We conducted a classroom PS-I intervention with N=221 students in an introductory data science course offered at a large public university in Switzerland. Based on data from a previous course iteration, two topics Spurious Correlation (SC) and Anscombe's Quartet (AQ) were chosen to develop learning materials. Problem-solving based on these topics had demonstrated different initial failure rates, and different levels of improvement after students were presented with clues pointing them to the correct answer (SC task, 40% $\rightarrow$ 23%; AQ task, 81% $\rightarrow$ 38%). The SC learning goal was to help students tease apart the difference between strong versus meaningful relationships among dataset variables. The AQ learning goal was to help students understand the complementary importance of numerical and graphical representations in reasoning with data. Students worked individually in an online problem-solving environment (Python Jupyter notebook) that was dynamically executable, and helped in offloading procedural or syntactical aspects of the computation required (for task details, see www.tinyurl.com/CogSci2019Tasks).

Experimental Design and Scaffolding Rationale

A mixed experimental design was followed. Scaffolding in initial problem-solving (SD, FD) was the between-subject variable, and problem-solving topic (SC, AQ) was the within-subject variable. Students were randomly assigned to experimental conditions, and ordering of problem-solving topics was counterbalanced within each condition. We had two conditions representative of SD scaffolding with varying degrees of specificity, and two conditions representative of FD scaffolding with varying levels of suboptimality. For all four conditions, the instruction phase was kept constant. Student solutions were compared and contrasted with the canonical one.

The rationale for the concrete design of scaffolding in our research was inspired by mechanisms of structuring and problematizing student work (Reiser, 2004). Structuring scaffolds reduce degrees of freedom to lower task complexity, help students maintain direction, and make problem-solving tractable. Problematizing scaffolds increase degrees of freedom to challenge student's current understanding, and highlight discrepancies between what they might generate and critical/canonical task features. We chose an initial set of structuring and problematizing scaffolds in line with keeping the generative characteristics of the problem-solving phase intact, as well as explicitly increasing success or failure likelihood as the intended design rationale.

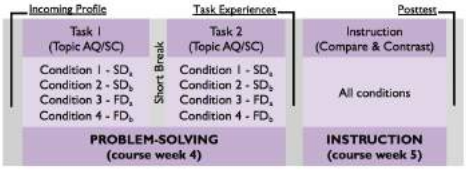

Figure 1: Experimental Design. SD_a, SD_b, FD_a, FD_b are two instantiations of success-driven (SD) and failure-driven (FD) scaffolding in the problem-solving phase respectively.

Structuring scaffolds included a combination of prompts, hints and bottom-out hints for different task topics. Prompts point students to the problem conditions that should likely remind them of the knowledge component's relevance. Very little information is divulged, thus encouraging students to do most of the thinking themselves. Our design of hints incorporates the idea of teaching students the knowledge component that is actually relevant in the current problem-solving context (what to do but not how). Finally, bottom-out hints tell students precise (and potentially optimal) ways of moving ahead in the problem-solving task. Such a scaffolding sequence mimics the behavior of expert human tutors, and is almost universally used in tutoring systems (VanLehn, 2011).

Problematizing scaffolds included asking students to explicitly generate suboptimal RSMs to facilitate problem-space exploration in a more comprehensive manner, rather than following an isolated solution path. In essence, students are led towards questionable decision-making by being asked to consider a subset of conceptual domain factors (that don't lead to the canonical solution), and reason with those partially-gained insights. No former PS-I work has looked directly into such "explicit" failure scaffolding. However, one could view the classic PF design as providing "implicit" opportunities for students to create suboptimal RSMs (Kapur & Bielaczyc, 2012). This is because rich problem design "inherently" affords multiple RSM generation, and targets concepts students haven't learnt yet. Work on preparatory benefits of vicarious failure activities before receiving instruction suggests the evaluation of suboptimal or failed RSMs generated by others as a significant predictor of learning (Kapur, 2014).

As a concrete example, when reasoning about the relationship between two variables, a prompt would give students general information about statistical dependence between variables, a hint would provide explanation of the exact phenomena under consideration (e.g., SC, AQ), and a bottom-out hint might ask for reasoning with a scatterplot (optimal graphical representation). Alternatively, reasoning with a 2-

Table 1: Examples of constructive reasoning coding applied for the analyses of posttest reasoning/code

Category	Sub-category	Sub-sub-category	Examples from data
Non-mathematical elaboration	Graphical	Complete	*Thinking for a good distribution that fit with this theory we can imagine a bar in the middle and nothing around. That means that all the people have the same degree of wealth. Looking at the plots we can already see that the distribution that seems what we have imagined is the normal distribution for the scenario A. We can also look at the standard deviation that confirm this reasoning*
		Not Complete	*Taking into account histogram with 50 bins, a better idea of distribution of wealth between citizens is given*
	Numerical	Complete	*By using a histplot, we see that for B there is no middle class, only rich and poor people =>not socialist.*
		Not Complete	*I add the values of each person and I divide by the number of person to find if the money is well distributed*
Mathematical elaboration	Graphical	Complete	*Datasets are almost identical specially in descriptive statistics but when we see plot of wealth distribution we can see that in B, there are more people with less wealth distribution specially after median and with similar reasoning we can say that as C is upper than B and A in most cases, it is the worst*
		Not Complete	*Linecharts show that C has the most wealth in the middle*
	Numerical	Complete	*Using the variance of each set, we can see that the values of dfA are much more centered around the mean (and thus a more egalitarian society). Followed by C then B*
		Not Complete	*comparing the median values of the different datasets*

D or 1-D histogram are examples of suboptimal RSMs. Here, information is lost because of binning and/or the lack of directly perceivable information about co-variation in the data.

Analytical Procedures

Due to dropout at various stages of the study (12%-57%), we applied standard multiple imputation (MI) procedures (n=5) to fill missing dataset values (Van Buuren, 2018). Discarding missing data may result in the complete cases being no longer representative of the target population, and consequently, estimates derived from them being subject to non-response bias. MI accounts for the process that created the missing data, and preserves uncertainty among relations in the data. Logistic regression and its variants (multinomial, ordered) were used for binary, nominal (>2 categories) and ordinal data respectively. Predictive mean matching was used to impute numeric data. Density plots of observed and imputed values were visually inspected for validity. Non-parametric statistics were used to see differences in ordinal posttest scores (e.g., Kruskal-Wallis tests, follow up Dunn tests). Multiple comparisons were adjusted using the Benjamini-Hochberg method. For non-significant results ($p > 0.05$), equivalence tests were performed to provide evidence for absence of a meaningful effect (Lakens, Scheel, & Isager, 2018). Here, the smallest effect size of interest was set within Cohen's d bounds of $\pm$ 0.2.

We also developed a coding scheme (Krippendorf's $\alpha >$ 0.7) for qualitative analyses of student's posttest reasoning and code, based on prior work (Chi, 2009; Kapur & Kinzer, 2009). First, we identified if reasoning was constructive (meaningful elaborations that went beyond what was presented). If yes, we identified if the elaborations were non-mathematical or mathematical. The former refers to elaborations that explain inferences leading up to the results, while the latter refers to elaborations that explicitly mention mathematical formalisms in words and/or in the code and base solution inferences on these formalisms. Next, for each kind of elaboration, we further checked if the elaborations comprised one or more graphical/numerical representation(s), meaning graphs, plots or other quantitative indices. Finally, we checked if these representation(s) were complete. Non-mathematical elaborations were coded as complete if all variables were set in relation to each other, and the result could be clearly derived from the elaboration. No information was missing and the connection between evidence and claim was fully explained using reasoning. Mathematical elaborations were coded as complete if all necessary methods in order to derive results were mentioned in words and/or presented in the code. Table 1 provides examples from the data.

Measures

Before the problem-solving phase, we collected student's prior knowledge using high school math scores as a proxy. No explicit pretest was conducted to prevent redundancy with the problem-solving phase. Based on prior literature on inter-individual factors that characterize heterogeneity in student's approach to FD and SD learning, we also included questionnaires assessing incoming profile variables like effort regulation (Pintrich et al., 1991), self-esteem (Jones, 1973), learning goal orientation (LGO) (Dweck, 1992) and attitude towards mistakes (ATM) (Leighton, Tang, & Guo, 2015). Effort regulation reflects a commitment to completing one's goals despite difficulties. High self-esteem triggers positive attributional style towards success and failure. An LGO disposition affects whether students view failures as learning opportunities. Finally, ATM, which includes the utility of making mistakes and induced affective reactions, enhances or impedes receptivity to failures. After the problem-solving phase, students answered task experience questionnaires, in line with PS-I preparatory mechanisms (Loibl et al., 2017).

These experiences included perceived awareness of knowledge gaps at the current moment (Glogger-Frey, Gaus, & Renkl, 2017), state curiosity about task actions and what they would like to know (Naylor, 1981), germane and extraneous cognitive load induced by problem-solving (Leppink, Paas, Van Gog, van Der Vleuten, & Van Merrienboer, 2014), and the experienced cognitive dissonance. Cognitive dissonance, defined as a state of discomfort associated with detection of conflicting concepts (Levin, Harriott, Paul, Zhang, & Adams, 2013), has not been studied in prior PS-I work because of lack of work on problematizing. Consistency of both incoming profile and task experience questionnaires was good for our dataset (McDonald's $\omega >$0.7). After the instruction phase, students solved an isomorphic and a non-isomorphic conceptual understanding posttest for each of the two task topics.

Results

Variable-centered Approach

We first performed variable-centered analyses to look at overall patterns of the impact of SD and FD preparatory activities on conceptual understanding in PF (figure 2).

Task topic SC For the SC topic, we found a significant omnibus effect of the experimental grouping on the

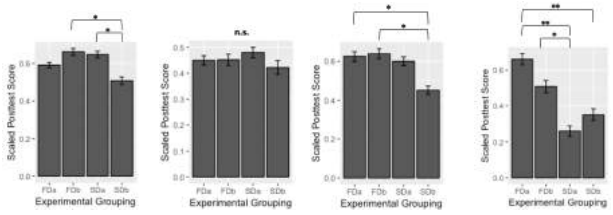

Figure 2: Scaled posttest scores with inferential error bars (L to R: SC non-isomorphic, SC isomorphic, AQ non-isomorphic, AQ isomorphic). Significant differences marked.

non-isomorphic conceptual understanding posttest ($\chi^2(3) = 11.73$, $p = 0.008$, Cohen's $d = 0.409$). The FD condition was better than the SD condition that offered the more-specific clue, in this case a hint describing the SC phenomena. However, the FD conditions were equivalent to the SD condition that offered the less-specific clue, in this case a prompt describing what statistical dependence among variables is. The two FD conditions here asked students to generate/reason with a correlation table and scatterplot matrix respectively, both of which reflect suboptimal numerical and graphical representations respectively. This is because they don't fully allow inferences on the nature of relationships (strength and/or meaningfulness) between dataset variables. No significant omnibus difference in scores on the isomorphic conceptual understanding posttest was observed across the four experimental conditions ($\chi^2(3) = 1.37$, $p = 0.712$, Cohen's $d = 0.174$). Equivalence testing suggested that the observed effect was neither statistically different from zero nor statistically equivalent, indicating insufficient data to draw conclusions.

Qualitative analysis suggested that for the non-isomorphic conceptual understanding posttest, the trend mirrored posttest scores. Students in the FD conditions had higher percentage of complete mathematical (32.1%, 38.7% >> 27.3%) and non-mathematical elaborations (44.7%, 56.7% >> 27.3%), compared to the SD condition with the more specific clue. Additionally, completeness of reasoning was almost identical between the FD condition and the SD condition with the less specific clue. However, for the isomorphic conceptual understanding posttest, student reasoning was often dominant in either complete mathematical or complete non-mathematical elaborations across the experimental conditions. The SD conditions had comparatively higher percentage of the former (38.9%, 45.8% >> 32.4%, 25%), while the FD conditions had comparatively higher percentage of the latter (33.3%, 48.8% >> 43.3%, 23.6%). This might be one reason why we saw no posttest score differences.

Task topic AQ For the AQ topic, we found significant omnibus effects of the experimental grouping on both the non-isomorphic ($\chi^2(3) = 10.84$, $p = 0.012$, Cohen's $d = 0.387$) and isomorphic ($\chi^2(3) = 20.16$, $p = 0.0001$, Cohen's $d = 0.586$) conceptual understanding posttest. Follow up pairwise comparisons suggested that scores for students in FD condition were greater than those in the SD condition with the more specific clue, in this case a bottom-out hint asking for scatterplot generation. However, the difference did not reach significance when comparing the FD condition and SD condition with the less specific clue, in this case a hint describing the AQ phenomena. The two FD conditions here asked students to generate/reason with a 2-D and 1-D histogram respectively. Both reflect suboptimal graphical representations.

We separated the coding of numerical and graphical representations to assess their independent usage in student reasoning. Qualitative analysis suggested that for the non-isomorphic conceptual understanding posttest involving graphical representations, students in the FD conditions had higher percentage of complete mathematical (72.2%, 68.7% >> 33.3%, 40%) and non-mathematical elaborations (44.4%, 37.5% >> 26.6%, 40%), compared to the SD conditions. This also held true for complete mathematical (27.7%, 37.5% >> 20%, 0%) and non-mathematical elaborations (27.7%, 31.2% >> 13.3%, 0%) involving numerical representations. For the isomorphic conceptual understanding posttest, a similar trend held for elaborations involving graphical representations. We did not see clear trends in qualitative differences in student reasoning for elaborations involving numerical representations, the less straightforward (and dominant) approach for this isomorphic question. Taken together, despite no posttest score differences between students who received FD scaffolds and the less-specific SD scaffold, there were salient differences in reasoning quality.

Person-centered Approach

We performed complementary person-centered analyses to go beyond an average FD or SD learning pattern (figure 3). The rationale here was to factor in the interactions among incoming student characteristics, in order to understand the impact of this heterogeneity on learning. We used latent profile analysis to first cluster students based on incoming profile variables like prior knowledge, effort regulation, learning goal orientation, self-esteem and attitude towards mistakes. This approach provides an elegant way to discover subgroups by "simultaneously" considering interactions among "more than one" incoming cognitive and motivational student characteristic. Non-parametric multivariate finite mixture models were used (Hickendorff, Edelsbrunner, McMullen, Schneider, & Trezise, 2017). A two-cluster solution (figure 4) reflected parsimonious fit to the data (based on model fit ($loglik = 530.41$), mixture distributions and visual inspection of mixture density plots when fitting more than two clusters).

Cluster assignments for students into these homogeneous subgroups were based on posterior probability distributions. These cluster assignments allowed us to then use this information for studying interaction effects (reported below). Statistically, we found one of these clusters (henceforth, Cluster_{high}) to have significantly higher scores on all of these incoming characteristics, compared to the other cluster (Cluster_{low}). Cluster_{low} reported higher extraneous cognitive load than Cluster_{high} ($W = 7319.5$, $p = 0.001$) after problem-solving. All other task experiences were statistically similar.

Task topic SC/AQ Not surprisingly, we did find that students in Cluster_{high} scored significantly higher than those in

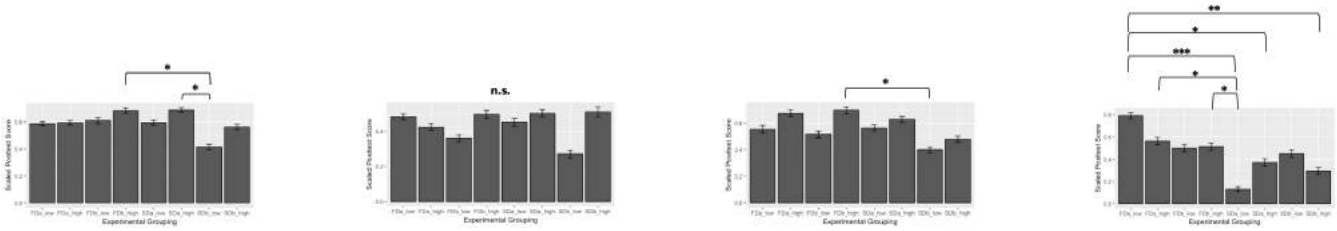

Figure 3: Scaled posttest scores with inferential error bars (L to R: SC non-isomorphic, SC isomorphic, AQ non-isomorphic, AQ isomorphic). Significant differences marked. *Low* and *High* represent students from Cluster$_{low/high}$ within a condition.

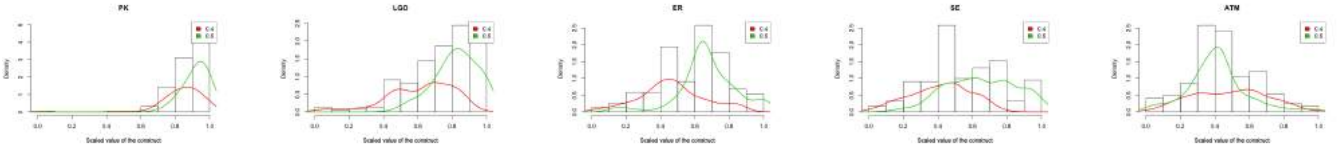

Figure 4: Mixture density distributions when clustering students based on incoming cognitive and motivational characteristics (L to R: Prior knowledge, Learning goal orientation, Effort regulation, Self-esteem, Attitude towards mistakes)

Cluster$_{low}$ on the non-isomorphic conceptual understanding posttest. This trend held for both SC ($W = 4885.5$, $p = 0.04$) and AQ task topics ($W = 4811.5$, $p = 0.02$). On the other hand, both Cluster$_{high}$ and Cluster$_{low}$ performed equally well on posttests scores for the isomorphic conceptual understanding question. Equivalence testing results were inconclusive.

Interaction We finally looked at impact of the interaction between experimental grouping and incoming student profile on posttest. Results suggested that the omnibus trend for difference in non-isomorphic conceptual understanding posttest still held for the SC topic ($\chi^2(7) = 17.16$, $p = 0.016$, Cohen's $d = 0.448$). Descriptively, students in the FD sub-groupings outperformed those in the SD sub-groupings. As before, the omnibus effect was still not significant for the isomorphic conceptual understanding posttest ($\chi^2(7) = 11.5$, $p = 0.118$, Cohen's $d = 0.294$). Equivalence testing showed 24/28 pairwise comparisons to be inconclusive.

For the more difficult topic AQ, again, as before, exposure to failure-driven scaffolds benefited students on both the non-isomorphic ($\chi^2(7) = 16.91$, $p = 0.017$, Cohen's $d = 0.442$) and isomorphic ($\chi^2(7) = 27.16$, $p = 0.0003$, Cohen's $d = 0.647$) conceptual understanding posttest. Descriptive trends for students in FD sub-groupings scoring higher than their counterparts in the SD sub-groupings still held. This also suggests that perhaps task difficulty and the extent to which student reasoning requires manipulation and integration of multiple representations, might be an important factor when looking at the relative efficacy of FD and SD scaffolds.

Underlying Mechanisms

We computed partial correlations between student's task experiences during the problem-solving phase and their posttest scores, controlling for experimental grouping (SD, FD) and incoming student profile (Cluster$_{high/low}$). For the more difficult topic (AQ), we saw positive associations of both isomorphic and non-isomorphic posttest scores with awareness of knowledge gaps ($\rho = 0.112^{+}$, 0.172*) and germane cognitive load ($\rho = 0.114^{+}$, 0.120^{+}). The correlation between these task experiences and posttest scores was not significant for the easier topic (SC). Experiencing higher state curiosity ($\rho = 0.158$*, 0.184**) and cognitive dissonance ($\rho =$ 0.193**, 0.187**) was positively associated with only with non-isomorphic posttests, however for both SC and AQ topics. Finally, experiencing greater extraneous cognitive load was negatively associated with posttest scores for both SC ($\rho =$ -0.243**, -0.236**) and AQ ($\rho =$ -0.185**, n.s.) topics.

Manipulation Check and Design Implications

Students in every experimental condition had the opportunity to make two solution attempts (prior/post exposure to the scaffold) during the problem-solving phase. This design allowed us to assess the percentage of students who improved/degraded their solution across these two time points within the initial problem-solving. We computed a summary index S (ranging from -100 to 100) for each condition and task topic, by subtracting (i)ΔD, the percentage of students who degraded (got the right answer pre-scaffold, but wrong answer post-scaffold), from, (ii)ΔI, the percentage that improved (got the wrong answer pre-scaffold, but right answer post-scaffold). For the two FD conditions, we found S to be highly negative ($\Delta D > \Delta I$) for the more difficult task topic AQ (-72%, -47%), suggesting that the problematizing scaffold indeed pushed students towards explicit failure. For the easier task topic SC (-51%, -34%), S was still negative but comparatively lower in absolute terms.

Interestingly, for the two SD conditions, S was not positive or ΔI was $\not>$ than ΔD (as one might intuitively expect). Overall, despite S being lower in absolute terms compared to the FD conditions, it was still negative for both the AQ (-52%, -54%) and SC (-40%, -6%) task topics. This suggests that although explicit structuring prior to instruction led to greater net solution accuracy (compared to explicit problematizing), it was still not enough to push majority of student solutions to match the canonical answer. Taken together, these analyses show that students may not necessarily be prepared to receive explicit structuring during initial exploration, especially for difficult topics. It also opens up questions about re-calibrating the specificity of structuring scaffolds so that $\Delta I > \Delta D$.

Discussion and Conclusion

Table 2: posttest differences across experimental grouping

	Non-isomorphic conceptual understanding posttest	Isomorphic conceptual understanding posttest
Topic SC (Variable-centered)	$\chi^2(3) = 11.73$, $p = 0.008$ Cohen's $d = 0.409$	$\chi^2(3) = 1.37$, $p = 0.712$ Cohen's $d = 0.174$
Topic SC (Person-centered)	$\chi^2(7) = 17.16$, $p = 0.016$ Cohen's $d = 0.448$	$\chi^2(7) = 11.5$, $p = 0.118$ Cohen's $d = 0.294$
Topic AQ (Variable-centered)	$\chi^2(3) = 10.84$, $p = 0.012$ Cohen's $d = 0.387$	$\chi^2(3) = 20.16$, $p = 0.0001$ Cohen's $d = 0.586$
Topic AQ (Person-centered)	$\chi^2(7) = 16.91$, $p = 0.017$ Cohen's $d = 0.442$	$\chi^2(7) = 27.16$, $p = 0.0003$ Cohen's $d = 0.647$

To summarize, our results indicate the efficacy of FD over SD preparatory activities on student's conceptual understanding. We go beyond prior PS-I work by performing stringent comparisons between explicit ways of pushing students towards success and failure in problem-solving prior to instruction, and investigating their impact on learning. Overall, we found a significant main effect for experimental grouping on the non-isomorphic conceptual understanding posttest, with the FD conditions outperforming the SD condition with the more-specific clue, but not the SD condition with the less-specific clue. Posttest score similarity between the latter comparison indicates that FD and SD approaches might potentially offer two distinct but effective paths to learning. Nudging students to make them realize by themselves the extent to which their activated knowledge is (ir)relevant for solving the problem (we can have both SD and FD ways towards this end), is better than directing their activation of relevant prior knowledge (via a highly specific SD scaffold).

However, we also found that a comparatively higher percentage of students who received FD scaffolds demonstrated reasoning with complete mathematical or non-mathematical elaborations, indicating better quality of reasoning than students in the SD conditions. This result supports the idea that focusing on the pragmatic goal of performing the correct procedure (in presence of SD scaffolding) without appropriately articulating understanding (non-reflective work) can lead to fragile conceptual gains (Jonassen, 2010). We also found a significant main effect for the incoming student profile on the non-isomorphic conceptual understanding posttest, with students having high self-reported scores significantly performing better. There was no evidence for an interaction effect. Exposure to FD scaffolds had a greater impact on posttest scores for the more difficult topic (AQ). Finally, we found mechanistic task experiences to be positively associated with posttest scores (stronger associations for AQ task topic and for non-isomorphic posttests), controlling for experimental grouping and incoming profile.

What might explain the superiority of problematizing scaffolds over structuring scaffolds in the PS-I design? Although scaffolding for success might push for speed/accuracy to facilitate fluency in knowledge application for one form of independent performance (Schwartz, Sears, & Chang, 2007), both posttest scores and qualitative analysis of reasoning suggest that it does not guarantee improved conceptual understanding. Correct performance of a procedure scaffolded via structuring might stem from the lack of awareness and appreciation of long-term sub-optimality of a solution that works reasonably well in the short-term (Schwartz, Chase, & Bransford, 2012). The resulting quick/easy success may be insufficiently disruptive to challenge existing thought processes, and induce inattention when learning from instruction.

Existing meta-analysis of PS-I literature (Loibl et al., 2017) also suggests that students need to be made aware of the limitations to their knowledge (knowledge gaps). Further, we must instill in them a strong desire to know more about the canonical solution to fill these knowledge gaps. Finally, the learning design needs to facilitate understanding of which solutions don't work and why. In line with these vital pre-instructional goals, the suboptimal RSM generation strategy triggers "effortful activation" of prior knowledge conceptually relevant to the targeted learning concept.

By exposing students to additional exploration of the problem-space structure that doesn't necessarily lead to the canonical solution, suboptimal RSM generation provides support for meaningful variation in reasoning (Soderstrom & Bjork, 2015), which aids in improved conceptual understanding. Further, the uncertainty induced about consequences of partially-gained insights during solution revision is likely to trigger momentary curiosity driven by student's problem-solving experiences. One's own failed attempt is also likely to better prepare students for acquisition of negative knowledge regarding applicability conditions of solution strategies during instruction. Finally, at a methodological level, we see an improvement in effect sizes compared to a traditional variable-centered approach for both task topics (table 2). Complementary person-centered analyses provide a more accurate assessment of the impact of our PF intervention, since they factor in the differential benefits arising due to individual differences in SD and FD learning.

The scaffolding implemented in this work can be embedded into metacognitive tutors (Joyner & Goel, 2015) that deploy computer agents to imitate functional roles of teachers - "guides" to offer structuring, and "critiques" to problematize exploration. Limitations of this work stem primarily from the classroom time constraints. This was reflected, for e.g., in choice of datasets we used. For future work, we will design rich(er) datasets (that allow greater scope of inferences). The allocated time budget also led us to design one-step SD or FD scaffolds, and collect single task experience questionnaire after students finished solving problems on both topics (SC, AQ). Finally, optional university attendance resulted in considerable student dropout over the two study weeks, despite our efforts to mitigate this threat via participation reminders.

