development for environmental regularities with which entities and their labels co-occur. Even in these accounts, these regularities are ultimately overwritten. However, several findings highlight a potential importance of co-occurrence regularities *throughout* development.

First, statistical learning studies suggest that sensitivity to the regularity with which different entities co-occur is apparent from very early in development (Bulf, Johnson, & Valenza, 2011). Moreover, numerous findings attest to the influence on children's reasoning of semantic relations that may be derived from co-occurrence, such as *schematic* relations between entities that occur in the same context (e.g., *cow* and *barn*) and *thematic* relations between entities that play complementary roles (e.g., *nail* and *hammer*) (Blaye, Bernard-Peyron, Paour, & Bonthoux, 2006; Fenson, Vella, & Kennedy, 1989; Lucariello et al., 1992; Walsh, Richardson, & Faulkner, 1993). Additionally, a handful of studies conducted by Fisher, Godwin and Matlen (Fisher, Matlen, & Godwin, 2011; Matlen, Fisher, & Godwin, 2015) point more directly towards an influence of co-occurrence on children's semantic reasoning. In these studies, participants were asked to infer whether a property (e.g., "has blicket inside") attributed to a target (e.g., glove) was shared by either a strongly taxonomically related item (e.g., mitten) or a more weakly taxonomically related item (e.g., sweater). These studies revealed that four year old children only reliably chose the strongly taxonomically related item when its label co-occurred with the target either in corpora of children's speech input (e.g., bunny-rabbit, Fisher et al., 2011) or an empirically manipulated speech stream (Matlen et al., 2015). These findings suggest that accounts of semantic development that do not posit any role for co-occurrence are at best incomplete.

Second, a handful of findings suggest that semantic relations that may be derived from co-occurrence continue to shape semantic organization into adulthood. For example, Lin and Murphy (2001) found that relations between entities that adult raters judged as associated in scenes or events (which likely co-occur) had a pervasive influence on adults' categorization and reasoning that was frequently greater than the influence of taxonomic relations. This evidence is inconsistent with restructuring accounts, in which an early influence of co-occurrence is eventually overwritten.

Finally, the potential contributions of co-occurrence regularities are highlighted by a mechanistic account and corroborating behavioral evidence presented by Sloutsky, Yim, Yao, and Dennis (2017). According to this account, exposure to co-occurrence regularities in language fosters both the learning of associations between concepts whose labels directly co-occur in sentences (e.g., *fork* and *spaghetti*), and between taxonomically related concepts whose labels share patterns of co-occurrence (e.g., *spaghetti* and *pie*). However, whereas co-occurrence in a sentence can be directly gleaned from input and therefore rapidly learned, shared patterns of co-occurrence that often link members of the same taxonomic category are learned more slowly because they can only be derived from multiple instances of direct co-occurrence. This account predicts both that (1) direct co-occurrence should contribute to semantic organization throughout development, and (2) the contributions of direct co-occurrence to semantic organization should be evident earlier in development than the contributions of taxonomic relatedness. Initial evidence for this account comes from a series of experiments presented in Sloutsky et al. (2017) in which children and adults were asked to infer the category membership of a novel word (e.g., whether it was an animal or a machine) that was presented within a list of familiar words. Both children and adults readily inferred the category membership of the novel word when it appeared in a list of words that are associated (and therefore likely to co-occur) with the same category. For example, participants inferred that the novel word referred to an animal when it appeared in a list of words including "furry" and "zoo". However, only adults inferred this meaning when the novel word appeared in a list of words referring to *members* of the category, such as "lion" and "bunny".

Together, these prior findings suggest that co-occurrence regularities may shape semantic development. However, in addition to being overlooked in traditional theoretical accounts of the development of semantic organization, this possibility has received only limited empirical investigation to date, and the way in which it has been investigated has not been designed to assess relational knowledge for items that *actually* co-occur in the environment. Critically, this research has instead investigated knowledge for relations between items either judged by researchers or participants as co-occurring according to researcher-specified criteria, or produced in free association tasks. Neither ratings nor free associations are inputs from the environment from which semantic relations can be learned: They are *outcomes* of relations already learned and present in semantic knowledge (Hofmann, Biemann, Westbury et al., 2018). A more direct investigation of the role of co-occurrence in shaping semantic development could be accomplished by assessing

the contributions of co-occurrence regularities present in actual environmental input.

Current Study

The overall purpose of the current study was to investigate the contributions of co-occurrence regularities and taxonomic relatedness to the organization of lexico-semantic knowledge from early childhood to adulthood. This investigation was designed to arbitrate between competing theoretical accounts of the development of knowledge organization. Specifically, restructuring accounts predict that co-occurrence should contribute to knowledge organization in childhood, but be replaced by taxonomic relations in adulthood. Both taxonomic bias and featural learning accounts are agnostic about the contributions of co-occurrence, but whereas the former predict that taxonomic relations should contribute from childhood through to adulthood, the latter predict that the contributions of taxonomic relations should substantially increase with age.

A different developmental pattern is predicted by recent proposals that highlight a key role throughout development for co-occurrence in which it both directly fosters relations between concepts, and indirectly fosters relations between concepts that share patterns of co-occurrence and are often taxonomically related (e.g., Sloutsky et al., 2017). Specifically, such proposals predict that the contributions of co-occurrence should be evident in both children and adults, whereas contributions of taxonomic relatedness should be evident only later in development.

We accomplished this investigation by measuring the degree to which familiar concepts were related in young children (4-year-olds) and adults' semantic knowledge when either the concepts' labels reliably co-occur in linguistic input, or when they are members of the same taxonomic category. To target actual experienced co-occurrence, we identified pairs of words familiar to young children that co-occurred more reliably with each other than with other words in corpora of child-directed speech.

To measure the contributions of co-occurrence and taxonomic relations to children and adults' lexico-semantic knowledge, we used a Cued Recall paradigm to measure the effects of co-occurrence and taxonomic relatedness on memory retrieval. We selected this paradigm for two reasons. First, the sensitivity of this task to semantic relatedness is attested by numerous findings that semantic relatedness influences the accuracy with which people (including children) recall word pairs and lists (Bjorklund & Jacobs, 1985; Blewitt & Toppino, 1991). Second, this task facilitates a comparison between children and adults because it measures contributions to lexico-semantic knowledge without requiring participants to reason about relations, which adults may more easily.

Table 1: Pairs of words used in the Co-Occur, Taxonomic, and Unrelated conditions

Co-Occur		Taxonomic		Unrelated	
bottle	baby	ball	puzzle	crayon	frog
foot	shoe	pig	bear	towel	bread
brush	hair	horse	bunny	blocks	cereal
cup	juice	carrot	banana	balloon	tree
cheese	mouse	fork	bowl	sheep	pancake
car	street	popcorn	fries	pizza	lion
soup	spoon	airplane	boat	fish	bed
milk	cow	sock	pajamas	duck	swing

Method

Participants

The sample included 30 4-5 year old children (M_{age}=4.50 years, *SD*=1.62 years), and 29 Adults (M_{age}=20.16 years, *SD*=3.66 years). The child age group was selected because the 4-5 year period is one during which the nature of relations that organize lexico-semantic knowledge has been the subject of active debate (Lucariello et al., 1992; Nguyen & Murphy, 2003; Waxman & Namy, 1997). Children were recruited from families, daycares, and preschools in a metropolitan area in a Midwestern US city. Adults were undergraduates from a public university in the same city and participated in exchange for partial course credit.

Stimuli and Design

The primary stimuli used in this experiment were word pairs that belonged to one of three Semantic Relatedness conditions: Co-Occur (pairs that reliably co-occurred with each other more often than with other words in child speech input), Taxonomic (words close in meaning from the same taxonomic category) or Unrelated. (words that neither reliably co-occur nor are similar in meaning).

Co-Occurrence Criteria. The first step taken to select pairs in each condition was to identify a set of words for which lexical norms collected using the MacArthur-Bates Communicative Development Inventory (MB-CDI) were available from WordBank (an open database of children's vocabulary development, Frank, Braginsky, Yurovsky, & Marchman, 2016), and measure their rates of co-occurrence in 25 child speech input corpora from the CHILDES database (MacWhinney, 2000). To reduce the computational expense of measuring word co-occurrence rates, some classes of words that would *a priori* not be used as stimuli were removed, such as sounds (e.g., "moo"), leaving a list of 538 words. Additionally, to ensure that co-occurrences were measured from speech *input*, CHILDES corpora were pre-processed to remove speech produced by children. Co-occurrences between these words were then calculated by taking all possible pairs of words in this set, and calculating how frequently they co-occurred with each other within a 7-word window across 25 CHILDES corpora. Finally, to account for the fact that more frequent words co-occur with other words simply by chance, t-scores (Evert, 2008) were calculated for each word pair using the formula below based on their measured co-occurrence frequencies (O), adjusted for the frequency of co-occurrence expected by chance based on their respective frequencies across the corpora and the size of the corpora (E):

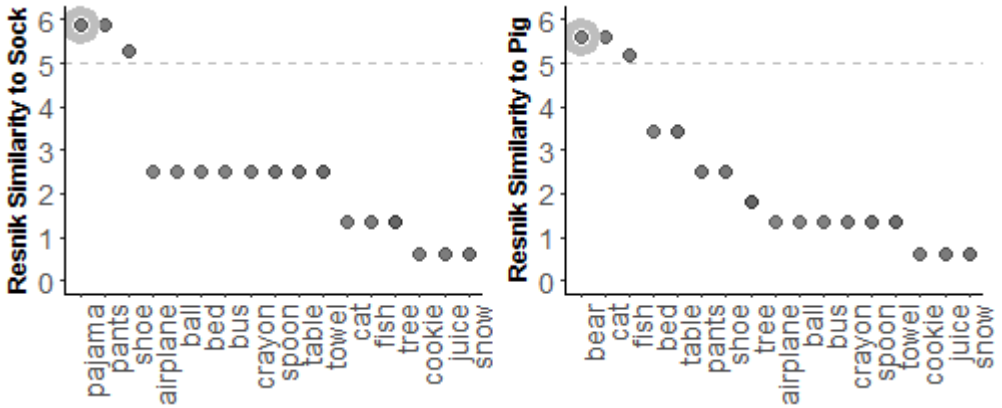

Figure 1: Graphs depicting Resnik similarity between one item from a Taxonomic pair and: (1) The other item from the pair (highlighted), (2) Other items from the same taxonomic category, and (3) Items from other categories.

$$t.score = \frac{O - E}{\sqrt{O}}$$

Word pairs for use in the Co-Occur condition were then selected as pairs of nouns with t-scores > 2.5 (following Baayen, Davidson, & Bates, 2008) in which, according to lexical norms accessed from WordBank, both words were produced by >80% of 36-month-old children (one year younger than children in our sample).

Taxonomic Criteria. Taxonomic relatedness was determined based on both the membership of concepts in the same taxonomic category (e.g., clothing, foods, animals) and similarity in *meaning* between their labels. Similarity in meaning was measured as similarity between the definitions of candidate words from WordNet (a database of word definitions composed by lexicographers). This measure captures the essence of taxonomic relatedness – i.e., close similarity in meaning – without relying on participant judgments that may be influenced by non-taxonomic relations (Wisniewski & Bassok, 1999). In WordNet, nouns are first grouped into sets of synonyms, which are in turn linked into a hierarchy according to "IS A" and part-whole relations. Similarity in meaning between word pairs was measured using Resnik similarity, i.e., the information content (specificity) of the word lowest in the WordNet hierarchy within which the pair of words is subsumed. For example, *dog* and *cat* are subsumed within *carnivore*, whereas *dog* and *kangaroo* are subsumed within mammal; because the information content of carnivore is greater than the information content of mammal, Resnik similarity is higher between dog and cat versus dog and kangaroo.

Candidate Taxonomic pairs nouns with Resnik similarities of > 5 and t-scores < 1.5 in which both were produced by at least 80% of 36-month-old children according to WordBank norms. The rationale of the Resnik similarity criterion of > 5 is illustrated in Fig. 1, which shows that this value distinguished between same- vs. different-category items.

Unrelated Criteria. Candidate Unrelated word pairs were noun pairs that met the WordBank production norm criterion with t-scores and Resnik similarities of < 1.5.

Composition of Full Set. From the sets of candidate pairs, eight pairs were selected for each of the Relation conditions (Co-Occur, Taxonomic, and Unrelated) such that: 1) The mean percentage of 36-month-olds who produced the words in the pairs according to Wordbank norms was equated across conditions, and 2) No words appeared in more than one condition (Table 1). An additional 4 nouns that met the WordBank production norm criterion were selected to construct pairs used for demonstration and practice (see Procedure below). All words were recorded by both a male and a female speaker using an engaging, child-friendly intonation.

The eight pairs in each Relation condition were divided into two Stimulus Sets, each with four pairs in each condition, because pilot testing indicated that 12 pairs was the maximum number that could be presented to children without producing floor effects. Within each Stimulus Set, each word in a pair was randomly assigned to be either the Cue or Target. In the experiment, Cue words were presented using the male speaker's voice, and Targets using the female's voice. Additionally, the 12 word pairs were pseudorandomized into three blocks, such that each block contained 1-2 pairs from each condition. The order of these blocks was counterbalanced across participants.

Procedure. Adult participants were tested in a quiet space in the lab, and children were tested either in a quiet space in the lab, or at their preschool or daycare. The procedure was identical for adults and children (including the auditory presentation of the same recorded Cue-Target pairs), with the exceptions that: 1) Instructions were conveyed by an experimenter for children, and as text on a computer screen for adults, and 2) Children made verbal responses recorded by the experimenter, whereas adults typed responses.

To start, participants were informed that they were going to play a game with two sock puppets depicted on the computer, Izzy and Ozzy, in which Izzy and Ozzy would say pairs of words. The two demonstration/practice unrelated Cue-Target spoken word pairs were then played, while animations depicted one puppet "saying" the Cue word, and the other saying the Target word. Participants

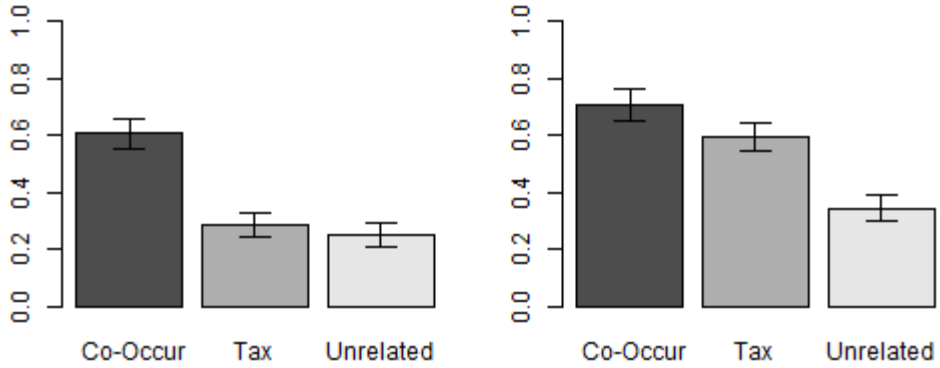

Figure 2: Accuracy in children (left) and adults (right) in the Relation Conditions. Error bars represent standard errors.

then completed two practice rounds with the same Cue-Target pairs consisting of a Study Phase, in which participants were instructed to remember the words that went together in pairs, and a Test phase, in which only the Cue in each pair was presented and participants were prompted to either say or type the Target that had been spoken by Ozzy. Participants received corrective feedback after each practice trial, and completed up to three practice rounds until they either responded with the correct Target for both Cues within around, or the experiment was terminated.

Participants then proceeded to complete the three blocks of Cue-Target pairs in the Stimulus Set to which they had been randomly assigned. Each block followed the same Study and Test phase format as the practice rounds, with the exception that participants did not receive feedback.

Results

The primary outcome measure of interest for this study was the accuracy with which participants recalled Target words paired with Cues in each of the three Relation conditions: Co-Occurrence, Taxonomic, and Unrelated[1]. Responses were scored as accurate when participants made responses identical to the Target, morphological variants of the Target (e.g., "spoons" instead of "spoon"), or close synonyms to the Target (e.g., "road" instead of "street").

All analyses were conducted in the R environment. Mixed effects models were generated using the lme4 (Bates, Maechler, Bolker, & Walker, 2015) package, and corresponding χ^2 or F-statistics for main effects and interactions were generated using the car package (Fox & Weisberg, 2011).

Preliminary Analyses: Stimulus Set Comparison

We first tested whether any effect of condition varied across the two Stimulus Sets in children and adults. For data from each age group, we generated a binomial generalized linear mixed effects model with Accuracy (0 or 1) as the outcome variable, Relation condition (Co-Occurrence, Taxonomic, and Unrelated) and Stimulus Set (1 vs. 2) as fixed effects, and participant and item as random effects. This analysis revealed no significant interaction between Relation condition and Stimulus Set (ps > .23). For all subsequent analyses, we therefore collapsed across Stimulus Sets.

Primary Analyses

Accuracy by age and condition is presented in Figure 2. To test the relative influences of Relatedness conditions (Co-Occurrence, Taxonomic, and Unrelated) on accuracy, we generated an omnibus binomial generalized linear mixed effects model with Accuracy (0 or 1) as the outcome variable, Relatedness condition and Age group (children and adults) as fixed effects, and participant and item as random effects. This analysis yielded main effects of Relatedness condition ($\chi^2(2)=25.26$, $p<.001$) and Age group ($\chi^2(1)=10.36$, $p=.001$) that were qualified by an interaction ($\chi^2(2)=7.87$, $p=.02$).

To investigate the interaction between Relatedness condition and Age group, we conducted two sets of analyses: A first set in which we compared the effects of the different Relatedness conditions in each Age group, and a second set in which we compared the effects of each Relatedness condition in children versus adults.

Relation Conditions in Each Age Group. In these analyses, we generated for each age group a binomial generalized linear mixed effects model with Accuracy as the outcome variable, Relatedness condition as a fixed effect, and participant and item as random effects. These models

[1] We also analyzed participants' errors to test the frequency with which the incorrect responses participants in each age group produced either co-occurred with or were taxonomically related to the Cue. However, these analyses did not contribute meaningfully to our results. The majority of incorrect responses in both age groups were other words from the set of word pairs the participant heard (64% in children, 82% in adults). Of these responses, only a small minority (7-14%) were either co-occurring with or taxonomically related to the Cue, which was likely the result of the random chance with which some words from the list, when randomly recombined with Cues, happen to be related to them in some way. Of responses not drawn from the list of word pairs, the only detectable pattern was a tendency for children to respond with incorrect words that co-occurred with the Cue (52%) more often than words that were taxonomically related to the Cue (6%). This pattern mirrors the results of analyses of children's accuracy.

revealed significant effects of Relatedness condition in each age group (ps < .001) (Figure 3). To conduct pairwise comparisons of the Relatedness conditions in each age group, we re-generated the model for each age with each of the Relatedness conditions as the reference level, and applied Bonferroni-adjustments to the resulting p-values. In children, these analyses revealed significant differences between the Co-Occurrence (M=0.60, SD=0.49) and both Unrelated (M=0.25, SD=0.43) and Taxonomic conditions (M=0.29, SD=0.45) (ps < .001), but no difference between the Taxonomic and Unrelated conditions (p > .99). In adults, these analyses revealed a significant difference between the Co-Occurrence (M=0.71, SD=0.46) and Unrelated conditions (M=0.34, SD=0.48) (p < .0001), the Taxonomic (M=0.59, SD=0.49) and Unrelated conditions (p=.033), and no significant difference between Co-Occurrence and Taxonomic conditions (p=.237).