When Productive Failure Fails

Tanmay Sinha, Manu Kapur
ETH Zürich, Switzerland

Abstract

Productive Failure (PF) is a learning design that intentionally designs for and uses failure in preparatory problem-solving for learning. Over the past decade, there has been growing evidence supporting the effectiveness of learning from PF. The purpose of this paper, however, is to critically examine evidence for when PF fails. We analyze 95 experimental comparisons from 57 studies reported in 44 articles into the extent to which they conform to PF design criteria. These criteria, as outlined in the original PF work, span the problem-solving activity, the participation structures, and the social surround. Results suggest lack of design fidelity as a critical factor for when PF fails to outperform alternative instructional approaches on conceptual knowledge and/or transfer.

Keywords: Direct Instruction; Productive Failure; Scaffolding

Introduction

The past decade has seen a growing body of evidence for the efficacy of Productive Failure (PF) for developing conceptual knowledge and transfer (for a review, see Kapur (2016); Loibl, Roll, and Rummel (2017)). PF comprises an initial problem-solving phase where learners generate and explore representations and solution methods (RSMs) to complex problems based on concepts they have not formally learnt yet, followed by an instruction phase where an expert or a teacher builds upon student-generated solutions to teach them the targeted concepts. According to PF, generating solutions to novel problems prior to instruction can help students learn better from the instruction, even if students fail to generate the correct solution in the problem-solving phase (Kapur, 2016). Thus conceived, PF can be seen as a subset of a general class of designs where problem-solving precedes instruction (or PS-I). It must be noted that not all PS-I designs are PF, but only those in which students generate multiple solutions but fail to generate the correct one.

In experimental comparisons, PF is typically compared with a design where students are initially given instruction on the targeted concepts, followed by problem-solving practice. Loibl et al. (2017) referred to this design as an Instruction-followed-by-Problem-Solving (I-PS) design. Findings in support of PF suggest that both PF and I-PS are similar in the development of procedural knowledge, but PF significantly outperforms I-PS in conceptual understanding and transfer (Kapur, 2016). Evidence comes not only from quasi-experimental studies conducted in the real ecologies of classrooms (e.g., Kapur (2012); Kapur and Toh (2013); Schwartz and Bransford (1998); Schwartz and Martin (2004)), but also from controlled experimental studies (e.g., M. S. DeCaro and Rittle-Johnson (2012); Kapur (2014); Loibl and Rummel (2014a); Roll, Aleven, and Koedinger (2011); Schmidt and Bjork (1992); Schwartz, Chase, Oppezzo, and Chin (2011)).

Although we now have substantial empirical evidence for when PF succeeds (Loibl et al., 2017), we argue it is equally important, if not more, to examine evidence when PF fails and delineate boundary conditions for how, when and why PF works. By success of PF, here we mean experimental comparisons in which PF significantly outperforms alternative instructional approaches (usually instruction followed by problem-solving (I-PS), but also scaffolded problem-solving followed by instruction (+PS-I), or a different preparatory activity followed by instruction (!PS-I)[1]). By failure of PF, here we mean experimental comparisons between PF and I-PS, PF and +PS-I, PF and !PS-I, where I-PS, +PS-I, !PS-I conditions significantly outperform PF on measures of either conceptual understanding or transfer.

At the same time, we also examine experimental comparisons with null results, that is, when there was no significant difference between PF and these three alternate experimental conditions. Although attribution of null effects to causal factors is not always straightforward, examining null effects may nevertheless shed light on the critical factors that confluence efficacy of PF. Bridging the gap between instructional decision-making and the science of learning from failure necessitates prescribing conditions under which positive or negative failure effects emerge and how to foster them.

Search Criteria

Our search process and the criteria for including and excluding comparisons for this analysis included articles in the Google Scholar databases that (i) cited either of the two seminal PF articles (Kapur, 2008; Kapur & Bielaczyc, 2012), and those that cited other key follow-up PF articles (Kapur, 2014, 2015, 2016), and (ii) reported experimental or quasi-experimental comparison between PF and I-PS, or between PF and +PS-I, or between PF and !PS-I; and (iii) assessed conceptual knowledge and/or transfer. Criteria i resulted in close to 700 articles as of 29th June 2018. Of these, 44 articles met criteria ii and iii. These 44 articles reported 57 studies and comprised 95 experimental comparisons[2]. Table 1 presents a breakdown of their demographic characteristics, with majority of the studies spanning Europe, North America and Asia, and covering mathematics concepts for 6th-10th graders. We also see evidence for PS-I work gradually expanding to different student populations at the post-graduate and professional levels within other STEM domains like physics, chemistry, biology, as well as within non-STEM domains like psychology and medicine.

Using a two-phase workflow, we now report key findings synthesized from these experimental comparisons. The first phase comprised a fidelity check for examining conformity of

Table 1: Demographic characteristics of articles included in the review (Number of comparisons = 95)

	Variable of Interest	# of Comparisons (%)
1. Geographical distribution	Europe (Germany, Switzerland, UK)	30 (31.6%)
	North America (USA, Canada)	31 (32.6%)
	Asia (Singapore, Taiwan, India, Hong Kong, Saudi Arabia)	27 (28.4%)
	Australia	7 (7.4%)
2. Learner grade	6th - 10th graders	59 (62.1%)
	2nd - 5th graders	17 (17.9%)
	Undergraduates	16 (16.9%)
	Others (Postgraduates, Professionals)	3 (3.1%)
3. Targeted concept	Math (equivalence, geometry, fractions, variance, linear functions, central tendencies, least squares fitting, weighted averages, z-scores, statistics process control)	63 (66.3%)
	Physics (average speed, density, collision, electricity, mechanics)	16 (17%)
	Medical (dental hygiene, dental surgery)	4 (4.2%)
	Chemistry (solutions, atomic structure)	3 (3.1%)
	Psychology (memory)	2 (2.1%)
	Domain general skill (control of variables strategy)	2 (2.1%)
	Biology (genetics)	2 (2.1%)

PS-I implementations to PF design criteria (for detailed criteria definition, refer Kapur and Bielaczyc (2012)). A detailed breakdown of these PF fidelity check criteria for the current analyses is shown in table 2. Looking vertically across the table (from comparisons with positive results for PF to those with null and negative results for PF), the decrease in fidelity along many of the PF design criteria is striking. This suggests that our evidence base comprises a mixture of the original PF design as well as its low-fidelity versions. In the second phase, we explored additional reasons that could not be convincingly explained by fidelity check parameters alone. The rest of the article focuses on 44 of these 73 comparisons, 54.6% of which had significant negative ($p<0.05$) or null results ($p>0.05$) with I-PS as the comparison condition, 25% of which had negative or null results with +PS-I as the comparison condition, and remaining 20.4% of which had negative or null results with !PS-I as the comparison condition.

Negative Results for PF (compared to I-PS)

PF fidelity check revealed that most of the 7 experimental comparisons in this cluster (Loehr, Fyfe, & Rittle-Johnson, 2014; D. A. DeCaro, DeCaro, & Rittle-Johnson, 2015; Schalk, Schumacher, Barth, & Stern, 2017; Marei, Donkers, Al-Eraky, & van Merrienboer, 2017) considered affective draw of the problem (5/7), and provided evidence for multiple RSM generation during the initial problem-solving phase (5/7). However, what is striking is that in none of the comparisons did follow-up instruction build on failed or suboptimal learner generated solutions, or include group work as the participation structure. Since such consolidation and knowledge assembly is often a key component of PF (Kapur & Bielaczyc, 2012), we would not necessarily expect these low fidelity PF implementations to be better than I-PS comparison conditions. Other salient factors influencing results from these comparisons are described below.

First, learners with high performance orientation, who primarily seek to demonstrate ability, may view challenging task situations as a threat to this goal and withdraw their effort. Such learners are less likely than those with a learning-goal orientation disposition to focus on viewing failures as opportunities to learn, processing negative feedback as ways to improve performance, and experiencing positive emotions following failure (Dweck, 1992; Tulis & Ainley, 2011). Thus, there is no reason to believe that challenging exploratory problem-solving phase of PF might benefit them more so than an instruction-first approach (D. A. DeCaro et al., 2015).

Second, the presence of additional problem-solving practice following the PS-I routine allows learners to use the taught information immediately and integrate it with prior knowledge. Thus, PF can be expected to fail when the overall learning design lacks this practice activity, or, when the overall learning design includes this activity, but such an activity invokes application of procedural knowledge to solve problems and correct errors to a greater extent, rather than influencing processing and development of conceptual knowledge. Empirical evidence suggests that these negative effects were mitigated to some extent in a follow-up study (although not fully) when learners self-checked initial solutions immediately after instruction (Loehr et al., 2014).

Third, implementation-level details of preparatory problem-solving activities are important. PF can be expected to fail when the problem-solving phase comprises too loosely anchored instruction (e.g., an idealized contrasting case that represents a principle in an abstract and generic fashion, followed by self-explanation prompts). PF can, however also fail with relatively more anchored instruction (e.g., a grounded contrasting case that situates a principle in a specific context but also potentially contains (irr)relevant details, followed by self-explanation prompts).

In Schalk et al. (2017) for instance, idealized contrasting cases were operationalized by providing no labels for the axes of coordinate systems when introducing the concept of linear slopes in mathematics, while grounded cases had axes labeled with meaningful concepts (e.g., filling level in a rain barrel on the y-axis, and time in hours on the x-axis). Schalk et al. (2017) conjecture that although self-explanation prompts can help learners to abstract from the context provided in the grounded cases (Chi, De Leeuw, Chiu, & LaVancher, 1994), contextual details from the learning materials are likely to be preserved in the encoded knowledge representation (De Bock, Deprez, Van Dooren, Roelens, & Verschaffel, 2011). This can hamper transfer.

The detrimental effect of grounded cases might exist even if self-explanation prompts in the problem-solving phase are

Table 2: PF fidelity check criteria for the PS-I design, with 60 I-PS and 13 +PS-I and 22 !PS-I experimental comparisons. Results separated by positive, null and negative effects for PF. Table values show number (percentage) of comparisons. We describe an analyses of experimental comparisons with null and negative effects for PF in this paper.

Comparison condition	Effects for PF	Problems affording multiple RSMs	Evidence for multiple RSM generation	Affective draw of the problem	Group work as the participation structure	Building on learner solutions in Instruction
1. I-PS	Positive	36 (100%)	29 (80.5%)	32 (88.9%)	25 (69.4%)	23 (63.8%)
	Null	17 (100%)	8 (47%)	13 (76.4%)	9 (52.9%)	6 (35.3%)
	Negative	7 (100%)	5 (71.4%)	5 (71.4%)	0 (0%)	0 (0%)
2. +PS-I	Positive	2 (100%)	2 (100%)	2 (100%)	2 (100%)	2 (100%)
	Null	7 (100%)	7 (100%)	7 (100%)	3 (42.8%)	1 (14.2%)
	Negative	4 (100%)	2 (50%)	4 (100%)	2 (50%)	2 (50%)
3. !PS-I	Positive	11 (100%)	6 (54.5%)	11 (100%)	5 (45.4%)	4 (36.3%)
	Null	5 (71.4%)	2 (28.5%)	5 (71.4%)	2 (28.5%)	2 (28.5%)
	Negative	4 (100%)	3 (75%)	4 (100%)	1 (25%)	2 (50%)

replaced by explicit invention prompts. From an instructivist point of view, the need to come up with unifying functional relations already makes the invention prompt inherently challenging. Addition of grounded cases can further overburden learners with unnecessary details. Experiencing increased extraneous load can negatively affect invention quality and subsequently transfer, placing learners in the PF condition at a disadvantage. More work is needed, however to understand relative efficacy of concrete or abstract preparatory activities.

Null Results for PF (compared to I-PS)

PF fidelity check revealed that most of the 17 experimental comparisons in this cluster (Schwartz & Martin, 2004; Belenky & Nokes-Malach, 2012; Matlen & Klahr, 2013; Loehr et al., 2014; Loibl & Rummel, 2014b; Fyfe, DeCaro, & Rittle-Johnson, 2014; D. A. DeCaro et al., 2015; Hsu, Kalyuga, & Sweller, 2015; Mazziotti, Loibl, & Rummel, 2015; Chase & Klahr, 2017; Tam, 2017; Marei et al., 2017; Newman & DeCaro, 2018) considered affective draw of the problem (13/17), about half of them provided evidence for multiple RSM generation during the initial problem-solving phase (8/17), while about one third of the comparisons included follow-up instruction building on learner generated solutions (6/17). This suggests moderate conformity to the PF design criteria, and calls for a nuanced understanding of the results.

While young learners (e.g., 2nd - 5th graders) may have insufficient prior knowledge about cognitive and metacognitive learning strategies to generate RSMs on their own (Mazziotti et al., 2015), adult learners with very high incoming mastery-approach orientation are likely to transfer regardless of the type of instruction. This is because the inventing activity in and of itself provides motivational impetus to learn the targeted concepts (Belenky & Nokes-Malach, 2012). These null results suggest that learners with such incoming cognitive or motivational profiles may not necessarily benefit from PF.

The nature of problem-solving task is an important factor as well. Tasks with high element interactivity (Sweller, 1988) have high expected error rate. As Loibl and Leuders (2018) suggest, revision of mental models following instruction for such tasks is contingent on whether or not learners spontaneously elaborate on erroneous solutions generated during initial problem-solving. As long as learners are prompted to explicitly compare and contrast their suboptimal solutions with the canonical solutions, they are likely to integrate negative knowledge in their repertoire of future problem-solving strategies. Consequently, there is no reason to suppose that such learners will benefit from problem-solving first (Hsu et al., 2015; Loibl & Leuders, 2018). While the sole impact of solution generation on the efficacy of PF is not yet clear, what is clearer is that the form of instruction matters (Loibl & Rummel, 2014b). Without instruction that compares and contrasts learner solutions with a canonical solution, PF can be expected to fail. Further, impact of the ordering of such instruction (before or after problem-solving) is less clear.

PF can also be expected to fail when the task provides no explicit feedback regarding what problem-solving actions are actually failures. Consequently, learners might not be in a position to use their awareness of knowledge gaps to consolidate information during the instruction phase (Matlen & Klahr, 2013). Finally, as Chase and Klahr (2017) suggest, when learning domain-general skills, the problem-solving phase in and of itself is less likely to provide implicit feedback about what goals to adopt during the inquiry process (that strongly impacts learning). For instance, learner's goals in pursuing inquiry might be scientific (finding out whether a variable impacts an outcome) or engineering-oriented (guarantying some desired outcome). In such situations, aligning learner's goals to a scientific one takes precedence over the relative ordering of the instruction phase in which this might happen.

Shifting focus to learner solutions, a key recurring factor for failure of PF is lack of evidence for learning to learn, i.e., spontaneous internalization of skills needed for application of domain-knowledge in novel situations. Gaining knowledge of how to perform a correct procedure after the consolidation phase of PF does not necessarily mean gaining high depth of understanding of the domain principle (Vollmeyer, Burns, & Holyoak, 1996; Schwartz, Chase, & Bransford, 2012; Soderstrom & Bjork, 2015). Self-regulated reasoning strategies (e.g., solution evaluation, unprompted self-explanation) require sufficient practice opportunities to get internalized (Schwartz & Martin, 2004; Tam, 2017). Finally, with respect to the overall learning design, PF is expected to fail or produce comparable effects to an I-PS design when the pretest targets concepts similar to the invention activity. Engaging learners in important exploratory learning processes such as prior knowledge activation, attention to knowledge gaps etc create redundancy with initial problem-solving phase of the PS-I setting, thus diluting effects (Newman & DeCaro, 2018).

Negative/Null Results for PF (compared to +PS-I)

PF fidelity check revealed that all the 11 experimental comparisons in this cluster (Kapur & Bielczyc, 2011; Holmes, Day, Park, Bonn, & Roll, 2014; Kim, Pathak, Jacobson, Zhang, & Gobert, 2015; Roelle & Berthold, 2016; Kuo & Wieman, 2016; Loibl & Leuders, 2018) considered affective draw of the problem, most of them provided evidence for multiple RSM generation during the initial problem-solving phase (9/11). However, about half of the comparisons used group work as the participation structure (5/11), and even fewer included follow-up instruction building on learner generated solutions (3/11). This suggests moderate conformity to the PF design criteria.

Evidence suggests that the extent to which activated prior knowledge is conceptually related to the targeted learning concept affects whether the failure resulting from it is productive. This can impact whether and when PF outperforms a scaffolded PS-I condition. If learners are scaffolded to detect high number of relevant similarities and differences in the contrasting cases during an initial problem-solving phase, this can lead them to focused elaboration/explanation regarding deep features of the problem after the instruction phase, resulting in improved conceptual understanding (Roelle & Berthold, 2016). Goal specificity research also suggests that the benefits of preparatory activities with low to medium goal specificity (as in the PS-I design) are contingent on affording opportunities for relevant prior knowledge activation, e.g., by guiding learners towards strategies that facilitate reasoning with the deep problem structure (Vollmeyer et al., 1996), or, by illustrating desirable sub-goals along a solution path that requires learners to focus on relevant task relationships (Miller, Lehman, & Koedinger, 1999). We describe such forms of scaffolded problem-solving in more detail below.

In the study by (Vollmeyer et al., 1996) for instance, explicit instruction in a systematic strategy (varying a single factor while holding other factors constant at zero) during the initial exploratory task fostered acquisition of the casual structure of a biological system. This was based on the premise that despite the presence of a nonspecific goal during the exploratory task, learners might not spontaneously make full use of effective rule-induction strategies. In the study by (Miller et al., 1999) where learners had to work in an exploratory micro-world to understand interactions of electrically charged particles, specializing the learning goal assisted learners in activating relevant prior knowledge. Illustrating a particular path and asking learners to arrange charged particles so that the moving charges would follow the illustrated path as closely as possible achieved this.

Richland and Simms (2015), more generally, have documented the importance of scaffolding exploratory problem-solving through a series of studies on induction within (non-) STEM domains. They emphasize explicit support in noticing the relevance of relational thinking, providing adequate processing resources to mentally hold and manipulate relations, and facilitating recognition of both similarities and differences when drawing analogies between systems of relationships. This is because learners may not spontaneously search for a common deep structure across problem instances.

Similar findings have been echoed in prior PS-I work (Schwartz et al., 2011; Kapur, 2015), which suggest that the benefits of prior knowledge activation such as noticing inconsistencies across multiple problem instances, encoding critical features from instruction etc are contingent on relevance of the activation. For instance, in an invention with contrasting cases study on the topic of density (Schwartz et al., 2011), students who recalled the deep structure of ratio from their invention activity were the ones who ultimately benefited from activating their prior knowledge on assessments of transfer. Scaffolding initial problem-solving as part of the PS-I design might then be one means to help learners activate relevant prior knowledge before receiving instruction.

Prior research on the mechanisms of errorful generation suggests that benefits are more likely when learners generate information semantically related to relevant task concepts and/or when subsequent feedback is related to these concepts (Clark, 2016). For e.g., in word-pair generation tasks, generations based on word stems or rhyming are unlikely to produce as much semantic activation, and do not show the beneficial effects of generation. Conceptual processing (guesses) afforded by error generation facilitate richer memory trace through ordered relations between errors and targets (leading to better recall and problem-solving performance), compared to, non-conceptual processing (lexical guesses) that is more likely to create retrieval noise without effortful semantic elaboration on part of the learner (Cyr & Anderson, 2015). Taken together, we can say that in absence of spontaneous task reasoning with relevant induction criteria (that can potentially be scaffolded within a +PS-I design), PF can fail.

However sometimes, even if task reasoning comprises relevant induction criteria, PF can be expected to fail if such task reasoning is then followed explicit instructions to come up with a unifying functional relation (how variables interact to produce a single quantitative result). Finding a very high number of similarities and differences in the contrasting cases (as part of initial task reasoning) can actually hurt posttest performance. Inventing can be expected to decrease learner's willingness to deeply process subsequent instruction because of clinging on to these self-generated suboptimal inventions (Johnson & Seifert, 1994), and valuing self-made products highly (Norton, Mochon, & Ariely, 2012). This can result in failure to recognize deficiency in problem-solving performance. Often, learner inventions fail to consider all factors necessary for developing the canonical solution, but focus only on subsets of these contrasting cases. In +PS-I work by Roelle and Berthold (2016), such detrimental effects increased as a function of the number of detected similarities and differences for which learners had generated inventions.

PF can fail if the delay caused in reaching an appropriate solution makes learners less interested and less self-efficient. As Glogger-Frey, Gaus, and Renkl (2017) found in their

work, this invoked feelings of knowledge insufficiency during preparation and consequently low confidence. With repeated failures, it becomes harder to perceive the value of engaging in good inquiry behaviors during the problem-solving phase because of lowered expectations and increased self-doubt (Ilgen & Hamstra, 1972), acceptance of absence of control (Mikulincer, 2013), susceptibility to demotivation and negative emotions like stress (LePine, LePine, & Jackson, 2004), and increased stability of future failure expectancies (Weiner, 1974). In +PS-I research conducted by Lee (2017) in physics, task failure in the form of circuit explosion (entire electrical circuit goes up in flames and a restart is required) was found to be negatively related to learning outcomes, perhaps because learners were not able to meaningfully grapple with the task complexity and lacked understanding of basic task elements. Prompts for metacognitive reflection did not help learners address these recurring failures.

Further, the temporal distance between the problem-solving and instruction phase matters. PF can be expected to fail if the instruction phase is temporally detached from all the conceptual exploration and reflection, compared to multiple smaller cycles of problem-solving and instruction happening closely together (Kim et al., 2015). The latter offers differentiated and redundant scaffolding opportunities (Tabak, 2004) to address the magnitude/diversity of knowledge assembly that learners need for understanding different conceptual task elements during the consolidation phase. Finally, PF can be expected to perform as well as +PS-I when cognitive support offered in the initial problem-solving phase is focused on principle-based guidance (covering definitions, conditions of applicability, relevant equations etc), as opposed to, being focused on clarifications and hints regarding correct solution steps, accuracy feedback etc. When learners have no or little relevant prior knowledge related to the target learning content, providing principle-based guidance during their initial problem-solving reduces extraneous cognitive load and in turn facilitates attention to critical task concepts.

Negative/Null Results for PF (compared to !PS-I)

PF fidelity check revealed that most of the 11 experimental comparisons in this cluster (Aleven, Koedinger, & Roll, 2009; Roll et al., 2011; Glogger-Frey, Fleischer, Grüny, Kappich, & Renkl, 2015; Kapur, 2015; Likourezos & Kalyuga, 2017; Newman & DeCaro, 2018) considered affective draw of the problem (9/11). However, about only half of these comparisons provided evidence for multiple RSM generation during the initial problem-solving phase (5/11). Further, only one third comparisons included follow-up instruction building on learner generated solutions (4/11) and used group work as the participation structure (3/11). This suggests low conformity to the PF design criteria. Comparison of such low fidelity versions of PF with !PS-I implementations indicates relatively lower extraneous load in !PS-I conditions as a key factor for the pattern of results. The !PS-I conditions usually include worked example followed by instruction, but sometimes also preparatory activities such as evaluating pre-designed solutions, problem-posing, reading/summarizing text etc followed by instruction.

One way to interpret the null results across these comparisons is by considering the relative contribution of different instructional activities and the socio-cognitive processes they trigger. As Kalyuga and Singh (2016) suggest, high(er) extraneous load for the PS-I condition is compensated by increase in intrinsic load (because of the diversity of instructional goals in the problem-solving phase such as prior knowledge activation, deep feature identification etc, as opposed to a solitary goal of solution schema acquisition). Also, PF learners experience motivational effects (acceptance of challenge, resolving conflict etc) that are different from those experienced by learners in a !PS-I condition (belief of success probability etc). Thus, one might conjecture the relative efficacy of PF over !PS-I implementations to depend on the balance between extraneous load and intrinsic load triggered by sequences of instructional tasks (that individually achieve different sub-goals). More research is needed along these lines.

Summary and Conclusion

We articulated factors representative of learner's situatedness relative to their problem-solving experiences to examine boundary conditions for failure of PF. PF (or more generally, PS-I) was compared with three alternate experimental conditions, (i) I-PS (instruction followed by problem-solving), (ii) +PS-I (scaffolded problem-solving followed by instruction), (iii) !PS-I (preparatory activity other than problem-solving followed by instruction). To summarize, our current analyses suggested low design fidelity (weak conformity to PF design criteria) as the starting point for when PF fails. However, deeper exploration into experimental comparisons with negative and null results for PF highlighted four important factors.

First, incoming cognitive and motivational characteristics (e.g., mastery orientation, self-regulation skills, inquiry goals) influence whether learners can be expected to benefit from PF. Second, nature of the problem-solving task (e.g., task difficulty/calibration to prior knowledge, triggered socio-cognitive processes, domain specificity, implicit task feedback) sheds further light into when PF can be expected to fail. Prior knowledge activation is a key cognitive mechanism that explains the beneficial effects of problem-solving based preparatory activities within the learning design of PS-I (Loibl et al., 2017). The boundary conditions explored in this work open up new research opportunities for developing variants of PF, or combining PF with other cognitively activating instructional methods (Hofer, Schumacher, Rubin, & Stern, 2018) for achieving stronger and more sustainable results. Such methods, which focus on learner's naïve concepts and beliefs as the starting point for knowledge construction and reorganization (Schneider & Stern, 2010) can include self-explanations, metacognitive questioning etc.

Third, learner solutions during the problem-solving phase (e.g., usage of relevant induction criteria, evidence for internalization, behavior rigidity) and the extent to which they

are scaffolded impacts learning from PF. Finally, nuances related to the overall PS-I learning design (e.g., redundancy of pretest, anchoring of initial problem-solving tasks, feedback in instruction phase, additional practice activities after instruction) matter for efficacy of PF activities over alternate designs. Although not exhaustive, these factors synthesized from studies around PF (and more broadly the PS-I literature) provide evidence-driven rationale for more careful design/labeling of future implementations. We hope this will spur lines of inquiry (e.g., see Sinha et al. (2019)) that design for balancing the incommensurable goals of learning versus performance (Soderstrom & Bjork, 2015), given the differential relationship of failure to these goals (Kapur, 2016).