Comparison of Children and Adults. To compare the accuracy of children versus adults in each Relatedness condition, we generated a binomial generalized linear mixed effect model for each Relatedness condition, each with Age Group as a fixed effect, and participant and item as random effects. Additionally, we applied Bonferroni-adjustments to all p-values to correct for multiple comparisons. These analyses revealed only a significant difference between children and adults in accuracy in the Taxonomic condition (p<.001). In comparison, there was no significant difference in accuracy between children and adults in either the Co-Occur or Unrelated conditions (ps>.2).

General Discussion

The purpose of the present experiment was twofold: (1) To investigate how semantic development is shaped by co-occurrence regularities and taxonomic relatedness, and (2) More broadly, to investigate whether the development of semantic organization involves the maintenance of early-emerging taxonomic organization throughout development (as in taxonomic bias accounts), the restructuring of semantic organization (as in restructuring accounts), or the addition of new semantic knowledge that does not replace earlier-emerging knowledge.

In this experiment, we observed substantial effects of co-occurrence in both young children and adults. In contrast, an influence of taxonomic relatedness was only apparent in adults. Importantly, due to our use of an implicit measure of semantic knowledge, this developmental pattern is unlikely to be attributable to developmental improvements in reasoning. These findings therefore support a key role for co-occurrence in semantic development, and are consistent with an overall developmental trajectory in which some types of semantic knowledge (such as taxonomic) tend to supplement rather than supplant earlier-emerging knowledge.

Generalizability of Findings

In order to evaluate the support for a key role for co-occurrence in lexico-semantic development, it is important to consider the possibility that the cued recall paradigm used in this experiment biased the results in favor of this outcome. Specifically, accurately recalling pairs of words may better evoke participants' prior knowledge of word pairs that they have experienced occurring together than their knowledge of taxonomically related words.

However, this possibility is undermined by corroborating evidence from very different paradigms that do not involve recalling word pairs. First, as described in the introduction, findings from studies conducted by Fisher, Godwin, and Matlen (Fisher et al., 2011; Matlen et al., 2015) have provided evidence for the contribution of co-occurrence to semantic reasoning. Specifically, these studies found that young children only reliably infer that an item shares a property with another, strongly taxonomically related item when their labels co-occur (e.g., bunny-rabbit). Moreover, the pattern of results in adults and children has recently been replicated using another, very different paradigm in which the contribution of a given form of relatedness is measured based on the degree to which it interferes with participants' ability to identify when a picture (e.g., of a baby) does *not* depict the same thing as a preceding word (e.g., "bottle") (Unger & Sloutsky, Under Review). Taken together, these findings suggest a general contribution of co-occurrence to lexico-semantic knowledge that is not dependent upon the use of a cued recall-based assessment.

Impatient to Receive or Impatient to Achieve: Goal Gradients and Time Discounting

Oleg Urminsky
University of Chicago, Chicago, Illinois, United States

Indranil Goswami
University of Buffalo, Buffalo, New York, United States

Abstract

When people behave impatiently, prioritizing sooner outcomes at the expense of latter ones, is it because they value achieve their goal sooner, or because they value receiving the benefits sooner? Prior research has often confounded goal gradient (the stronger motivational effect of more proximal goals) and time discounting effects on decision-making. We first establish a preference to invest in the earlier of two equally difficult goals (e.g, a first-goal preference) that could be explained either by relative goal gradients or by differences in time discounted value. We then experimentally separate the timing of goal completion and reward receipt. We find separate and disassociated large goal gradient and somewhat smaller time discounting effects. Our results suggest that goal gradient effects may provide a partial, but substantial, explanation of time discounting and, consequently, can inflate estimated discount rates when not accounted for.

Structural Thinking about Social Categories: Evidence from Formal Explanations, Generics, and Generalization

Nadya Vasilyeva (nadezdav@princeton.edu)

Tania Lombrozo (lombrozo@princeton.edu)

Department of Psychology, Princeton University, Princeton, NJ, 08540, USA

Abstract

Most theories of kind representation suggest that people posit internal, essence-like factors believed to underlie kind membership and the observable properties of members. Across two studies (N = 234), we show that adults can construe properties of social kinds as products of both internal and *structural* (stable external) factors. Internalist and structural construals are similar in that both support formal explanations (i.e., "category member has property P due to category membership C"), generic claims ("Cs have P"), and a particular pattern of generalization to individuals when the individuals' category membership and structural position are preserved. Our findings thus challenge these phenomena as signatures of essentialist thinking. However, once category membership and structural position are unconfounded, different patterns of generalization emerge across internalist and structural construals, as do different judgments concerning category definitions and property mutability. These findings have important implications for reasoning about social kinds.

Keywords: structural explanation; kind representation; generalization; essentialism; inherence; social categorization

Introduction

Kind representations allow people to organize, store, and use conceptual information efficiently and productively. We rely on our representations of social groups and natural kinds to make sense of the world, generate explanations, and make predictions about the individual category members we encounter. Most theories of kind representation, especially for natural and social kinds, emphasize an internalist bias, a tendency to look "within" the kind for deep, causally active, and explanatorily powerful factors that hold categories together, and that shape and maintain the properties of their members. This internalist bias can take the form of assumptions about internal causal structure (psychological essentialism; Gelman, 2003), or a preference for explanations citing factors that are inherent, as opposed to contextual or extrinsic (inherence heuristic; Cimpian & Salomon, 2014). Different manifestations of internalist bias have been widely documented (Haslam et al., 2010; Gelman, 2003; Rangel & Keller, 2011), and it has been proposed as a conceptual default, with profound – and often negative - consequences for the way we think about and behave towards members of social categories. For example, explaining a dearth of women in mathematics by appeal to their "essential" or inherent nature can discourage girls from pursuing careers in this field (Leslie, Cimpian, Meyer, & Freeland, 2015).

Some linguistic forms have been argued to promote internalist construals, in particular of social kinds. Generic expressions, which attribute a property to a category in general (e.g., "women fail math tests") have received particular attention (e.g., Cimpian, 2010; Cimpian & Markman, 2010; Rhodes, Leslie, & Tworek, 2012). There is also evidence that formal explanations, which appeal to category membership to explain a property (e.g., "Priya doesn't like math because she's a girl"), reflect internalist beliefs (Gelman, Cimpian, & Roberts, 2018; Prasada & Dillingham, 2006).

While internalist modes of thinking have been extensively explored in the psychological literature, alternative ways of representing kinds have received much less attention. One such alternative is *structural thinking*, and in particular, a structural construal of category-property connections (Haslanger, 2015; Vasilyeva, Gopnik, & Lombrozo, 2018). On a structural construal, stable associations between categories and their properties arise from stable external constraints acting on category members. For example, the categories "women," "men," "Blacks," and "Latin@s" occupy relatively stable social positions within a given social structure. These positions can differ across cultures and possess their own properties. To illustrate, the generics "women don't drive," or "women are bad a math," can be true in one social system but false in another. Such culture-dependence is one cue that a property-category association should be attributed to a *social position* rather than to *the category occupying that position.*

Because a social position and the category that occupies it can share the same label (e.g., "women"), we contend that generics and formal explanations can be interpreted in either internalist or structural terms. For example, a person could endorse a formal explanation ("He ended up in prison because he's Black") or a generic ("Black men end up in prison") for different reasons: under an internalist construal, attributing the property ("being in prison") to the category itself (e.g., presumed criminal inclinations), or under a structural construal, attributing the same property to the social position, constituted by a conglomeration of stable constraints acting on members of the category in virtue of occupying that position (e.g., unequal opportunities for Black youth, biased hiring and other barriers to wealth, racial profiling by the police, etc. – all the factors that together constitute the social position "Black" in the US).

In the current research, we test the prediction that adults can construe property-category associations in either

internalist or structural terms, and that both construals support formal explanations (Study 1) and generics (Study 2). However, we also investigate important ways in which internalist and structural construals are expected to differ. Because internalist and structural construals allocate different roles to category membership (vs. a category's social position) in explaining an associated property, we expect internalist and structural construals to result in different intuitions about using the property in category definitions (Study 1), different "mutability" judgments about true category membership when the property is removed (Study 1), and different patterns of property generalization as category membership and/or social position change (Study 2).

Documenting these predicted patterns of similarity and difference across internalist and structural construals is important for a number of reasons. First, alternatives to internalist thinking have rarely been articulated and tested. Documenting a psychologically real alternative can thus enrich our understanding of the mental representations that support our thinking about social (and potentially non-social) kinds. Second, given that internalist construals have been linked with the perpetuation of stereotypes and other negative social effects (Bastian & Haslam, 2004; Cimpian, 2010), an alternative form of construal could identify changes in mindset that would mitigate these effects. A structural construal is especially promising in that it explains (rather than ignores) property-category associations that in fact obtain (such as a low proportion of women in math) while also pointing to structural factors that could be targets of intervention.

While structural explanation has received attention within the philosophy of social science (Ayala, 2018; Ayala & Vasilyeva, 2015; Haslanger, 2015; Garfinkel, 1981), there has been little empirical work on the topic to date. In a recent paper, Vasilyeva, Gopnik, and Lombrozo (2018) reported a study investigating structural thinking in adults and children aged 3-6. Using open-ended explanations, category definition tasks, mutability judgments, and measures of formal explanation, they found that even 3-year-olds showed signs of early structural thinking, with greater differentiation between internalist and structural construals in older children and adults. The present work goes beyond Vasilyeva, Gopnik, and Lombrozo (2018) in five important ways: in using more realistic social categories (a group of immigrants); in exploring structural reasoning about novel social groups; in using a wide range of properties matched in terms of property/cue validity (Study 1) or content (Study 2); in the introduction of a control condition (Study 1 and Study 2), and in exploring judgments concerning generics and generalizations under different conditions (Study 2).

Study 1

In Study 1, we introduce participants to a novel social category ("Borunians," an immigrant group in the fictional country of Kemi), along with a suite of associated properties (e.g., holding low-paying jobs). Across properties, we vary whether the category-property connections are explained in a way that is internalist (e.g., appealing to group identity), structural (appealing to social position), or incidental (the associations just happen to be true). To test whether this manipulation is successful in inducing different construals, we adapt measures originally developed in Prasada and Dillingham (2006, 2009) to differentiate "principled" and "statistical" connections, and used also in Vasilyeva, Gopnik, and Lombrozo (2018). These measures include partial definition evaluation (i.e., whether the category can be defined in terms of the property), category mutability ratings (i.e., whether an individual missing the property is a true category member), and formal explanation evaluation (i.e., whether the presence of the property can be explained by appeal to category membership).

First, as explained in the introduction, we expected both internalist and structural construals to support formal explanations (e.g., "He holds a poorly paid job because he's a Borunian"). Second, we expected the internalist and structural conditions to differ with respect to partial definitions and mutability. A definition of a category in terms of an "essential"/inherent feature should be more appropriate than a definition citing a feature that holds only in virtue of a category's position in a social structure. Likewise, removing an internal feature should produce more damage to category membership than removing a feature acquired through a social position, and therefore contingent on external structure. These predictions found support in Vasilyeva, Gopnik, and Lombrozo (2018); we test them here with a more realistic social kind, a broader range of features, and a modified mutability measure.

Finally, and going beyond Vasilyeva, Gopnik, and Lombrozo (2018), we included features with an "incidental" explanation for which we predicted a profile of effects different from either internalist or structural thinking, based on Prasada and Dillingham (2006, 2009). We expected that incidental features would not support definitions and would be seen as easily mutable (like structural features), but that they would not support formal explanations (in contrast to both internalist and structural features).

Method

Participants Seventy-seven participants (38 women, 39 men; mean age 33) were recruited on Amazon MTurk in exchange for $1.50; in this and subsequent studies participation was restricted to workers with an IP address within the United States and with a HIT approval rating of 95% or higher from at least 50 previous HITs. An additional 33 participants were excluded for failing a memory check.

Materials, Design, and Procedure Participants read a short vignette introducing the novel social category of "Borunians" - a group of immigrants settled in a fictional country, *Kemi*, who originally immigrated from Bo-Aaruna. Borunians were characterized by 18 unique features, with 6 of each type: *Internalist* (tying the feature to Borunians' tradition and identity), *incidental* (roughly equivalent to Prasada and Dillingham's (2006) "statistical"), and

Table 1. Examples of features used in Study 1.

Internalist: Borunian traditions are extremely important to them, and form part of their identity: Borunians have a special tattoo on one arm.	*Incidental:* Here are some statements about Borunians that are true, but there's nothing about these features that ties them to Borunian culture, tradition, personality or anything about their place in Kemi society: Borunians barbeque in their back-yards all year round, so they buy a lot of barbequing coal all year round.	*Structural:* Here are a few characteristics that Borunians have due to their position in the Kemi society and governmental policies applying to Borunians: Borunians are *not* allowed to take any job with an income over 20,000 Kemi dollars per year (approximately 20,000 USD) if other appli-cants for the same job include Kemi citizens who are equally or more qualified. Due to this regu-lation, Borunians hold mostly poorly paid jobs.

structural (tying the feature to the structural constraints acting on Borunians due to their position within Kemi society). Sample features are shown in Table 1. All features were presented in generic form. A norming study with a separate group of 23 participants verified that the three feature types did not differ in mean cue and category validity.

After learning the features, each participant performed one of three judgments – formal explanation (e.g., Question: Why does he hold a poorly paid job? Answer: Because he is a Borunian. How good is this explanation? 1 not good at all - 7 very good), *partial definition* (e.g., Question: What is a Borunian? Answer: A Borunian is a person who holds a poorly paid job. How good is this answer? 1 not good at all – 7 very good), or *mutability* (e.g., Imagine an alternative world where people we call Borunians do not hold mostly poorly paid jobs. From your perspective, would you call them really and truly Borunians? (1 definitely no - 7 definitely yes). Each judgment involved 18 ratings, one about each feature. Prior to the main set of ratings, participants practiced the judgment type they were assigned on two practice trials that involved rating a feature of a dog ("has four legs") and of a barn ("is red").

In sum, the study implemented a 3 (judgment type: formal explanation, partial definition, mutability; between subjects) by 3 (feature type: internalist, structural, incidental; within subjects) design.

Results and Discussion

Participants' ratings were analyzed in an ANOVA with feature type as a within-subjects factor and judgment as a between-subjects factor, followed by planned *t*-tests. The main effect of judgment was significant, $F(2,74) = 5.70$, $p = .005$, $\eta_p^2 = .133$, and the main effect of feature type was marginal, $F(2,148)=2.99$, $p=.053$, $\eta_p^2=.039$. However, of most theoretical importance was the significant interaction between judgment and feature type, $F(4,148)=31.54$, $p<.001$, $\eta_p^2=.460$. As shown in Figure 1, each feature type had a unique "profile" across the three judgments. As predicted, and replicating Prasada and Dillingham's (2006, 2009) findings, internalist features (relative to incidental features) better supported formal explanations ($p=.003$) and definitions ($p<.001$), and were judged less mutable ($p< .001$). Also as predicted, structural features (relative to internalist features) supported definitions less strongly, and mutability judgments more strongly ($ps<.001$). However, they supported formal explanations to the same extent ($p=.327$), and more strongly than incidental features did ($p<.001$).

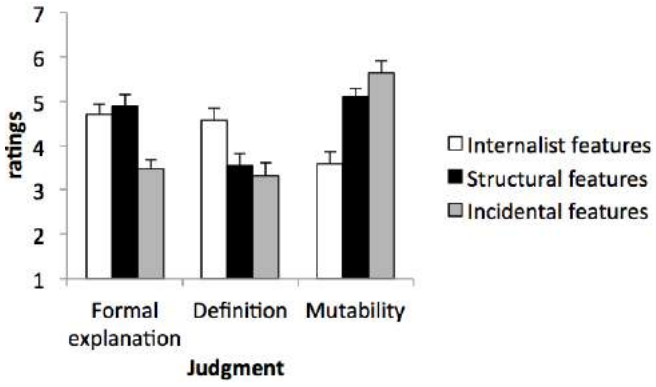

Figure 1: Participants' ratings as a function of feature type and judgment in Study 1. Error bars represent 1 SEM.

In sum, we find the predicted profile of effects for category-property associations introduced with a structural explanation. These associations behaved like internalist features in supporting formal explanations, but like incidental features in terms of partial definitions and mutability. It is worth noting that this structural pattern of responses was elicited by offering appropriate cues in the feature description, but did not require any explicit guidance or training in structural reasoning. This suggests that this mode of thinking may occur naturally in adults' cognitive lives when appropriate cues are present. It's also notable that the cues took the form of explanations, which presumably fed into causal-explanatory models that supported a representation that attached the property to the category versus the social position it occupied.

Study 2

In Study 2, participants received information about the prevalence of a property in the Borunian population, as well as an internalist, structural, or no explanation for the category-property association. Participants then rated their endorsement of a corresponding generic claim ("Borunians [have property]"), and generalized the properties in question to individual targets that varied both in category membership (same or different) and in social position (same or different).

This design allowed us to test two predictions. First, we predicted that internalist and structural construals would similarly support generic claims, with higher endorsement the greater the prevalence. Prior work has already shown that an internalist construal is not *necessary* for a generic to be endorsed; even statistical connections can support generics (Prasada & Dillingham, 2006, 2009; Tessler & Goodman, 2016). However, a structural construal additionally supports an interpretation of a generic claim whereby the category label refers to the social position that the category occupies.

Second, we predicted different patterns of generalization for properties explained internally vs. structurally as the generalization target varied in category membership and social position. In most real-life contexts, social category and social position are confounded, meaning that both internalist and structural explanations support the extension of category properties to individual category members (albeit for different reasons). De-confounding the category and position in our task, however, allows a predicted divergence between internalist and structural consturals to emerge. We expected a structural explanation to support greater generalization on the basis of shared position (relative to internalist), and an internalist explanation to support greater generalization on the basis of shared category (relative to structural). Additionally, we expected the effect of prevalence on generalization to be moderated by explanation, such that for participants who received a structural explanation (vs. internalist), prevalence effects would be weaker when social position was not preserved, and for participants who received an internalist explanation (vs. structural), prevalence effects would be weaker when category membership was not preserved. Comparisons to the control condition allowed us to assess the extent to which these effects were driven by a structural construal, an internalist construal, or both.

Method

Participants One-hundred-and-fifty-seven adults (76 women, 80 men, 1 agender; mean age 37) participated online in exchange for $1.50. An additional 30 participants were excluded for failing memory and attention checks.

Materials, Design, and Procedure We developed a new set of twelve features describing a fictional immigrant category, Borunians, introduced as in Study 1, and an internalist explanation and a structural explanation for each feature (see Table 2 for sample features and explanations). For the internalist condition, we intentionally chose a range of explanations spanning from more biological to those citing group preferences, values, and traditions (see further comments on this in the General Discussion). We also took care to keep the internalist and structural explanations of similar average length.

Each participant was assigned to one explanation condition (internalist, structural, or control), and completed two blocks of measures: generic truth ratings, and individual generalizations. In the generic truth rating block, participants saw the 12 features of Borunians, one at a time, in a random order, each accompanied by prevalence information (e.g., "Percentage of Borunians who hold poorly paid jobs: 48%"). For participants in the internalist or structural conditions, this was also accompanied by an explanation of the corresponding type (e.g., "Reason: in order to hire a Borunian for a well-paid job, employers in Kemi are required to file complicated government paperwork"). The feature prevalence (i.e., the percentage of Borunians with the feature) was drawn from a pool of 12 unique values, binned into Low (M=25%, range 20-29), Medium (M=50%, range 46-55), and High (M=75%, range 71-80). Below the prevalence information and explanation (if presented), participants read a generic statement attributing the feature to the category (e.g., "Borunians hold poorly paid jobs"), and were asked to classify it as "True" or "False."

In the individual generalization block, participants were asked to generalize a property from the kind (Borunians) to an individual. Participants were asked to rate their confidence that one of the properties previously attributed to Borunians (e.g., "holds a poorly paid job") held for that individual on a 9-point scale ranging from -4 (I'm confident it's false) to +4 (I'm confident it's true). Crucially, we manipulated both the category membership and the social position of the target individual: same vs. different category membership, and same vs. different social position. The resulting four scenarios are described in Table 3.

To ensure that participants still remembered the prevalence level and the explanation of each feature, the generalization rating block was split into three sets of four questions each. Each set of four questions was preceded by a reminder display with four features along with their prevalence levels and explanations (repeating the information from the first block). Further, to reduce memory load for prevalence levels, all four features in a set were pulled from the same prevalence bin (e.g., all had High prevalence). Following the reminder, participants saw

Table 2. Sample features and explanations used in Study 2. Each explanation was presented within the frame "Reason: [explanation]."

Feature	**Internalist Explanation** [Reason: ….]	**Structural explanation** [Reason: ….]
Follow a largely vegetarian diet	… a deficiency in digestive enzymes required for digesting meat	…special access to municipal subsidies to purchase vegetables directly from local farmers
Sell artisan souvenirs	…a natural affinity for design and great facility with fine-motor tasks	....special subsidies from the Kemi government to Borunians to obtain vendor permits for artisan booths
Get sunburn easily	…a genetic variation which makes Borunian skin very vulnerable to the effects of sunlight	…a high proportion of contaminants and skin irritants in the neighborhoods where Borunians live; these substances make their skin vulnerable to the effects of sunlight
Participate in donkey races	…agility and inherent skill with animals	…not allowed to participate in horse or car races
Live with their parents through adulthood	…a special value attached to family and elders, as well as living in tight-knit communities	… inability to afford the cost of maintaining independent residences
Hold poorly paid jobs	… strong preference to work regular hours; avoidance of demanding jobs that may require over-time	…in order to hire a Borunian for a well-paid job, employers in Kemi are required to file complicated government paperwork
Have poor credit ratings	…Borunians' reliance on a peculiar calendar with a different month length results in frequent late payments	….government banks imposed an additional step to verify every transaction for new immigrants, resulting in frequent late payments

Table 3. Descriptions of generalization targets produced by crossing same/different social category with same/different social position (note: social position is not the same as geographic location; non-Borunians in Kemi occupy a different social position from Borunians).

Scenario	Category	Position	Description
ALL SAME	Same	Same	Azz is a Borunian, and lives in Kemi.
MOVED	Same	Different	Nuvo is a Borunian who moved from Kemi a long time ago, and now lives in a completely different country, with an entirely different social system and regulations.
ADOPTED	Different	Same	Pau is a NON-Borunian by birth, who was adopted into a Borunian family in Kemi at a very young age, a long time ago, in a secret adoption (meaning the fact of adoption was never revealed, nobody except the parents knew that the child was adopted, and the child was brought up as a Borunian).
ALL DIFFERENT	Different	Different	Eken is a NON-Borunian who lives in Kemi.

the four generalization questions (one from each row of Table 3), in random order. The assignment of features to prevalence levels and question types, as well as the order of question sets, were counterbalanced across participants.

At the end of the survey, participants responded to a series of memory and comprehension checks (e.g., asking them to classify a list of characteristics and explanations as mentioned vs. not mentioned in the survey), as well as individual difference measures that are not analyzed here.

Results

Generic Truth Ratings Data were analyzed in a mixed effects logistic regression, predicting generic truth ratings from numerical prevalence, explanation, and their interaction (allowing for random intercepts for participants and items). To compare all three explanation conditions in this and the following regression models, the model was fit with the control condition as the reference group, and then re-fit with the structural condition as the reference group. Prevalence was the only significant predictor ($p<.001$): the odds of a "true" judgment increased 1.10 times per unit of increase in prevalence. Binning the prevalence predictor into three levels, the mean proportions of "true" responses were .25 (Low), .74 (Medium), and .94 (High). All other predictors were not significant, $ps \geq .244$, indicating that explanation condition did not affect overall generic endorsement, nor moderate the effect of feature prevalence.

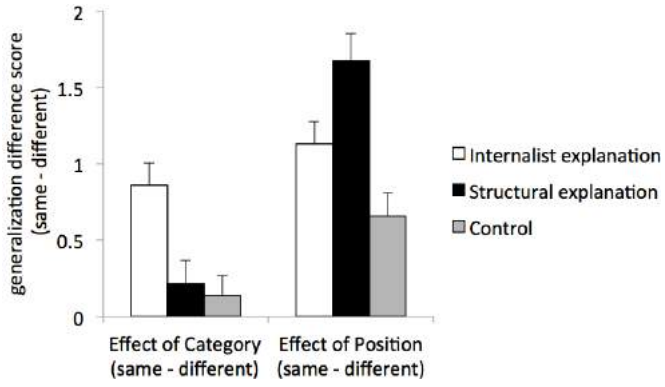

Figure 2: To represent the interactions between explanation condition, shared category membership, and shared social position, we created "generalization difference scores" (mean difference in generalization to individual in same vs. different category, and same vs. different social position). Error bars represent 1 SEM.

Individual Generalization A hierarchical linear model predicting individual generalization from centered numerical prevalence, explanation condition, shared category (yes or no), and shared social position (yes or no), with random intercepts across participants, revealed a four-way interaction, $p=.001$. To investigate this interaction further we ran additional analyses. First, to evaluate the prediction that an internalist explanation elevates the importance of shared category membership as a basis for generalization (relative to structural or control), we dropped prevalence and shared social position from the model, and predicted individual generalization from condition and shared social category. As expected, we observed significant interactions between regressors. The effect of shared category membership was stronger in the internalist condition relative to structural, $p=.006$, and to control, $p=.002$, which did not differ from each other, $p=.734$ (Figure 2). Second, to evaluate the prediction that a structural explanation elevates the importance of shared social position as a basis for generalization (relative to internalist or control), we predicted individual generalization from condition and shared social position. Again, we observed the expected interactions between regressors (see Figure 2), revealing a stronger effect of shared social position in the structural condition than either the internalist, $p=.014$, or control condition, $p<.001$. The internalist condition also heightened the relevance of social position relative to the control condition, $p=.036$, which suggests that our internalist explanations (perhaps by appealing to culture) also involved some social / structural elements.

Next, we addressed the prediction that the effect of prevalence on generalization would be moderated by explanation type. Given that the prevalence estimates that were offered corresponded to Borunians in Kemi (and not necessarily to non-Borunians or Borunians in other social positions), we expected the effect of prevalence to weaken with distance from the "ALL SAME" generalization target. However, we also expected that a change in category membership would attenuate the effect of prevalence more strongly in the internalist than in the structural condition, and that a change in social position would attenuate the effect of prevalence more strongly in the structural than in the internalist condition. To address this prediction, we considered the two cells that crossed category membership and social position ("ADOPTED" and "MOVED"; see Table 3), and ran separate models predicting individual generalization from prevalence and explanation condition (see Figure 3).

In the "MOVED" scenario, prevalence positively predicted generalization, β=.41, p<.001. Mirroring the results presented in Figure 2, participants were also *less* likely to generalize in the structural condition than in the internalist condition, B=-.45, p<.001, or in the control, B=-30, p=.008 (the latter two did not differ, B=.15, p=.181). Most crucially, however, we also observed interactions, such that the effect of feature prevalence was *weakened* in the structural condition relative to the internalist condition (B=-.31, p=.002) and control (B=-.33, p=.001); the effect of prevalence did not vary across the latter two explanation conditions (B=.018, p=.865).

In the "ADOPTED" scenario, prevalence positively predicted generalization, β=.67, p<.001. However, the predicted interaction between prevalence and explanation, with an attenuated effect of prevalence in the internalist condition (relative to control) was only marginal, B=-.19, p=.0502. Moreover, contrary to our expectations, the effect of prevalence was significantly attenuated in the structural condition (relative to control), B=-.33, p=.004. The extent to which the prevalence effect was attenuated, relative to control, did not differ across the two explanation condition, p=.117.

Finally, we considered the remaining two generalization targets, "ALL SAME" and "ALL DIFFERENT," for which we did not predict differential effects of explanation type. In

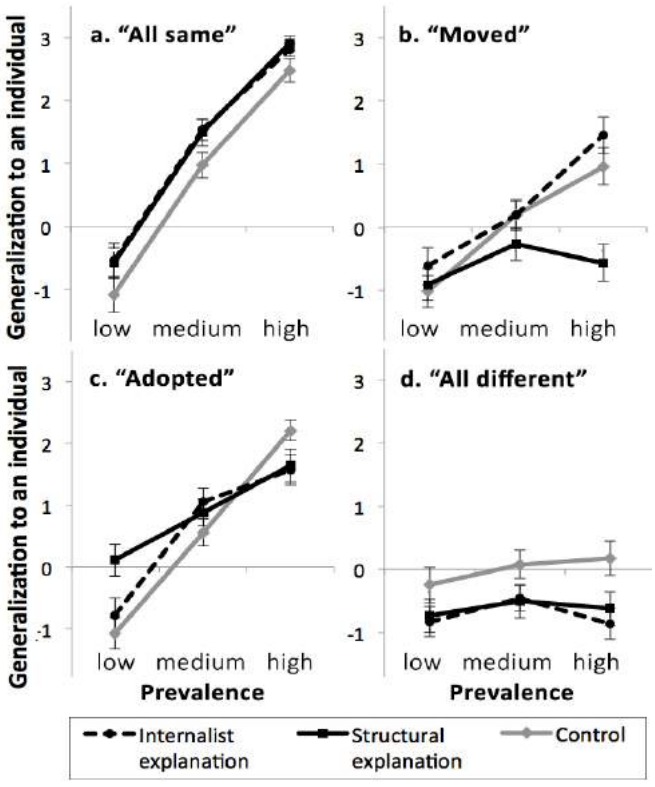

Figure 3: Mean individual generalization ratings as a function of within-category feature prevalence (binned into low, medium, and high ranges for presentation) and explanation type, split by the scenario (same or different category, and same or different social position). Error bars represent 1 SEM.

predictor of generalization, β = 70, p<.001, and both the "ALL SAME" scenario, prevalence was a positive internalist and structural explanations boosted generalization relative to control (B_{Int}=.20, p=.031; B_{Str}=.19, p=.036); the internalist and structural explanations did not differ, p=.945. As predicted, there were no significant interactions, ps ≥.780.

In the "ALL DIFFERENT" scenario, feature prevalence did not predict generalization, β=.10, p=.162. Participants were less likely to generalize in either explanation condition, relative to control ($B_{Int\ vs.\ control}$ =-.39, p=.005; $B_{Str\ vs.\ control}$ = -.34, p=.013); the two explanations did not differ, p=.708. As predicted, there were no significant interactions, ps >.238.

Discussion

Study 2 identified important respects in which internalist and structural construals overlap: both support generics, and both are equally sensitive to within-category/position statistics when it comes to endorsing generics or drawing generalizations to individuals within the same category/position. On the other hand, internalist and structural construals diverge when it comes to generalizations that break the typical confounds between categories and social positions: an internalist construal favors generalization (and reliance on within category/position statistics) across changes in social position; a structural construal is less sensitive to the preservation of category membership. These patterns emerged clearly in the "MOVED" scenario; the "ADOPTED" scenario (which was also the most unusual) was less clear.

In real life, the divergence between internalist and structural construals might be even more pronounced than that observed here. For experimental purposes, we used the same features across explanation conditions; as a result, many invoked culture and group identity, possibly downplaying more internalist factors. Indeed, shared social position was more influential overall than shared category, and shared position boosted the generalization of internalist features relative to control (Figure 2). Plausibly, the internalist condition could have been made "more internalist" by using different feature sets across conditions and citing exclusively biological factors in internalist explanations, as is common within the abundant literature documenting essentialist (or more broadly internalist) reasoning. Given that our goal was instead to document the reality of a structural construal as distinct from an internalist construal, we opted for greater experimental control over maximally representative features.

General Discussion

Across two studies we document underappreciated flexibility in people's construal of social kinds: in addition to adopting an internalist construal (familiar from prior research), people are capable of adopting a structural construal, which makes sense of observed correlations between properties and categories without tying them to the inherent nature of the category. Given the dangers of internalist construals in the social domain, an alternative that

makes sense of observed correlations without perpetuating them could be of no small social value.

Contrary to the dominant view, generic language does not necessarily convey or induce essentialist beliefs: in Study 1, the generic language that introduced a category-property association did not prevent an alternative construal, and in Study 2, both construals supported the endorsement of generic claims. This calls for refining numerous claims about generics and formal explanations as ways of inducing essentialism or signaling which kinds should be essentialized (e.g., Rhodes, Leslie, & Tworek, 2012). At the same time, it remains a possibility that internalist construals are the default, or cognitively less demanding.

Our generalization results also have important implications: from a theoretical standpoint, they offer yet another illustration of how explanation shapes generalization (Lombrozo & Gwynne, 2014; Sloman, 1994; Vasilyeva & Coley, 2013; Vasilyeva, Ruggeri, & Lombrozo, 2018), directing it along the dimensions of shared category and/or position. From a methodological standpoint, they offer a cautionary note about interpreting generalization measures as indices of essentialism; willingness to generalize a category's property can signal either an internalist *or* a structural construal. Finally, from a practical standpoint, getting a fuller picture of how people generalize from categories to individual has important real-life implications (e.g., a manager deciding whether to hire a woman, based in part on an inference about whether she'll take a parental leave).

One interesting question that deserves future attention is how people represent and reason about the "cultural" properties of social groups, such as food or religious customs. Where do such features fall on the internalist-structural continuum? One possibility is to identify "cultural" with "structural." However, many aspects of culture, including preferencves, values, and attitudes, can be understood in internalist terms, where cultural properties reflect shared internal characteristics. Consistent with these dual interpretations, the very same cultural properties in Study 2 were treated as internalist (through explanations citing "a special value attached to family and elders" or "a strong preference to work regular hours") or as structural (by attributing them to stable external constraints). However, the question of how people reason about "cultural" features in more naturalistic contexts remains open.

In sum, across two studies, we show that internalist and structural construals elicit different representations of categories: in the former case a property is attached to the category, in the latter case to its social position. While both kinds of representations can effectively track environmental statistics and support inferences, they work differently, in ways that could have tangible social consequences.

Onomatopoeia, gestures, actions and words: How do caregivers use multimodal cues in their communication to children?

Gabriella Vigliocco (g.vigliocco@ucl.ac.uk)
Yasamin Motamedi, Margherita Murgiano, Elizabeth Wonnacott, Chloe Marshall, Iris Milan Maillo, Pamela Perniss

Abstract

Most research on how children learn the mapping between words and world has assumed that language is arbitrary, and has investigated language learning in contexts in which objects referred to are present in the environment. Here, we report analyses of a semi-naturalistic corpus of caregivers talking to their 2-3 year-old. We focus on caregivers' use of non-arbitrary cues across different expressive channels: both iconic (onomatopoeia and representational gestures) and indexical (points and actions with objects). We ask if these cues are used differently when talking about objects known or unknown to the child, and when the referred objects are present or absent. We hypothesize that caregivers would use these cues more often with objects novel to the child. Moreover, they would use the iconic cues especially when objects are absent because iconic cues bring to the mind's eye properties of referents. We find that cue distribution differs: all cues except points are more common for unknown objects indicating their potential role in learning; onomatopoeia and representational gestures are more common for displaced contexts whereas indexical cues are more common when objects are present. Thus, caregivers provide multimodal non-arbitrary cues to support children's vocabulary learning and iconicity – specifically – can support linking mental representations for objects and labels.

Keywords: language development; word learning; iconicity; onomatopoeia; co-speech gestures; child directed speech; naturalistic observation.

Introduction

Understanding how children acquire language, its onset and the developmental path thereafter - is one of the great challenges for the social sciences, with critical implications for education and for intervention in atypically developing children. Vocabulary learning is a central part of language development and is characterized as a hard problem: How do children know that the sounds people produce are 'words' for objects, actions and properties? At the core of most existing proposals is the long-held assumption that language is purely arbitrary: there is no recognizable link between a label and the corresponding referent in the world (e.g. between the English word *dog* and the furry, four-legged animal; de Saussure, 1916). Arbitrariness makes the task of learning words especially hard: how can children learn the correct referent in a visually cluttered world (where multiple objects, actions and properties are all possible candidates for a given label), or even worse, when the objects, actions and properties talked about are absent from the immediate environment?

However, in addition to being arbitrary, language presents also other types of form-meaning mapping characterized by a more transparent and motivated link (Dingemanse et al. 2015). For example, iconicity, across languages, can be found in the phonology of words, e.g. in onomatopoeia such as *meow* or *drip*. This expressive richness is particularly prominent once we look at the multimodal communicative context in which language is learnt: prosodic modulations (e.g. prolonging a vowel to indicate prolonged extension, *loooong*), iconic, representational gestures (e.g., tracing an up and down movement with the index finger while talking about a bouncing object), points and hand actions with objects (e.g., showing a toy hammer to a child or showing how to use the toy hammer) also contribute to the meaning of the message. In vocabulary learning, these iconic and indexical communicative cues may scaffold the mapping between words and world (Perniss et al., 2010; Perniss & Vigliocco, 2014).

Such cues have been previously documented. Onomatopoeia are over-represented early on in children's language development, both in children's vocabularies (Laing, 2014) and in the input they receive (Perry et al., 2017), though this prevalence declines as children age. Points have been reported as the most common gestures used by caregivers especially with very young children (under the age of 2, Iverson et al. 1999; Özçalıskan & Goldin-Meadow 2005), helping to isolate the referent from a complex scene and to link it to the provided label. Though points are common, iconic gestures are also present in parental input from early on in child development (Rowe et al., 2008), and present in the gestural repertoires of children (Acredolo & Goodwyn, 1988). Furthermore, Rowe et al. (2008) showed that parents' gesture use (including points and iconic gestures) predicts children's gesture use, which in turn predicts later vocabulary development, suggesting the importance of such cues for overall language development. Lastly, research has shown a link between direct manipulation of objects (i.e., hand actions) in caregiver-child interaction and children's learning (see Rohlfing 2011 for a review). However, most previous studies focus on a single cue (e.g. gestures or hand actions), rather than considering how the different cues are used together (and together with speech). Cartmill et al. (2013) find that the quality of parental communication, operationalised as how predictable certain words are given the surrounding context (e.g. speech, gesture, surrounding

objects), predicts child vocabulary size at 54 months. Though this suggests that the multiplex nature of child-directed communication might scaffold language learning, they do not analyse the information provided by different cues. Moreover, most studies have focused on learning contexts where label and referent co-occur spatially and temporally (e.g., when objects are present in the visual scene, or words are uttered while actions are ongoing). However, displaced contexts (i.e., when objects are absent) can also provide learning opportunities and previous research indicates that children do learn in these contexts (e.g., Tomasello, Stroberg & Akhtar 1996).

Here, we provide a first investigation that comprehensively assesses the distribution of iconic and indexical cues both in learning contexts in which objects are present, and contexts in which they are absent. We expect to find that iconic cues (onomatopoeia and representational gestures) will be especially important in displaced contexts because iconicity can evoke perceptual or auditory features of the object, in this way providing an imagistic link with the referent and help in bringing it to the 'mind's eye. Both iconic and indexical (points and actions with objects) cues can single out referents, when present, in complex and messy visual scenes, and thus provide cues to solve the referential ambiguity problem.

We use a semi-naturalistic method in which we video-recorded caregivers interacting with their child talking about objects (provided by the experiments) which were either known and unknown to the child. We introduced this manipulation as cases in which the child is unfamiliar with the object and its label are more clearly learning episodes. Moreover, we manipulated whether the objects talked about are either present or absent. We focus on children aged 2 to 3 years old as this is a time of remarkable vocabulary growth in which all critical elements of child-directed language are present, communication about displaced referents is present, and finally, at which children are assumed to be able to understand and produce iconic gestures (Özcaliskan & Goldin-Meadow, 2005).