Abstract

Effective problem solving requires both *exploration* and *exploitation*. We analyze data from a group problem-solving task to gain insight into how people use information from past experiences and from others to achieve explore-exploit trade-offs in complex environments. The behavior we observe is consistent with the use of simple, reinforcement-based heuristics. Participants increase exploration immediately after experiencing a low payoff, and decrease exploration immediately after experiencing a high or improved payoff. We suggest that whether an outcome is perceived as "high" or "low" is a dynamic function of the outcome information available to participants. The degree to which the distribution of observed information reflects the true range of possible outcomes plays an important role in determining whether or not this heuristic is adaptive in a given environment.

Keywords: exploration; exploitation; networks; social learning

Introduction

Search—a dynamic maximization problem where outcomes depend on the agent's location in the problem space—is a fundamental part of our cognitive experience (Hills et al., 2015). When in a new city, we sample from different restaurants in order to find the best places to eat (Mehlhorn et al., 2015). When coming up with a new idea for a research project, the amount of intellectual and social "reward" we expect to experience is a function of whether the point in conceptual space we're interested in is novel and appreciated by others.

Effective search requires both *exploration*, or sampling from the space of outcomes to gain information about what's available, and *exploitation*, or taking advantage of the information available and resampling from places known to produce good outcomes. Should the traveller stick with the first decent restaurant she finds, or keep exploring her options? Should the scientist stick with her current line of work, or branch out into unchartered intellectual territory?

We analyze data from a group problem-solving task to gain insight into how participants use information from past experiences and from others to achieve explore-exploit trade-offs in rugged, networked environments. When the world is uncertain, complex and interconnected, the optimal trade-off between exploration and exploitation depends on the degree of complexity, on the extent of interconnectedness—and on the strategies individuals adopt to process and act on the information they encounter (Barkoczi, Analytis, & Wu, 2016; Barkoczi & Galesic, 2016; Toyokawa, Whalen, & Laland, 2019). In some cases, we may adapt our exploration level to the environment we're in, even when the shape of the environment is unknown to us (Mason & Watts, 2012).

We add to existing work that has looked at behavioral patterns of exploration in different environments, and examine the mechanisms that lead to the individual- and group-level patterns we observe. Our contributions are both methodological and theoretical. From a methodological perspective, we specify a generalization gradient and propose it as a useful measure of both individual- and group-level exploitation in smooth search spaces. From a theoretical perspective, we document exploration patterns and systematic behavioral responses to outcome information. We find that context-dependent explore-exploit trade-offs emerge even when participants are not told what kind of environment they're in, and speculate that differences in exploration patterns can be explained by differences in the outcome information available to participants.

Methods

Experimental paradigm

We analyzed data from the group search task designed and implemented by Mason, Jones, and Goldstone (2008). Each participant guessed numbers between 0 and 100 and a computer revealed to them how many points were obtained from the guess by consulting a hidden *fitness function*[1] that translates a guess into a number of points. Random noise was added to these points so that repeated sampling was necessary to accurately determine the underlying function relating guesses to scores. On each trial, a group of participants was assigned to one of several conditions (discussed below). Trials consisted of 15 rounds, over which each member of the

[1] We will use the terms "fitness function" and "fitness landscape" interchangeably.

group tried to maximize their total number of earned points. Importantly, on each round, participants got feedback not only on how well their own guess fared, but also had access to information about the actions and outcomes of their neighbors.

Two aspects of the environment were experimentally manipulated: the social network (the network topology that determines who counts as neighbors) and the complexity of the task (the shape of the fitness function that converted guesses to earned points). These are discussed in the sections below.

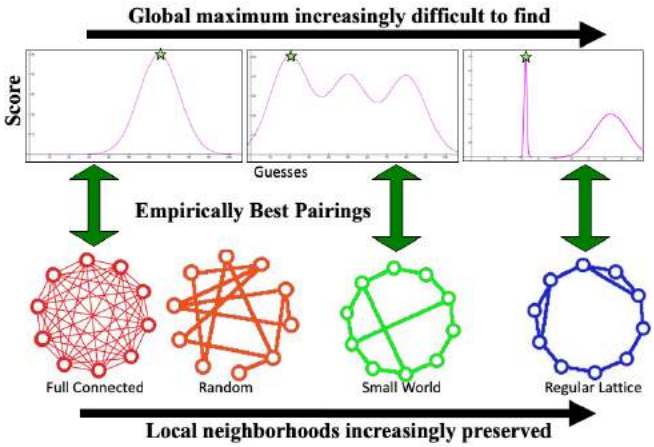

Figure 1: The network structures and fitness functions used in Mason et al. (2008). Reproduced from Goldstone et al. (2013) with permission of the authors.

Social network structure Neighborhoods of participants were created to reflect *random*, *regular lattice*, *small world*, or *fully connected* networks. Examples of the graph topologies for groups of 10 participants are shown in Figure 1. In the random graph, connections are randomly created under the constraint that the resulting graph is connected. Participants in random graphs tend to be connected to others via relatively short paths.

The regular lattice configures a group with an inherent spatial ordering such that people are connected to each other if and only if they are close to one other. The regular lattice also captures the notion of social "cliques": If there is no short path from A to Z, then there will be no direct connection from any of A's neighbors to any of Z's neighbors. The paths connecting people are much longer, on average, in lattice than in random graphs.

"Small world networks" have both cliques and a short average path length (Watts & Strogatz, 1998). From an information processing perspective, small-world networks are attractive because the spatial structure of the networks allows information search to proceed systematically, and the short-cut paths allow the search to proceed quickly (Kleinberg, 2000).

A fourth network, a fully connected graph, allowed every participant to see the guesses and outcomes of every other participant.

	Full	Small world	Random	Lattice	Total
Unimodal	11	11	19	11	**52**
Trimodal	9	12	20	11	**52**
Needle	28	27	18	28	**101**
Total	**48**	**50**	**57**	**50**	**205**

Table 1: Number of trials of each condition in our data.

Environmental complexity Three hidden fitness functions for converting guessed numbers to points were tested across two experiments. The *unimodal* function has a single best solution that can eventually be found with a hill-climbing method. The *trimodal* function increased the difficulty of the search by introducing local maxima. A local maximum is a solution that is better than all of its immediate neighboring solutions, yet is not the best solution possible. Thus, a simple hill-climbing search might not find the best possible solution. Finally, the *needle* function has one very broad local maximum, and one hard-to-find global maximum.[2] The height and variance of the global maximum in the unimodal conditions, global maximum in the trimodal conditions, and local maximum in the needle conditions are all equal (the height of these peaks is 50, while the height of the needle's global maximum is 70).

After excluding some trials due to apparently incomplete data, we used 205 trials in total for our analyses. The number of trials in each conditions is reported in Table 1. The number of players in each trial ranged from 5 to 19, with a mean of 11.89 ($SD = 4.05$).[3]

Measuring exploration

To measure the degree to which a sequence of guesses exploited a location of the search space (or, conversely, didn't explore the space), we developed a similarity metric (hereafter referred to as *similarity*) that captures the average degree of closeness of all pairwise combinations of the elements of a set of guesses along a generalization gradient[4] adapted to the specific problem space:

$$similarity(G_i, G_j) = e^{-(\frac{G_i - G_j}{c})^2}$$

[2]Mason et al. (2008) collected data on variations of the needle function in two separate experiments. In our analyses, when referring to the needle conditions we pooled data from the two experiments.

[3]Each group of participants was assigned to several conditions in sequence (for more details on the experimental procedure, see Mason et al. (2008)). We consider a "trial" to be uniquely specified by a combination of a group and a condition. In other words, if a group completed the task in n conditions, this is recorded in Table 1 as n distinct observations.

[4]A *generalization gradient* is a function that transforms distance in some space to distance in another—usually more psychologically interesting—space.

where $c = .07$ was set to reflect the variance of the global maxima on the unimodal and trimodal landscapes, and the local maxima on the needle landscapes. The total average similarity of a group of guesses G is

$$similarity(G) = \frac{\sum_{i,j} similarity(G_i, G_j) - n}{n^2 - n}$$

where $n = |G|$. We use $1 - similarity(G)$ as our measure of the degree to which G spans—or explores—the problem space.

While other measures, such as variance or the average volatility measure developed by Mason et al. (2008), capture the average distance between guesses, they do not directly capture the idea of the extent to which a set of guesses spans the problem space. Consider a participant A who alternates between guessing 0 and 100, and a participant B who guesses a number at every multiple of 10. We'd like to say that B is the better explorer, because their guesses are spread across the landscape. However, the variance and average volatility of participant A's guesses are much higher than the variance and volatility of B's guesses. By taking the average of *all* pairwise combinations of guesses, our similarity metric captures the *spread* of guesses, rather than simply the extent of their range.

In addition, our metric captures the intuition that similarity drops off steeply with the distance between two nearby solutions, but quickly flattens out (see Figure 2). The choices to jump 99 or 100 units away from where one is are considered effectively identical, while the choices to jump 0 or 1 unit away are much less similar.[5]

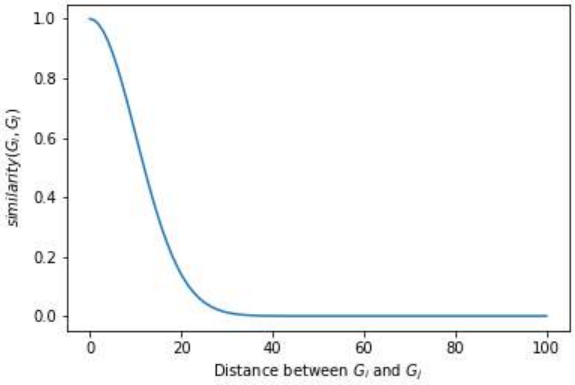

Figure 2: The shape of the generalization gradient underlying the *similarity* metric.

Some evidence suggests that a gradient of this form is a good approximation of how people make inferences about unseen locations in spatial search tasks (Wu, Schulz, Speekenbrink, Nelson, & Meder, 2018). However, here we invoke *similarity* only to operationalize the degree of "exploratoryness" of a set of guesses, not to model participants' inferences.

[5]The Gaussian shape of the fitness functions is compatible with the Gaussian similarity drop-off gradient we used. While this captures many of the same intuitions, it differs from the well-known exponential similarity function (Shepard, 1987). All our results are robust to the use of an exponential similarity function.

Exploration patterns

Individual exploration

Figure 3 shows the heterogeneity in the amount of exploration between participants. Higher density on the right side of the histograms indicates that participants in that condition tended to distribute their guesses more evenly across the problem space.

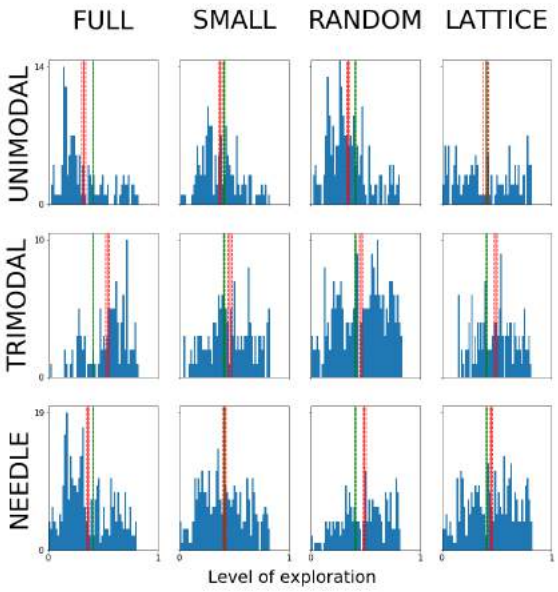

Figure 3: Histogram of participant-level exploration levels. A participant i who makes a sequence of guesses G_i has an exploration level equal to $1 - similarity(G_i)$. The green lines indicate the global mean and standard error of exploration levels across participants in all conditions (.408 (SE = .004)). The red lines indicate the mean and standard error of exploration levels across all participants *within* the respective condition. If a person participated in several conditions, they are treated as a separate participant in each condition.

Individuals tend to explore less than average on the unimodal landscapes, which were explicitly constructed so that their global maxima were easy to find. When the best solution can be found with very little exploration, more extensive search may just lead to foregone payoffs rather than valuable information. We tested this intuition by looking at the correlation between participants' exploration levels and their average payoffs. As expected, this correlation is much lower on the unimodal landscapes than on the more complex landscapes.

Exploration levels tend to be lower than average in one other condition: the fully-connected network on the needle landscape. Mason et al. (2008) found that when confronted with the difficulty of the needle landscape, participants tended to do better when in the sparsely-connected lattice network (see Figure 1). They speculated that this was because distributing social information hindered bandwagoning, or collective convergence on the tempting local maximum. Our results corroborate this speculation: While participants in the fully-connected networks explore the needle landscape less than average, the mean exploration level in the lattice networks is higher than the global average.

Collective exploration

The similarity metric allows us to calculate the "exploratoryness" of an arbitrary sequence of guesses. In particular, we can also use it to measure *group-level*, or collective, exploration.

Figure 4 shows the evolution of collective exploration over rounds, alongside the proportion of participants who were within one standard deviation of the global maximum on each round. Collective exploration declines quickly on the unimodal and needle landscapes. While this coincides with more participants finding the global maximum on the unimodal landscape, the proportion of participants who find the global maximum in the needle condition remains relatively low. These patterns reflect dynamics analogous to the individual-level patterns we discussed in the previous section: The group explores less when there is a salient local maximum, and especially so when outcome information is rapidly broadcast throughout the network.

The consequences of early exploration

Our explanations for many of the results in the previous sections depend on our assumption that exploration is more important in some cases than in others. In some environments, low exploration may cause high payoffs; quick convergence on promising areas of the landscape may cause the average payoff to rise. In others, maintaining a high amount of exploration and broadly surveying the problem space could lead to subsequently higher payoffs. This section further unpacks the sequentially contingent relationship between exploration and expected reward in the different conditions.

Figure 5 plots the cross-correlations between average payoffs and the collective exploration level within a round. It's unsurprising that all the correlations are below zero; as shown Figure 4, collective exploration subsides while payoffs increase over time. More informative for our purposes is the *difference* between the correlation of early exploration with later payoffs, and the correlation of early payoffs with later exploration. An interpretation that exploration causes higher downstream payoffs would require that the former be higher than the latter. The insets of the plots shows this difference for each condition. When the blue line is above zero, this indicates that exploration now is more highly correlated with payoffs later, than payoffs now are with exploration later.

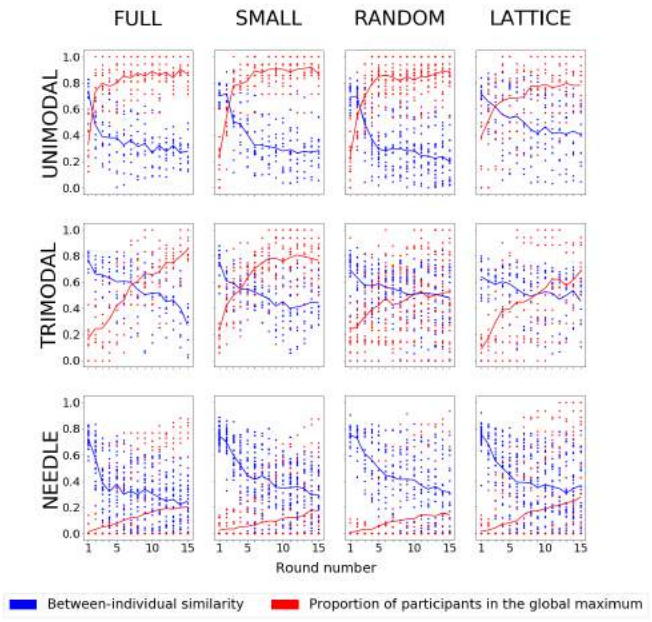

Figure 4: Collective exploration levels (blue) and proportion of players within one standard deviation of the global maximum (red) over rounds. Each dot represents one trial. On round t, group k has an exploration level equal to $1 - similarity(G_{k,t})$ where $G_{k,t}$ is the set of all guesses the members of group k made on that round. The blue line plots the mean exploration level across trials, and the red line plots the proportion of all players across trials who were within one standard deviation of the fitness function's global maximum.

The positive trend in the inset is most consistent across the needle and regular lattice conditions. When connectivity is low and finding the global maximum is especially difficult, group-level exploration leads to higher downstream payoffs. While this pattern is also consistent with an account that higher payoffs cause quicker collective convergence, the "exploration leads to downstream payoffs" account has the advantage that it predicts the particularly strong positive trend for the needle landscape, which is explicitly designed so that the global maximum is hard to find without considerable exploration.

WSLS: Win-shift-less, lose-shift-more

Win-stay, lose-shift (WSLS) is a heuristic applicable to search tasks by adaptive biological and artificial systems. The rule is simple: When you're successful, stay close to where you currently are. When you're unsuccessful, move further away (Bonawitz, Denison, Gopnik, & Griffiths, 2014; Nowak & Sigmund, 1993; Robbins, 1952).

WSLS is usually applied in contexts with discrete binary outcomes that can be easily dichotomized into wins and losses. However, the problem space facing the currently considered participants, like many real-world problem spaces, is both smooth—similarity of actions predicts similarity of

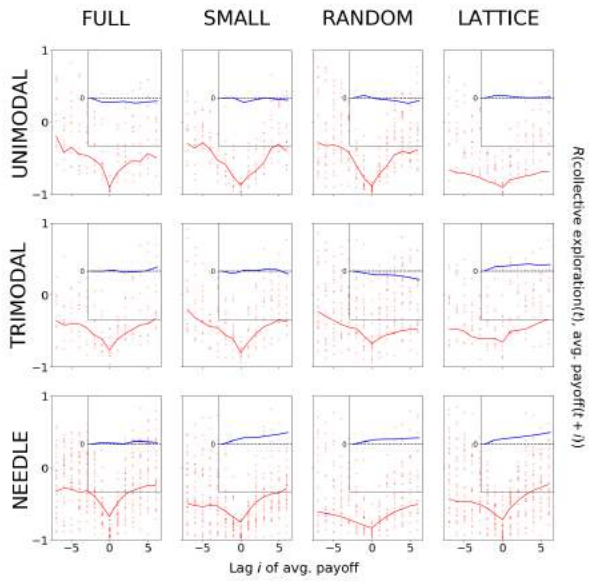

Figure 5: Cross-correlations between group exploration level and payoffs. On round t, group k has an exploration level equal to $1 - similarity(G_{k,t})$ where $G_{k,t}$ is the set of all guesses the members of group k made on that round. Payoff observations are the average payoff participants experienced on round t. A lag of i on the x-axis indicates the correlation between group exploration level at time t and average payoffs at time $t+i$. Each dot corresponds to the correlation using the data from one trial. The red lines plot the correlations across trials. Insets show the difference between the cross-correlation coefficients at lag i and lag $-i$ for $0 \leq i \leq 7$.

outcomes—and continuous. In this section, we show that participant behavior is consistent with a generalization of WSLS: The degree to which participants stray from promising locations varies with both the absolute and relative amount of reward they've experienced there. Participants shift less when they win, and shift more when they lose.

In many situations, WSLS or close variants can lead to approximately optimal search behavior on intractable problem spaces (Bonawitz et al., 2014; Robbins, 1952). To the participants facing the task at hand, the range of possible outcomes is unknown. We suggest that they dynamically incorporate outcome information into their understanding of what's a "win" and what's a "loss". When good outcomes are easy to find, the outcome information participants accumulate accurately reflects the range of attainable payoffs. In these cases, the application of WSLS-like rules may lead to adaptive explore-exploit trade-offs. But when the best outcomes are difficult to find, participants do not get full outcome information about the range of possible payoffs. They fail to appropriately calibrate their "shift-more" and "shift-less" responses. On the needle landscape, WSLS-like rules may lead participants to prematurely converge on the local maximum. In short, when good outcomes are hard to find, information flow is reduced, and individuals cannot appropriately tune their behavior to the relevant search space, resulting in suboptimal individual- and group-level outcomes.

Absolute "wins": Responses to high payoffs

Figure 6 shows how the similarities between participants' preceding guesses (blue) and subsequent guesses (red) covary with the payoffs they experience. Recall that the similarity of two guesses is a measure of the closeness of the guesses. If a participant's guesses on round t and round $t+1$ are more similar than their guesses on round t and round $t-1$, we say they are *exploiting* more on round $t+1$ than on round t.

In all conditions, there is some payoff value above which participants tend to exploit more than explore. The blue vertical lines mark the normalized payoff values where the trend in participants' future level of convergence dips below their past level of convergence—participants begin to shift more (explore). The red vertical lines indicate payoff values where the reverse switch occurs—participants begin to shift less (exploit). In general, participants shift more when payoffs are low, and shift less when payoffs are high.

Where this switch occurs varies by landscape. We speculate that these differences are a direct effect of differences in the outcome information available to participants, and how they adjust their beliefs about the range of possible payoffs based on their observations (Parducci, 1965). In the trimodal conditions, the "switch point" is shifted to the right (participants wait for relatively high payoffs before they begin to settle down), but so is the density of payoff observations. As shown in Figure 1, payoffs on the trimodal landscape remain relatively high even when participants stray from the global maximum. When they observe that locations that lead to "wins" are distributed widely across the landscape, participants are more reluctant to settle down.

By contrast, in the needle conditions, both the switch point and the bulk of the density is shifted towards the left side of the plot. Few participants stumble upon the narrow global maximum, and most experienced payoffs are a smaller proportion of the highest possible payoff. The emergent patterns resemble those in the unimodal conditions because most participants do not have outcome information to suggest that they *are not* on a well-behaved landscape with a similar payoff distribution.

Relative "wins": Responses to improving payoffs

Figure 7 shows how the similarity of participants' guesses changes as a function of the difference between their most recently experienced payoffs. Points to the right of the y-axis correspond to instances where a player had just experienced an immediate increase in payoff. Points above the x-axis correspond to instances where the player's round-to-round exploration level decreased. In general, immediate gains lead to convergence, and losses lead to continued exploration.

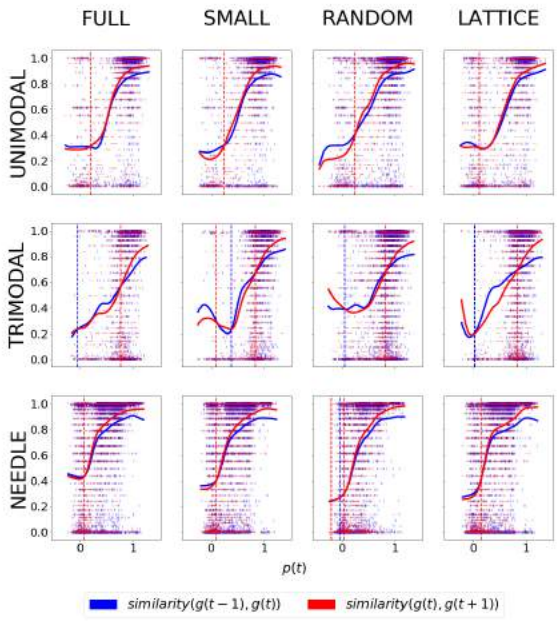

Figure 6: Experienced payoffs against similarity of guesses. $p(t)$ denotes the payoff a player experienced at time t (normalized by the height of the global maximum in each condition), and $similarity(g(t), g(t'))$ denotes the similarity between a guess made at time t and a guess made at time t'. Each dash corresponds to one experienced outcome. Solid lines show the estimated Gaussian kernel regressions. Vertical lines mark shifts between exploitation and exploration (see text).

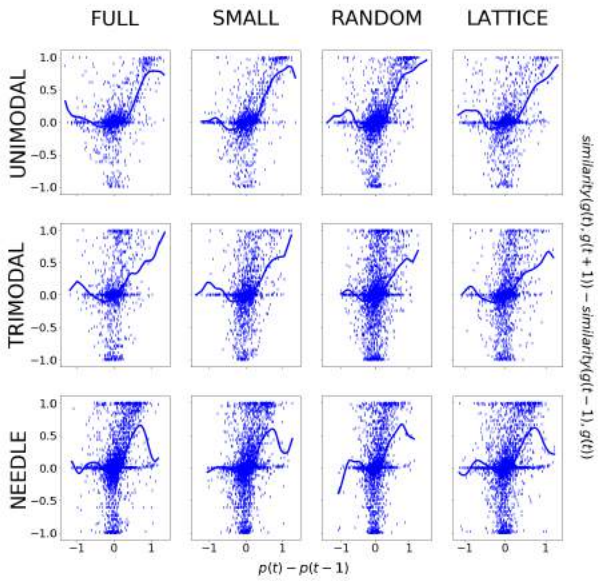

Figure 7: *Differences in* experienced payoffs against *differences in* similarity of guesses. Notation is the same as in Figure 6. Each dash corresponds to one experienced outcome. Solid lines show the estimated Gaussian kernel regressions.

Note the inverted U-shaped trend recovered by the kernel regression across the needle landscapes. Participants who have just experienced an exceptionally large improvement tend to shift more than those who have just experienced a moderate improvement. This is consistent with our understanding of WSLS as a dynamic process: Participants who stumble upon the global maximum dynamically adjust their understanding of the range of possible payoffs, and are less willing than before to settle with what they have.

Discussion

We argued that the behavioral patterns we observe are consistent with the application of a dynamic, continuous variant of win-stay, lose-shift. While participants tend to "stay" in areas where they've experienced both high and improving payoffs, they use information from themselves and others to adapt their willingness to "stay" and "shift" to their environment.

One phenomenon we have only briefly addressed is Mason et al. (2008)'s finding that participants in the lattice network were more likely than participants on other networks to find the needle landscapes' global maxima. Our central claim is that reduced information flow can lead to suboptimal outcomes when participants do not have full information about the range of possible payoff values. Why would the network that restricted information flow the most perform the best when the search task is especially hard?

Visual inspection of Figure 6 suggests that the payoff values at which participants switch from exploration to exploitation do not vary much as a function of the network structure, but depend more on the underlying fitness function. The lattice network's structural restriction of information flow could mean that it takes participants even longer to reach their threshold value or "switch point". Participants may search longer for "wins", resulting in more exploration where it matters the most.