Method

Participants. Thirty-four caregiver-child dyads participated in the study. The language used between the caregiver and the child was British English. All children included in our sample were aged between 24 and 42 months.

Materials. We used toys from four categories: foods, musical instruments, animals and tools. We chose these categories because they are very common for children of this age and because they offer opportunities for vocal and manual iconicity. We created sets of 6 toys from each of the four categories, such that each set contained 3 toys known and 3 toys unknown to the child (based on parental reports). Toys were selected for each child from a larger set of about 20 toy items per category, each of which were used for a roughly equal number of participants.

Procedure. Caregiver-child interactions took place in the families' homes. Before the session, caregivers were given a list of toy names from our full list and they were asked to indicate whether their child knew those objects and those words. They were also asked to fill in the Oxford Communicative Development Inventory (OCDI)[1]. During the session, two experimenters visited the family, and recorded interactions with two videocameras (one focusing on the caregiver, one focusing on the child and the interaction space). One experimenter checked the correct working of the videocameras while the other carried out the manipulations. The interactions were carried out at a table with the caregiver and the child sitting at 90 degrees from each other. Caregivers were asked to interact with their child in a natural way, as they usually did, but to try to talk about each of the objects provided. Drawings of the set of toys was given to the caregiver to help them remember which toys were in the set. The order of object present vs absent was counterbalanced across participants. When the interaction started with objects present, the experimenter brought to the table 6 toys from one category (e.g., animals) and left the room. The dyad talked about these toys for 3-5mins, then the experimenter re-entered the room, asked the child to help in tidying up the toys and then left the room for the displaced condition asking the caregiver and child to continue to talk (again for 3-5mins) about the toys they just played with. The experimenter then reappeared with a new set of toys until all toy categories had been used. When the toy absent condition came first, the caregiver was asked to begin talking about the toys that were about to come while she was going to get them from another room (caregivers were first familiarised with the toys). After 3-5mins, the experimenter brought in the set of toys, repeating this process for all four categories. The whole recording session lasted approximately 45-60 mins.

Coding of caregiver communication. The caregiver communicative behaviour was coded in the following manner.

(1) Speech. Data was transcribed by *utterance*, which is our unit of analysis (Berman & Slobin 1994). Lexical elements were transcribed further for *onomatopoeias* (including lexical onomatopoeia as well as sound effects) and for explicit mention of the referent (the toys in our sets) label. For each utterance, we coded the *topic*, as the specific toy (or multiple toys) that each utterance referred to, regardless whether labels were produced or not. Utterances were assigned to the known/unknown condition on the basis of their topic. Utterances not about the toy referents were coded as "other" for topic and were not included in any analysis.

(2) Points: gestures (using the index finger or the whole hand) that single out a referent by pointing to it*;*

[1] Performance on the CDI was at ceiling and therefore no analyses including this measure are reported.

(3) Iconic/representational gestures: gestures that represent referents by e.g. depicting aspects of their shape or manipulation.

(3) Hand actions: We coded hand actions and movements performed while holding or manipulating an object. These were divided into (i) *deictic* (i.e., showing) and (ii) *depicting* (e.g., demonstrating the use of a tool). Hand actions were only coded for the toys we provided, and thus can only occur in the toy present condition.

Thus, we distinguish in our coding between iconic cues (onomatopoeia and representational gestures) and indexical cues such as points. Another category is hand actions. Hand actions are indexical in that they direct attention to the referent. They can however, differ and we coded separately those that depicted some properties of the referent (depicting hand actions) from hand actions that showed the object to the child (deictic hand actions). We consider the distinction between iconic and indexical cues to reflect two different manners in which cues can be non-arbitrary: iconic cues *stand for* the object; indexical cues provide a visual link to the object but they do not stand for it. Fig. 1 shows screenshots of the different categories.

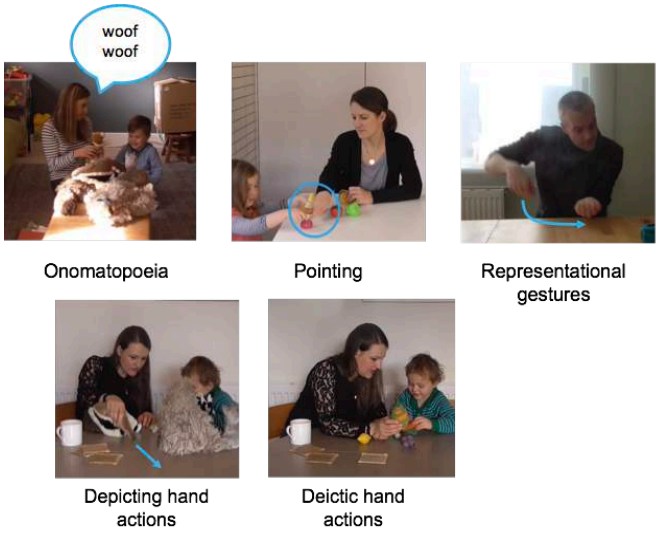

Figure 1. Examples of communicative behaviors coded in the different categories.

Results

Before looking at the distribution of the multimodal cues, we examined the distribution, across our four conditions, of caregiver utterances. Figure 2 illustrates how often parents talk about objects across conditions. Parents talk more when toys are present, and talk more about items unfamiliar to the child than those that are familiar. The larger number of utterances with objects present may indicate that it is easier to maintain the child's attention, or greater ease of production about present objects than about objects that need to be recalled.

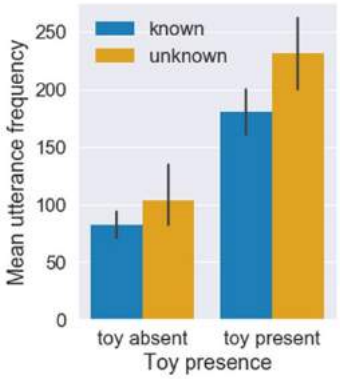

Figure 2. Mean utterance frequency

Iconic and indexical cue use. The primary aim of this study is to understand whether, and how, parents use onomatopoeia, representational gestures, points and hand actions (deictic and depicting) in their interactions with children. As such, we analysed whether age, familiarity (known vs. unknown object) and presence (present vs. absent) affect the use of each cue type.

Analyses use logistic mixed effects models to asses which factors affect the presence of absence of different cues. Age of the child (in months), presence or absence of the object, and familiarity of the label (known/unknown) were included as centered fixed effects, as well as their interaction, and the centered fixed effect of category (category is a control variable). We included a random intercept for participant with random slopes of presence/absence and label familiarity, plus their interaction. Dependent variables are presence/absence of each cue – referent label, onomatopoeia, representational gesture, point, hand action – in an utterance in a given condition). This model structure is used in all models throughout this section, unless otherwise specified. In the interest of space, only the effects of interest are reported here. Full results from the models can be found at https://osf.io/yegxh/.

First, we find that parents make use of all of these cues: approximately 39% of all utterances (11, 755 out of 30,283 utterances) in the dataset are modified by at least one iconic or indexical cue. Figure 3 shows the proportion of each cue across conditions in the study. Second, the proportion of points is low in comparison to the other, especially manual, cues. We attributed this to the affordances of the interaction context: toys were in close proximity to the caregiver and the child, therefore hand actions in this context can take the place of points (indeed, deictic hand actions represent 57% of all hand actions). Deictic and depicting hand actions are by definition only present when objects are present. These are more common for unknown than known objects and their frequency is not modulated by the children's age. *Points* are more common when objects are present, but we find no modulation regarding the familiarity of the label, or based on the age of the child.

Crucially, iconic cues that can be used across all our four conditions (onomatopoeia and representational gestures) show a clear effect of both toy presence and familiarity. In particular, for *onomatopoeia* we find that caregivers use them more often when toys are absent. We also find an interaction between familiarity and toy presence. When toys are present, caregivers use onomatopoeia more with known items. However, when toys are absent, we see the reverse, such that onomatopoeia occur more for unknown items. Interestingly, onomatopoeia decrease as the child's age increases; parents use fewer onomatopoeia with older children. For *representational gestures*, we see that these are overwhelmingly used when toys are absent and for unknown objects. No effect of age is observed. Table 1 summarises the model results.

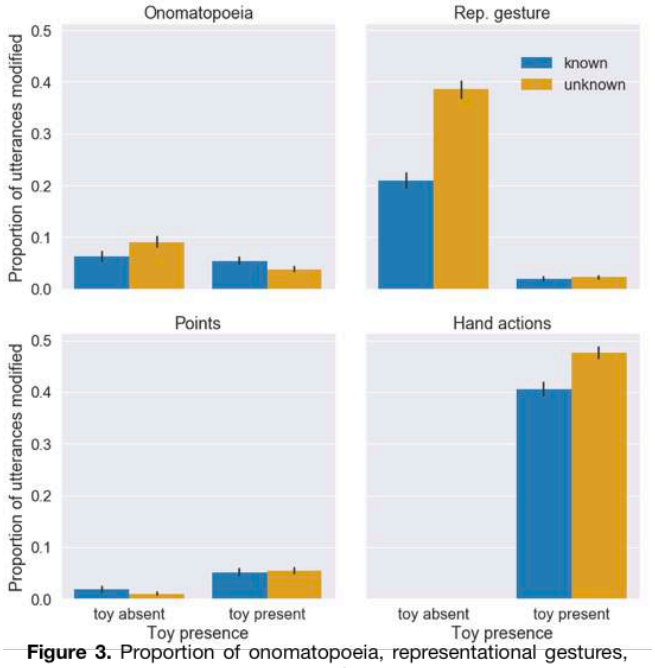

Figure 3. Proportion of onomatopoeia, representational gestures, and points across conditions (toy presence – situated vs displaced, and status – known vs. unknown). Hand actions can only be found in the situated condition. Error bars represent 95% confidence intervals.

Within utterances, cues can co-occur with other cues within and across modalities (e.g., in an utterance we may have a hand action and a representational gesture; or we may find an onomatopoeia and a hand action). Co-occurrences between cues (e.g., between onomatopoeia and hand actions) were remarkably rare in the dataset, occurring in only approximately 3% of parent utterances. Although we have a high proportion of cue modifications, we do not see a high proportion of cases where multiple cues co-occur.

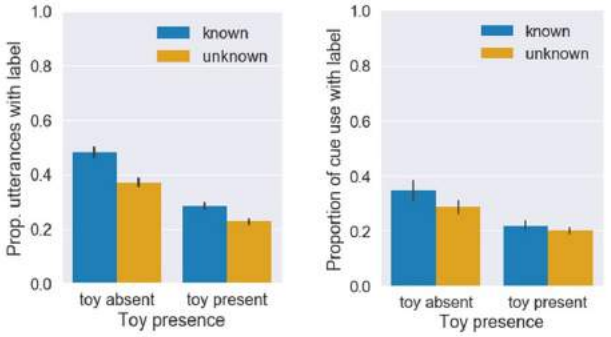

Figure 4. a) Mean proportion of label use, and **b)** Mean proportion of multimodal cues that co-occur with a label.

Label use. Finally, we looked how often parents use explicit labels for the objects (e.g. saying the word 'cat'). We find that parents use explicit referent labels more when the objects are not present, and tend to use the label more for familiar objects than unfamiliar objects. Analysis of a model predicting referent use confirms this: a decrease in referent use for unknown labels, compared with known ones (β=-0.43, SE=0.06, z=-7.60, p<0.001), and a decrease in referent use in the toy present condition, compared to the toy absent (β=-0.90, SE=0.08, z=-11.22, p<0.001). We also address the question of whether and when any of our multimodal cues co-occur with explicit naming of referents. If cues specifically help to link label and referent, then we might expect that use of multimodal cues occur in close proximity to the referent.

Onomatopoeia	β	SE	z	p
Age	-0.05	0.02	-2.39	0.02
Label familiarity	-0.04	0.13	-0.33	0.74

Label familiarity	0.07	0.14	0.45	0.65

Table 1. Summary of model results from logistic mixed effects models. Output variable given in bold. Note that the model for hand action does not include toy presence, as hand actions are not possible in cases where toys are absent.

All of the cues we coded for can co-occur with explicit labelling of the referent (e.g., naming the referent while producing a hand action or representational gesture; naming the referent in the same utterance in which an onomatopoeia is produced). We found that, overall, the multimodal cues occur with explicit naming of a referent approximately 35% of the time. Figure 4 illustrates referent-cue co-occurrence across conditions. We subsetted rows in the dataset where

any of our four cues were produced, to analyse how co-occurrence between cues and labels differed across conditions. The model revealed both an effect of familiarity (β=-0.32, SE=0.08, z=-4.30, p<0.001), and of toy presence (β=-0.58, SE=0.12, z=-4.98, p<0.001). Label-cue co-occurrence occurs more when toys are absent, and when the label is known to the child.

Discussion

The work reported here aimed to characterize the distribution of iconic and indexical cues in the input to 2-3 year-old children. We see that approximately 40% of the clauses produced by caregivers contains at least one of these multimodal cues which often co-occur with explicit labelling of objects especially when toys were present and unknown to the child.

Iconicity as a bridge between words and world

One main goal was to establish if multimodal cues are differentially distributed across contexts: (i) whether the child knows the object and its label, and (ii) whether the objects being talked about are present in the communicative context vs. absent. The latter manipulation has been introduced in order to assess the extent to which the multimodal communicative strategy of caregivers is responsive to the presence vs. absence of object, and whether they modify their language based on the physical setting in which the communication takes place.

The hypotheses we have test is one in which non-arbitrary cues in learning provide a stepping stone to the child to bridge between words and world (Perniss & Vigliocco, 2014). Both iconic and indexical cues can single our referents when these are present in the environment. Moreover, iconic cues can be used when the objects are absent to bring to the mind's eye properties of referents. Thus, indexical and iconic cues may play an important role in learning. We see that this is the case in our data. With the exception of points, which are equally likely for familiar and unfamiliar objects (and labels), all other cues are more commonly used for unknown objects (learning contexts). Crucially, the iconic cues (onomatopoeia and representational gestures) are also used more often when the objects are not present in the physical environment. The results for iconic cues are in line with previous work using a similar paradigm, where it was found that deaf caregivers modify iconic signs in British Sign Language (BSL) to highlight iconic properties of signs (e.g., enlarging the up-and-down movement path of the arm in the sign HAMMER) far more often when objects where absent than present (Perniss et al., 2017), suggesting that this tendency holds across language modalities. In contexts where the label is known to the child, we see that while representational gestures are still overwhelmingly most common for displaced contexts, this is not the case for onomatopoeia. Another interesting difference between onomatopoeia and representational gestures (as well as all other cues) is that onomatopoeia show a decrease with age, in the age range we considered (24-42 months). This finding is in line with previous work showing that use of onomatopoeia in caregivers and children's speech decreases from 0.8 to 2 years (Kauschke & Hofmeister, 2002; Kauschke & Klann-Delius, 2007; Laing, 2014). It has been suggested that for spoken languages, iconicity embedded in wordforms as onomatopoeia may act as a bootstrapping mechanism, a sort of protolanguage, guiding infants' attention to the fact that what comes out of the mouth is linked to what happens in the world (see Imai & Kita, 2014; Laing, 2014).

Iconic vs Indexical cues

We have distinguished points from representational gestures: points don't stand for an object - like representational gestures do - but they direct attention to the object via direct deixis. Just like representational gestures, they are non-arbitrary. Although, in principle iconic cues could be found both when objects are present as well when they are absent, they are far more common in displaced contexts (note however that we observe depicting hand actions in situated contexts); points also, in principle could be found in both contexts, but they are overwhelmingly more common in situated contexts (and deictic hand actions can only be present in situated contexts). This is in line with what was observed in a previous study in BSL where pointing was also much more common in situated than displaced contexts, though the use of indexing to abstract locations in space is common in signed language (Perniss et al., 2017). In the introduction, we mentioned two ways in which non-arbitrary cues can support language development. First, they can help singling out referents when these are present. Both iconic and indexical cues can do this, however, indexical cues may be better placed, as they can be used from earlier age and they provide an unambiguous visual link to the referent. Second, they can help evoking - via imagery - properties of referents that are not present. Iconic cues are best suited to support this type of learning scenario. Note that our study might have called for the use of iconic cues also linked to learning about properties of novel objects. When children were presented with unfamiliar objects, caregivers also used iconicity (especially depicting hand actions) to show the child how the object is used, or how it moves.

How are cues orchestrated?

Previous work suggests that some cues co-occur. For example, Laing et al. (2017) showed that onomatopoeia are usually prosodically marked and Kita (1997) reports that representational gestures tend to co-occur with onomatopoeic and other sound-symbolic words in Japanese. However, we did not observe any tendency for cues to co-occur (although we did not code for prosody in our dataset at this point and therefore we acknowledge that things might be different when considering prosody). For the cues we have considered, it is clear that caregivers choose one cue, presumably on the basis of affordances of the objects (e.g., onomatopoeia for toy animals, representational gesture for tools) to associate to

each utterance. We found that explicit label productions are more likely to co-occur with a multimodal cue when objects are absent and when objects are known to the child. Precisely why this may be the case is unclear; given that labels themselves appear more frequently when toys are absent, it may be that parents use the label in conjunction with cues when toys are absent to make reference to a given object more salient. When the toys are present, it is possible to interact with or point to the toys, making direct reference less necessary.

Conclusions

This study provides a first snapshot of the distribution of multimodal cues in child-directed language. We found a clear indication that iconic as well as indexical cues are well represented in caregivers' input and crucially, they are especially used in those contexts where they may be most useful to children: namely in learning contexts, where the objects and labels talked about are unfamiliar to the child and when the learning occurs in displaced contexts where the objects are not available. It is important to note that the work reported here only provides a partial picture, however. First, the interactions in this study are focussed on contexts of play, which may not be representative of other interactional contexts. Secondly, missing from the current picture is prosodic modulation, which is a key feature of child-directed speech (e.g., Fernald & Simon, 1984; Fernald, 1989; Fernand et al., 1989) and which has been shown to be associated to onomatopoeia (Laing, 2017). Finally, and most important, is the fact that the present work focuses on the communication by the caregiver only, without considering the child's communication, thus giving the impression that the child is a passive receiver of input from caregivers. There is clear evidence this is not the case (e.g. Pereira, Smith & Yu 2014), however, while we plan to code the children's productions, we nonetheless believe that considering the distribution of multimodal cues in caregivers' communication can already provide insight into important questions that has received little attention so far such as which and how cues are used in displaced contexts.

Abstract

Formal theories of grammar and traditional parsing models, insofar as they presuppose a categorical notion of grammar, face the challenge of accounting for gradient judgments of acceptability. This challenge is traditionally met by explaining gradient effects in terms of extra-grammatical factors, positing a purely categorical core for the language system. We present a new way of accounting for gradience in a self-organized sentence processing (SOSP) model, which generates structures with a continuous range of grammaticality values. We focus on islands, a family of syntactic domains out of which movement is generally prohibited. Islands are interesting because, although most linguistic theories treat them as fully ungrammatical and uninterpretable, experimental studies have revealed gradient patterns of acceptability and evidence for their interpretability. We report simulations in which SOSP largely respects island constraints, but in certain cases, consistent with empirical data, coerces elements that block dependencies into elements that allow them.