While our analyses were motivated by our desire to understand the relationship between individual- and group-level exploration dynamics, we did not assume that participants make this trade-off explicitly. Rather, we suggested that participants may be using simple heuristics from which an apparent trade-off emerges. We adopted an information processing framework (Oppenheimer & Kelso, 2015): The environment affects behavior and outcomes via its effect on the information group members receive and broadcast to others. By analyzing participant behavior through the lens of *information flow*, we can come closer to understanding what determines the search conditions under which we do well, and the conditions under which we could do much better.

Abstract

Previous research on adjective ordering in linguistics and psychology has focused primarily on the unmarked or default order of adjectives, as in *large blue car*. Inverted word order, as in *blue large car*, which violates the proposed semantic constraints on adjective placement, received relatively little attention. In two studies we show that the inverted order is not as limited in scope as previous researchers have argued. We propose that the inverted word order reflects the *subjective distance* principle: the attribute that is psychologically closer to the speaker is mentioned first. Our explanation draws on research on word order in binomials, thus connecting two previously unrelated research traditions on word order in linguistics and cognitive psychology.

Keywords: adjective ordering; binomials; context-dependency; semantics; pragmatics; subjective distance

Introduction

Why does *Itsy bitsy teeny weeny yellow polka dot bikini* sound so good to the ear? One possible factor is the choice of adjectives and their artful arrangement. What factors determine the 'right' order of adjectival modifiers in a phrase has been a topic of active inquiry in linguistics and psychology (Cinque, 2014; Danks & Glucksberg, 1971; Kotowski & Härtl, 2019; Martin, 1969; Scontras, Degen, & Goodman, 2017; Truswell, 2009; Wulff, 2003). According to the semantic approach, the order of adjectival modifiers is dependent on their semantic class, such as e.g. Color and Size. The underlying assumption is that semantic classes form a scale with respect to some psychological property, such as subjectivity. If class Size precedes class Color on the subjectivity scale, we expect that adjectives denoting size (e.g., *teeny weeny*) will precede adjectives denoting color (e.g., *yellow*)(cf. Dixon, 1982; Hetzron, 1978; Whorf, 1945).

Most of the research in the semantic tradition aims to explain the unmarked or default adjective order, as in *large blue car*. While many authors acknowledge that in some communicative situations the default, semantically determined word order can be overridden, the mechanisms that give rise to the inverted word order, as in *blue large car*, have received relatively little attention in the literature. One exception is a series of studies by Danks and co-authors in the early 70s (Danks & Glucksberg, 1971; Danks & Schwenk, 1972). These authors advocate a pragmatic approach and propose that the order of adjectives depends on how well they differentiate among salient contextual alternatives: the most discriminative adjective is mentioned first. For example, in a context in which two large cars, one red and one blue, are equally salient, color would be more discriminative than size, and would give rise to the inverted word order: *blue large car*. In this approach the communicative goals of conversation participants rather than semantic classes of adjectives and their properties determine adjective ordering.

One of the limitations of the pragmatic approach proposed by Danks and co-authors is that it only applies to cases in which the set of potential discourse referents and their attributes (the two cars in the example above) have already been established. Our two experimental studies demonstrate that the inverted adjective ordering is also attested in contexts without previously established referents. Such cases cannot be explained by reference to discriminative attributes, because there are no alternatives that need to be differentiated. Our explanation of the inverted word order in such contexts is based on research on flexible word order in binomials, i.e. constructions with two conjoined nouns or adjectives, as in *Democrats and Republicans* (Iliev & Smirnova, 2016; see also Cooper & Ross, 1975). Specifically, we propose that the inverted adjective order reflects the same psychological principle that was proposed to explain word order in binomials – the *subjective distance principle*. According to this principle, the attribute that is psychologically closer to the speaker is mentioned first. Our paper offers a principled explanation for inverted word order and uncovers parallels between two previously unrelated domains of research: word order in binomials and word order in adjectival modifiers.

Two Approaches to Adjective Ordering

The Semantic Approach

According to the semantic approach, the meaning of adjectives is responsible for the observed word order (Martin, 1969; Scontras et al., 2017). Several semantic features have been proposed in the literature as determinants of adjective ordering, including definiteness of denotation, inherentness (also referred to as intrinsicalness, substantiveness, and closeness to the noun in meaning), and subjectivity.[1] An adjective's definiteness of denotation is determined both by the number of nouns it can modify and by the number of senses an adjective may have in different contexts (Martin, 1969; Wulff, 2003). Adjectives which are relatively limited in the number of nouns they may modify, and whose denotations remain constant across varying contexts, are said to be more definite, and are positioned nearer to the noun (Martin, 1969). Thus, *old embroidered pillow* sounds more natural than *embroidered old pillow*, because the more definite adjective, *embroidered*, is positioned closer to the noun.

In one of the first psychological studies on adjective ordering, Martin (1969) contrasted different semantic features of adjectives and found that definiteness of denotation is the most reliable predictor of an adjective's position in a phrase (cf. Wulff, 2003). Martin proposed that the definiteness of denotation is directly related to an adjective's accessibility, which in turn determines the placement of adjectives. Definite adjectives are accessed faster than indefinite ones, because their meaning does not vary depending on the noun they modify. Therefore, less time is needed to scan the meaning of the definite adjective and to establish the relation between the property denoted by this adjective and the meaning of the modified noun. In this approach, the adjectives that are accessed faster – definite adjectives – appear closer to the noun. In production, the adjectives that were accessed first come last in a sequence of adjectives.

An adjective's inherentness is defined as the extent to which its intrinsic, essential properties reflect the properties of the noun it modifies. Adjectives denoting color, material, breed, nationality, and function are considered to be more inherent than adjectives denoting size, shape or similarly non-intrinsic qualities (Martin, 1969). More inherent adjectives are positioned closer to the noun. The scale in (1) ranks different semantic classes in terms of their inherentness.

(1) Personal judgment < Size < Color < Place of origin **Noun**

less inherent ⟷ more inherent

[1] Other possible determinants of adjective ordering are morphological weight, as well as various semantic considerations, including whether the adjectives refer to temporary or permanent properties, whether adjectives are subsective or intersective (Truswell, 2009), etc. See Scontras et al. (2017) and Kotowski and Härtl (2019) for evaluation of these models' predictions.

According to the scale in (1), based on the adjective classification in Danks and Glucksberg (1971), adjectives denoting size will be placed before adjectives denoting color, because the latter are more inherent and should be positioned closer to the nominal head (Noun).

Besides definiteness of denotation and inherentness, which dominated research on adjectives in the 60s and 70s, another semantic feature – subjectivity – came to the attention of psychologists and linguists (Hetzron, 1978; Quirk et al., 1985; Scontras et al., 2017). According to Quirk et al. (1985: 1341), there is "one principle accounting for all premodifiers: a subjective / objective polarity. That is, modifiers relating to properties which are […] visually observable, and objectively recognizable or assessible, will tend to be placed nearer to the head and be preceded by modifiers concerned with what is relatively a matter of opinion, imposed on the head by the observer, not visually observed, and only subjectively assessible."

Scontras et al. (2017) conducted the first experimental studies probing the effect of subjectivity on adjective ordering. The authors first measured ordering preference by eliciting naturalness ratings for adjective-adjective-noun sequences. Experimental participants were asked to indicate which ordering sounded more natural, e.g. *big blue box* or *blue big box*. Once ordering preferences were established, the authors tested adjective subjectivity by asking participants to indicate the subjectivity of the same adjectives on a sliding scale, ranging from "complete subjectivity" to "complete objectivity". Results indicated that adjective subjectivity indeed predicts ordering preference, where the higher an adjective's subjectivity is, the farther it is placed from the noun it modifies. The authors concluded that subjectivity alone was more reliably predictive of adjective ordering than other semantic features, including the adjectives' inherentness.

A common feature of all semantic accounts is that they are designed to explain the unmarked / default adjective ordering. While most authors working in this tradition acknowledge that the unmarked order can be violated, little is known about the mechanisms that regulate the ordering of adjectives in such cases. The exception is a series of work by Danks and colleagues, to which we turn next.

The Pragmatic Approach

According to the pragmatic approach, communicative goals of conversation participants affect how adjectives are positioned in a noun phrase (Danks & Glucksberg, 1971; Danks & Schwenk, 1972). Specifically, more discriminative or informative adjectives tend to be mentioned first. In different communicative contexts, different features will be more informative, which explains variation in adjective ordering. In the experimental paradigm employed by Danks and co-authors, participants were presented with a set of objects, and were asked to choose the description of the target object (or referent) that would help the listener to distinguish it from non-referents. For example, if the set of objects consists of two cars, which have the same size,

large, but differ in color, one is blue and another one is red, the color is the most informative feature, and is predicted to be mentioned first. Thus, if the target object in question is the blue car, the participants are expected to describe it as *the blue large car*, mentioning the color attribute first, and violating the default word order (e.g., *the large blue car*), where size precedes color, as predicted by (1). The results of experimental studies confirmed this prediction in both comprehension and production tasks. Danks and Schwenk (1972) found that when color is the discriminative feature, it is mentioned first in 57 % of the cases. In the control condition, the normal word order, i.e. size before color, was preferred in 85% of cases.

Danks and co-authors argue that the pragmatic rule is more general and that the semantic rule based on inherentness, which explains the default adjective ordering, is in fact "the most *frequent* case of the more general pragmatic rule" (Danks & Glucksberg, 1971). That is, since more intrinsic adjectives tend to be less informative, they are less likely to discriminate between referents and non-referents, and, therefore, are less likely to appear first in a sequence of adjectives.

The pragmatic approach proposed by Danks and co-authors was criticized by the advocates of the semantic approach. For example, Martin and Ferb (1973) observe that the unmarked and marked adjective orders have different phonological and syntactic properties. The unmarked word order is characterized by constant stress on all adjectives (or by increasing stress) and by the lack of juncture (pause) between the adjectives, e.g. *large blue car*. Syntactically these phrases are argued to have a flat, multiple-branching structure. On the other hand, the contextually-determined order shows contrastive stress on the discriminating adjective, and a juncture, e.g. *BLUE, large car* Syntactically these constructions have a right-branching structure (see Kotowski & Härtl, 2019; Scott 2002; Sproat and Shih, 1988 for discussion). Since the unmarked and marked structures have different properties, they cannot be accounted for by the same rule, i.e. the general pragmatic principle proposed by Danks and co-authors.

Martin and Ferb (1973) and Richards (1975) further argue that while communicative demands can sometimes trigger the inverted word order observed in Danks and Schwenk's (1972) experiments (*BLUE large car*), the same effect can be achieved by preserving the unmarked order but stressing the informative adjective, as in *large BLUE car*. Richards (1975) argues that in the paradigm adopted by Danks and Schwenk (1972), the color adjective must be stressed to produce preference for the inverted word order. Another weakness of Danks and Schwenk's studies is that they only take into consideration two classes of adjectives: color and size. Based on these observations, Richards (1975: 213) concludes that "the speakers are reluctant to give up their a priori preference for normal order and will do so only under highly specialized circumstances." From this perspective, the inverted order is seen as an optional, limited in scope phenomenon, which is peripheral to the study of adjective ordering in general.

While some of the criticism against the pragmatic approach might be justified, neither Martin and Ferb (1973), nor a more recent study by Scontras et al. (2017) offer a principled explanation of contextually-induced order. In what follows, we (i) present the results of two experimental studies which show that the inverted order of adjectives is more common and appears in a larger number of contexts than what was previously assumed, and (ii) propose that some cases of the inverted order can be explained by the *subjective distance* principle, which was proposed to explain word order in binomials (Iliev & Smirnova, 2016).[2] In the next section we compare the two phenomena and formulate our hypothesis about the effect of the subjective distance principle on inverted adjective ordering.

The Subjective Distance Principle in Binomials

Binomials are constructions with two conjoined elements belonging to the same lexical class, such as *Democrats and Republicans* (two nouns are conjoined) or *good and bad* (two adjectives are conjoined). While research on adjective ordering and word order in binomials has developed independently, there are surprising parallels between the two phenomena. First, word order in both domains is rather flexible, unlike word order in English in general. For example, while reversing the position of the subject and the verb results in purely ungrammatical constructions (**Slept John*), adjectives and binomials show more flexibility, despite the fact that there is often a clearly preferred word order. Thus, while the binomial *men and women* is more frequent, *women and men* is also possible (Iliev & Smirnova, 2016).[3] Similarly, in the domain of adjectives, *large blue car* sounds more natural than *blue large car*, but the latter is also possible.

Second, in both domains phonological factors might affect word order to some extent. For example, in binomials and adjectives, word length and the number of syllables appear to affect word order: the shorter word and the word with a lesser number of syllables tends to be mentioned first. This explains *bread and butter* and *boots and saddles* in binomials (Cooper & Ross, 1975: 79), and the order of adjectives in *the long intelligent book* (Wulff, 2003). Importantly, however, the phonological rule explains some of the data, but reference to semantic and pragmatic constraints, which in turn are seen as a reflection of deeper psychological principles, is needed in both domains.

One explanation for the word order in binomials is the *subjective distance* principle proposed by Iliev and Smirnova (2016). According to this principle, the attributes that are psychologically closer to the speaker – more

[2] Not to be confused with subjectivity in Scontras et al. (2017), discussed in the previous section.

[3] Binomials with relatively flexible word order, such as *men and women*, should be distinguished from the so-called freezes, where the order is fixed, as in *here and there* (cf. the ungrammatical **there and here*).

desirable, more familiar, or closer to the identity of the speaker more generally – will tend to be mentioned first in binomials (cf. Cooper & Ross, 1975). A series of studies confirmed this prediction in the domain of consumer preferences, political orientation, religion, gender, race, and geographic locations. For example, the analysis of the corpus of senate speeches showed that in the domain of political orientation, liberals are more likely to use *Democrats and Republicans*, thus mentioning their own political party first, while conservatives prefer the reversed word order: *Republicans and Democrats*. In another study, Iliev and Smirnova (2016) analyzed the distribution of gender words in binomials, looking at the literary work of more than 6000 authors. They found that female authors, when compared to male authors, tended to mention words referring to females first, as in *sister and brother*, *women and men*, and *daughter and son*. The distribution of gender words in binomials is particularly illuminating as it shows how the subjective properties of the speakers can override the default or more common word order, such as *men and women*.

We hypothesize that the subjective distance principle can also explain some cases of inverted word order in adjectival sequences. Specifically, we predict that the attribute that refers to a more desirable property according to the speaker would be mentioned first. The two studies below test this hypothesis for written and spoken modality.

Experimental Studies

Study 1: Adjective Order in Written Language

Participants Twenty-one participants were recruited from Amazon Mechanical Turk web service. All participants indicated that they were native speakers of English. The average age was 38 years old (the youngest 19, and the oldest 69). 48% were male, and 52% were female. The participants were compensated for their participation.

Stimuli Each stimulus consisted of two adjectives followed by a noun. All nouns referred to common objects: shoes, table, scarf, bike, watch, cat, and restaurant. The adjectives within the same nominal phrase belonged to different semantic classes, e.g. color and material in the case of *brown suede shoes*. We intentionally avoided modifiers belonging to the same semantic class within a query, since it has been observed that members the same semantic class are not ordered with respect to each other. For example, both *clever brave man* and *brave clever man* are possible, where *brave* and *clever* belong to the same semantic class – human propensity (Dixon, 1982). Moreover, unlike Danks and Schwenk (1972), who used only color and size adjectives, we included adjectives belonged to different semantic classes, including color, material, size, origin, and composition.

Design and Procedure At the beginning of the study, the participants read a short story introducing the main protagonist, Jim. Jim was looking for an object or place online, and needed help formulating his search queries.

Next, participants saw 7 questions, each dedicated to a particular item that Jim was looking for. The seven items were Shoes, Table, Scarf, Bike, Watch, Cat, and Restaurant. Each item had two attributes, e.g. color and material for shoes. For each item, there were two conditions. In one condition (Condition A), the context of the story specified that one attribute was more important than another. In another condition (Condition B), the importance of the attributes was reversed. For example, in condition A for Shoes, the participants learned that the color (brown) is very important to Jim, but material (suede) is less important. In condition B for the same item, the material (suede) was very important and the color (brown) was negotiable. (See the Appendix for the exact formulations.)

The participants then saw two alternative formulations of a query. Each formulation mentioned the two attributes but in a different order, e.g. *brown suede shoes* and *suede brown shoes*. The participants were asked to choose the formulation that is more appropriate given the context. Each participant saw only one condition per item (between-subject design). The conditions and the choice of the order in which two alternative queries were presented were randomized. Table 1 shows the list of stimuli and the two alternative formulations for each query.

Table 1: List of stimuli and the default word order predicted by semantic theories.

Items	Two alternative formulations of a search query	Default order
Shoes	brown suede shoes suede brown shoes	✓
Table	large oak table oak large table	✓
Scarf	long wool scarf wool long scarf	✓
Bike	red aluminum bike aluminum red bike	✓
Watch	silver quartz watch quartz silver watch	✓
Cat	short-haired white cat white short-haired cat	✓
Restaurant	Indian vegetarian restaurant vegetarian Indian restaurant	✓

Results To analyze whether the order of adjectives depended on the importance of a particular attribute to the speaker, we used the following coding scheme: When the participants chose the query in which the most important attribute in a given context was mentioned first, their answer was coded as 1. The answer in which the less important attribute was mentioned first was coded as 0. For example, if the context specified that the color of the shoes was more

important than their material, and the participant chose the query in which the color preceded the material (*brown suede shoes*), the answer was coded as 1. If in the same context the participants chose the reverse order (*suede brown shoes*), the answer was coded as 0.

If adjective ordering is not dependent on the subjective importance of the attribute, and the same (default) word order is preferred across different conditions, then the participants' answers will be at the chance level. Specifically, if a participant in Condition A chose *brown suede shoes*, her answer is coded as 1; and if the participant in the B condition chose the same query, her answer is coded as 0. The mean of the two answers is 0.5. If, however, adjective ordering is affected by the subjective importance of the attribute, then the answers for each condition will be higher than the chance level.

Collapsing across items, there was a strong tendency for mentioning the most important attribute first (m=.80, SD=.21). The choices were significantly higher than the chance level, which was .5 ($t(20)$=6.63, $p < .001$, one-tailed). The results are shown in Figure 1. These results support our hypothesis that adjective order is dependent on the subjective preferences of the speaker.[4]

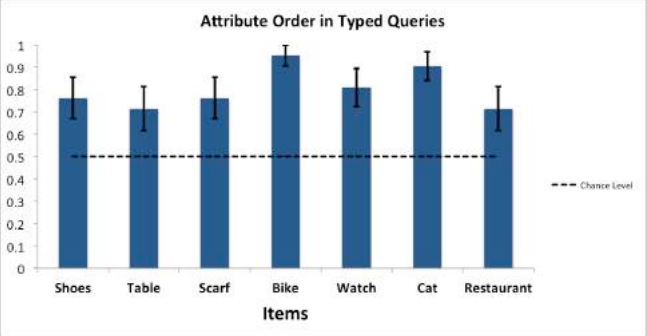

Figure 1: The proportion of times word order preferences are driven by the subjective importance of attributes in written language (typed queries). Higher numbers on the y-axis show greater association between adjectival order and the subjective distance. Values at the chance level would show that participants disregard subjective importance and chose the same word order in both conditions. Error bars represent +/-1SE.

[4] A reviewer raised the point that the inclusion of the congruent condition (canonical order and importance) is not informative. In our design, the congruent condition serves as a control for the incongruent condition. It might be the case that the canonical order expected by the researcher is incorrect, or that there is a substantial variance in the preference for canonical order among subjects. By averaging across the congruent and incongruent choices we control for that risk, so that the deviation of mean choices higher than .5 could safely be interpreted as importance preference, and mean choices lower than .5 would indicate reversed importance preference.

While the results from Study 1 provide support for the hypothesis that the subjective preferences of the speakers affect word order of adjectives, they are limited to a particular modality – written language. In Study 2 we test whether the same principle holds for spoken language. This question becomes particularly important in light of the criticism of the early pragmatic approaches about the role of intonation.

Study 2: Adjective Order in Spoken Language

Participants Thirty participants were recruited from Amazon Mechanical Turk web service. All participants indicated that they were native speakers of English. The average age was 32 years old (the youngest 23, and the oldest 53). 67% were male, and 33% were female. The participants were compensated for their participation.

Stimuli We used the same adjectives and nouns as in Study 1. Unlike Study 1, all stimuli were presented in audio format. The stimuli were read by a male native speaker of English. Each attribute within a query was read with even intonation, and there were no contrastive stress or juncture between attributes. This design intentionally separates intonation from word order, and thus can help us to assess the criticism that the inverted word order alone is not sufficient to convey the importance of the attribute in a given context (Richards, 1975).

Design and Procedure The study had the same design as Study 1, except that this time participants had to click on a button to hear a search query. As in Study 1, the order of the conditions and the order of the stimuli were randomized. Each participant saw only one condition per item.

Results We used the same coding scheme as in Study 1: all answers in which the order of the attributes matched the context, i.e. the most important attribute in a given context was mentioned first, were coded as 1. The answers in which the most important attribute was mentioned second were coded as 0. As in Study 1, we found strong preference for the most important attribute to be mentioned first (m=.68, SD=.35). The answers differed significantly from the chance level ($t(29)$=2.77, p=.004). The results of Study 2 are shown in Figure 2.

The results of Study 2 confirmed our findings in Study 1. We controlled for intonation and prosodic features and found that word order of adjectival modifiers reflects subjective preferences of the speaker, which is seen as manifestation of the subjective distance principle. The subjective distance principle extends to both written and spoken domains.

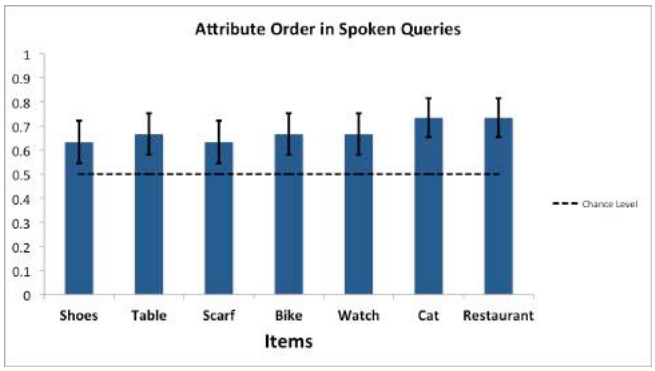

Figure 2: The proportion of times word order preferences are driven by the subjective importance of attributes in spoken stimuli. Error bars represent +/-1SE.

General Discussion

Our paper makes empirical and theoretical contributions to research on adjectival word order, and inverted order, specifically. First, our study shows that inverted word order is not limited to contexts with previously established salient referents, as in the original studies by Danks and co-authors. Second, we demonstrate that the inverted word order is manifested in both spoken and written domains. Our experimental design in Study 2 divorces intonation from word order, and we find that word order alone is meaningful and can convey the value of a particular attribute to the speaker, contra Richards (1975). Third, we propose that the inverted word order can be accounted for by the same psychological principle that explains word order in binomials. If a particular attribute, e.g. material, is more important to the speaker than color, this attribute would be mentioned first and would be positioned further away from the noun. Our explanation connects two previously unrelated research domains: binomials and adjectival modifiers.

One important question raised by a reviewer pertains to the applicability of the subjective distance principle to languages with post-nominal adjectives. It is worth to point out that the default ordering preferences based on a semantic principle are reversed in such languages. Specifically, the adjectives that tend to be mentioned first in languages with pre-nominal modifiers are usually mentioned last in languages with post-nominal modifiers. Despite the differences in word order, the distance between the head noun and the adjectival modifier remains more or less the same (Hetzron 1989; Scontras et al. 2017). Whether the subjective distance principle is also reversed in languages with post-nominal adjectives, is a question for future research.

Unlike Danks and his co-authors, we do not assume that the default and inverted word order should be explained by the same principle. It is plausible that the default word order can be explained with the semantic principle, such as adjective's subjectivity, as Scontras et al. (2017) argue. On the other hand, the inverted word order, at least in some cases, can be explained by the subjective distance principle, and the importance of a particular attribute to the speaker, specifically, as we show here. That the default and inverted word orders are explained by different principles is not surprising and is consistent with a more general observation in the literature that one principle, phonological, semantic, or pragmatic, is not sufficient to explain word order phenomena (Benor & Levy, 2006; Cooper & Ross, 1975 on binomials, Wulff, 2003 on adjective ordering).

Appendix: Stimuli

Study 1: General Instructions

Jim has just moved to a new city and is now in the process of settling down. He looks to buy several items online, and he also plans to use online information to find certain places in his new hometown. However, Jim is not sure how exactly to formulate his queries, and he needs your help deciding which query would be more effective. In what follows, you will see the description of the items that Jim is looking for. You need to help him choose which of two alternative queries he should use.

Specific Instructions: Shoes – Condition A

Jim is looking for a pair of shoes. He would prefer a pair that is made of suede and is brown. He is firm about the material – he wants suede and not leather – but he can compromise on the color. If he finds a pair he likes, and it's in black instead of brown, he might still take it. If he can enter only one query in the search box, which query should he choose? (The participants were then presented with two alternative formulations of a query).

Specific Instructions: Shoes – Condition B

Jim is looking for a pair of shoes. He would prefer a pair that is made of suede and is brown. He is firm about the color – he wants brown and not black shoes – but he can compromise on the material. If he finds a pair he likes, and it's in leather instead of suede, he might still take it. If he can enter only one query in the search box, which query should he choose? (The participants were then presented with two alternative formulations of a query).

Abstract

The mnemonic benefits of animate (e.g., Tiger) over inanimate (e.g., Table) stimuli have been demonstrated across several different memory paradigms. Given the ubiquity of inanimate, computer-generated voices we investigated if the animacy of a presentation source confers mnemonic benefits. We asked: is information delivered by a human voice better remembered than information presented by a computer-generated voice? Word-lists were presented auditorily by either a human or a computer-generated voice and memory was measured using a free recall assessment. In Experiment 1, words presented in a human voice were better remembered than words presented in a computer voice. Experiment 2 demonstrated that beliefs about the animacy of a computer-generated voice were not sufficient for any benefits to accrue, suggesting a possible boundary condition for the effect. Both experiments replicated the mnemonic benefits of animate words and demonstrated further extensions of the effect to spoken word presentation.