Keywords: whether islands; subject islands; D-linking; acceptability; ungrammaticality; gradient effects; self-organized sentence processing model; SOSP

Introduction[1]

Acceptability judgments are gradient: sentences' acceptability spans from full acceptability to full unacceptability passing through a range of intermediate values which can be statistically distinguished. Grammaticality, on the contrary, is traditionally conceived of as categorical: sentences are either grammatical or ungrammatical but cannot be "partially" (un)grammatical. Degrees of acceptability have been attributed to extra-grammatical factors, such as memory limitations, plausibility etc. It is commonly assumed that this view comes with the advantage of simplicity: a grammar admitting only two states is claimed to be simpler than a grammar involving a continuous, infinite, number of states. We argue that, despite its apparent simplicity, this position is actually less parsimonious than one that accounts for graded acceptability judgments as deriving from the grammar itself. We present a self-organized sentence processing (SOSP) framework, which accounts for gradient effects through a single mechanism of structure building (e.g. Tabor & Hutchins, 2004; Smith & Tabor, 2018; Villata, Tabor, & Franck, 2018). Unlike most classical parsing and grammatical models, SOSP conceives of grammar as residing in a continuous space where fully grammaticality and fully ungrammaticality are two endpoints of a continuum (e.g. Kempen & Vosse, 1989; Cho, Goldrick, & Smolensky, 2017). As a result, gradient effects are understood as generated by the grammar itself, rather than deriving from extra-grammatical factors. To test this theory, we focus on what is arguably one of the most prototypical, and yet also most theoretically challenging syntactic phenomena: islands. Islands are encapsulated syntactic environments out of which almost nothing can be extracted (Ross, 1967). Islands come in two flavors: strong and weak. Strong islands are claimed to block all kinds of extraction. In particular, non D(iscourse)-linked (e.g. *what*, *who*) and D-linked elements (e.g. *which NP*) are equally unextractable from strong islands. This is illustrated in (1) and (2) for subject islands, where the NP (*what* or *which dissertation*) is extracted from a NP subject (*the first chapter of*)[2]:

(1) *__What__ do you think [the first chapter of _] is full of errors?
(2) *__Which dissertation__ do you think [the first chapter of_] is full of errors?

In contrast, weak islands are traditionally claimed to be selective: they prohibit the extraction of non D-linked wh-elements, but allow the extraction of D-linked wh-elements (e.g. Cinque, 1990; Rizzi, 1990). This is illustrated in (3) and (4) for whether islands, where the extraction of the NP is from a whether-clause:

(3) *__What__ do you wonder [whether the student read _]?
(4) __Which book__ do you wonder [whether the student read _]?

The sharp distinction between the examples in (1), (2) and (3) on the one hand, which are standardly deemed ungrammatical, and (4) on the other, which is typically considered grammatical, is very much in line with the traditional, categorical view of grammar, which only admits binary outcomes. However, with the development

[1]This work was supported, in part, by a grant from the Marica de Vincenzi Foundation.

[2]The island domain is in brackets, and the asterisk indicates ungrammaticality.

of finer-grained techniques for gathering acceptability judgments, experimental studies have revealed gradient patterns of acceptability for island effects. Here we focus on three empirical facts indicating gradient island effects.

First, acceptability judgment studies have revealed that weak island acceptability is gradient (e.g. Sprouse, Wagers, & Phillips, 2012; Sprouse & Messick, 2015). In particular, D-linked whether islands (4) are more acceptable than non D-linked ones (3), and yet still ungrammatical, contra the traditional wisdom that conceives of D-linked whether islands as grammatical (see Villata, Rizzi, & Franck 2016 for similar evidence for wh-islands). These studies used a 2x2 factorial design that isolates the island effect from two processing factors that are known to interact with the effect: (i) STRUCTURE TYPE (island vs. non-island),[3] and (ii) DEPENDENCY LENGTH (long vs. short) (5). The contrast between (5a) and (5c) isolates the cost of structure, while the contrast between (5a) and (5b) isolates the dependency length effect. We define the island effect as a statistical interaction between the two factors: it is what remains after the linear sum of the two processing factors is taken into account.

Sprouse & Messick (2015) found a significant interaction for both non D-linked and D-linked whether islands, indicating an island effect in both cases. However, the island effect was stronger in the non D-linked condition as compared to the D-linked condition, providing evidence that D-linking reduces the island effect in weak islands (see Figure 5; empirical data are in black).

(5) Factorial design measuring the whether island effect

a. NON-ISLAND, SHORT
Who/Which woman _ thinks that John bought a car?
b. NON-ISLAND, LONG
What/Which car do you think that John bought _?
c. ISLAND, SHORT
Who/Which woman _ wonders whether John bought a car?
d. ISLAND, LONG
What/Which car do you wonder whether John bought _?

The second empirical fact is that D-linking interacts with island types: while D-linking ameliorates the acceptability of weak islands, it does not help strong islands — e.g., subject islands. Example (6) shows a corresponding factorial design for subject islands, and Figure 6 (black lines) shows the empirical data from Sprouse & Messick (2015).

(6) Factorial design for measuring the subject island effect

Who/Which leader _ thinks the speech interrupted the TV show?
b. NON-ISLAND, LONG
What/Which speech does the leader think _ interrupted the TV show?
c. ISLAND, SHORT
Who/Which leader _ thinks the speech by the president interrupted the TV show?
d. ISLAND, LONG
Who/Which politician does the leader think the speech by _ interrupted the TV show?

Third, D-linked whether islands with an intransitive embedded verb (e.g., *Which joke does the comedian wonder whether the audience* ***laughed****?*) are less acceptable than those with a transitive embedded verb (e.g.,*Which necklace does the detective wonder whether the thief* ***stole****?*), an effect that was significant for both D-linked and non D-linked whether islands, although it was greater for the former (Villata, Sprouse, & Tabor, 2018) (Figure 1). We take this result as evidence that whether islands, though ungrammatical, are interpreted. This suggests that the dependency between the extracted wh-phrase and the gap inside the island can, at least sometimes, be established.

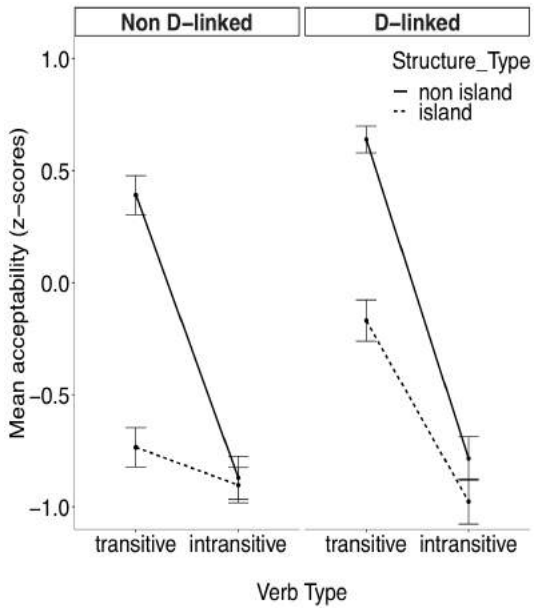

Figure 1: Acceptability proportions for weak islands (data from Villata, Sprouse, & Tabor (2018)).

Summarizing: First, weak islands are ungrammatical. Though D-linking improves their acceptability, it does not cancel the island effect. Hence, their acceptability is gradient. Second, D-linking does not improve the acceptability of strong islands. Hence, gradience is not evident in all cases. Third, the evidence suggests that weak islands are interpreted. Hence, the dependency between an extracted wh-phrase and a gap inside the island can sometimes be established. The last fact seems to point to an account of islands not couched in terms of perfectly impenetrable syntactic domains.

In the next section we introduce the SOSP model. In the section *Model Implementation* we describe SOSP's implementation and, in the section *Simulations*, we describe

[3] "Island" here does not refer to an island-violating structure, but to the mere presence of a structural domain that does not tolerate extractions, like a whether embedded clause or a complex subject.

how the model accounts for the data at hand.

The SOSP Model

In SOSP, structures are formed through continuous dynamical interaction among their constituent elements. Building on several linguistic foundations (Fillmore et al., 1988; Fodor, 1998; Gazdar, 1981) and following the psycholinguistic formulation of Kempen & Vosse (1989), we take the constituent elements to be treelets. Treelets are subtrees formed by a mother node and a finite number of daughter nodes that become active when a word is encountered. Each treelet is associated with a vector of syntactic and semantic features that specifies the properties of the word and its expected dependents. Treelets interact in all possible ways to form structure, creating competition for attachment. Attachments between treelets with a good feature match generally outcompete attachments with a poor feature match, which leads the system to stabilize, most of the time, on a grammatical structure. Structures in which all attachments perfectly satisfy the requirements of the feature vectors of the treelets receive the maximum *harmony value* of 1. Harmony is a formal measure of the degree of coherence in a set of interacting treelets — details below (e.g. Smolensky, 1986).

Importantly, SOSP also allows the generation of intermediate structures, i.e. structures with a harmony value strictly between 0 and 1 (0 harmony = no structure). This happens when an attachment is made between treelets whose features only partially match. This can happen in two ways. First, due to noise in the system, attachments between treelets with a poor feature match can sometimes outcompete attachments between treelets with a good feature match. However, this will happen in a small proportion of the cases, for attachments with a good feature match tend to win competitions. Second, when no optimal bond is available, as in ungrammatical sentences and difficult garden paths, the system forces the attachments to form anyway, generating (sub-optimal) structures. This leads to a variety of differently-valued outcomes which are *internally* generated (i.e. generated by the functioning of the system itself), rather being the result of factors that are external to the system.

Model Implementation

The implemented model (Smith & Tabor, 2018) consists of sets of differential equations that converge on fixed points corresponding to locally optimal structures. Treelets are encoded as banks of feature vectors (all of the same dimensionality, $nfeat$) with one bank for each attachment site (mother/daughters). The general implementation is achieved by first determining all the possible structures (both fully and partially grammatical) that can be formed from the vocabulary of the language, treating the concatenated banks of features and link values as forming a single vector space, and identifying the location of each locally optimal structure in this space. The local harmony, h_i, associated with such a point in the feature space is given by (1):

$$h_i = \prod_{l \in links} \left(1 - \frac{dist(\mathbf{f}_{l,daughter}, \mathbf{f}_{l,mother})}{nfeat}\right) \quad (1)$$

where $dist(\vec{x} \cdot \vec{y})$ is Hamming distance between $\vec{x}$ and $\vec{y}$. In other words, the local harmony is a product, across links, of a measure of similarity between the daughter feature vector $\mathbf{f}_{l,daughter}$ and the mother feature vector $\mathbf{f}_{l,mother}$ on the end of each link. Thus, if every link has a perfect match, then h_i is maximal and equals 1. The minimum possible value is 0, and various degrees of mismatch give intermediate values.

For each such structural locus, we specify a radial basis function (RBF), ϕ_i (Muezzinoglu & Zurada, 2006):

$$\phi_i(\mathbf{x}) = \exp\left(-\frac{(\mathbf{x}-\mathbf{c}_i)\ (\mathbf{x}-\mathbf{c}_i)}{\gamma}\right)$$

Here, $\mathbf{x}$ is the state of the system encoding the values of all features on all activated treelets and all possible links between them, $\mathbf{c}_i$ is the location of the ith (partial) parse, denotes the vector transpose, and γ (a free parameter) specifies the width of the RBFs. We define the harmony function $H(\mathbf{x})$ as the height of that RBF among n RBFs that is maximal at x, where n is the number of optimal and partially-optimal structures (harmony peaks) that can be formed with the currently activated elements, and h_i is the height of the i'th mode:

$$H(\mathbf{x}) = \max_{i \in 1...n} h_i \phi_i(\mathbf{x}) \quad (2)$$

This equation interpolates a harmony landscape between the structural loci, c_i, associated with the local harmony peaks.[4]

Parsing starts with all features equal to 0. The perception of the first word of a sentence causes features of a lexical treelet associated with that word to be turned on. This, in turn, causes links and additional treelet feature banks corresponding to the most viable parse of just that word to be turned on. In SOSP, treelets are interacting subsystems that attempt to assemble themselves through local interactions that locally maximize harmony. This is implemented as noisy gradient ascent on the harmony surface, $H(\mathbf{x})$:

$$\frac{d\mathbf{x}}{dt} = \nabla_{\mathbf{x}} H(\mathbf{x}) = -\frac{2}{\gamma} h_{i_{max}} (\mathbf{x} - \mathbf{c}_{i_{max}}) \phi_{i_{max}}(\mathbf{x}) + \sqrt{2D}\, dW \quad (3)$$

where $D > 0$ scales the magnitude of the Gaussian noise process dW. In other words, the system moves approximately uphill on the harmony landscape as it processes each word. Moving uphill is equivalent to growing the link structures and adjusting values of unspecified or conflicting features to

[4] This definition differs from the form specified in Smith & Tabor (2018) who summed the RBFs to form H. We have found that, in systems with many harmony peaks, if a summation is used, there are often ganging effects that influence the structure of the gradient and flummox effective parsing: many proximal ungrammatical structures gang together to pull the state toward their mean and away from a lone worthy grammatical candidate. Humans seem to be strongly influenced by the presence of a good candidate even if there are also many bad ones around, so the max method yields more plausible parsing than does the summing method when the language model is realistically rich.

reach a locally optimal parse state. After a local optimum is reached, new features specified by the next word are turned on (moving the system off its current hilltop and into a nearby valley). The gradient ascent process then begins anew and a new harmony maximum is reached, corresponding to the next step of the parse. Across multiple trials, the noise produces a distribution over the harmony maxima, generally favoring those that correspond to plausible parses of the input seen up to the present moment. At the end of parsing a sentence, the system will be at a particular harmony peak that has a value between 0 and 1. We take this harmony value to correspond to the model's assessment of the acceptability of the sentence.

Simulations

In the terms of the model, based on the empirical results reviewed above, we identify the following desiderata: (i) non D-linked whether islands should receive a low harmony value, and D-linked whether islands should receive a higher, but not maximal, harmony value; (ii) the high-but-not-maximal harmony for D-linked whether islands should be generated by linking the gap to the filler inside the island with some strain, in line with experimental findings suggesting that these structures are interpreted (Villata, Sprouse, & Tabor, 2018); (iii) subject islands should receive a low harmony value irrespective of the presence of D-linking (comparable to non D-linked whether islands) .

Figure 2 portrays the model's processing of a non-D-linked whether island. The model considers, in parallel, all conceivable parses of the input string. However, since many of these parses have extremely low harmony and do not have much influence on the processing, the figure only shows those that play a significant role in the parsing dynamics. One reads the figure from left to right and bottom-up.[5] Typically, when a word is perceived, bonds between treelets form. For example, when "you" is perceived, a bond between "NP_{you}", the mother of "you", and "NP_{you}", the daughter of "S/NP_{what}", typically forms. Bonds between treelets that are formed by the system are illustrated with dashed lines, while straight lines indicate the treelet's structure as it is defined in the lexicon based on phrase structure rules (e.g. S $\rightarrow$ NP VP). Crucially, the treelet feature vectors are mutable within a range of values corresponding to the syntactic/semantic range that the treelet affords. For example, in the present case, the mother of the "S $\rightarrow$ NP VP" treelet has mutated to acquire a slash buffer that specifies the syntax and semantics of the fronted element "what". Due to this mutation, links can often achieve a perfect feature match, causing the relevant term in Equation (1) to take on the value, 1.

The crucial developments in the case of the non-D-linked whether sentences occur when the words "wonder" and "whether" are perceived. As shown in Figure 2, the system is deciding between two possible, not-fully-grammatical structures at "wonder". The first, shown by the left

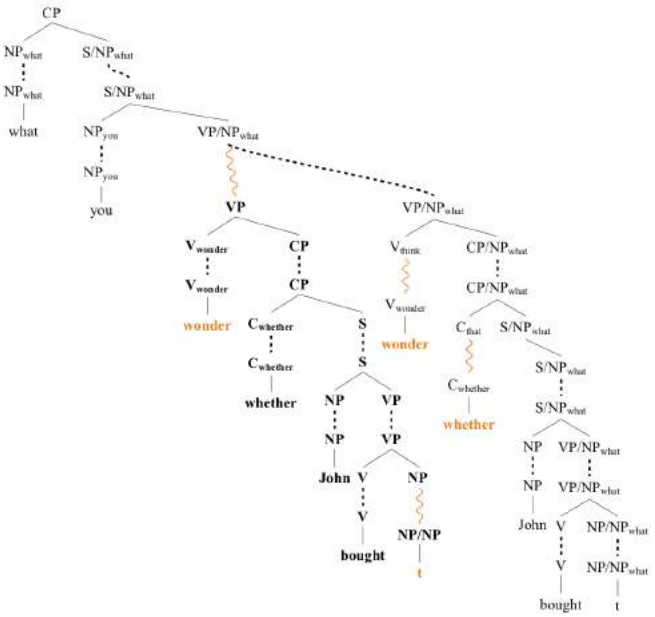

Figure 2: Simplified tree for non D-linked whether island. Subscripts indicate which feature has been transmitted to the node (e.g. S/NP_{what} means that *what* has been propagated to the S node). Words in orange are those that trigger coercion. Wavy orange lines illustrate the dynamic of the coercion. Here the parsing that ultimately wins out in most trials is the one on the left branch (bold font).

VP-branch, respects the constraint imposed by the verb "wonder", which cannot take as a complement an element with a slash feature. This implements the "islandhood" of the CP-complement of "wonder". This parse makes it possible for "$V_{wonder} \rightarrow$ wonder" to attach with perfect harmony to its CP-complement, but at the cost of failing to propagate the slash buffer ("$/NP_{what}$") onto the VP node below. We assume this failure has a cost, but not a severe cost because "what" is a very abstract element, so its encoding plausibly contains only a few features — that is to say, the difference between the "NP_{what}" slash buffer and an empty slash buffer is a small difference. This mild penalty is indicated by the orange color of the link between "VP/NP_{what}" and "VP". The second parse in Figure 2, shown by the right-branch, takes an opposite approach: it propagates the slash buffer, "$/NP_{what}$", onto the VP node below, but it can only do this by coercing "wonder" into a verb that licenses slash propagation. We have taken the verb "think" as a canonical example of such a verb. The orange squiggly line from "V_{think}" to "V_{wonder}" indicates this penalty. Again, this penalty is not extreme because the semantics and syntax of "wonder" and "think" are fairly similar. At the next word, "whether", the system undergoes a second coercion, of "whether" into "that". This coercion, which is triggered by the requirements of the verb "think", allows the slash buffer to propagate down the tree, for "that", unlike "whether", does not act as a slash propagation blocker. As before, although this coercion comes at a cost, the cost is mild, because of the similarity of the two complementizers.

[5]The model employs slash-propagation (Gazdar, 1981) to implement long-distance dependencies.

We now consider the case of the D-linked whether-island, illustrated in Figure 3. In this case, not propagating the slash feature onto the VP node (the parse on the left-branch) comes with a strong penalty (illustrated by the red squiggly line in the figure). This is because, D-linked words, unlike non D-linked ones, are associated with a rich bundle of semantic and syntactic features. As a result, failing to propagate the features associated with D-linked NPs incurs a strong penalty. The system therefore tends to prefer the second parse (right-branch): the close analogy between "think" and "wonder", and "that" and "whether" makes the mild coercions option better than any other parsing option, leading the parser to stabilize on the option that propagates the slash buffer inside the whether island.

In subject islands, on the contrary, there is no such close analogy between the words in the sentences and alternatives in the lexicon. As a result, the parser systematically fails to consider the possibility of propagating the slash feature down the subject branch and then is caught up short when a gap appears in the subject, and no gap appears in the main verb phrase (see Figure 4).

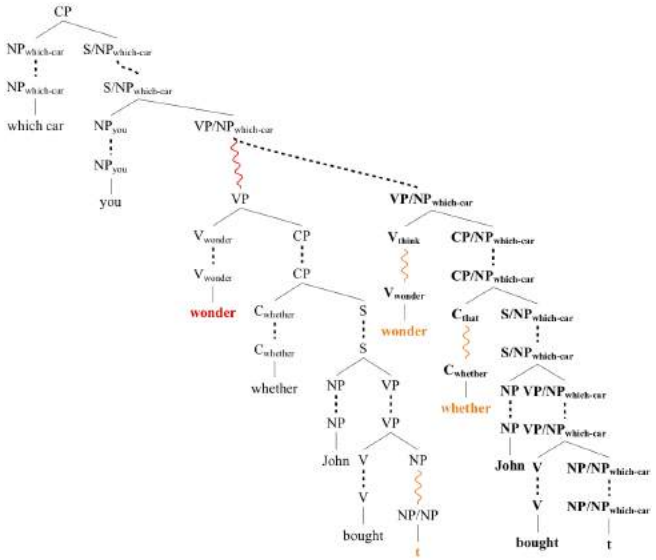

Figure 3: Simplified tree for D-linked whether island. Words in orange trigger a mild coercion, while words in red trigger a severe coercion. Here the parsing that ultimately wins out in most trials is the right branch (bold font).

We ran 20 runs of the model on simplified versions of each sentence in examples 5 and 6 (no determiners, ignoring English do-support). The model, somewhat revised from the one described in the first, reviewed version of this paper, is both an elaboration and a simplification of the model described in Smith & Tabor (2018).[6] It used 45

[6]We describe the revised model here rather than the original one because its assumptions are more plausible and easier to describe, as requested by several anonymous reviewers, and the causal dynamics by which it produces the data points reported here—specified in the analyses above—are the same as those previously described.

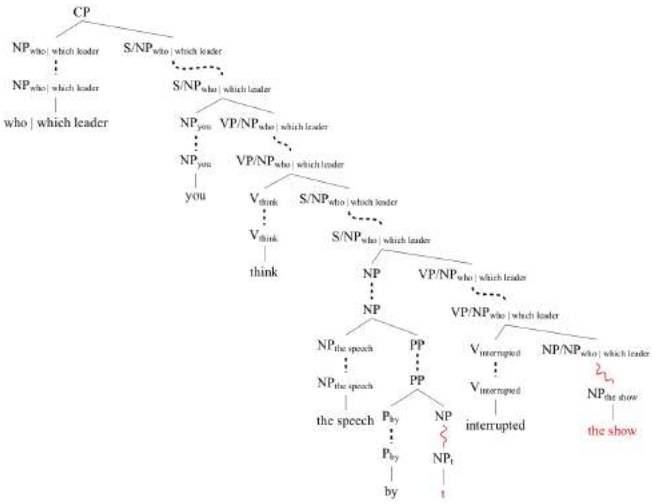

Figure 4: The low-harmony structure that stabilizes when the model is presented with a subject island.

distinct feature vectors for coding the lexical and syntactic nodes needed for the tree configurations described in the analyses above (as well as variants needed for all the stimulus sentences listed in (5) and (6)). Whereas previous versions of the model were hand-coded with roughly plausible linguistic features, the current version started by generating random bit vectors in 20 space for each feature vector (which was either a mother or a daughter of a treelet). This made all the feature vectors relatively distant from one another. Then, in keeping with the hypotheses described above, the vector for "wonder" was made to be equal to the vector for "think" except in two dimensions where it had contrasting bits; the vector for "whether" was analogously made similar to the vector for "that"; and the vector for "CP/What" was analogously made similar to the vector for "CP" (i.e., to CP with an empty slash buffer). SOSP entertains a plethora of possible ways of combing the treelets, most of which give rise to very low harmony structures. In the simulations reported here, motivated by the assumption that many of the low-harmony variants have little effect on the parse trajectory and to simplify implementation, we only considered the variants that we have mentioned as alternatives in the analyses above. An earlier version of the model had trouble telling sentences apart if many were included in the stimulus set. Here, we introduced a two-fold magnification of the dimension coding the features for the lexical elements. This effectively moved the harmony peaks for sentences with different word forms farther apart from one another, causing the system to prefer parses that are faithful to the input, though not rigidly—see Levy (2008). To allow the model to detect harmony maximization upon processing of each word, we allowed the dynamics to settle through a quadratic velocity profile: the model had to speed up (associated with reaching the steep section of one of the RBF humps) and then slow down (indicating that it was topping out on a harmony maximum) before moving on to the next word.

In addition to the number of feature dimensions (20) and the degree of lexical isolation (2 x) mentioned above, important free parameters are γ, specifying the width of the RBFs, D, specifying the magnitude of the noise, and ρ which takes its values in [0, 1] and determines how far over the velocity "hump" the model must travel before moving to the next word ($\rho = 1$ implies immediate transition, $\rho = 0$ implies infinite processing time per word), and Δt which specifies the step size in the Euler Integration that we used to approximate the dynamics. We explored these parameters by hand finding a way to roughly optimize behavior in a test grammatical sentence and the D-linked whether island extractions (D-linked, whether, island, long) to establish the settings $\gamma = 4$, $D = 7 \times 10^{-1}$, $\rho = 0.4$, $\Delta t = 0.5$ and then examined the results in the other fourteen conditions.

One other point about the implementation is particularly important. The current versions of SOSP add dimensions to the state space with every new word (these dimensions correspond to the feature banks in treelets that the word introduces, and to the links this treelet can potentially form with other activated treelets). The behavior of the dynamical equations is sensitive to the dimensionality, so to achieve reasonable parsing, such an implementation needs to change the dynamical parameters (γ, D, ρ, Δt) as the sentence grows. We do not think this is very plausible. Instead, we think the dimensionality of human processing is kept roughly constant via a focusing mechanism (possibly related to what is called "Working Memory" in other work). We suspect that the form of this focusing involves fractal scaling as has been proposed in work on neural encoding of arbitrary dependency languages (Plate, 2003; Tabor, 2000). However, we do not know how to apply such scaling techniques to the SOSP encodings, so we have used a kind of Poor Man's focusing method: run the dynamics on just the vectors associated with the current word and the previous word. Coupled with slash propagation, this technique is capable of tracking of all the dependencies needed for the current stimuli.

Figures 5 and 6 present a comparison of the predicted island effects by the SOSP model (in red) and the observed island effects (in black)—the model exhibited very little variance within trials so no model error bars are shown.[7] Indeed the qualitative behavior of the model matched the desiderata we have mentioned, often succeeding in linking the gap to the fronted element in D-linked whether islands, and in extractions from non-islands, but not in the subject islands, and rarely in the non-D-linked whether islands.

[7]For subject islands, Sprouse & Messick (2015) report a reverse effect of D-linking, with D-linked subject islands showing a stronger interaction than non D-linked ones. However, this reverse D-linking effect appears to be driven by the non-island/long condition, which exhibited lower ratings in the non D-linked than the D-linked condition. Although it is unclear what might have driven this effect, for current purposes it is sufficient to observe that the reverse D-linking effect is not driven by the island condition itself. Moreover, the ratings for the island condition are comparable with those obtained by the non D-linked whether island, and also by the Complex NP and adjunct islands tested by Sprouse & Messick (not reported here), for which no reverse D-linking effect was observed.

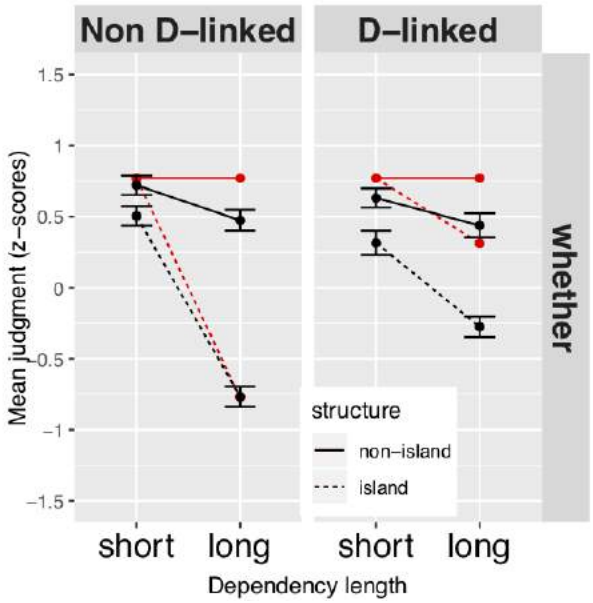

Figure 5: Interaction plots for whether island. The points correspond to the 4 conditions in (5). Empirical results are in black (data from Sprouse & Messick, 2015) and results from the model's simulation are in red.

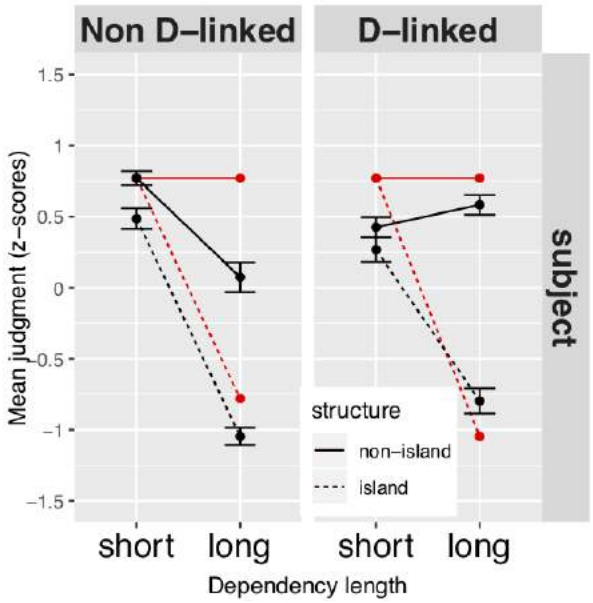

Figure 6: Interaction plots for subject island. The points correspond to the 4 conditions in (6). Empirical results are in black (data from Sprouse & Messick, 2015) and results from the model's simulation are in red.

Discussion

We reported three empirical findings from the literature pointing to gradient effects in island acceptability. We presented a new way to account for islands' ungrammaticality in a self-organized sentence processing (SOSP) framework.

SOSP's key novelty lies in its conception of grammatical states as lying in a continuum of grammaticality values. As a consequence, and unlike traditional theories of grammar, SOSP treats degrees of acceptability as deriving from the grammar itself, rather from extra-grammatical factors. This occurs because self-organizing treelets, not being under the control of a central coordinator, build whatever structure they can, sometimes achieving only partial coherence. This is the case of D-linked whether islands: the system succeeds in coercing them into a non-island structure, leading to the propagation of the slash feature inside the island, thus rendering these structures interpretable, in line with empirical findings. However, coercion comes at a cost, which is what causes the sentence to be given a suboptimal harmony value by the model, thus accounting for the fact that D-linked whether islands, although improved as compared to non D-linked ones, are still degraded. Importantly, the system is also able to generate extreme grammaticality values, in line with classical models. On the ungrammatical side, this happens when no grammatical parse is available and no coercion can take place, either because no grammatical structure is similar-enough to the to-be-parsed structure or because the system is not sufficiently prompted in undergoing the coercion. The first case is illustrated by subject islands, where no alternative (coerced) parse is available. The second case is illustrated by non D-linked whether islands: here the non D-linked wh-phrase is not powerful enough to cause the system to discover the coercion, resulting in failure to propagatied the slash feature inside the island, and very low harmony value.

Shortcomings of the current model are that the treelet forms are based on linguistic theorizing, not on a machine-learning method. A machine learning approach would make the method more completely formalized. Also, the feature vector composition, which ends up determining the harmony values, was mainly random. It will be valuable to explore more realistic feature analyses motivated by linguistic theory. Finally, as noted above, it is desirable to find a more principled method of keeping the state space finite.

All in all, we argue that SOSP offers a valuable new way of approaching the relationship between grammar and processing. It is closely related to generative linguistic theory. Nevertheless, it differs in non-trivial ways from traditional assumptions, notably continuity, and a central role for processing in grammatical explanation. We hope our results will spur new discussion on these topics.

Abstract

What are the categorical distinctions shared between conceptual and visual representations? One distinction may be between bounded and unbounded entities. Previous research in sign language has shown that even non-signers associate signs with repetitive motion with atelic verbs, such as "run", and signs with sudden motion with telic verbs, such as "arrive". In our first study, we show this distinction holds even when the visual stimuli depicted bear no intrinsic linguistic reference: we used non-linguistic random dot motions. In our second study, we demonstrate this association occurs spontaneously, even when subjects are not making explicit semantic judgments about verbs. We use a cross-modal lexical decision task in which verbs and non-words appear superimposed on bounded or unbounded dot stimuli. We find congruency when the motion boundedness matches the conceptual boundedness of the verb. Together, these studies provide evidence for an automatic link between visual and conceptual boundedness in the mind.

Keywords: telicity; motion perception; visual boundedness

Introduction

Language allows us to describe our own perceptual experience and understand the experiences of others. As social creatures, this is critical. Thus, an understanding of how and what information is common between language and perception is both interesting and important. One category of information that might be shared across these two systems is boundedness. In the current work, we investigated whether the visual perceptual system makes a distinction between bounded and unbounded stimuli, and whether this distinction is common across visual and linguistic experience (i.e., through verbs and verb phrases).

To understand what we mean by visual boundedness, imagine you're observing an event (e.g., something moving across your field of vision), but everything is blurred so that you cannot make out objects or what category of event is taking place. Because the low-level motion properties of the scene are preserved, you could still perceive the motion properties of the event, such as whether it started and stopped. In other words, there are perceptual correlates of boundedness even when you do not have access to high-level information about objects, goals, or events.

A second form of boundedness is telicity, or conceptual boundedness. Telicity is a similar concept to visual boundedness but in the linguistic domain. Telicity refers to whether an event described by a verb or verb phrase is construed as having an intrinsic endpoint (telic) or an undefined one (atelic; Vendler, 1957). For instance, "run" is an atelic verb. While a person could not run forever, the verb itself does not entail an endpoint. This is as opposed to a verb such as "arrive." There is a definite endpoint entailed by the verb such that the event has only occurred when someone arrives at their destination. A simple test for this distinction is to probe the felicity or grammaticality of a sentence when adding the phrases "for an hour" (atelic) and "in/within an hour" (telic; Todorova, Straub, Badecker, & Frank, 2000). For example, one could say someone *ran for an hour* but could not say someone *ran in an hour*; conversely, it is infelicitous to say someone *arrived for an hour* but fine to say someone *arrived within an hour*.[1]

One way to investigate the link between visual and conceptual boundedness is through sign language, as sign language is inherently both linguistic and visual. In Malaia & Wilbur (2012), signers were instructed to produce signs for verbs, and motion capture technology was used to record the maximum deceleration, maximum velocity, and duration of the signs. It was found that the motion properties of the signs for atelic verbs, e.g. "run", are consistent with one another, and visually distinct from telic verbs, e.g. "arrive". Such findings suggest that signs carry information about verb telicity iconically in the form of the sign itself.

However, although this study showed that a difference in telicity may be visually distinct, it does not indicate whether humans have access to this boundedness distinction (whether implicitly or explicitly). Strickland et al. (2015) addressed this issue: they demonstrated that even among non-signers, there is an implicit bias to map atelic signs (i.e.

[1] However, this rule is not absolute. For example, the telic verb die can be used with both "in an hour", an instantaneous event, and "for an hour", an extended process with an undefined endpoint.

signs for atelic verbs) onto atelic verbs and telic signs (i.e. signs for telic verbs) onto telic verbs. In that study, English-speaking individuals without sign language experience were shown an atelic or a telic sign and were forced to choose one of two verbs that they believed matched the meaning of that sign. For example, participants viewed the sign for "float" (an atelic verb) and were asked to choose between two words that differed in telicity (e.g., "float" vs. "leave"). Participants significantly preferred the verb that matched the sign in telicity, even when neither verb referred to the true meaning of the sign (e.g., "talk" vs. "buy"), and even for verbs with no visual correlate (e.g., "think" vs. "decide"). This shows that the human mind has access to boundedness information in visual input and can associate it implicitly with word meanings that are conceptually bounded, even though iconicity for telicity does not exist in their own language.

Although the Strickland et al. (2015) results are compelling, the scope of their conclusions is limited to perception within linguistic communication. Sign language is inherently linguistic and referential. Thus, participants can presume that these visual cues have specific linguistic meanings. This raises the question of whether these results only hold when people are performing a task where they must map from one language to another (even if one of the languages is a visual one that they have no knowledge of).

We address this question here via a new set of experiments. We used visual stimuli that were not overtly referential. Participants were shown non-linguistic motion composed of scrambled dots (extracted from biological motion stimuli) that could not be recognized as interpretable events, but nevertheless contained motion information consistent with bounded or unbounded events.

In the first experiment, participants were asked to make atelic vs. telic verb choices after viewing the visual stimulus, just as in Strickland et al. (2015). As these random dot motions are not linguistic or referential, positive findings would offer strong support for a connection between visual and conceptual boundedness. In the second experiment, we test whether such an association is automatic. In a cross-modal lexical decision task, we observed a congruency effect, such that participants were faster to confirm that a stimulus was a word when the background motion matched the boundedness of the displayed verb.

Experiment 1: Verb-Motion Matching

In this experiment, each trial consisted of the participant viewing a 3-second video clip of scrambled moving dots derived from biological motion stimuli, after which the participant had to indicate which of two visually presented verbs (one atelic and one telic) best described the clip. The video clip was designed to depict an unbounded or a bounded event as determined by separate ratings of the repetitiveness of the motion. It was predicted that participants would be more likely to select telic verbs for bounded events and atelic verbs for unbounded events. Following Strickland et al. (2015), effects of motion boundedness were tested within three different semantic domains of verbs: Physical (e.g., *fly* vs. *hit*), Social (e.g., *argue* vs. *give*) and Mental Verbs (e.g., *think* vs. *decide*). If effects hold for all three types of verbs it suggests that motion boundedness is linked to the abstract notion of telicity rather than, for example, spatial-motion aspects of the events denoted by these verbs.

Method

Participants Twenty-four participants were recruited from the University of Pennsylvania undergraduate body and participated for course credit. This was the same number as in the Strickland et al. (2015) study as their effect size was not available for a power analysis. All participants were fluent speakers of English with normal or corrected to normal vision.

Visual Materials A personal computer running the Psychophysics Toolbox Version 3 for MATLAB was used to run this experiment (Kleiner et al., 2007). Sixty biological motion, or biomotion, videos of three seconds from the CMU Graphics Lab Motion Capture Database were used with the BioMotion Toolbox (van Boxtel & Lu, 2013).

Biomotion videos are produced via motion capture, whereby each joint on a person's body is attached to a sensor. The positions of these sensors are then recorded during movement. This produces a video, composed of dots, in which the overall shape, size, and movement of an individual is maintained but the fine details and body form are removed.

Crucially, in our versions, body structure information was removed from these videos while preserving the overall motion signal. This was done by randomizing the start point of each individual dot, but then preserving its relative motion path from that start point. For example, the dot that corresponded to the person's right elbow may, at the start of the animation, be located to the left of where their left ankle was and the dot corresponding to their left ankle may now start right above where their right knee was. This removes the benefits of being able to tell what action is occurring (because the intact structure of the body is removed) and ensures that participants only get information about the motion properties of the dots, e.g., velocity and acceleration.

Selection and Norming of Video Materials Videos were initially selected by JW, and then their boundedness was confirmed using a norming procedure. JW rated a random set of 574 scrambled videos from the CMU database on perceived boundedness. Subsequently, we presented 79 unbounded and 61 bounded candidate videos to twenty-two undergraduates in a norming study. Although the CMU database includes descriptions for each video, they were ignored for video selection. Using these ratings, we chose a set of 60 videos to use in the subsequent experiments.