Keywords: Animacy; Recall; Memory

Introduction

Evolutionary psychologists have long argued that our minds have been adapted through the forces of natural selection (Cosmides & Tooby, 1994). Extending this evolutionary logic, it is further argued that our memory system has been adapted to serve the purposes of surviving in our distant ancestral environments. A recent example of this work would be the effect of "survival processing" by which mnemonic benefits are observed for stimuli experienced in evolutionarily salient contexts (Nairne, Thompson, & Pandeirada, 2007). Another example of adaptive memory is the finding of superior memory for animate compared to inanimate stimuli (Bonin, Gelin, & Bugaiska, 2014; Nairne, VanArsdall, Pandeirada, Cogdill, & LeBreton, 2013; VanArsdall, Nairne, Pandeirada, & Cogdill, 2015).

The *animacy effect* (henceforth *item-animacy*) has been observed in several memory paradigms such as free recall (Nairne et al., 2013), paired-associate recall (VanArsdall et al., 2015), and recognition (Bonin et al., 2014). Nairne and colleagues (2013) posit that our memories would be better attuned to animate entities in the environment for several evolutionary reasons. These include the special threat that living entities can pose, the sustenance that they can provide, and their broad social utility given that interactions with other animate entities (e.g. humans) were crucial for survival and reproduction.

It is this last reason relating to human sociality that drives the current investigation. The central question considered here is: does the animacy of the source of information matter for memory performance? In our modern computer-age, we are constantly interacting with voices generated by computers. How does the perceived humanness of such voices affect our cognition? Could it be that information delivered by Siri would be remembered differently than information provided by an actual person? It's possible that the findings regarding the animacy effect might bear on such questions. To the extent that such computer voices are perceived as inanimate (or at least less animate), there is a possibility that our memories might be worse for the information produced by a computer voice.

This ostensible *source-animacy* effect might emerge due to possible animacy contamination mechanisms (Cogdill, Nairne, & Pandeirada, 2016; as cited in Nairne, VanArsdall, & Cogdill, 2017). For example, Nairne and colleagues (2017) had participants read sentences in which two objects come in contact with each other. Target inanimate words in these sentences are "touched" by either animate ("The mouse is touching the sled.") or inanimate ("The lamp is touching the bottle.") stimuli. They found superior recall performance for inanimate target words when they were "touched" by the animate stimuli as compared to inanimate ones. Nairne and colleagues suggested that the "law of contamination" (Rozin, Millman, & Nemeroff, 1986) may account for such effects, with the property of animacy being conferred contagiously to inanimate words. Therefore, it may be the case that words spoken by the human voice are "contaminated" by the animacy of the voice, thus conferring a benefit for their recall.

Another account points to the importance of the voice itself. The quality of humanness in auditory perception might be especially well-processed. Evidence suggests that, from infancy, there is a predilection for human speech over non-speech analogues (Vouloumanos & Werker, 2007). There is also precedent in the music literature regarding the importance of human vocality for memory. For example, melodies sung by humans are better remembered than instrumental melodies (Weiss, Trehub, & Schellenberg, 2012). The authors proposed that we are especially attuned to human timbres because of their biological significance.

Due to the paucity of research on the subject and the implications for our interactions with machines in daily life, the current study was undertaken. The present experiments employed a free recall test on stimuli delivered through the auditory modality. The central manipulation involved the animacy of the voice delivering the word lists to be recalled (human vs. computer-generated). There were three main objectives: 1) To examine the influence of animate vs. inanimate sources on recall, 2) To provide a direct reproduction of the standard item-animacy effect in an auditory modality with a free recall assessment (see Aslan & John, 2016 for a paired-associate animacy effect using the auditory modality; see Stori, Zaar, Cooke, & Mattys, 2018 for a recognition memory assessment), and 3) To explore whether there would be an interaction between item-animacy and source-animacy. Following the evolutionary reasoning of Nairne and colleagues (2013), superior recall should be evidenced for words delivered by the human (animate) voice.

Experiment 1

The aim of Experiment 1 was to extend the classical item-animacy effect to an auditory source paradigm. Past research exploring animacy has typically consisted of the visual presentation of word lists that included animate and inanimate words (Nairne et al., 2013).The key departure from many past studies is that these lists are presented aurally through two different voices to manipulate source-animacy (cf. Aslan & John, 2016) along with a free recall assessment (cf. Stori et al., 2018). One of these voices was human and the other was computer-generated. Based on the animacy and evolutionary literature, memory should be superior for those words presented by the human-voiced (animate) compared to the computer-voiced (inanimate) source. Furthermore, this paradigm should replicate the standard item-animacy effect.

Method

Participants Binghamton University undergraduates (N = 51) participated in this study. An additional participant did not complete the entire experiment and was excluded.

Materials and Design Thirty-six English words were used in this experiment (18 animate, 18 inanimate). Thirty-two of these words (17 animate, 15 inanimate) were selected from word lists used in Nairne and colleagues (2013) and VanArsdall and colleagues (2015). An additional 1 animate and 3 inanimate words were obtained from the MRC database (Wilson, 1988) to supplement the lists. Following Nairne and colleagues (2013), all words were concrete nouns and matched on several dimensions: age of acquisition (19 words were missing data), number of letters, familiarity, imageability, concreteness, Kučera and Francis written frequency and number of categories, and mean Colorado meaningfulness.

Two versions of each word were recorded using version 2.1.3 of Audacity® (Audacity, 2014). The human spoken words were recorded by an experimenter that read each word aloud into the built-in microphone of an Apple Macbook laptop computer. A second Macbook computer was used to recreate the same set of words voiced by a computer using the voice-over accessibility function that comes standard with Apple computers and recorded via the built-in microphone of the first Macbook. The result of each recording was a continuous WAV file for each human- and computer-voiced word list. These continuous files were edited into discrete WAV files in Audacity for all of the words in both human- and computer-voiced presentations. All words were adjusted to have comparable volumes in both the human- and computer-voiced conditions (range: 9-15 dB). As a pilot test for clarity in the presentation of the words, a research assistant listened to both human- and computer-voiced presentations of all words and wrote them down. All words used in the present study were clearly perceptible to the research assistant, however, an additional four words were unclear and instead used as buffer words.

Two lists of intermixed animate and inanimate words were used for each experiment session and randomly assigned to either human- or computer-voiced conditions. Words were assigned to each list such that both human- and computer-voiced conditions were balanced on the aforementioned item-level variables. Two fixed buffer words were presented at the beginning of the first list and the end of the second list. Recall for these words were not coded nor included in the final analyses. PsychoPy psychophysics software version 1.8.3 (Peirce, 2007) was used to randomly select the word-to-list assignment, and to present each list in a randomly determined order.

Recall packets were printed on paper and included a maze (distractor task), a blank recall sheet, and a four-item questionnaire to assess the clarity and pleasantness of each word list using 7-point Likert scales.

Procedure For each session, between one and five participants were seated in a quiet room and told that they were participating in a memory experiment. The experiment was displayed on a 48 in. LCD television. Participants were presented with instructions both verbally and on-screen. They were instructed to face forward during presentation of the word lists and to focus on a black fixation cross on a white background. The words were not presented visually on the screen, but the display helped ensure that all participants were attending to the list presentation. Additionally, they were instructed to listen carefully and to expect a recall test later in the experiment.

Participants were then presented with the two word lists via speakers on the television. Each list was either presented using the human- or computer-voiced recordings in their entirety, with the alternative list being subsequently presented. Counterbalancing, which occurred across sessions, determined what source they heard first (human- or computer-voiced). The presentation of the first and the second list was separated by a 30 second break. Following the presentation of the second list, participants were handed a recall packet and directed to begin the maze distractor task. After one minute, participants were instructed to flip the page

and recall as many words as they could from both word lists. Participants were given an unlimited amount of time for recall but were told that they could turn the page if they could not remember any more words. On the final page of the packet, participants were asked to indicate the level of clarity and pleasantness of each source-animacy condition.

The following criteria were used to score a participant response as a correct recollection: correctly spelled target words (e.g., 'rabbit'); incorrectly spelled, but closely approximated target words (e.g., 'rabit'); different forms (i.e., tense, plurality) of target words (e.g., 'rabbits'). Responses that were confusable with a non-target word (e.g., 'rabid') were not counted as a correct recollection.

Results and Discussion

There were two main predictions about recall. First, that the animacy effect would be replicated with an auditory presentation of word lists and free recall assessment. Specifically, recall performance would be higher for animate words than inanimate words. Second, it was predicted that presentations voiced by a human should lead to better recall than presentations from a computer. A repeated measures ANOVA that contained item-animacy and source-animacy tested these predictions. There was a main effect of item-animacy such that animate words (M = .298, SD = .180) were recalled at a higher rate than inanimate words (M = .192, SD = .159), $F(1, 49) = 13.557$, $p < .001$, $\eta_p^2 = .217$. There was also an effect of source-animacy, where human-voiced words (M = .288, SD = .158) were recalled at a higher rate than computer-voiced words (M = .203, SD = .186), $F(1, 49) = 21.401$, $p < .001$, $\eta_p^2 = .304$. There was no significant interaction between item- and source-animacy ($F < 1$). (See Figure 1).

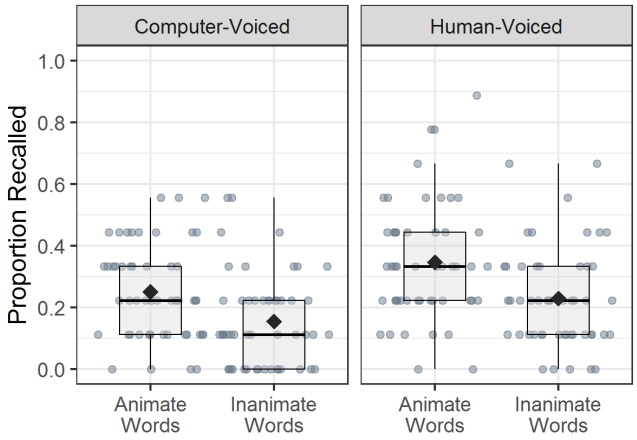

Figure 1: Proportion of words recalled in Experiment 1. The left panel presents both animate and inanimate words in the computer-voiced source animacy condition while the right panel reflects the human-voiced condition. Each point represents a participant's proportion of words recalled. Diamonds represent the overall mean for each condition.

Cumulative-link regression models were used to assess if human-voiced words were perceived as clearer and more pleasant than computer-voiced words. Each model predicted the rating of interest with source-animacy, the presentation order of human- and computer-voiced sources, and their interaction. Human-voiced words were rated as clearer than computer-voiced words (β = 1.873, SE = 0.525, Wald Z = 3.569, $p < .001$). There was no significant difference in ratings based on the order in which human- and computer-voiced sources were presented (β = -0.585, SE = 0.513, Wald Z = -1.140, p = .254) and no significant interaction (β = 0. 432, SE = 0. 713, Wald Z = 0.606, p = .544). Likewise, the human-voiced source received significantly higher pleasantness ratings than the computer-voiced source (β = 2.399, SE = 0.548, Wald Z = 4.378, $p < .001$). Again, there were no significant differences in ratings based on the order in which human- and computer-voiced sources were presented (β = 0.852, SE = 0.537, Wald Z = 1.587, p = .112), and no significant interaction (β = -0.871, SE = 0.727, Wald Z = -1.198, p = .321). (See Figure 2).

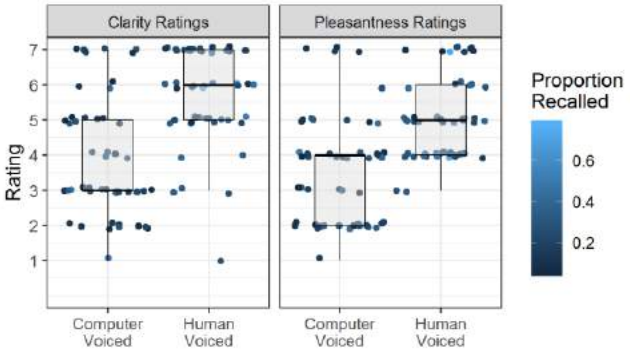

Figure 2: Clarity (left) and pleasantness (right) ratings for each source-animacy condition. Each point represents an individual participants' rating. The shading of each point reflects that participant's proportion of successfully recalled words within each condition. While both clarity and pleasantness ratings differed between source-animacy conditions there was no relationship between ratings and recall.

Mixed-effects logistic regression models that predicted recall success of each word tested if a series of control variables could account for either animacy effect. The baseline model included participants as random intercepts, source-animacy as random slopes, and source-animacy, item-animacy, and their interaction as fixed effects. Control variables were individually entered into the baseline model as an additional fixed effect. Clarity ratings (β = -0.075, SE = 0.050, Wald Z = -1.507, p = .132), pleasantness ratings (β = -0.058, SE = 0.055, Wald Z = -1.07, p = .287), the list participants received (β = 0 .035, SE = 0.171, Wald Z = 0.203, p = .839), and counterbalance order of source-animacy conditions (β = -0.105, SE = 0.167, Wald Z = -0.630, p = .529) were not predictive of recall successes. None of these variables altered the significance of item- and source-

animacy effects, or significantly improved the model's ability to account for variance in recall (all *p*s > .14).

Experiment 1 replicated and extended the standard item-animacy effect by demonstrating that animate words were better recalled than inanimate words when using auditorily presented stimuli. Animacy effects were not just observed for items, but also for the sources that presented items. This is reflected by the source-animacy effect: words presented by an animate, human voice were better remembered than items presented by an inanimate, computer-generated voice. The human-voiced source was rated as clearer and more pleasant than the computer-voiced source, however, follow-up analyses revealed that differences in ratings between the presentation source conditions could not account for the source-animacy effect. Taken together, these results provide evidence of the systemic effects of animacy on human memory.

Experiment 2

A potential limitation of the previous experiment was that there may have been differences between the human and computer voice that were not controlled for and that are not related to animacy or evolutionary mechanisms. One such difference was the human-voiced source being rated as clearer than the computer-voiced source (although clarity was not found to be predictive of recall success). The difficulty in controlling human and computer voices across relevant dimensions such as familiarity, tonality, and articulation (which may all contribute to clarity) raised the question of whether the source-animacy effect is contingent upon these differences (i.e. it is due to intrinsic qualities of the human voice) or participants' beliefs about the animacy of the source. To address this question, Experiment 2 circumvented the issue of auditory differences entirely. Instead of two different voices, the words in Experiment 2 are all delivered by one computer-generated voice. While the source (i.e. the voice) was held constant for both conditions, the belief regarding the animacy of the source was manipulated between conditions. Those in the stated-computer condition were told that the voice is computer-generated, while those in the stated-human condition were told that the voice is human.

Instead of serving as a direct replication of Experiment 1, the present experiment tested two hypotheses about the source-animacy effect. The belief-based hypothesis states that the source-animacy effect is determined by participants' belief about animacy independent of the auditory signal. This hypothesis predicts that when participants are presented with a computer-voiced source and their belief in the animacy of the source is manipulated, a source-animacy effect will be observed between the stated-human and stated-computer conditions. The intrinsic qualities hypothesis states that the source-animacy effect is determined by intrinsic qualities of the source. This hypothesis predicts that when presented with a computer-voiced source, no differences between the stated-human and stated-computer conditions will emerge as they are listening to the same computer-generated auditory signal.

Method

Participants Binghamton University undergraduates (N = 95) participated in this experiment. Two additional participants were dropped due to technical problems.

Materials and Design The word stimuli were the same as those used in Experiment 1 except that the buffer words were omitted. The audio was produced using Natural Readers online software, a text-to-speech tool[1]. All words recorded for this experiment were produced using a single computer voice from this software, which resembled a British-accented male. The procedure used to convert each word into an audio file was identical to Experiment 1, except that a human voice was not also recorded.

The WAV files for each word were presented through PsychoPy software in a random order to each participant. A between-subjects presentation of the words was used, such that all 36 words were presented to each participant through the one computer voice—the only difference being whether the participant was told that the voice was human or a computer program. In this way, all participants heard the same audio, ensuring that there were no aural or linguistic confounds between the animate and inanimate conditions.

Procedure Participants were randomly assigned to either the stated-computer or stated-human condition. In the stated-computer condition, the participants were told that each word was produced by a computer and in the stated-human condition, they were told that the words were produced by a human.

Each participant was brought individually into a room and told that they would be participating in an experiment that would require them to judge the clarity of a series of words that were to be used as part of a later experiment, which they would *not* be participating in on that day. These clarity judgments served as an incidental encoding task that was followed by a surprise free recall test that immediately followed the clarity judgment task. Participants were provided with closed ear headphones to listen to the words.

Each word of the study list was presented aurally through the headphones in a randomized order across the 36 trials. During each trial, a fixation cross appeared on the screen to focus their attention while the words were presented. A clarity rating scale replaced the fixation cross at the onset of each word. The participant would render their clarity rating on a 5-point Likert scale, with the wording being different according to the condition they were in ("Please rate how clear this human/computer produced word is", 1= not at all clear, 5 = extremely clear). Selecting a rating on the scale would begin the next trial (i.e. the following word).

[1] Navigate to https://www.naturalreaders.com/online/ to access the text-to-speech tool. The voice used was Peter at -1 speed.

At the end of the clarity judgment phase, participants were asked to recall as many words as possible from the list they just heard. They were given an unlimited amount of time to type their responses into an array of boxes that appeared on the screen. Once they completed this recall session, participants were asked how much they believed in the story they were told in the beginning of the experiment as a manipulation check. Those in the stated-computer condition were asked the extent to which they believed the voice they heard came from a computer, while those in the stated-human condition were asked how much they believed the voice to be from a human. Participants were probed about their beliefs on a 5-point scale. The criteria for a correct recollection were the same as in Experiment 1.

Results and Discussion

Data were first analyzed using a two-way ANOVA, with item-animacy as a within-subjects factor and source-animacy as a between-subjects factor. In line with our predictions, the standard animacy effect was replicated in this analysis as a main effect for item-animacy, $F(1, 93) = 52.008$, $p < .001$, $\eta_p^2 = .359$, with a greater proportion of animate words ($M = 0.25$, $SD = .10$) recalled than inanimate words ($M = 0.16$, $SD = .10$). However, there was no main effect found for source-animacy ($F < 1$). No interaction was found between item- and source-animacy ($F < 1$). (See Figure 3). Given the lack of an effect of source-animacy and the intrinsic qualities hypothesis's prediction of a null result, the stated-computer ($M = .202$, $SD = .129$) and stated-human ($M = .216$, $SD = .107$) conditions were analyzed with a Bayesian independent samples t-test. The Bayes Factor indicated substantial support (Jefferies, 1961) for the null hypothesis, (i.e., no differences between conditions), $BF_{01} = 4.425$.

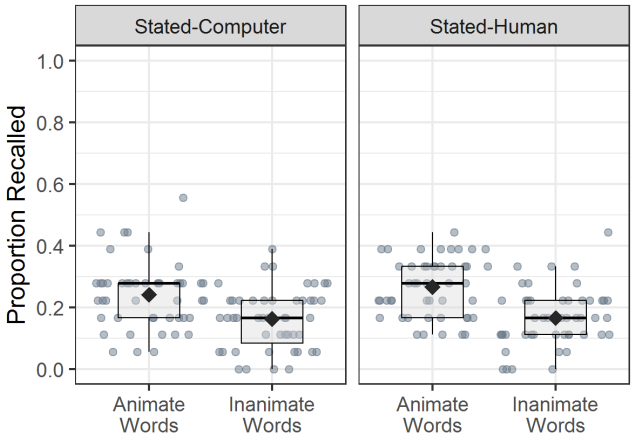

Figure 3: Proportion of words recalled in Experiment 2. The left panel presents both animate and inanimate words in the stated-computer source animacy condition while the right panel reflects the stated-human condition. Each point represents a participant's proportion of words recalled. Diamonds represent the overall mean for each condition.

Cumulative-link regression was used to test if clarity ratings differed as a function of both item- and source-animacy. Animate words were judged as clearer than inanimate words ($\beta = 0.338$, $SE = 0.063$, Wald $Z = 5.363$, $p < .001$). Despite both source conditions receiving identical stimuli, there was a significant difference in perceived clarity across the two source conditions, such that participants in the stated-computer condition judged the words they heard as clearer than those in the stated-human condition ($\beta = 0.297$, $SE = 0.063$, Wald $Z = 4.714$, $p < .001$). Regarding the manipulation check, the analyses revealed no significant differences between source-animacy conditions in the extent that participants believed the cover story ($\beta = 0$, $SE = 0.2637$, Wald $Z = 0$, $p = .999$). Participants who were told that the items were produced by a computer accepted this story to a similar degree as those who were told the voice was human. The median belief across conditions ($Mdn = 3$) suggests a moderate belief in the manipulation, with perhaps some degree of uncertainty.

Mixed-effects logistic regression models that predicted recall success of each word were used to test if any control variables could account for the observed item-animacy effect. The baseline model included participants as random intercepts and source-animacy, item-animacy, and their interaction as fixed effects. Source-animacy was not allowed to vary as random slopes, as in Experiment 1, because it was not a significant predictor of recall and did not alter the subsequent pattern of results. Control variables were individually entered into the baseline model as a fixed effect. Clarity ratings for each item ($\beta = 0.268$, $SE = 0.046$, Wald $Z = 5.794$, $p < .001$) were a significant predictor of recall success, such that recall was more likely for items with higher clarity ratings. While including clarity ratings into the model did not alter the observed item-animacy effect, the model did account for significantly more variance in recall than the baseline model, $\chi^2(1, N = 1) = 36.615$, $p < .001$. Participants' belief in the cover story ($\beta = 0.063$, $SE = 0.05$, Wald $Z = 1.233$, $p = .217$) was not a significant predictor of recall, did not alter the significance of the item-animacy effect, and did not significantly improved the model's ability to account for variance in recall, $\chi^2(1, N = 1) = 1.506$, $p = .22$.

The present experiment failed to find evidence of a source-animacy effect. It is important to note that participants were not actually exposed to an animate source, and instead those in the stated-human condition were told an inanimate source was animate. This result provides support for the hypothesis that some intrinsic qualities of the auditory signal are necessary for a source-animacy effect to accrue and suggests a boundary condition for the source-animacy effect: beliefs about the animacy of sources alone do not confer mnemonic benefits. This appears congruent with the evolutionary argument that the human voice has a special status in information processing, which may have been selected for by similar evolutionary forces that gave rise to the item-animacy effect. The present experiment provided an additional replication of the item-animacy effect within both an auditory presentation modality and an incidental encoding task.

General Discussion

The key finding of Experiment 1 was that words presented by the human-voiced source were better remembered than words presented by the computer-voiced source. This novel result suggests that the animacy of the source, and not only of the word presented, influences recall. The item-animacy effect was also replicated in an auditory modality. While prior work has explored auditory presentation of nonwords paired with animate or inanimate characteristics (Aslan & John, 2016) or auditory presentation of items followed by a recognition memory test (Stori et al., 2018), the present extension of the item-animacy effect demonstrated that it can also be observed with auditorily presented words and a free recall assessment, which is consistent with the evolutionary explanation of the animacy effect (Bonin et al., 2014; Nairne et al., 2013), as human speech emerged before written communication.

Experiment 1 demonstrated that animacy not only influences the memorability of items, but also the memorability of items presented by an animate source. One possible explanation of this source-animacy effect may be a contagion mechanism (Rozin et al., 1986), where the animacy of the source confers a mnemonic benefit to the information presented by it through association. A second possible explanation is that the human voice holds a special status in memory (Weiss et al., 2012), which may have been conferred through natural selection and may possibly extend to other animate sources. While the present experiments were not intended to disambiguate between these two explanations, future work should attempt to uncover its underlying mechanism.

Though not a direct replication of Experiment 1, Experiment 2 also examined source-animacy using an auditory modality. This experiment explored whether the mnemonic benefit of animate sources is determined by belief about animacy independent of the auditory signal or if it is determined by intrinsic qualities of the auditory signal itself. To this end, participants were presented with a single voice and their belief about whether it was from a human-voiced or computer-voiced source was manipulated. No differences in recall were found under these conditions, which provides support for the intrinsic qualities hypothesis: the human voice may be necessary for the source-animacy effect to emerge and that belief about the source's animacy is not sufficient for the effect to emerge. The necessity of the human voice may arise from either perceptual expertise with human voices or a particular biological significance. Under this hypothesis, the computer-generated voice in Experiment 2 would be treated fundamentally differently than a human voice regardless of what participants are told, or believe, about the source. One possible alternative explanation to this is that the suggestion was not strong enough for participants in the stated-human condition to treat the computer-generated voice in the same way they would a human voice. A stronger suggestion could be provided to increase belief in the manipulation and possibly give rise to a source-animacy effect. With this alternative explanation in mind, future research is warranted to further disambiguate these possible accounts.

Both experiments included additional analyses to mitigate possible alternative explanations. While pleasantness and clarity differed between source-animacy conditions, they were not related to recall performance and could not explain either of the observed item- or source-animacy effects. The divergence in clarity ratings between source-animacy conditions were not related to recall, which is theoretically interesting. There is some research suggesting a desirable difficulty effect in memory such that difficult-to-perceive words are better remembered (Rosner, Davis, & Milliken, 2015). Besken and Mulligan (2014) provided evidence supporting the benefits of desirable difficulties by demonstrating that aurally-distorted words were better remembered on a free recall assessment than non-distorted words. Experiment 1 results showed, however, that although the computer-voiced words were judged as less clear, they were not better recalled, inconsistent with a desirable difficulty effect. It is possible that the source-animacy effect overwhelmed any benefits of perceptual dis-fluency.

The results of Experiment 2 further complicate the role of perceptual clarity. Participants in the stated-computer condition rated the words they heard as significantly clearer than those in the stated-human condition. This is despite that the voices used were identical in both conditions. Though the results of Experiment 2 suggest that while beliefs might play a negligible role in a possible source-animacy effect, they may influence how people judge perceptual clarity. Whatever the case, the results suggest that clarity differences between the voices cannot account for the mnemonic benefit of human-spoken words.