Participants were asked to rate each video for repetitiveness or deceleration (between subjects) on a scale

of 1 to 7, e.g "Rate the video based upon how repetitive you think the motion is" or "based upon how fast you think the motion decelerates." These properties were used as they were found to be indicators of boundedness in previous studies (Malaia & Wilbur, 2012; Strickland et al., 2015).

Although our intention was to define bounded videos as those with the highest deceleration and least repetition in the motion, deceleration ratings proved inconclusive as across all videos there was little deviation from the average of 4. That is, across all 140 videos participants tended to choose a middle value (*SD* = 0.85). This was perhaps due to the difficulty of the task and the nature of the stimuli (independently moving dots). In contrast, repetition ratings had high variety across items and participants (*SD* = 1.51).

As a result, only the repetition ratings were used to select the sixty videos for the main study. The sixty videos were selected by taking the 40 videos with the highest average ratings and the 40 videos with the lowest average ratings and then sorting these videos by lowest standard deviation across ratings. The 30 videos from each group with the lowest standard deviation were then selected. We considered the videos with high repetition ratings as Unbounded and videos with low repetition ratings as Bounded. The mean repetition rating for unbounded videos was 5.70 and for bounded videos was 1.91, and the two groups differed reliably (p = <0.0001).

Verbal Materials Five atelic and five telic verbs were chosen from each of three separate conceptual domains: physical, social, and mental. This resulted in fifteen telic and fifteen atelic verb pairs. Each pair consisted of one telic and one atelic verb, approximately matched for log frequency. Fourteen of the 18 Strickland et al. verbs were used (4 not used due to low frequency), with an additional sixteen verbs (seven telic and nine atelic) generated by author JW to maintain approximate match in log frequency. The verbs were the following. Atelic: *run, fly, play, paint, sing, think, consider, imagine, dream, study, talk, discuss, fight, love, argue*; Telic: *enter, die, leave, hit, grab, decide, accept, forget, choose, remember, marry, sell, buy, give,* and *take*. To create each participant's list of paired verbs for each trial, the atelic and telic verbs for each domain were shuffled and then paired (within domain) to produce fifteen total pairs (five for each domain). This shuffling was performed four times (60 trials in total). Verb pairs (trials) were shuffled and paired randomly with videos.

Procedure During the experiment, participants were instructed that they would be shown a short clip of moving dots and asked to choose which of two verbs better fit the clip. They were told to use their intuition to make their verb choice and that there was no right answer. After the instructions, two practice trials were given.[2] On each trial, participants were shown the video twice before making their selection, to ensure they could adequately perceive the motion. The video slowly faded in over the first half second and then faded out during the last half second to diminish influences of motion onset. After the video disappeared, the two verbs appeared on the screen, one on each side. Participants then made their selection (f for left or j for right). See Figure 1 for a schematic of trial types.

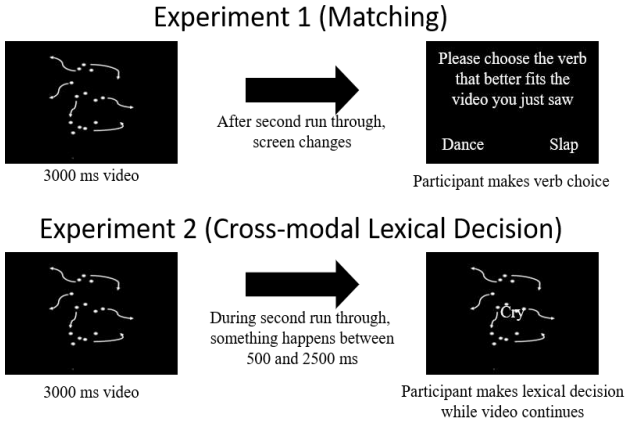

Figure 1: Trial schematics for Experiment 1 (explicit matching) and 2 (lexical decision). In Exp. 1, participants watched a 3 second video twice, then made a choice of which of two verbs better fit the video. In Exp. 2, during the second viewing, they were instead given a lexical decision (word/nonword) or attention task. Lines with arrows illustrate motion paths and were not seen by subjects.

Results

Figure 2 presents the mean proportion of telic verbs selected (subject means) as a function of whether the motion event was unbounded or bounded, overall and separately for each verb domain. As predicted, telic verbs were selected less often for Unbounded motion events (M=0.39, SE=0.02) than for Bounded motion events (M=0.55, SE=0.02). Moreover, the effect of motion Boundedness was very similar for each verb domain.

To test for reliability, we used a multilevel logistic regression to model binary trial-level choices for the telic verb. Fixed effects consisted of motion Boundedness (bounded vs. unbounded), Verb type (physical, social or mental), and the interaction. The maximal random effects structure was used for each subject and a random intercept was used for each item (each video). The significance of factors was performed by comparing likelihood-ratio values for nested models that included main effects and interactions of factors to models without them.

The best-fitting model showed a reliable effect of motion Boundedness (β=0.339, SE=0.096, z=3.531, p=0.0004), but no reliable effects or interactions with Verb type. Removing Verb type and the interaction from the model did not decrease the fit of the model ($\chi^2(4)$=4.38, p=0.346), but further removing the effect of Boundedness did ($\chi^2(1)$= 27.92, p<0.0001) – indicating that the motion Boundedness of the videos reliably predicted telic choices.

[2] Thus, there were 2 practice videos and 58 trial videos. Later "test" trials using these videos were discarded from analysis.

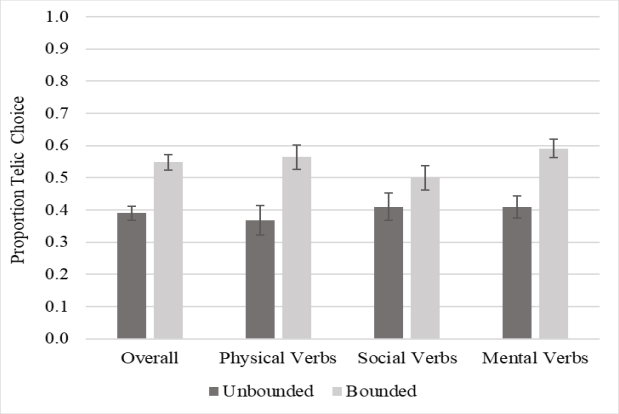

Figure 2: Mean proportion of telic verb choices as a function of Motion Boundedness (Unbounded, Bounded), overall, and by verb domain. Average of Subject Means. Error bars indicate ±1 Standard Error.

One concern is that people may have developed a strategy over time or discovered the purpose of the experiment and acted accordingly. Although unlikely, as no participant revealed an explicit awareness of the hypothesis or purpose when questioned, we examined the time course of the effect. If it was an explicit strategy, we might expect a difference between the beginning and the end of the experiment. We tested whether there was a statistical difference between the first twenty trials and last twenty trials regarding whether participants showed a differing proportion of telic verb preference for bounded and unbounded videos. This test showed no significance (paired t (23) = -0.635, p = 0.532), suggesting a strategy did not emerge during the experiment.

Discussion

The current results show that the visual system can distinguish between "bounded" and "unbounded" motion stimuli, as defined by repetitiveness. Furthermore, people are biased to associate visual boundedness with conceptual boundedness in verbs. Surprisingly, this occurs even when these verbs have no visual manifestation, as is the case for the domain of mental verbs. This implies that people were implicitly encoding boundedness and telicity when observing these biomotion stimuli. Put another way, these results show that the distinction of boundedness that is present in both the visual and linguistic systems is shared or otherwise accessible by the two systems. This extends Strickland et al. (2015) by demonstrating that this association is not just due to the referential task (associating two linguistic items), but rather it exists even when using visual stimuli that have no inherent referential properties (i.e. scrambled biomotion stimuli). Thus, it appears that conceptual boundedness is a basic property of the visual and linguistic systems.

Although we find these results to be compelling, it would be of interest to understand if similar results can be obtained when participants are not attempting to link the video of the motion event to the linguistic stimuli. That is, could such a connection between motion boundedness and linguistic telicity arise spontaneously, even when linguistic judgements do not involve connecting the verb to the motion video? If so, it would suggest that the perception of motion boundedness automatically activates linguistic telicity. We explore this issue in Experiment 2.

Experiment 2: Cross-Modal Lexical Decision

In this experiment, we present preliminary results from two versions of a cross-modal lexical decision task. Each trial involved the participant viewing the same clips used in Exp. 1. However, participants were not presented with a forced choice task. Instead, for target trials, a single telic or atelic verb appeared centrally over the video, and the participant's task was to make a lexical decision (word / nonword). The core prediction of this experiment is the following: *If the perception of motion boundedness spontaneously activates linguistic telicity, then we would expect a congruency effect, such that Bounded motion events would speed judgments of telic verbs whereas Unbounded motion events would speed judgments of atelic verbs.*

The results are preliminary because each version of the experiment suffered from some issues related to response time measurement precision, such that we may have been underpowered to detect robust results in either alone. Nevertheless, across versions, the patterns are significant and consistent with our hypothesis. Thus, we present both sets of results together, noting differences between versions below as needed. Further versions of the experiment with more precise RT measurements are planned.

Differences between Versions of the Experiment Each version of the experiment suffered from precision issues with RT collection. In version 1 of the experiment, participants used a keyboard to make their responses (f for word, j for nonword, or spacebar if the dots changed color). However, due to a coding error, responses were only recorded at each screen refresh (every 16.67 ms); thus, these measurements were imprecise. In version 2, we used an E-prime button box instead of keyboard, since it is known for its measurement precision. Mean accuracy and mean RTs were nearly on par across experiments. However, the buttons on the button box used in version 2 were differentially sensitive; 4-5% of trials were timeouts, while those in version 1 were nearly 0%, suggesting that sometimes the buttons were not responsive.

Other differences were the following. In version 1, unbounded videos were randomly assigned one of the onset times for the bounded video. In version 2, this assignment was fixed for each list. That is, in version 2, unbounded video A would always have onset time of bounded video 1, video B would have onset time of bounded video 2, etc.

Method

Participants Experiment 2 consisted of two separate versions. A total of 116 subjects were recruited from a

university's undergraduate student body. Participants were excluded based on pre-determined criteria: accuracy below 80% on any of the three tasks (described below). After exclusion, there were 54 in the first version and 47 in the second. For both versions, the goal sample size was determined by doubling the sample size of experiment 1. The data from participants 49-54 from version 1 were included due to this experiment being underpowered (described below). Students signed up to participate in exchange for study credit. All participants were fluent English speakers with normal or corrected to normal vision.

Materials The same materials from Experiment 1 were used (i.e., the same fifteen telic and atelic verbs across three domains and the same sixty test videos).

An additional sixty videos from the CMU Graphics Lab database were used for filler attention trials (described below). An additional twelve videos and four verbs were used for practice trials. Sixty-four non-words were created using Wuggy, a word generation tool that creates nonwords matched with inputted real words on phonotactics and word length (Keuleers & Brysbaert, 2010). These non-words were used for the lexical decision task (described below).

Although our videos were rated for overall boundedness in the previous norming study, this does not indicate *when* in the video a boundary occurred. To ensure that the onset time of the word stimulus coincide with a motion boundary (for bounded videos), study authors JW and AH and research assistants chose the boundary point by watching each video frame by frame. In version 1, JW and AH individually watched and chose the points. If the differences between the two values was more than thirty frames, JW re-watched the video and made the final decision. If the difference was less than thirty frames, the average of the two was taken. In version 2, to get a more reliable value for boundedness point, median frame values for each video across an additional four research assistants, in addition to JW and AH, were taken. The average difference between the first and second experiment version was three frames. Since each video was only 3 seconds long, boundaries closer than 0.5 seconds towards the beginning or end of the video were constrained to be at 0.5 or 2.5 seconds, respectively. Since they do not have a motion boundary, the distribution of onset times for unbounded videos and filler (attention) videos were matched to the bounded videos.

Procedure During the experiment, there were three trial types: two were lexical decision (word or non-word). In these trials, participants simply had to press one button if the string of letters that appeared was a word, and another if it was not. The third trial type was an attention catch task, designed to ensure participants attended to the visual dot stimulus. In this catch task, dots would briefly change color from white to blue (0.5 sec); thus, this task made no reference to visual motion.

Participants were instructed to press a different key for each of these three trial types. On each trial, one of the three visual changes would appear: a word superimposed on the dot stimuli, a non-word on the dot stimuli, or the color change type. Participants were not made aware of what the current or next trial would be ahead of time. After the instructions were given, twelve practice trials (four of each type) were given. On each trial, participants were shown the 3-second video twice to ensure they could adequately perceive the full motion. The visual stimulus appeared at the pre-determined onset time during the second viewing. The videos faded in and out over the first and last half second to avoid sudden visual transients.

The visual stimuli (word, non-word, color change) appeared either *at* the pre-selected onset frame, or 0.25 sec *after* (counterbalanced with each condition). However, this timing factor was collapsed over in analyses.

Each verb and nonword was paired once with a bounded video and once with an unbounded video. There were 192 total trials (60 word, 60 non-word, 60 catch, 12 practice).

Results

The results for the first and second version of the experiment are being presented together. For an explanation and discussion of this decision, see below. Reaction times +/- 2.5 *SDs* from each subject mean were excluded (2.9% of trials), as well as timeout trials. Word trials: Accuracy 94.8% (*SD* 3.5%), mean RTs 676 ms (*SD* 119ms); Non-word trials: Accuracy 92.3% (*SD* 5.1%), mean RTs 808ms (*SD* 155ms); Attention trials: Accuracy 94.1% (*SD* 4.0%), mean RTs 629ms (*SD* 139 ms). All statistical analyses were performed on inverse RTs (-1000/RT), on accurate word trials only. Inverse RTs were used to improve normality of RT distributions for model fitting (Baayen & Milin, 2010).

Figure 3 presents the inverse reaction time (subject means) as a function both of verb telicity (telic vs. atelic), and motion boundedness (whether the visual stimulus was unbounded or bounded). As predicted, we observe an interaction between verb telicity and visual boundedness on reaction times for lexical decision: reaction times to atelic verbs were faster when the visual motion was unbounded, and reaction times to telic verbs were faster when the visual motion was bounded. However, the effect here was subtler than in Exp. 1, as should be expected: participants were not performing an explicit matching task but deciding whether the word that appeared was a real word or a non-word (or were performing a color change detection task, for filler trials).

To test for reliability, we used a multilevel linear regression to model inverse reaction time. Fixed effects consisted of Verb Telicity (telic vs. atelic), Motion Boundedness (bounded vs. unbounded), Verb Type (physical, social or mental), and all relevant interactions. To account for mean RT differences in experiment versions, a main effect of experiment Version was also included. The maximal random effects structure that converged was used for each subject (random intercept and random slopes for telicity and motion boundedness), and a random intercept was used for each verb. We compared nested models with and without these factors and interactions.

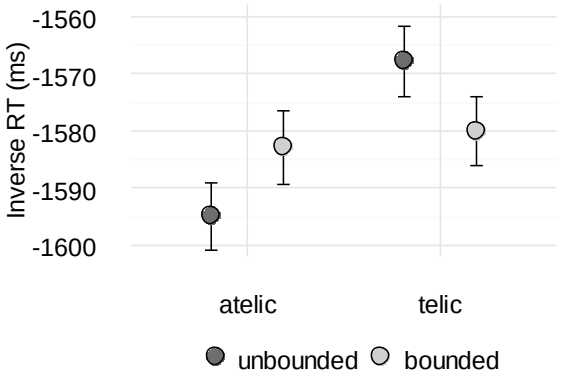

Figure 3: Mean inverse response times (-1000/RT) on lexical decision trials (word only), as a function of verb telicity (telic, atelic) and motion boundedness (unbounded, bounded). Average of Subject Means. Error bars indicate ±1 Standard Error. Up indicates slower RTs, down faster RTs, as is standard for raw RT plots.

The best fitting model was one that included main effects and interactions of Verb Telicity and Motion Boundedness, and Verb Type and Motion Boundedness. This model produced a reliable interaction between Verb Telicity and Motion Boundedness (β=6.56, *SE*= 2.91, t(5555)=2.26, p=0.024). Telicity and Motion Boundedness were contrast coded in the following way: telic=1, atelic=-1; unbounded=1, bounded=-1. Thus, the positive β indicates greater RTs for the mismatched conditions (e.g. telic+unbounded or atelic+bounded). Adding a triple interaction of Telicity, Boundedness, and Verb Type only marginally improved the fit (χ^2(4)=8.34, p=0.08). Further, removing the interaction of Telicity and Boundedness *did* decrease the fit of the model (χ^2(1)=5.09, p=0.024). This confirms the interaction of Verb Telicity and Motion Boundedness that we expected.

Discussion

Experiment 2 results produced a pattern of congruency that would be expected if the perception of motion boundedness activated linguistic telicity. Reaction times to atelic verbs were faster when preceded by Unbounded as opposed to Bounded motion events whereas the opposite was found for telic verbs. That this effect arose even though participants were not trying to relate the verbs to the motion videos suggests that the relation between boundedness and telicity occurs spontaneously, without conscious effort.

There are a few important issues that force us to see these results as preliminary and necessary of replication. Even though the timing issues mentioned in the Method section merely decrease RT precision, it is also the case that the results of both versions were pooled post-hoc, after discovering these RT precision issues. Although these are not small issues that should be overlooked, we believed it was still worthwhile to report on these data as they are promising, consistent with the judgment data of Experiment 1, and spur the need for replication.

Although we did not find strong evidence for differences among verb domains in the congruency effect, future replications with higher power will allow us to determine whether this difference is real, and if so, whether only certain of the domains (e.g. physical) demonstrate the effect. Nevertheless, results of Experiment 1 (matching) and Experiment 2 (lexical decision) do suggest that the congruency effect is general, regardless of domain.

General Discussion

We have shown here that the motion properties of what can only be characterized as scrambled moving points of light yield systematic and expected interpretive responses from observers, concerning the detection of motion boundedness, and its relation to conceptual and linguistic telicity.

In Experiment 1, we observed that participants were more likely to choose a telic verb over an atelic verb to describe a bounded non-repetitive motion, even when the meanings of these verb pairs denoted abstract mental events (e.g., *think* vs. *decide*). This extends the Strickland et al. (2015) findings to visual stimuli more generally, even stimuli without linguistic and referential properties (signs). Experiment 2 offered preliminary results that activation of conceptual telicity from motion signals arises automatically, such that telic verbs show a congruency effect with bounded motion and atelic verbs show an effect with unbounded motion. Activation of concepts from motion signals has been observed before in similar tasks, e.g., that upward motion will speed reaction time to *rise* as opposed to *fall* (Meteyard et al., 2008). Additionally, previous research has shown that the ability to judge an action verb on a lexical decision task is correlated with the ability to judge a non-scrambled point-light action on an action decision task, e.g. is this a valid human action (Bidet-Ildei & Toussaint, 2015). What is surprising in the present study is that activation is for a highly abstract categorical feature (boundedness) that arises from seemingly continuous motion signals, and that the activation affects judgments even for verbs labeling events in the social and mental domains, which have no overt visual boundedness cues.

Observing an implicit association between visual and linguistic boundedness suggests there is an underlying amodal conceptual distinction that both systems have access to: a distinct categorical representation of boundedness, which may indeed be a conceptual primitive similar to that proposed for causation (see, e.g., Jackendoff, 1996; Rolfs, Dambacher, & Cavanagh, 2013). Of course, a representation of boundedness is not limited to the event domain; things may be conceived of as objects or substances, which have perceptual consequences of their own (vanMarle & Scholl, 2003). In future work we plan to refine our experimental tasks to replicate our lexical decision effects in the event domain, and to determine if they extend to boundedness across conceptual domains (events and objects).