Despite the noteworthy finding of the source-animacy effect and the replication of the item-animacy effect in Experiment 1, it is necessary to consider some important limitations. First, the materials were recorded using a limited number of voices. In order to ensure that these findings are generalizable, future studies must use a wider variety of voices, both computer-generated and human. Second, Experiment 1 rested on an experimenter-defined source-animacy manipulation without testing whether participants viewed the human-voiced source as more animate than the computer-voiced source. Third, while the stimuli were tested for perceptibility by a single research assistant, it is possible that participants may have had more difficulty in perceiving each word. Future work would benefit from more robust norming of the animacy and perceptibility of the auditory sources. Fourth, as Experiment 2 was a between-subject manipulation, participants may have anchored their clarity ratings differently based on whether they were told it was from a computer or human, which may have biased the clarity ratings and obscured a potential relationship between clarity and source-animacy condition. To address this concern, future work should provide a fixed reference for participants to evaluate clarity with respect to. Finally, though clarity and pleasantness were found not to affect the main findings, there may have been other potentially nontrivial differences in vocal variables (e.g. tempo, pitch) that were not recorded or analyzed in the present experiments.

The Director Task Fails to Differentiate Young Adult Theory of Mind Abilities: An IRT Analysis

Mikhail Sokolov (MishaSokolov@cmail.carleton.ca)

Abstract

The goal of the present study was to demonstrate the potential application of Item Response Theory (IRT) outside its traditional use in assessing questionnaires by applying it to data from behavioural task. We did this by validating a perspective taking task called the Director Task used to assess Theory of Mind (ToM) abilities in young adults. IRT and convergent validity analyses indicated that, contrary to our hypotheses, the Director Task had an unduly narrow range of responding for measuring ToM. Furthermore, the Director Task did not correlate with other established measures of ToM. Our results suggest that the task should be used with caution when assessing a young adult population. Furthermore, since convergent validity was not established, it is uncertain what specifically the task measures. Overall, we show how IRT may serve as a useful tool in evaluating behavioural measures.

Keywords: Theory of Mind, Item Response Theory, Director Task

Introduction

Item Response Theory is an approach to assessing the psychometric properties of measures designed to measure psychological constructs such as attitudes. Modern test construction methodology suggests that simply having a range of scores on a measure is not a sufficient determinant of the psychometric properties of a test. In the current research article, we extend the use of Item Response Theory (IRT) methodology from its traditional application of evaluating personality scales and achievement to validate the effectiveness of a behavioural task, specifically, a Theory of Mind task called the Director Task.

IRT provides sample invariant information for each item at varying levels of the underlying traits or ability (Embretson & Reise, 2000; Thissen & Wainer, 2001). The simplest IRT model is the dichotomous Rasch (1960) model which is applied to tests, or other tasks, where each trial can be classified as correct or incorrect. The Rasch model allows us to calculate the difficulty of each item (1PL), its discriminatory power (2PL), as well as account for the effect of guessing (3PL). By calculating the probability of answering each question correctly based on assumed trait levels, IRT can supply researchers with information about the suitability of individual test items, as well as the test in general. IRT provides a number of advantages over classical test construction methods, such as allowing for identification of sensitivity and difficulty of individual items (Embretson, 1996; Hambleton & Swaminathan, 2013). Most crucially, IRT allows researchers to empirically assess the suitability of the test at varying levels of the trait of interest. This information allows researchers to determine the effective range of discrimination for the tool.

IRT models make four major assumptions: unidimensionality, local independence, monotonicity, and a normally distributed latent trait. Unidimensionality of the trait and local independence are generally assumed to coexist. Unidimensionality is the assumption that there is only one latent trait being measured, whereas local independence is the assumption that each response is independent and only conditional on the latent trait. Monotonicity is the assumption that as the latent trait increases, so does the probability of correctly responding to each trial. Finally, the assumption of a normally distributed latent trait is common to many parametric tests used in psychology research. To our knowledge, IRT has never been applied to data from a behavioural task. However, there are, in principle, no conceptual restrictions that would restrict the use of IRT for the assessment of a behavioural measure.

Theory of Mind (ToM) is a cognitive ability that allows individuals to mentalize about other's minds (Heider, 1958). ToM is believed to be an important component of empathy which, along with emotion empathy, allows individuals to accurately recognize and understand other's emotional states (Smith, 2006). Disruptions in ToM abilities can lead to impairments in adult functioning where individuals are less able to interpret the beliefs and intentions of others (Perner, Frith, Leslie, & Leekam, 1989). Theory of Mind deficiencies are closely associated with Autism Spectrum Disorders (Baron-Cohen, Leslie, & Frith, 1985).

Unlike emotion perception, which is largely an inborn ability and therefore, develops extremely early (Grossmann, 2010), ToM abilities continue to develop beyond childhood. For example, infants can discriminate emotional faces at 3.5 months (Montague & Walker-Andrews, 2002), or possibly earlier, and at 6.5 months are able to differentiate between emotional postures of adults (Zieber, Kangas, Hock, & Bhatt, 2014a, 2014b). In contrast, ToM skills develop much later in life (Calero, Salles, Semelman, & Sigman, 2013; Frith & Frith, 2001). ToM development is even believed to stretch into early adulthood (Dumontheil, Apperly, & Blakemore, 2010), as evidenced by the continued neurodevelopment of brain regions responsible for ToM such as the medial frontal gyrus, the anterior paracingulate, and the right temporoparietal junction (Kana, Keller, Cherkassky, Minshew, & Just, 2009) into late adolescence and early adulthood (Shaw et al., 2008).

From a practical point of view, the assessment of ToM abilities poses a particular difficulty for clinicians and researchers. Many tasks that measure the development of ToM abilities, such as the presence of false beliefs or perspective taking, have ceiling effects since these abilities are well developed by the age of 5 (Wellman, Cross, & Watson, 2001). Other measures, such as the Reading the Mind in the Eyes Task (Baron-Cohen, Wheelwright, Hill, Raste, & Plumb, 2001), are confounded by the emotion perception aspect of the task. However, some perspective taking tasks, such as the Director Task (Keysar, Barr, Balin, & Brauner, 2000) have been shown to discriminate ToM abilities later into adolescence, and even early adulthood (Keysar, Lin, & Barr, 2003).

The Director Task is a perspective taking task where the participant is instructed to follow directions of a confederate who has a different view of a 4 x 4 grid. The grid contains various items that the participant must manipulate based on the director's instructions. Some of the grids are closed to the view of the director, but not the participant (see Figure 1). During the experimental trials of the task, the director gives an ambiguous instruction to the participant to move an item (e.g.: "Move the bottom block"). In this example, there would be two distractor blocks, one of which is the lower most from an egocentric perspective, but is closed off (i.e., unable to be seen) from the view of the director, and therefore is not the target. If participants select the lower-most block that is visible to them, they would not have taken the director's perspective into account, and would thus commit an error.

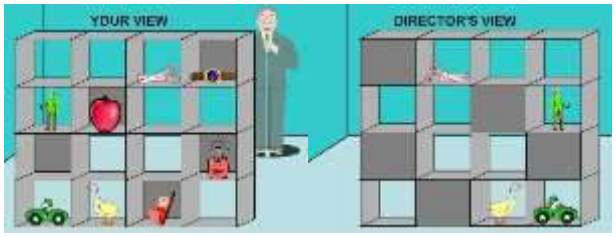

Figure 1. Instruction examples given to participants to demonstrate the director's perspective.

In previous studies, the Director Task showed that even adults have a natural tendency for the egocentric perspective (Keysar et al., 2003), and that the task reliably differentiates between youth and young adults (Dumontheil et al., 2010). These findings indicate that the Director Task may be a useful tool to differentiate between Theory of Mind abilities within the young adult/ adult population. If it is true that the task can reliably differentiate between young adults on ToM abilities, this would allow for the study of ToM perspective taking using convenience samples, making ToM research more accessible.

Present Study

The purpose of the present study was to assess the Director Task using IRT. Specifically, would the Director Task prove suitable for use with the young adult population as a tool for discriminating between individuals who are low and those who are high in Theory of Mind abilities? We hypothesize that a modified, computer based, version of the Director Task would allow for the discrimination across a sample of young adults on the basis of ToM abilities, and the results would show convergent reliability with more established measures of ToM. Although the Director task has already been shown to differentiate between age groups (Dumontheil et al., 2010), this finding does not automatically extend to within group differentiation.

With regard to convergent validity, two established ToM tasks were selected, the Reading the Mind in the Eyes Task ("Eyes Task") (Baron-Cohen et al., 2001) and the 40-item Empathy Quotient (EQ 40) (Baron-Cohen & Wheelwright, 2004). Although these tasks are sufficiently different from the Director Task, we predicted that a weak, but significant positive correlation would be observed between these tasks and the Dirtector Task.

Method

Participants

94 Carleton University undergraduate students (20 male) with a mean age of 19.8 (SD = 4.3) volunteered to participate in exchange for course credit. All participants self-identified as right-handed.

Measures

As part of a larger study participants completed the Eyes Task (Baron-Cohen et al., 2001), as well as the 40 item Empathy Quotient (Baron-Cohen & Wheelwright, 2004). The Director Task (Keysar et al., 2000) used was kindly provided by Dumontheil et al. (2010) and modified for use with PsychoPy software (Peirce, 2007). The Director Task was modified to exclude the non-director items, allowing a doubling of the number of Director trials to 95. Altogether, 16 trials were experimental trials, 16 trials were control trials, and the rest of the trials were filler trials. If our hypothesis is correct, by increasing the number of experimental trials, a grater range of scores will be observed, and with it, a finer discrimination of individuals along the latent trait associated with ToM.

Procedure

After providing informed consent, participants were tested individually in a sound-attenuated booth. Instructions, stimuli, and questionnaires were presented on a PC using PsychoPy software (Peirce, 2007). The task was presented to participants as a static image with verbal instructions played over computer speakers. For each trial the target item was overlaid by a 3 cm^2 invisible square which would record mouse button presses. All mouse presses outside of the target square were scored as incorrect; trials with no mouse button presses were discarded. Each Director Task maximum trial length was set to 5 seconds from the onset of audio instructions. Trials in the Director Task were presented to participants in a predetermined order. Next, participants completed the Eyes Task and the EQ 40 task.

Trials in these latter tasks were randomized. The study required approximately 45 minutes to complete. Participants were debriefed as to the purpose of the experiment after they completed the EQ 40 task.

Results

Responses were tallied and scored using custom Visual Basic scripts. Outliers were identified based on deviations from predicted Mahalanobis distance using the R package "careless" (Yentes & Wilhelm, 2018). One case was identified as unusual and removed leaving 93 participants (see Figure 2). Descriptive statistics are presented in Table 1. Scores from the Director Task appeared to take on a bi-modal distribution, with upper and lower scores trending towards extremes (see Figure 3).

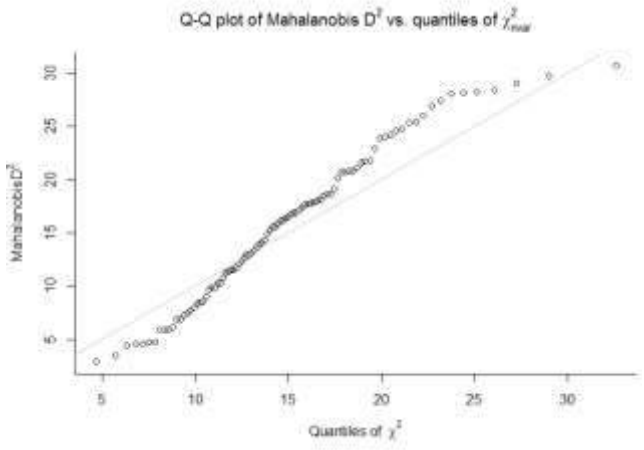

Figure 2. q-q plot of actual vs predicted Mahalanobis distance

Table 1. Overall descriptive statistics for each measure.

	M	SD
EQ 40 Score	68.21	7.80
Eyes Task	26.80%	5.39%
Director Task	53.14%	35.74%

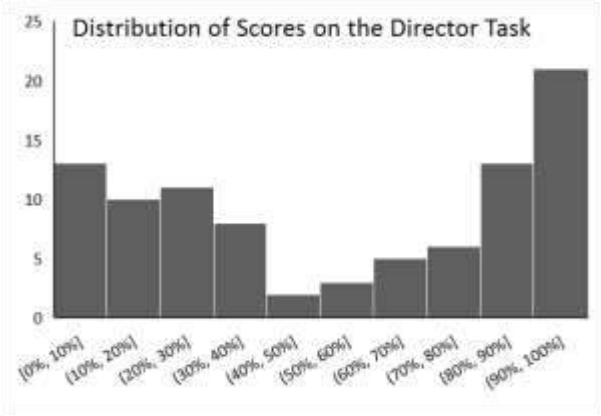

Figure 3. Histogram showing the distribution of accuracy scores on the Director Task

A paired samples t-test showed a significant decrease in accuracy when comparing the control trials with the experimental trials (t (92) = -9.05, $p < .01$) but not reaction times (t (92) = -1.14, *ns*). This suggests that performance on the task deteriorated as expected due to the increased difficulty of the experimental trials compared to the control trials.

IRT

The IRT analysis was performed using the ltm (Rizopoulos, 2006) package in the R environment (R Core Team, 2013). A constrained One-Parameter Logistic Model (1PL) and unconstrained Two-Parameter Logistic Model (2PL) dichotomous models was run to determine which created a better fit. The constrained model assumes that each item on the unidimensional scale is equally good at discriminating between individuals with varying trait levels whereas the unconstrained model does not make this assumption. Since the two models are nested, a χ^2 difference test was performed to assess model fit.

Significant model fit improvement was observed when the model was unrestricted from constrained to the unconstrained discrimination parameters (χ^2 (14) = 27.97, p = 0.014). As such, a 2PL model was selected for the analysis of the Director Task. A 3PL model was not used because the Director Task is not strictly a forced choice multiple choice test, and therefore it is improbable that participants would attempt to randomly select their answers.

Results of the individual item difficulty and discrimination, under the 2PL model, are presented in Table 2. Figure 4 contains the Item Information Curves (IIC) and Figure 5 Shows Total Test Information Function relative to Standard Error of measurement. Standard errors were estimated using the delta method.

The results from the model suggest that, congruent with our hypothesis, all the experimental trials of the Director Task have good discriminatory power. However, contrary to our hypothesis, the difficulty of the items appears quite low with only half of the items showing a significant deviation from 0.

Table 2. Difficulty and discrimination of the experimental items of the Director Task

Trial	Difficulty (*b*)	Discrimination (*a*)
4	-0.33	1.40**
14	-0.03	1.16**
20	-0.18	2.43**
26	-0.06	2.52**
30	-0.27*	2.66**
36	-0.34**	3.10**
40	-0.07	4.00**
49	-0.026	3.62**
59	-0.61**	2.22**

65	-0.40**	3.32**
70	0.17	2.25**
74	-0.67**	1.66**
78	-0.36**	3.72**
84	-0.18	2.21**
88	-0.44**	2.38**

Note: * $p < .05$; ** $p < .01$

The IIC plot visually confirms that, although the information content of many trials is very high, the range of ToM ability that they represent is poor.

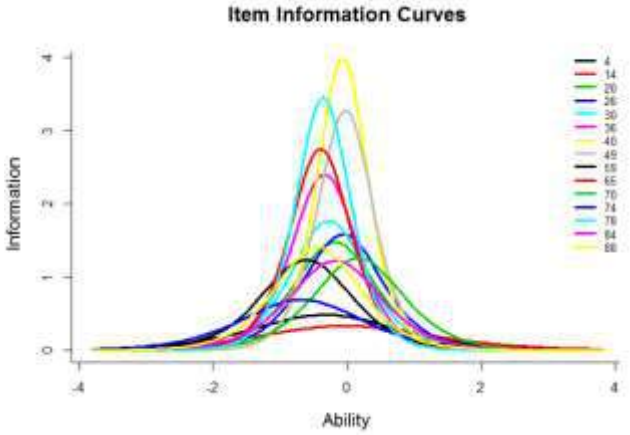

Figure 4. Item Information Curves for the experimental items of the Director Task

Finally, Figure 5 shows that the information content of the Director Task as a whole is very large, with an area under the curve of 38.66. However, 55% (20.75) of this information content falls within 0.5 standard deviations of the mean, and 82.5% (31.89) within 1 standard deviation. This once again reaffirms that the Director Task is poor at discriminating between individuals of different ToM abilities.

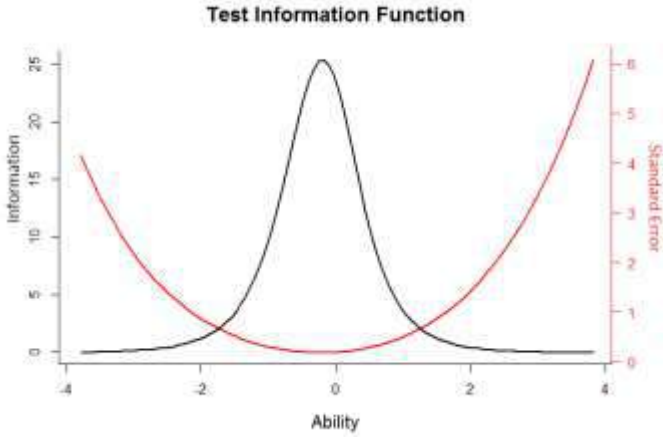

Figure 5. Total Test Information Function relative to Standard Error of Measurement.

Convergent Validity

Convergent validity for the Director Task were assessed using a self-report measure of ToM, the EQ 40, as well as a behavioural discrimination task, the Eyes Task. The results are presented in Table 3.

Table 3. Correlation matrix for the Director and other convergent validity tasks

	1	2
EQ 40	-	
The Eyes Task	-0.102	-
The Director Task	0.065	0.114

Contrary to our hypothesis, we did not find any significant correlations between the Director Task, or any of the other two popular tasks for assessing ToM abilities.

Discussion

Our findings did not support the hypothesis that the Director Task is good at discriminating between Theory of Mind abilities in a sample of young adults. Our findings are surprising in light of previous findings with the same (Dumontheil et al., 2010) or similar (Keysar et al., 2003) tasks allowing for discrimination in the young adult population.

Our sample showed significant variability in the range of scores on this task, which under normal circumstances would be an encouraging finding. However, IRT analysis showed that despite strong information content of the individual trials (discrimination), the Director Task does not measure well different levels of the ToM trait (difficulty). We interpret these findings as a strong indication that the Director Task is able to differentiate participants as either good or bad at TOM abilities, with little useful information beyond that. This interpretation is supported by both the poor difficulty gradient of the trials, as well as the tendency for participant scores to conform to a bimodal distribution.

Beyond the poor psychometric properties of the task, we failed to observe convergent validity between the Director Task and other established ToM tasks. This finding brings into question what trait or state the Director Task actually is measuring. One possible explanation for the lack of relationship between the three ToM Tasks examined in this study is that there is a sufficiently large distinction between the perspective taking ToM component, and emotion perception ToM component. However, this would not explain the lack of relationship between the Eyes Task and the EQ scores. Another possible explanation is that the Director Task is measuring some other quality, such as selective-attention to the task (Rubio-Fernández, 2017).

Regardless, we would caution researchers using the Director Task in its present form. Specifically, the task suffers from overly homogenous difficulty of trials. Nonetheless, there is potential for a modified version of this

task to be more successful. If the task is modified such that there is a greater range of experimental trial difficulty, with some being more difficult, while others being easier, the likely utility of the task will greatly improve. Finally, it is possible that by assessing other behavioural measures beyond the accuracy of answers, such as mouse-tracking or eye-tracking (Symeonidou, Dumontheil, Chow, & Breheny, 2016) we could use the extra sources of information to supplement our inferences about participants' ToM abilities.

Regarding the more general goal of extending IRT to assess the results of a behavioural task by validating the Director Task, the present results suggest that IRT can provide useful information about the relationship between participants' responses and the construction of tasks. IRT is often associated with pen and paper test construction, however, the underlying probability models are agnostic to the source of the data. With many available statistical packages, and a well developed literature, IRT is easily accessible to all researchers. We encourage the use of IRT as a readily available tool to aid the validation of measures.

Conclusion

In this study we used Item Response Theory to validate the Director Task (Keysar et al., 2000) as a tool in studying Theory of Mind abilities in young adults. Contrary to our hypotheses, we found that the task performed poorly in discriminating between levels of the latent trait. Furthermore, a convergent validity measure brought into question what latent trait is being measured using the Director Task. Overall, the present study provided a novel demonstration of how an Item Response Theory analysis can be profitably extended to assess behavioural measures.

Abstract

We employ a scenario-sentence-verification paradigm to investigate the role of scenario-given alternatives for the processing of affirmative and negative sentences. We show that for both affirmative and negative sentences the N400 amplitude is larger if the context model provides multiple alternatives for a true sentence continuation relative to the case when it provides only a unique referent. Additionally, we observe a late positivity effect for negative relative to affirmative sentences, independent of the context model.

Keywords: Negation; alternatives; N400; P600

Introduction

Negation occurs in every human language and is essential for communication. Nevertheless, negative sentences seem to require elevated processing resources when compared to affirmative ones and negation has posed a challenge to psycholinguistic theories. Language comprehension is generally considered to happen incrementally, i.e. as the linguistic input unfolds in real time; yet, empirical evidence suggests that negation is not compatible with this view, and it is argued that negation may be integrated into sentence meaning only at a later stage of the comprehension process. Furthermore, language processing is considered to be predictive, meaning that we not only process incoming linguistic information but also anticipate upcoming content (cf. DeLong et al., 2005; Pickering & Garrod, 2007; Van Petten & Luka, 2012; Kuperberg & Jaeger, 2015). However, despite of the large amount of experimental literature on prediction, it remains an open question to what extent and at which processing stage the number of contextually available alternatives for an upcoming word modulates the prediction of that word during sentence comprehension. Furthermore, as it is unknown at which stage negation becomes a part of compositional meaning, it is also not clear whether and how negation modulates predictive processing.

In the psycholinguistic literature emphasis has been put on providing a model of negation processing and experimental work has focused on investigating the cognitive costs related to the processing of sentences with negation. Since negative sentences are structurally more complex, they are expected to involve more cognitive resources than their affirmative counterparts. From a semantic point of view, the potential need to suppress positive information is also likely to result in an increase of processing costs. Early on it has been shown that negative sentences are associated with higher error rates as well as longer response and reading times than affirmative sentences (Just & Carpenter, 1971; Clark & Chase, 1972; Lüdtke & Kaup, 2006; Dale & Duran, 2011).

Early electroencephalography (EEG) studies on negation processing further suggested that the integration of negation into the compositional sentence meaning is delayed. For instance, many studies (Fischler et al., 1983; Dudschig et al., 2019) found no effect of negation on the N400 event-related potential (ERP) component. The N400 is a negative shift in the ERP waveform, of a latency between 200 and 600 ms post-stimulus onset and maximal over centro-parietal scalp sites. Its amplitude tends to be larger for words that are (semantically) less expected given the background context, or world-knowledge, as well as for words of lower corpus-based frequency (see Kutas & Federmeier (2011) for an overview). The N400 has furthermore been shown to be inversely correlated with the triggering word's cloze probability, i.e. the percentage of individuals who would continue a given sentence fragment with that word (Federmeier et al., 2007). Various theories interpret the N400 as a marker of (i) lexical retrieval (Brouwer & Hoeks, 2013), (ii) integration into the prior context (Hagoort et al., 2004), (iii) predictive preactivation (DeLong et al., 2005), or even (iv) meaning-related probabilistic prediction (Lau et al., 2013; Kuperberg & Jaeger, 2015; Rabovsky et al., 2018). According to a recent account (Rabovsky et al., 2018), the N400 reflects meaning-related prediction error, where prediction is understood in a non-intentional sense, as an implicit state of the system that is tuned to anticipate the upcoming input in a graded manner.

In the first ERP study on negation by Fischler et al. (1983), the N400 was only modulated by the lexical-semantic relation of the predicate to the main noun and it was larger for the sentence-final predicates when this relation was weak, as for instance in *A robin is/is not a truck* relative to the case when the relation was strong, as in *A robin is/is not a bird*, independently of the presence of negation in a sentence, which reversed the sentence truth-value. This result is usually interpreted as evidence that negation is not processed incrementally and thus is not immediately integrated into the compositional sentence meaning. This interpretation was further sup-

ported by an EEG-study employing a sentence-picture verification paradigm that revealed a delayed integration of the negation in the sentence meaning (Lüdtke et al., 2008). In their experiment, affirmative and negative sentences, such as *In front of the tower there is a/no ghost*, were followed by matching or mismatching pictures, e.g. a tower with a lion or a tower with a ghost, after a short (250*ms*) or a long (1500*ms*) delay. Note that in the case of the affirmative sentences, the matching pictures are explicitly mentioned and thus primed by the sentences, but the negative sentences primed the mismatching pictures. In the short-delay condition, the N400 ERPs reflected a priming effect, namely, for the affirmative sentences the mismatching pictures were associated with a larger N400 than the matching pictures, whereas for the negative sentences the effect was opposite. An effect of negation was only reflected by a late positivity effect that was identified as the P600 effect. In contrast, for the long-delay condition, main effects of truth-value and negation in addition to the priming effect were already observed in the N400 time-window. This result was taken as evidence that integrating negation into the sentence meaning required additional time after the sentence was read. The P600 effect observed in response to the use of negation is an especially noteworthy result. The P600 is a slow, late (around 500-800 ms post-onset) positive shift in the ERP waveform that is maximal over posterior scalp sites. It is often observed for structural violations, grammatical errors or syntactically more complex sentences (Hagoort et al., 1993) but also for some pragmatic and semantic anomalies (Kuperberg et al., 2003). It has been argued to reflect combinatorial aspects of linguistic processing (Kuperberg, 2007) or even semantic integration mechanisms (Brouwer et al., 2012). In the case of negative sentences it may be taken as a marker of the increased processing demands related to integrating the negation into sentence meaning.

However, the comprehension of negated sentences is facilitated if they are embedded into context. Nieuwland & Kuperberg (2008) showed that pragmatically licensed negative sentences such as for example *With proper equipment, scuba diving isn't very safe/dangerous...* did not lead to elevated N400-components for true compared to false sentences. Instead, without pragmatic licensing, e.g. *Bulletproof vests aren't very safe/dangerous...* the true negated sentences led to higher N400s than the false sentences, in line with Fischler et al. (1983). Tian et al. (2016) furthermore showed that for cleft-structures which narrow the scope of the negation and therefore the potential alternatives such as in, e.g. *It is John who hasn't ironed his shirt*, incremental comprehension of negated sentences is facilitated as well.