Abstract

The ability to anticipate, attend and respond appropriately to specific stimuli is involved in the execution of everyday tasks. The current investigation examined the relations between cognitive skills measured by the NIH Toolbox and changes in the power of mu oscillations during anticipation of and in response to a tactile stimulus. Electroencephalographic (EEG) activity was measured after a visuospatial cue directed adults (n=40) to monitor their right or left hand for upcoming tactile stimulation. In the 500 ms prior to the onset of the tactile stimulus, a desynchronization was apparent 8 – 14 Hz at contralateral central sites, consistent with prior investigations of mu rhythm; a widespread synchronization was apparent in the 250 ms proceeding delivery of the tactile stimulus. The extent of contralateral reduction in mu power was associated with speed processing ability, while ipsilateral mu power was associated with flanker performance and marginally correlated with card sort performance. Regression further probe the significance and specificity of these effects. Increases in mu power following onset of the tactile stimulus were not associated with any behavioral measures. Mu modulation during attention to a specific bodily location appears related to variability in the broader ability to regulate behavior in a goal-directed manner, and perhaps to speed of stimulus processing.

Keywords: tactile; mu; EEG; executive function; sensorimotor; oscillations; anticipation;

Introduction

Anticipation of an impending event or sensation can guide perception and action. In experimental settings, when the presentation of a visual, auditory or tactile stimulus is preceded by a stimulus-relevant cue, participants report higher rates of accurate stimulus perception and demonstrate more rapid reaction time than when a stimulus is presented without a preparatory cue (Posner, 1980; Frey et al., 2015). These behaviors suggest prior to stimulus presentation, deployment of attention in a selective, focused manner is conducive to stimulus processing (van Ede & Nobre, 2017). Exploiting the temporal precision of electroencephalogram (EEG), we can eavesdrop on the changes in neural oscillations which occur before and after the presentation of a stimulus (Cheyne et al., 2003; Engel, Fries, & Singer, 2001), with the goal of identifying how these changes facilitate perception and the regulation of behavior.

In this study we assessed individual differences in oscillatory neural responses during anticipation of a tactile stimulus and in response to that stimulus. We investigate the association of subject-specific changes in oscillatory activity with variation in 1) reaction time in responding to the tactile stimulus, 2) general processing speed and receptive language abilities, as well as 3) executive function abilities, or the constellation of skills involved in the regulation of behavior.

The Active Role of Alpha Oscillations in Perception

Oscillatory activity in the alpha band of the EEG signal, broadly defined as activity within the 8-14 Hz frequency range in adults, has been identified as a correlate, gate and predictor of behavioral responses and cognitive functioning (Zanto & Gazzaley, 2009; van Ede & Nobre, 2017). As the most prominent oscillation in the EEG, alpha-range signals were originally associated with an 'idling' state but are now seen as more active in perceptual and cognitive processes (Klimesch et al., 1998). The oscillations apparent in the EEG signal arise from fluctuations in the polarity of cortical tissue, which reflect the shifting, homeostatic balance of postsynaptic potentials released by assemblies of excitatory pyramidal cells and inhibitory interneurons (Lopes da Silva, 2013; Cohen, 2016). The presence (or mere expectation) of a stimulus disrupts the default synchronized firing rate of post-synaptic potential which generated the rhythmic alpha activity, eliciting an event-related desynchronization (ERD) in the oscillatory signal (Haegens et al. 2011; Lopes da Silva, 2013). Changes in amplitude, phase and frequency of oscillations evoked by a discrete event can be computed using event-related spectral perturbation (ERSP), in which sinusoidal wavelets are used to estimate the shift in amplitude and phase of EEG oscillations in each successive, overlapping time window (Pfurtscheller & Da Silva, 1999; Makeig & Delorme, 2004). Thus, ERSP can quantify the changes in power of a given frequency range (relative to a baseline period), tracking the temporal sequence of postsynaptic potentials discharged synchronously from a particular neuronal population (Klimesch et al., 1998; Lopes da Silva, 2013).

To study changes in alpha power in anticipation of or in response to an upcoming event or stimulus, participants are presented with a cue that orients them to a feature of the forthcoming stimulus. In the widely-used Posner paradigm, a spatial cue indicates whether a visual stimulus will be presented to the participant's right or left visual field (Posner, 1980). During the interval following the cue but prior to the predicted onset of a visual stimulus, anticipatory ERD of

rhythmic alpha activity is observed over contralateral visual cortex, measured as a decrease in alpha power relative to baseline (Thut et al., 2006; Nobre & van Ede, 2017).

Contemporary accounts of 'top-down' or attention-related modulation of alpha-range activity rest upon the inhibition-timing hypothesis (Klimesch, Sauseng, & Hanslmayr, 2007), which explains that during rest, oscillatory EEG activity arises from the synchronized cortical firing of neurons that may limit the sampling of sensory events (Schroeder & Lakatos, 2009). When a stimulus disrupts the default state of rest or inattention, there is a reallocation of resources diverted to the local processing of the new or expected stimulus, which is facilitated by the suppression or inhibition of global neural activity. As such, widespread *increases* in alpha power from baseline reflect inhibited sampling of irrelevant sensory events, which permit concentrated cortical firing by neurons in the sensory cortex relevant to the stimulus. Focused attention and perceptual awareness of a stimulus is thus facilitated by concomitant *global increases* and *local decreases* in alpha power, indicating an adjustment in the sampling of sensory events adaptive to the expected temporal and spatial presentation of an upcoming stimulus (Frey et al., 2015; Schroeder & Lakatos, 2009; Thut et al., 2006). During anticipation, it is thought that sensory-specific alpha responses initiate the coordination of multisensory attentional control networks, enabling dynamic prediction of events across modalities and preparation for action (Engel, Fries & Singer, 2001; Sadaghiani & Kleinschmidt, 2016). In reaction to a stimulus, during rest and under most other conditions, these modality-specific alpha rhythms exhibit dissociable properties and operate independently (Mazaheri et al. 2009). Thus, the state of stimulus anticipation enables a unique opportunity for studying variability in oscillatory neural activity and centrality to behavior (Weiss et al., 2018).

Although much of the extant work on alpha power fluctuations has focused on the visual alpha rhythm at posterior occipital sites, another prominent alpha-range oscillation is the sensorimotor mu rhythm observed at central electrode sites (Jones et al., 2010; Pfurtscheller, 1989). Expectation of tactile stimulation in adults elicits changes in the mu rhythm which exhibit a somatotopic pattern (Anderson & Ding, 2011; Jones et al., 2010), in accord with the organization of the homunculus (Penfield & Boldrey, 1937). Jones et al. (2010) demonstrated reductions of mu power in anticipation of tactile stimulus, with responses lateralized according to the direction of a spatial cue (pointing left or right) as participants monitor their hands in expectation of sensation. Particularly when a distracting tactile sensation is presented simultaneous to the uncued hand, ipsilateral increases in mu power have also been demonstrated during the suppression of tactile attention (Haegens, Luther, & Jensen, 2012; van Ede, de Lange, & Maris, 2014). The utility of mu oscillatory power as an index of individual difference in behavior, beyond tactile stimulus processing to more general control of voluntary attention and action (executive functioning), has yet to be fully explored.

Anticipatory Mu Power and Tactile Processing

Across auditory, visual and tactile modalities, both contralateral alpha ERD and increases in ipsilateral alpha power during stimulus anticipation and response have been correlated with behavioral responses to stimuli (Thut et al., 2006; van Ede et al., 2014; Frey et al., 2015). In the tactile modality, the relation between mu power and behavioral indicators of tactile processing appears to differ depending on the strength and salience of the expected tactile stimulation, as well as the load on tactile attention (Haegens et al., 2012; Gomez-Ramirez, Hysaj, & Niebur, 2016). When a reliable spatial cue directs participants to expect tactile stimulation at the cued location, the magnitude of anticipatory mu ERD in electrode sites over the contralateral somatosensory cortices is linearly, inversely associated with rate of stimulus detection (Anderson & Ding, 2011; Haegens et al., 2011; Jones et al., 2010). Van Ede et al. (2012) examined anticipatory and post-stimulus mu power to parse their relative contributions to behavioral indicators of tactile processing. The authors reported that anticipatory mu ERD significantly accounted for the accuracy of participant's tactile judgements, while both the magnitude of anticipatory mu ERD and post-stimulus mu increases in mu power accounted for participant's reaction time to the stimulus. Reductions in anticipatory contralateral mu power have also been linearly associated with higher hit rates on tactile feature detection and temporal judgement tasks (Gomez-Ramirez et al., 2016).

Haegens, Handel and Jensen (2011) employed magnetoencephalography to investigate whether the lateralization of anticipatory mu oscillations varied according to how accurately a visual arrow cue relayed the location (right or left thumb) of an upcoming tactile stimulus. The authors reported that anticipatory contralateral mu power significantly distinguished between trials with above- and below-average reaction times, but not in accurate identification of the tactile stimulus (Haegens et al., 2011). This relation depended on the validity of the visual cue in predicting the location of the tactile stimulus. The authors found that the extent of oscillatory mu modulation reflects the predictability of the environment, such that differences in ipsilateral and contralateral mu power decreased under conditions with increasing uncertainty.

When tactile stimulation is expected simultaneously to a target location and another body part, it appears that variance in ipsilateral mu may index the suppression of tactile attention, partially accounting for behavioral responses to a tactile stimulus. In a subsequent MEG study, Haegens, Luther and Jensen (2012) reported that when tactile stimulation is presented simultaneously to the cued and uncued hand, both ipsilateral and contralateral mu power significantly distinguish between correct and incorrect trials. Thus, similar to the importance of increases in ipsilateral anticipatory alpha power in the visual modality in accounting for variability in stimulus response (Thut et al., 2006; Frey et al., 2015), anticipatory ipsilateral mu power may facilitate focus when tactile attention is under load.

To address inconsistencies in the literature associating oscillatory mu activity with task-specific indicators of tactile processing, we note the potential importance of subtle differences in task demands (Gomez-Ramirez et al., 2016). The dynamic adjustment of lateralized mu modulation to anticipated features of a tactile stimulus may be indicative of its sensitivity to the load on tactile attention, divided by managing competing expectancies, allocating tactile attention according to goals and bracing for potential distraction (Haegens et al., 2012).

One suggestion arising from work linking anticipatory neural responses to basic sensory responses is the proposition that 'low-level' indicators of attentional processing reciprocally influence, gate and cascade into individual level differences in the 'higher-order' ability to control behavioral responses (Engel, Fries & Singer, 2001; Gazzaley and Nobre, 2012; Sadaghiani & Kleinschmidt, 2016). We further suggest that executive function, defined by the planning, regulating and monitoring of goal-directed behavior, may partially be a manifestation of individual differences in how adults use information in their environment to anticipate upcoming sensory events and adjust their behavior to such expectancies.

The Present Study

The goal of the current investigation is to utilize an individual differences approach to the analysis of sensorimotor mu oscillatory activity during anticipation of and in response to a tactile stimulus. Our objectives were (i) to develop a subject-specific approach to identifying sensorimotor mu rhythm reactivity (ii) to examine whether mu reactivity is associated with variance in participant's reaction time in stimulus detection (iii) to test if mu reactivity is associated with variance in a battery of cognitive skills, which includes measures of receptive language, processing speed and executive function. We employed a task in which a visual cue directed adults to focus their attention on a specific bodily location (the left or right hand) in anticipation of a tactile stimulus to that location. Using a foot pedal, participants responded to the tactile stimulus to indicate whether they detected one or two stimuli. We expected neural indicators of heightened attention (greater mu desynchronization or ERD in the contralateral hemisphere, and greater mu synchronization or ERS in the ipsilateral hemisphere) to relate to higher-order cognitive abilities (i.e., the executive function measures) and response time to target stimuli.

The logic of presenting a preparatory cue in a *different* modality from the target stimulus allows temporal and spatial differentiation of anticipatory activity (over sensory cortex relevant to the target) from neural responses elicited by the cue. There are also several strengths of employing somatosensory rather than visual targets: (i) Compared with the visual modality, tactile attention is not complicated by factors such as ocular shifts or visual preference; (ii) Neural indices of anticipation of touch are readily measurable through EEG recordings from electrodes overlying somatosensory cortex (Anderson and Ding, 2011; Haegens et al., 2011; Jones et al., 2010); (iii) The ability to focus attention to a body part in expectation of touch may be amenable to change and enhancement via specific interventions (Jones et al., 2010).

Methods

Fifty undergraduate students received course credit in return for participation. Data from six participants were excluded from analyses due to technical issues. Four additional participants were excluded due to excessive artifact that contaminated more than 25% of trials. The final analyzed sample comprised 40 participants (mean age = 21.24 years; SD = 3.85; 37 females). All participants were right-handed according to the Oldfield Handedness questionnaire, neurologically healthy, and had normal or corrected vision. Once consented, participants were fitted with an EEG cap and tactile stimulators, seated at a table facing a computer screen, and instructed to rest their hands on their lap, out of sight.

Procedure

Participants were instructed to prepare for tactile stimulation to the index finger of the hand indicated by the direction of the arrow, and to indicate how many stimuli they detected (one or two) by pressing a foot pedal once or twice. The foot used to report stimulus detection was counterbalanced across participants. The specific sequence of visual stimuli in each trial comprised a fixation cross for 500 ms, followed by the arrow cue for 2250 ms, followed by a response screen that read "Copy with Your Foot!" (Figure 1). The tactile stimulation was delivered 1500 ms after the onset of the arrow cue, which remained on the screen for the 750 ms following tactile stimulation. The direction of the arrow was randomized, with an equal number (100) of left and right trials. Individual participant's reaction time was retrieved from the onset of the response screen to the foot pedal press. Two tactile stimuli were delivered in rapid succession ("double stimuli") on 20 out of the 200 trials, and 80 single-pulse trials were delivered to the right or left hands of participants. Prior to the experimental trials, 5 practice trials were presented to ensure that participants distinguished between the single and double tactile stimuli.

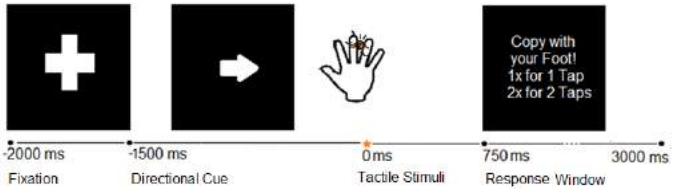

Figure 1. Trial structure: A fixation point was displayed for 500 ms, followed by an arrow spatial cue displayed continuously for 2250 ms, and the onset of the tactile stimulus occurred 1500 ms later (at 0 ms). The response prompt was displayed 750 ms after the tactile stimulus.

Tactile stimuli were delivered to the distal tip of the left and right index fingers using an inflatable membrane (10 mm diameter; MEG Services International, Coquitlam) mounted

in a plastic casing and secured with a finger clip. The membrane was inflated by a short burst of compressed air delivered via flexible polyurethane tubing (3 m length, 3.2 mm outer diameter). The compressed air delivery was controlled by STIM stimulus presentation software in combination with a pneumatic stimulator unit (both from James Long Company, Caroga Lake) and an adjustable regulator that restricted the airflow to 60 psi. To generate each tactile stimulus, the STIM software delivered a 10 ms trigger that served to open and close a solenoid in the pneumatic stimulator. Expansion of the membrane started 15 ms after trigger onset and peaked 35 ms later, with a total duration of membrane movement of around 100 ms.

EEG Recording and Processing EEG was recorded at a 512 Hz sampling rate using a stretch cap (ANT Neuro, Berlin) with electrodes placed at Fp1, Fpz, Fp2, F3, Fz, F4, F7, FC6, FC1, FC2, FC5, F8, Fz, C3, Cz, C4, CP1, CP2, CP5, CP6, T7, T8, P3, Pz, POz, P4, P7, P8, O1, Oz, O2, GND, and the left and right mastoids. Vertical EOG was recorded above and below the orbital rim of the left eye. Conducting gel was used and scalp electrode impedances were kept under 25 kΩ (values were typically lower). EEG channels were collected referenced to the vertex (Cz) and were re-referenced offline to an average mastoids reference prior to further analysis. The signal was amplified using optically isolated, high input impedance (> 1 GΩ) custom bioamplifiers (SA Instrumentation) and digitized using a 16-bit A/D converter (+/- 2.5 V input range). Bioamplifier gain was 4000 and filter (12 dB/octave rolloff) was set to .1 Hz (high-pass) and 100 Hz (low-pass).

Initial processing of the data utilized the EEG Analysis System (James Long Company) followed by analysis using the EEGLAB toolbox (Makeig et al., 2004) implemented in MATLAB. Independent component analysis was used to clear the EEG data of ocular and muscle artifact (Hoffmann and Falkenstein, 2008). Visual inspection of the EEG signal rejected epochs containing excessive remaining artifact. There was no difference in the number of usable trials between the left and right cued conditions ($p = 0.81$). Out of 80 trials, the mean number of artifact-free trials per condition was 69 ($SD = 5.62$).

For each single-pulse trial with a correct behavioral response, an epoch of 2500 ms was extracted (beginning 2000 ms prior to onset of the tactile stimulus and extending 500 ms after tactile stimulus onset). To avoid contamination of the anticipatory and response window by stimulus delivery, we set the initial membrane expansion as the onset of the tactile stimulus (0 ms) and the post-stimulus window to 20ms following the peak of membrane expansion. Spectral power over this epoch was estimated using Gaussian-tapered Morlet wavelets (Makeig & Delorme, 2004). Changes in power were computed as event-related spectral perturbation (ERSP) from initial visual cue presentation until after tactile stimulus presentation (i.e., -1500 to 300 ms) relative to a 500 ms baseline preceding the visual cue (i.e., -2000 to -1500 ms prior to tactile stimulation onset). For statistical analyses, a key variable was anticipatory mu ERSP, which was extracted from mean ERSP value at C3 or C4 from 8 – 14 Hz in the 500 ms prior to onset of the tactile stimulus to the onset of the tactile stimulus (0 ms). We extracted post-stimulus mean mu ERSP by extracting the mean mu ERSP for the period from the delivery of the tactile stimulation at 20 ms to the following 270 ms.

Behavioral Measures Following the tactile task and removal of the EEG cap, four tasks from the NIH Cognition Toolbox were administered (for details, see Zelazo et al., 2013): the Flanker task, the Card Sort task, a Processing Speed task, and a picture vocabulary test that measured Receptive Language. On the Card Sort task, participants selected one of two test stimuli which matched either the shape or color of the target stimuli. In the Flanker task, participants indicated the direction of a central arrow that was presented between distracting 'flanker' arrows. Processing Speed was measured by the average reaction time to detecting if two images were identical. Participant's scores on the Card Sort and Flanker tasks were calculated to reflect both accuracy and reaction time for participants who correctly identified targets on 80% of trials; accuracy alone was considered when this threshold was not met. For all four measures, we used t-standardized test scores (standardized around $\mu=100$) provided by the NIH Cognitive Toolbox.

Results

Behavioral Responses to Tactile Stimuli

Aggregated across the sample ($N = 40$), participants correctly identified the single or double tactile stimuli on 96.7% of trials. Reaction time was calculated as the duration from response screen until the initiation of the foot pedal press. Only single-stimulus trials were included in analyses.

Identifying Mu ERSP

Time-frequency plots (Figure 2) show a clear mu rhythm (8-14 Hz) ERD at the central electrode site (C3 or C4) contralateral to cue direction. In contrast, there was minimal change in mu power at the central electrode ipsilateral to the cue direction. Significant differences between contralateral and ipsilateral central sites (Figure 2) are driven by mu ERD during anticipation of tactile stimulation (-500 ms to 0 ms) at the site contralateral to the cue direction. At the left central electrode site (C3), mu ERD was apparent as participants attended to their right hand. At the right central electrode site (C4), mu ERD was present during attention to the left hand.