The role of alternatives for the processing of both negative and affirmative sentences was directly studied in an eye-tracking experiment by Orenes et al. (2014). They investigated whether the presence of multiple alternatives in the context has an effect on the processing of negative and affirmative sentences. An auditory context sentence was introduced that either indicated that all objects are possible choices (*multary* condition: *The figure could be red, green, blue, or yellow*), or restricted the choice to only two objects (*binary* condition: *The figure could be red or green*). Then, the visual context appeared, which always included four different objects, e.g. circles of different colors. The target sentence *The figure is red/not red* was presented auditorily while the four figures were shown on the screen and eye-movements were monitored. For affirmative target sentences subjects fixated the target object (*red circle*) in both context conditions. In contrast, for negative sentences, subjects fixated the target object (*green circle*) only in the *binary* condition, whereas in the *multary* condition they fixated the object that had the mentioned, negated feature (*red circle*). The interpretation of these results is problematic, since the affirmative and negative conditions were not logically comparable. Whereas affirmative sentences directly mentioned the target object, for negative ones the identification of the target was only possible in the *binary* condition, where one could infer the color of the target object from the pair of the context and the target sentence. In the *multary* condition the target object was not identifiable: The intended figure that was described as *not red*, could be blue, yellow, or green.

It is not surprising that in the case when the referent cannot be identified, the processing of a sentence differs relative to the case when the referent can be uniquely established in the context. However, the question arises whether this effect has anything specifically to do with negation. In our current experiment we aimed at directly comparing the processing of affirmative and negative sentences in situations when the context scenario provides multiple or unique potential true sentence continuations. Suppose that Julia is dealt three cards (*ace*, *king*, *queen*) and the game is to choose some of these cards, while rejecting the rest of them at the same time. If Julia selects one card (e.g. *ace*), one can describe her choice by saying that *Julia selected the ace*. There is only one card that can be mentioned in a true affirmative sentence. Additionally, about each of the remaining two cards one can say that it was not selected, e.g. *Julia did not select the king/queen*. In this case there are two potential true sentence continuations. The situation is exactly opposite if Julia had selected two cards, while rejecting only one. By manipulating a game situation of this type we can create unique and multiple contexts equivalent for negative and affirmative descriptions. It has previously been suggested that the N400 amplitude elicited by a given word seems to be directly dependent on the number of contextually given alternatives to this word. Spychalska et al. (2016) showed that, for sentences such as *Some pictures contain X*, if the context scenario provided additional objects *Y* that could be mentioned instead of *X*, the N400 was larger when *Y* would complete a true sentence (thus was a true alternative to *X*) relative to the case when *Y* would complete a false sentence (and was not a true alternative to *X*). Since the N400 is known to inversely correlate with the cloze probability of the triggering word, one can hypothesize that

if the context scenario provides alternative referents for a true sentence condition, the N400 should be larger relative to the case when the context allows to uniquely predict the referent. By contrasting negative and affirmative sentences in logically equivalent conditions, the design allows us to directly measure the effect of negation on the processing of a referent in the context with multiple alternatives.

Method

The experimental design used a scenario-sentence verification paradigm. Participants were informed that they follow a player's moves in a game. In each target trial the player (introduced in the form of a clipart-like image) was dealt three cards, each depicting a different object, which were presented on the screen. Then, the player selected or rejected one or two of the cards. Subjects were informed that this action leads to an exhaustive divide of the set of cards. Selection was marked by framing the selected cards green, which implied that the unframed cards are rejected. Rejection was marked by framing the rejected cards red, which implied that the unframed cards are selected. After the cards were marked, the scene disappeared and a sentence (in German) was presented phrase-by-phrase. At the end of the trial, participants were asked whether the sentence is a true description of the action taken by the player. The target sentences were either of the form 1a (*affirmative* conditions) or of form 1b (*negative* conditions), where *X* is a proper name referring to the player and *Y* denotes the critical noun.

(1) a. *X hat den/die/das Y ausgewählt.*
X has chosen Y.
b. *X hat nicht den/die/das Y ausgewählt.*
X has not chosen Y.

In each target scenario there was only one object of the given type, thus a definite article was used in the sentence. All objects presented in a given trial were of the same grammatical gender to rule out that the noun in the sentence could be predicted based on the article. We ran two experiments: In **Experiment I**, all target sentences referred to one of the **unframed** objects. Thus, negative sentences followed scenarios with green frames, whereas affirmative sentences followed scenarios with red frames. In this way, both the affirmative and negative conditions required the participant to make an inference about the unmarked cards from the information provided visually (i.e. the marked set of cards). In the **unique** conditions, two out of three cards were framed, which left only one possible and therefore unique referent (unframed picture) to be named in the target sentence, whereas in the **multiple** conditions only one card was framed leaving two and hence multiple possible referents (unframed pictures) to be potentially named in the target sentence. In **Experiment II**, all target sentences referred to one of the **framed** cards. Thus, negative sentences followed scenarios with red frames, whereas affirmative sentences followed scenarios with green frames. In this experiment both negative and affirmative target sentences directly described the player's action and did not involve any inferential step. Both experiments used a

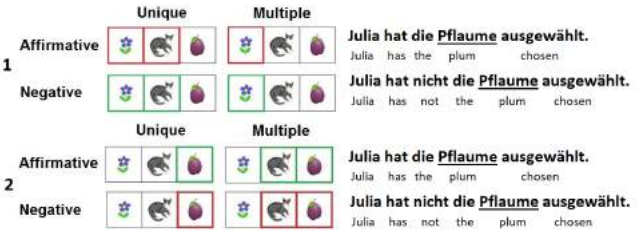

Table 1: Example for the conditions in Experiment 1 (top) and Experiment 2 (bottom)

2x2 design with the factors (i) *Alternatives* (unique/multiple); and (ii) *Polarity* (affirmative/negative), resulting in four conditions as shown in Table 1. [1]

Our main hypothesis was that the N400 recorded for the nouns referring to the target objects should be larger for the *multiple* relative to the *unique* context. This effect was in principle expected both for negative and affirmative sentences; however, we also hypothesized a possible interaction effect between *Polarity* and *Alternatives*, indicating that the processing of negative and affirmative sentences involves non-overlapping processes especially in the context where multiple alternatives are available. Furthermore, based on prior studies (Lüdtke et al., 2008), we hypothesized that the main effect of negation may occur in the late (P600) time-window.

Materials We created a list of 240 German nouns that are depictable and concrete. They were all mono- or bi-syllabic, moderately frequent[2], had a length between three to nine characters and were used in their singular form. The words were combined into 240 unique triples $\langle N_1, N_2, N_3 \rangle$, i.e. each word was used with each other word only once. These triples were used to generate scenarios presenting three different objects, assigned pseudo-randomly to experimental conditions, in such a way that each word was a critical noun only once. This resulted in 60 trials per condition, 240 target trials in total. To balance out the overall truth-value ratio and to make the material more variable we added 240 filler trials: 200 false and 40 true[3], based on a list of 84 new nouns and with affirmative and negative sentences evenly distributed. To rule out the possibility of creating expectations for negative or affirmative sentences based on the color of the frames, the framing of the filler's pictures exploited all possible options cross-balanced, so that affirmative/negative filler sentences followed red or green frames the same number of times.

Procedure Upon arrival participants signed an informed consent of participation. They were given a written instruction including few examples and completed an exercise ses-

[1] The framing was realized as a between-subject factor in order to have a sufficient number of trials per condition (60 in the current design) without inflating the length of the experiment. In addition, false filler sentences were needed to balance the materials (see below).

[2] The logarithmic frequency of all stimuli words was controlled with the use of Leipzig Wortschatz http://wortschatz.uni-leipzig.de/

[3] Overall, 41.6% of the trials in the experiment were false.

sion consisting of eight trials. Feedback was provided for the exercise to make sure that participants understood the task, especially the meaning of the framing and the exhaustive divide of the set of cards. The experiment comprised of eight blocks lasting approximately 10 minutes, with optional breaks in between.[4] The whole experiment lasted approximately 90 minutes. Each trial started with the presentation of three pictures in the center of the screen. The pictures were first shown without any frame. Subsequently, one or two of the objects were framed green or red, followed by the sentence that was displayed phrase-by-phrase on the screen (see Figure 1). The main ERP trigger was the noun referring to (one of) the selected or rejected target object(s). After each sentence, subjects had to respond to a truth-value judgment task by pressing a left- or a right-hand button on a response pad. The buttons were assigned pseudo-randomly by displaying "TRUE" and "FALSE" on the screen sides.

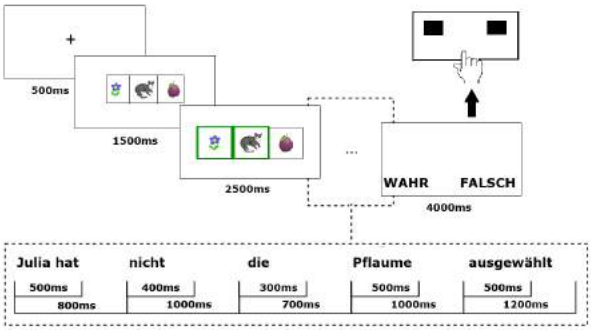

Figure 1: The time course of an example trial with presentation times. The main ERP trigger is the word *Pflaume* (*plum*).

EEG recording and data preprocessing The EEG was recorded with a BrainAmp acticap 64 channel recording system. Electrode position AFz was used as ground and FCz as physical reference. The electro-oculogram (EOG) was measured with four electrodes (PO09, PO10, FT9, FT10), which were reprogrammed and placed above and below the right eye and on both temples. Electrode impedances were kept below 5kΩ. The EEG was recorded with a sampling rate of 500Hz, a 10 sec low cut-off filter and an anti-aliasing hardware filter. The EEG-data was analyzed in the BrainVision Analyzer 2.0 software. We applied a 0.1-30 Hz off-line bandpass filter. All trials with an absolute amplitude difference over $200\mu V/200ms$ or with an activity lower than $0.5\mu V$ in intervals of at least $100ms$ were automatically rejected. The maximal voltage step that was allowed was $50\mu V/200ms$. Eyeblinks were corrected by means of an independent component analysis. The data was re-referenced to the averaged mastoids (TP9, TP10). The baseline-correction was done based on the $200ms$ pre-onset interval of the stimulus. Segments with any remaining physical artifacts (lower than -$90\mu V$ or higher than $90\mu V$) were removed before averaging. At least 50% of segments in each condition were preserved.

[4]For each block a player was introduced. In total, four different players (two female) appeared during one experiment, each assigned to two of the eight blocks.

Statistical analysis of the ERPs following the onset of the critical noun For the analysis of the ERPs we used a repeated measures ANOVA with the factors *Polarity* (negative/affirmative), *Alternatives* (multiple/unique) and *Region* (anterior/posterior).[5] The anterior ROI covered frontal, anterior frontal, frontal parietal, frontal temporal as well as frontal central regions of both hemispheres. The posterior ROI reached across temporal posterior, central posterior, posterior, posterior occipital and occipital regions of both hemispheres. The electrodes from the horizontal midline (central electrodes) were analyzed separately. We analyzed the averaged subjects' ERPs in two time-windows: 250-550 ms post-stimulus onset for the N400 effect and 550-850 ms post-onset for the P600. The assumptions of parametric data (e.g. normal distribution) were met.

Results

Twenty-five volunteers participated in Experiment 1 (nine male; mean age 25.2 ($SD = 4.42$, range $18-33$). In Experiment II we measured twenty-five new (not participating in Experiment I) volunteers (nine male; mean age 23.88 years (SD 3.94), age range 18-33). We excluded one subject per experiment from the analyses due to excessive artifacts in the EEG-data.

Behavioral results. Accuracy was at ceiling level in all conditions, indicating that the task was not too difficult for the subjects (see Table 2). Although minor differences are observed across conditions, due to space limitations, the statistical analysis of the behavioral data is omitted in the paper.

		Unique	Multiple
Experiment I	**Affirmative**	97.22(3.25)	94.17(7.17)
	Negative	95.63(5.83)	95.42(4.12)
Experiment II	**Affirmative**	97.01(2.82)	95.26(5.00)
	Negative	95.34(4.14)	95.27(4.74)

Table 2: Mean accuracy in Experiment I and II, in percentages, and the standard deviation ($\mu(\sigma)$) for all conditions

Polarity independent modulation of the N400 by alternatives. The visual inspection of the grand averages revealed that critical nouns in the multiple conditions elicited clearly larger N400 ERPs than critical nouns in the unique conditions for both sentence polarities and in both experiments. The ANOVA for the time-window **250-550 ms** for **Experiment I**, revealed a main effect of *Alternatives* ($F(1,23) = 30.040$, $p<.001$, $\eta^2 = .566$), with the mean difference between the multiple and unique conditions of $-2.157\mu V$ ($M_{mult} = -.59\mu V$, $M_{unq} = 1.567\mu V$). There was also a main effect of *Polarity* ($F(1,23) = 10.854$, $p = .003$, $\eta^2 = .321$), namely, the negative sentences showed more positive ERPs compared to the affirmative sentences ($\Delta_{Neg,Aff} = .919\mu V$),

[5]The regions were chosen based on the visual inspection of the effect's topography that suggested clear anterior-posterior differences, but no clear lateralization differences. Since we had no specific hypotheses regarding potential lateralization effects, we decided to include only AP as a factor in order to keep the analysis more transparent.

as well as an effect of *Region* ($F(1,23) = 67.535$, $p<.001$, $\eta^2 = .746$, $\Delta_{Post,Front} = 3.411\mu V$). The interaction *Alternatives*×*Region* was significant ($F(1,23) = 11.401$, $p = .003$. $\eta^2 = .331$), which can be attributed to a larger *multiple vs. unique* N400 effect in the posterior ($\Delta_{Mult,Unq} = -2.558\mu V$) relative to the frontal regions ($\Delta_{Mult,Unq} = -1.756\mu V$). Given that the three-way *Polarity*×*Alternatives*×*Region* interaction was also significant ($F(1,23) = 9.712$, $p = .005$, $\eta^2 = .297$), we broke down this interaction by *Region*. For the frontal region, there was a significant effect of *Alternatives* ($F(1,23) = 18.357$, $p < .001$, $\eta^2 = .444$, $\Delta_{Mult,Unq} = -1.756\mu V$), *Polarity* ($F(1,23) = 16.947$, $p < .001$, $\eta^2 = .424$, $\Delta_{Neg,Aff} = 1.232\mu V$) and the *Polarity*×*Alternatives* interaction ($F(1,23) = 5.288$, $p = .031$, $\eta^2 = .187$): The *unique vs. multiple* effect was larger for the affirmative sentences $\Delta_{Mult,Unq} = -2.4\mu V$ than for the negative sentences $\Delta_{Mult,Unq} = -1.112\mu V$. However, for the posterior region only the main effect of *Alternatives* was significant ($F(1,23) = 38.511$, $p < .001$, $\eta^2 = .626$, $\Delta_{Mult,Unq} = -2.557\mu V$). For the midline electrodes the effects were similar, i.e. there was a significant effect of *Alternatives* ($F(1,23) = 33.788$, $p < .001$, $\eta^2 = .595$, $\Delta_{Mult,Unq} = -2.473\mu V$), as well as of *Polarity* ($F(1,23) = 8.58$, $p = .008$, $\eta^2 = .272$, $\Delta_{Neg,Aff} = .943\mu V$), but no interaction.

The results of **Experiment II** were in line with the first experiment. There was a main effect of *Alternatives* ($F(1,23) = 21.045$, $p<.001$, $\eta^2 = .478$), i.e. the multiple conditions showed larger negativity than the unique conditions ($\Delta_{Mult,Unq} = -.972\mu V$), as well as *Region* ($F(1,23) = 36.042$, $p<.001$, $\eta^2 = .610$, $\Delta_{Post,Front} = 3.109\mu V$). No main effect of *Polarity* was observed. Unlike in the first experiment, there were no significant interactions. For the midline electrodes only a main effect of *Alternatives* was found ($F(1,23) = 24.920$, $p < .001$, $\eta^2 = .520$, $\Delta_{Mult,Unq} = -1.160\mu V$).

Alternatives independent Late Positivity for negated sentences. The visual inspection of grand averages revealed a late positivity effect for the negative relative to affirmative conditions, that was apparent for both alternatives conditions and both experiments. The analysis in the late time-window **550-850 ms** for **Experiment I** revealed a main effect of *Polarity* ($F(1,23) = 25.714$, $p<.001$, $\eta^2 = .528$), driven by the negative sentences showing more positive average amplitudes than affirmative sentences ($\Delta_{Neg,Aff} = 1.177\mu V$), as well as a main effect of *Region* ($F(1,23) = 108.986$, $p<.001$, $\eta^2 = .826$, $\Delta_{Post,Front} = 2.58\mu V$). No effect of *Alternatives* was observed; however, there was a significant *Alternatives*×*Region* interaction ($F(1,23) = 19.308$, $p < .001$, $\eta^2 = .456$): The mean amplitude difference between multiple and unique conditions was more negative in the frontal ($\Delta_{Mult,Unq} = -1.028\mu V$) than in the posterior region ($\Delta_{Mult,Unq} = .172\mu V$). There was also a significant three-way interaction *Polarity*×*Alternatives*×*Region* ($F(1,23) = 9.430$, $p = .005$, $\eta^2 = .291$), which we broke down by *Region*. In the frontal region, we found a significant effect of *Polarity* ($F(1,23) = 16.387$, $p < .001$, $\eta^2 = .416$, $\Delta_{Neg,Aff} = 1.192\mu V$), *Alternatives* ($F(1,23) = 11.088$, $p = .003$, $\eta^2 = .325$, $\Delta_{Mult,Unq} = -1.028\mu V$), as well as significant *Polarity*×*Alternatives* interaction ($F(1,23) = 6.867$, $p = .015$, $\eta^2 = .230$): the mean amplitude difference between the negative and affirmative sentences was larger for the multiple ($\Delta_{Neg,Aff} = 1.894\mu V$) than for the unique ($\Delta_{Neg,Aff} = 0.49\mu V$) condition. In the posterior region only the effect of *Polarity* was significant ($F(1,23) = 23.064$, $p < .001$, $\eta^2 = .501$, $\Delta_{Neg,Aff} = 1.161\mu V$). For the midline electrodes, we found an effect of *Polarity* ($F(1,23) = 29.341$, $p < .001$, $\eta^2 = .561$, $\Delta_{Neg,Aff} = 1.32\mu V$), but no effect of *Alternatives*, and no *Polarity*×*Alternatives* interaction.

The results for **Experiment II** were again generally consistent with **Experiment I**. There was a main effect of *Polarity* ($F(1,23) = 15.269, p = .001$, $\eta^2 = .399$) driven by the negative sentences showing more positive ERPs than the affirmative sentences ($\Delta_{Neg,Aff} = .883\mu V$), and a main effect of *Region* ($F(1,23) = 45.121$, $p<.001$, $\eta^2 = .662$, $\Delta_{Post,Front} = 2.234\mu V$), but there was no main effect of *Alternatives*. The interaction *Polarity*×*Region* was significant ($F(1,23) = 9.915$, $p = .004$, $\eta^2 = .301$): The difference between negative and affirmative conditions was larger in the posterior ($\Delta_{Neg,Aff} = 1.373\mu V$) than in the frontal regions ($\Delta_{Post,Front} = .393\mu V$). Additionally, and similar to the first experiment, the interaction *Alternatives*×*Region* was significant ($F(1,23) = 10.739$, $p = .003$, $\eta^2 = .318$, frontal $\Delta_{Mult,Unq} = -.214\mu V$ and posterior $\Delta_{Mult,Unq} = .688\mu V$). The interaction *Polarity*×*Alternatives* was not significant and neither was the three-way interaction. For the midline electrodes, again we only found an effect of *Polarity* ($F(1,23) = 17.516$, $p < .001$, $\eta^2 = .432$, $\Delta_{Neg,Aff} = 1.066\mu V$).

Comparison across experiments. Although both experiments showed similar main effects, some differences between the two framing variants were observed, in particular, some interactions showed significant in one experiment and not in the other. As the experiments were otherwise identical, as a meta-analysis we conducted a full-factorial ANOVA with *Polarity*, *Alternatives* and *Region* as within-subject factors and *Experiment* as a between-subject factor.

This analysis in the early time window **250-550 ms**, showed no main effect of *Experiment*; however, the interaction *Alternatives* × *Experiment* was significant ($F(1,46) = 7.029$, $p = .011$, $\eta^2 = .133$): the multiple vs. unique N400 effect was larger in Experiment I than in Experiment II. There was also a significant *Polarity* × *Region* × *Experiment* interaction ($F(1,46) = 5.311$, $p = .026$, $\eta^2 = .104$).[6] For the midline electrodes there was again no effect of *Experiment*, but the *Alternatives*×*Experiment* interaction was significant ($F(1,46) = 7.338$, $p = .009$, $\eta^2 = .138$).

No main effect of Experiment was found for the time-window of **550-850 ms**, but the interaction between *Alternatives* and *Experiment* was significant both in the main analysis

[6] See the experiment-specific analyses reported above for the relevant mean differences.

($F(1,46) = 4.808$, $p = .033$, $\eta^2 = .095$, $\Delta_{Mult,Unq} = -.428\mu V$ in Experiment 1, and $\Delta_{Mult,Unq} = .237\mu V$ in Experiment 2), as well as for the midline electrodes ($F(1,23) = 4.603$, $p = 0.037$, $\eta^2 = .091$, $\Delta_{Mult,Unq} = -.443\mu V$ in Experiment 1 and $\Delta_{Mult,Unq} = .305\mu V$ in Experiment 2).

Discussion

In two experiments we compared the processing of affirmative and negative sentences in two contexts: (i) a unique context, that allows to make a specific prediction of the critical noun to be mentioned in a true sentence, (ii) a multiple context, where two alternatives can potentially be mentioned in a true sentence. In our design the affirmative and negative conditions were fully comparable: In both cases, sentence verification either required inferring the status of the unframed cards from the status of the marked set of cards (Experiment 1), or no inference was involved, since the sentence directly referred to the marked cards (Experiment 2).

It is generally accepted that the N400 reflects meaning-related expectancy of the stimulus. What this means precisely remains debated and the theories vary between taking the N400 to be a marker of lexical retrieval, lexical predictive preactivation or even meaning-related probabilistic prediction. We hypothesized that the presence of multiple alternatives, where the processor cannot uniquely predict the referent, should lead to a higher N400 relative to the case of a unique referent. This hypothesis was supported, as we observed a larger N400 effect for multiple vs. unique conditions independent of the sentence polarity. Although it is well-established that the N400 is correlated with expectancy and cloze probability, no prior experiments focused directly on the relation between the N400 and the availability of equally predictable alternatives in the scenario. Furthermore, our study is the first that directly compares how the scenario-based cloze probability of the upcoming word affects the processing of that word in affirmative and negative sentences. As the main result we show that the effect of alternatives is similar for both sentence polarities, thus, the possibility of predicting a unique true sentence continuation facilitates the processing also under the scope of negation.

In addition we also showed that, for both alternatives conditions, the presence of the negative particle led to a late positivity effect at the sentence critical noun occurring after the negation, i.e. when the noun's expectancy was related to the prior use of negation in the sentence. This effect forms a clear and large P600 effect in both experiments, although in the first experiment some modulation is already observed in the early time-window. Under the assumption that the P600 amplitude reflects integration of the lexical information into the semantic representation of the sentence (see Brouwer & Hoeks, 2013), this effect may be taken to indicate that in the case of negative sentences the construction of the semantic representation was more effortful.

Although the main pattern of effects was the same in both experiments, the type of framing made a significant contribution to the size of the effects, namely, the N400 effect for multiple vs. unique alternatives turned out to be significantly larger in Experiment 1 than in Experiment 2, as shown by the *Alternatives*Experiment* interaction. Furthermore, only in Experiment I we observe an interaction between *Polarity* and *Alternatives* by *Region* in both time-windows, specifically, in the posterior region the effect of alternatives was similar for both sentence polarities, but in the frontal region it was larger for affirmative sentences. This interaction result indicates that, in Experiment 1, affirmative and negative sentences possibly engaged slightly different processes in the

two alternatives conditions. These between-experiment differences may be explained in terms of different task demands. Although from a logical perspective the two tasks were equivalent, cognitively they differ in an important manner. In Experiment 1, all target sentences referred to the unframed objects, whose status (chosen vs. unchosen) could only be inferentially determined based on the status of the framed objects and the assumed exhaustivity of the set divide. Thus, to determine the status of the unframed objects one had to include the so-called closed world assumption, which basically means that what is not known to be true is false. Given this assumption, in the negative condition, one could infer that if A was chosen (framed green), then B & C were not (or if A & B were chosen, then C was not). Similarly, in the affirmative condition, one could infer that if A was not chosen (framed red), then B & C were chosen (or if A & B were not chosen, hence C was). This inferential process is slightly different in the two conditions as it either goes from a negative premise to a positive conclusion, or the other way round. In contrast, in Experiment 2, all target sentences mentioned the framed, highlighted objects and hence there was no need to reason about the status of the remaining cards.

In sum, we showed that if the scenario allows to uniquely predict the upcoming word in a true sentence continuation, the processing of that word is significantly facilitated both in the case of affirmative and negative sentences, which is observed in the form of a reduced N400 component for the uniquely predicted words. The (higher) cognitive cost of processing the negative particle is observed in the form of a late positivity effect. Finally, the task demands, i.e. whether the status of the referent is directly marked or has to be inferentially determined, make a significant contribution to the size of the effects and appear to differently affect the negative and affirmative sentences. Further research should explore how the N400 is modulated by a larger number of alternatives provided and how the effect depends on the sentence truth-value.

Evidence for effort prediction in perceptual decisions

Nisheeth Srivastava

Abstract

The classic drift diffusion model of the 2AFC choice process assumes that observers select evidence accumulation thresholds to optimize some desired level of accuracy across the experiment. We argue that it is more ecologically natural to assume that decision-makers set this threshold adaptively, using information from recent trials to adjust it for upcoming ones. To test this hypothesis, we designed and conducted a pair of random dot motion discrimination experiment where the coherence parameter that controls task difficulty varies across trials in a predictable manner. To analyze data from these experiments, we also designed a hierarchical drift diffusion model that allows decision-makers to adapt their evidence threshold based on the trend of difficulty of previous trials. Our results suggest that observers rationally integrate cross-trial information about trial difficulty into perceptual decision-making by adjusting their internal evidence thresholds. We briefly discuss the implications of the existence of such trial-level effort inference on contemporary models of the choice process.

Keywords: drift diffusion model; ideal observer model; Bayesian modelling; cognitive effort; rational inference

Introduction

The drift diffusion model (DDM) is a very successful sequential sampling model of the choice process (Ratcliff & McKoon, 2008). Particularly when applied to perceptual decision-making tasks, where the stream of evidence is transparent to the experimenter, this model has shown excellent fits to choice and response time data from a wide variety of experimental paradigms, even generalizing across organisms (Brunton, Botvinick, & Brody, 2013). While it shares several components, including parallel accumulation and race-to-a-threshold with other competing paradigms such as leaky competing accumulation (Usher & McClelland, 2001) and decision field theory (Busemeyer & Townsend, 1993), its stochastic specification of important components of the choice process - rate of accumulation of evidence, response bias, and variability in the evidence accumulation rate - gives it excellent flexibility and interpretability in modelling the summary statistics seen in perceptual decision-making experiments.

While on the one hand, its mathematical construction makes the DDM an excellent *descriptive* model of the choice process, it simultaneously makes it challenging to associate its optimality criterion with the goals and costs faced by real decision-makers. Specifically, the drift diffusion model is known to implement the sequential probability ratio test (SPRT) (Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006), which is statistically optimal in the sense that for any choice of the decision threshold, using the DDM criterion for choice will yield the highest possible accuracy (Wald & Wolfowitz, 1948).

The relationship between the SPRT and DDM imbues it with a normative sense of optimality - observers are being statistically optimal in the SPRT-sense if we show that the DDM model fits their behavior well. But the underlying assumptions of SPRT - perfect evidence integration, approximately linear evidence accumulation rates, race to a fixed evidence threshold - are not good fits for the information and processing limitations that organisms face in real-world decision-making scenarios. In recent years, objections to these premises have been raised on both computational and empirical grounds. Deneve has documented how the conventional drift diffusion paradigm fails to accommodate situations where sensory inputs are unreliable (Deneve, 2012). Thura and colleagues have shown how reaction time distributions in perceptual decision-making tasks may be better described by evidence accumulation terminated by breaching a time-collapsing threshold responsive to an increasing 'urgency' signal than classic accumulation to a fixed threshold (Thura, Beauregard-Racine, Fradet, & Cisek, 2012). Glaze et al have demonstrated how perfect evidence integration - a fundamental assumption of drift diffusion models - is sub-optimal in the face of unsignalled context shifts in the decision-making environment (Glaze, Kable, & Gold, 2015). Thus, using DDM as a normative baseline, research is increasingly focusing on identifying aspects of the environment that constrain real-world decision-making.

Threshold adaptation as effort inference

We propose to revise the premise that decision-makers accumulate evidence up to a fixed threshold. Whereas such proposals have been made previously (Thura et al., 2012), they have focused on incorporating the opportunity cost of continued sampling in the form of a threshold that decreases over time (Drugowitsch, Moreno-Bote, Churchland, Shadlen, & Pouget, 2012). We focus on a different aspect of the threshold determination process - that decision-makers are likely to use information from previous trials to set decision thresholds for upcoming trials. Here again, it is well-documented that patterns of responding can introduce response biases in experiments (Ratcliff & McKoon, 2008). The drift diffusion model allows such biases to be modeled explicitly using changes in diffusion start-point parameters.

We consider a different normative possibility: we propose to model the threshold parameter used in drift diffusion modeling as a proxy for the amount of effort the observer believes is necessary for adequate performance, and we intend to investigate whether human observers can infers the effort needed for upcoming trials using effort observations in recent trials. Grounding this hypothesis in a perceptual decision-

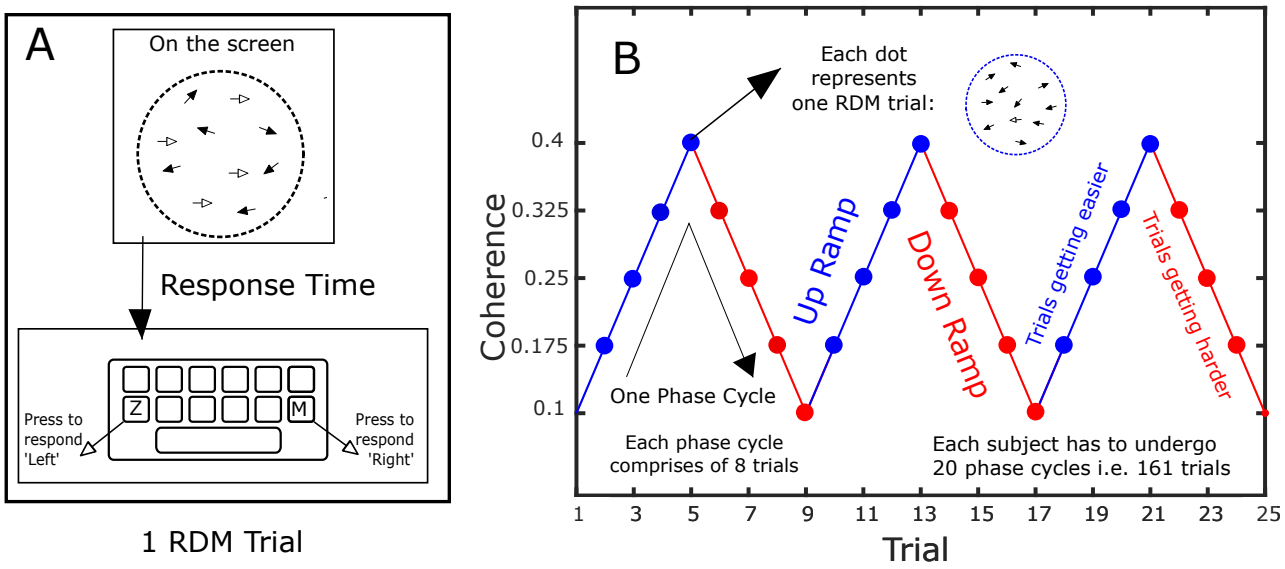

Figure 1: Schematic illustrating the experiment design. (A) On each experiment trial, participants saw a set of dots in Brownian motion, with a horizontal drift added to some fraction of the dots. Participants had to discriminate motion direction using key presses on a computer keyboard, and were incentivized to emphasize accuracy. (B) The sequence of trials each participant saw possessed a higher-order structure, with the difficulty of successive trials increasing and decreasing in a cyclic manner.

making task, we model behavior on this task using a hierarchical ideal Bayesian observer that performs 2AFC random dot motion (RDM) discrimination. The lower level of this hierarchical model simulates individual RDM trials using a classic drift diffusion setup. The higher level of this model uses a reinforcement learning-inspired controller to set appropriate values of the evidence threshold for each trial.

To test this hypothesis, we designed a specific variation of the standard RDM task. In the standard task, trial difficulty is either blocked or randomized across trials. We instead designed a sequence of trial presentation that introduced a predictable trend in the coherence parameter across trials. If people are adaptively tracking the amount of effort they are having to expend on individual trials, we expect such inference to inform their effort allocation on upcoming trials. A hierarchical extension of the drift diffusion model, with a top-down controller setting the evidence threshold adaptively across trials, would potentially fit choice and RT data gathered from such an experiment design better than a simple DDM that assumes a fixed evidence threshold.

Experiment 1

RDM with higher-order structure

Participants saw a screen with moving dots designed according to the following algorithm. Random motion of the dots was provided by allowing Brownian motion in the vertical direction, i.e. all the dots drifted vertically about their mean position by a distance chosen from a normal distribution. Horizontal motion was either randomly selected from a bidirectional (left/right) uniform distribution (for incoherent dots) or from a unidirectional uniform distribution (for coherent dots). The selection of dots as coherent or incoherent was determined at the beginning of each experimental trial using Bernoulli trials controlled by the coherence parameter c.

As in all RDM discrimination experiments, the critical manipulation of task difficulty was governed entirely by the coherence parameter c. We selected a range of values of the coherence parameter by running a calibration pilot with 5 participants, performing 280 trials of the discrimination task under accuracy emphasis. We picked a range of coherence values that permitted 65% accuracy at the low end of the range and 95% accuracy at the high end of the range.

Participants had to indicate the direction of motion of the overall dot pattern on each trial, as illustrated in Figure 1A. They were allowed to take as much time as they wanted to respond to each trial, and as much time as they wanted to rest between the trials. Each correct response fetched points. The scoring system was such that a correct response fetches 10 points; the score of each correct response doubled on responding correctly to three successive trials, and reset to 10 points in case the streak was broken. We further encouraged accuracy emphasis by promising a reward to the highest scorer.

The specific higher-order structure introduced in our experiment was a cyclic shift across the 5 specific values of the coherence parameter used in the experiment $\{0.1, 0.175, 0.25, 0.325, 0.4\}$. For example, a participant starting the experiment with a trial with coherence 0.1 would next see a trial with coherence 0.175, then one with 0.25, up to the maximum coherence level of 0.4, beyond which the coherence would begin dropping down to 0.325, then to 0.25 etc. Each such phase cycle from one coherence value through the other 4 and back to the original takes 8 trials, given we use 5 unique coherence values. Participants completed 20 such phase cy-

cles for a total of 161 trials per participant, as illustrated in Figure 1B.

Task

The task was administered via a web-based interface. Participants indicated responses with keyboard button presses, and were allowed to take as long as they liked before pressing the space bar to begin the next trial. Distance from the screen was not fixed, but the display size was selected such that the display was well within the foveal range (20 degrees visual angle) of normally sighted observers.

Participants

52 undergraduate and postgraduate students participated in the experiment for course credit (4 female, mean age 20.5 ± 1.57 SD). All participants had normal or normal-corrected vision. Since the experiment was conducted without personal supervision, some participants showed significant guessing behavior. Post-task, we excluded the data for 18 participants who had less than 85% accuracy on the highest coherence trials.

Results

We expected that an observer tracking the cross-trial variations in difficulty would end up tracking the repeated ramp-like movement of the coherence parameter, and take longer on an upcoming trial if the cross-trial coherence was trending downward (i.e. the trials were becoming more difficult) than if it was trending upward (i.e. the trials were becoming easier).

However, even observers insensitive to cross trial information are expected to show the same pattern globally in our data, because upcoming trials aren't just expected to be easier/harder on up/down ramps, they actually are easier/harder too. Therefore, the critical test for whether information from previous trials are affecting the current trial is to see whether trials of the same difficulty (coherence) level have longer RTs when they occur within a down coherence ramp (sequence of decreasing coherence, increasing trial difficulty) than when they occur within an up coherence ramp (sequence of increasing coherence, decreasing trial difficulty).

In Figure 2, we plot RTs stratified by coherence level of the immediate trial for the three intermediate coherence values in our experiment across all participants, separating out trials occurring during up and down ramps. For each of the three coherence levels, the difference between down ramp RTs and up ramp RTs is directionally in the predicted direction. While the data is noisy, the large sample size of our experiment (34 participants $\times$ 20 cycles = 680 data points per coherence level per ramp) allows us to assert statistical significance at Bonferroni-corrected $p < 0.01$ for two of the levels (0.175 and 0.325) in two-sample t-tests. The third comparison (for coherence level 0.25) does not yield a statistically significant difference in such a test.

These summative statistical results, while conceptually congruent with our hypothesis, are inadequate to draw strong inferences. The large standard deviations evident in Figure 2 reflect considerable inter-participant heterogeneity in response times. We therefore sought to test our hypothesis at a trial-by-trial level by developing a generative model of the information accumulation process involved in a 2AFC perceptual learning task that accommodates such adaptive control over the evidence threshold, and comparing its ability to explain our data vis-a-vis a fixed threshold evidence accumulation model.

A hierarchical drift diffusion model

The DDM, in its standard form is a Wiener diffusion process with drift,

$$dy = vdt + sdW, \tag{1}$$

where y is the diffusion state, v is the drift, s determines the amount of diffusion and dW represents the standard Wiener process. The model accumulates normally distributed pieces of evidence for either alternative until a bound on the cumulative evidence is crossed, and then emits the winning option as the choice.

We developed a hierarchical model of the choice process using a recently proposed Bayesian version of the DDM (Bitzer, Park, Blankenburg, & Kiebel, 2014). This takes the form of a sequential Bayesian update model that maps noisy stimuli observations to latent Gaussian representations

$$x_t \sim N(\mu_i, \sigma^2), \tag{2}$$

constructs a generative model of the likelihood of seeing certain latent feature values for each stimulus alternative,

$$p(x_t|A_i) = N(\hat{\mu}, \hat{\sigma}^2), \tag{3}$$

and updates beliefs about the correctness of a decision alternative given these noisy observations

$$p(A_i|X_{1:t}) = \frac{p(x_t|A_i)p(A_i|X_{1_t-1})}{\sum_{j=1}^{M} p(x_t|A_i)p(A_j|X_{1_t-1})}, \tag{4}$$

where x_t are noisy observations from stimuli belonging to category i, with true prototypical values μ_i and measurement noise σ, estimated prototypical values $\hat{\mu}$ and internal generative variability $\hat{\sigma}$, A_i as possible alternatives and M as the number of considered alternatives. Bitzer et al show that this intuitive ideal observer model is formally identical to the drift diffusion model given certain assumptions about the relationship between parameters of the model.

We augmented this model with a metalearner that estimates the expected sampling effort needed for upcoming trials based on effort allocation on previous trials. We assume a very simple model for this metalearner. It simply updates the effort estimate λ as

$$\lambda_t = \lambda_{t-1} + \gamma\Delta_t, \tag{5}$$

where

$$\Delta_t = z(RT_{t-1}) - z(RT_{t-2}), \tag{6}$$

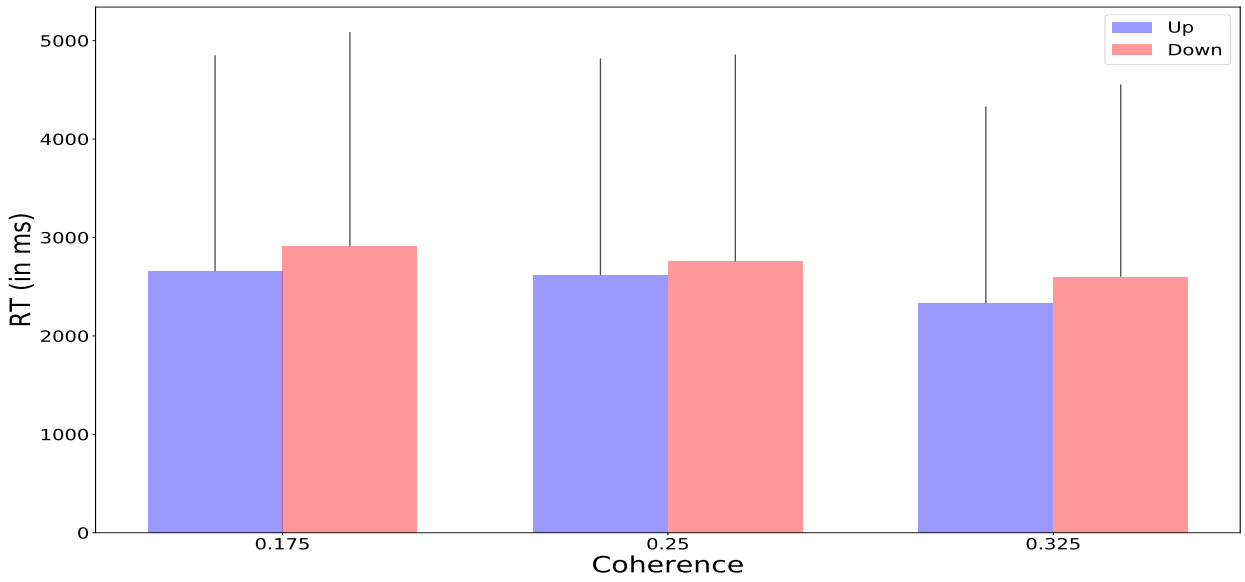

Figure 2: RT at intermediate coherence levels while the cyclic higher-order coherence trend is going up (blue bars) and down (red bars). Higher RTs seen for trials of equal difficulty, when coherence is trending downwards, i.e. trials are getting harder, is evidence for adaptive changes in the evidence threshold responsive to past trials. Error bars represent 1 S.D.

γ is a free scaling parameter, $z(RT)$ is the normalized z-score of RT at time t with respect to the RT distribution and λ_t serves as the threshold for the DDM for the t^{th} trial. This model is not meant to be comprehensive. We have designed it purely to simulate our expectation of the role of predictable up and down changes in dot motion coherence on observer behavior. We expect that observers will be sensitized to these trends and extrapolate from them to set decision thresholds for upcoming trials. Increasing effort on recent trials should yield a larger threshold for the upcoming trial and vice versa. Normalization is used to induce a natural scale on the size of the change in the threshold; the RT distribution is admittedly non-Gaussian so this assumption could be further refined in future work. Also, to avoid over-fitting, we have used the global RT distribution to normalize the RTs, whereas a more realistic model may use sequential summary statistics within participants. Indeed, a filtering-based model might capture the basic intuition of the metalearner more elegantly, but we wished to compare the augmented model with a complicated baseline using only choice and RT data, necessitating parsimony in parameter extension. The version of the meta-learner we have proposed has just one additional free parameter beyond the baseline.

As in (Bitzer et al., 2014), we reduced the set of estimated parameters of the Bayesian model from seven to three by assuming equal amount of drift for both stimuli. In practice we did this by setting $\mu = \hat{\mu} = \pm 1$ for the 2AFC case. Parameter fitting for the 3 parameters to be estimated $\theta = \{\sigma, \hat{\sigma}, t_{nd}\}$ also followed the procedure outlined in (Bitzer et al., 2014). We defined the log likelihood of the data given all parameters as

$$\begin{aligned}\log p(\text{Acc}, \text{RT}|\theta) &= \log p(\text{Acc}|\theta) + \log p(RT|\theta) \\ &\propto -w_{\text{acc}}\ (\text{Acc} - \text{Acc}(\theta))^2 \\ &- \sum_{e=0}^{1}\sum_{i=1}^{7} w_{q_{e,i}}\ (q_{e,i} - q_{e,i}(\theta)^2,\end{aligned}$$

where $q_{e,i}$ is the i^{th} of seven quantiles $(0.02, 0.05, 0.1, 0.3, 0.5, 0.7, 0.9)$ for either correct or error responses as indicated by e.

To evaluate the log likelihood function, again following the procedure in (Bitzer et al., 2014), we simulated our experiment with the Bayesian observer model for different parameter values, averaging the accuracy and RT quantiles obtained across 30 model runs per parameter tuple θ and setting the likelihood weights w to the inverse variance over these repetitions. We scaled each iteration in our simulation to 125 ms. However, we found the MCMC approach advised in (Bitzer et al., 2014) to be too slow (on the order of days) for fitting our hierarchical model that used different threshold values for each trial. Therefore, we used a two-stage grid-search of the parameter space (logarithmic exploration in one stage followed by linear refinement in the second) to optimize the negative log likelihood. In practice, we found that the grid search yields comparable mean parameter values for the baseline DDM model as the MCMC procedure implemented in (Bitzer et al., 2014).

Since we don't use MCMC to obtain a posterior distribution over the parameters, it is useful to average over multiple runs of the likelihood computation at the optimal parameter values to obtain representative likelihood values. After

Block	1	2	3	4
Δ BIC	12.4	-3.0	-0.07	-0.78

Table 2: Model comparison across four sequential blocks of 40 trials each from all participants. Block 1 contains the first 40 trials from each participant, etc.

finding optimal parameters via grid search for both models, we calculate model likelihood as the average likelihood obtained from 20 runs of the model for the optimal parameter values. The results from our model comparison using these average likelihood values are presented in Table 1. ΔBIC measures difference between baseline DDM and hierarchical DDM BIC. Positive values support the hierarchical DDM, negative values support the baseline model. ΔBIC values with magnitudes smaller than 2 imply insignificant differences between models; values larger than 10 constitute very strong support for a model. Using this measure, the hierarchical DDM is clearly preferable to the simple DDM, across data from all 34 participants (ΔBIC $= 7.8$ from Table 1).

We additionally ran a block-wise analysis, dividing each participant's trials into 4 sequential blocks of 40 trials and calculating model complexity statistics on the likelihoods emitted by the model for the best fitting parameter values of the overall model ($\sigma = 11, \hat{\sigma} = 8, t_{nd} = 250ms$). We anticipated that any evidence of gradual adoption or relinquishment of threshold metareasoning would show up in the relative model complexity tracked across these four blocks.

As the results in Table 2 show, the hierarchical model is heavily preferred over the simpler model during the first quarter of trials, measured across all participants. For later trials, both models are evenly matched, with the simpler model slightly preferred.

Experiment 2

The block-wise analysis of our data revealed an interesting property: participants behaved as if they were tracking higher-order structure at the beginning of the experiment, but appeared to switch away to behaving more like conventional DDM decision-makers later on. We thought this was because participants tried to use the higher-order structure between trials, but then shifted away from it, since doing so does not offer any material advantage. To falsify such an explanation, we conducted a followup experiment where tracking the higher-order structure would confer a material advantage.

RDM with helpful higher-order structure

This experiment design was equivalent to the first one, with an alteration only in score-keeping. Recall that the first experiment used scoring with a multiplicative boost for maintaining accuracy streaks. Score per correct response would double for every three consecutive correct responses, and reset to the default value on each error.

For this second experiment, we transformed the incentive system into an optional 'auto boost' mechanism, such that accurately responding on three consecutive trials would fill up a booster bar, and optionally selecting the booster bar would allow a participant to *buy* out any one trial of their choice. The bought out trial would be assumed to have been answered correctly, would not be displayed on screen, and would not count towards win streak counts.

Participants

31 undergraduate students (age = 20.6 ± 1.3 years, 8F) volunteered to participate in this experiment; none having participated in the first one. These participants performed the experiment under supervision using the same web-based interface as before. All other experimental protocols were identical to the first experiment. Post-task, we excluded the data for 5 participants who had less than 85% accuracy on the highest coherence trials.

Results

The primary difference between the two experimental tasks was that tracking higher-order structure could not help participants in the first one, but potentially could in the second one. Specifically, in this second experiment participants could hold on to filled up booster bars for what they *predicted* to be the hardest trials, considerably reducing their overall error and effort.

Block	1	2	3	4
Δ BIC	9.7	8.4	8.9	3.2

Table 3: Model comparison across four sequential blocks of 40 trials each (counting bought out trials) from all participants for Experiment 2. Block 1 contains the first 40 trials from each participant, etc.

A direct measure of whether participants did deploy such a strategy in this task is the relative distribution of trials on which participants used boosts across coherence levels. Random use of boosts would indicate no use of the optimal strategy outlined above, whereas exclusive concentration of boost use in the lowest coherence level would indicate perfect adherence to this strategy.

Empirically, we found that 45.5% of all boosts were used for the lowest coherence trials (chance 12.5%, $p < 0.005$), and 78.6% of all boosts were concentrated within the two lowest coherence levels (chance 37.5%), suggesting strong utilization of the optimal strategy.

As a secondary measure of strategy adherence, we fit both classic and hierarchical DDM to these participants' data following the same methodology as for the first experiment. Boosted trials were assigned correct responses and subject-specific mean RT for the corresponding coherence level during the simulations. For lack of space, we only present the difference in BIC values betwe en hierarchical and classic DDM fits for this data. Contrasting these ΔBIC results tabulated in Table 3 with those from the original experiment (see Table 2) strongly suggest that the manipulation of the incentive system does affect participants' behavior on the task in the predicted direction.

Discussion

With increases in computational power and experimental methods, behavioral researchers are increasingly able to track behavior with greater granularity, which makes hypotheses about intermediate computations underlying behavior tractable to investigation. This development is making the study of algorithmic aspects of the decision-making process increasingly more feasible. Not only does such research characterize biological observers' decision-making *processes*, it also provides constraints on the nature of the cost functions that computational theorists can reasonably set up for decision-making agents.

As part of this paradigm shift, recent work has begun to question the classic drift diffusion model's assumption of a fixed evidence threshold in recent years, basing these arguments on the temporal opportunity costs of continued sampling (Thura et al., 2012). In this work, we asked the same question from a different standpoint. We asked whether observers might be sensitive to higher-order statistics in decision-making tasks and adaptively adjust evidence thresholds on upcoming trials to use them efficiently.

To see if this can happen, we created a novel variation of the classic random dot motion discrimination task, introducing an up-and-down ramp in difficulty across trials (Gold & Shadlen, 2000). We predicted that observers would be sensitive to this variation. We designed an extension of the drift diffusion model that incorporates metacognitive adaptation of the evidence threshold based on the trend of difficulty of recent trials, and found that it offers a better explanation of participants' behavior in our experiment than a simple drift diffusion model. A followup experiment further demonstrated that participants' tracking of higher-order structure in this task was intentional - they shifted away from tracking when it offered no advantage and continued tracking when it did.

Our results support a shift in interpretation of the evidence threshold from its SPRT-driven association with *accuracy*, towards a more general view of it as an effort parameter influenced by a variety of information sources. Such an interpretation also makes it easier to generate normative accounts of decisions from memory using DDM-like models, building upon its descriptive success in modeling retrieval success and RT distributions in this domain (Krajbich & Rangel, 2011). Unlike in perceptual decisions where the evidence presentation rates are fixed, and decisions receive immediate feedback, decisions from memory are made with evidence streams of unknown provenance and without feedback. The empirical success of DDM in explaining data from such experiments warrants a broader interpretation of the normative principles of the framework, along lines proposed in this work.

Decision-makers minimize regret when calculating regret is easy

Nisheeth Srivastava
Department of Computer Science, IIT Kanpur
India

Abstract

This paper provides empirical evidence that human decision-makers use prospective regret minimization as their dominant decision strategy when regret calculations are cognitively easier to perform, and use expected utility maximization when they aren't. We designed a simple decision problem wherein utility maximization and expected regret minimization yield distinctly difference choices, and manipulated the cognitive effort involved in making regret calculations across respondent samples to arrive at our results. While previous research has associated ecological considerations like sense of responsibility and familiarity with this difference, we show that, at least in experimental settings, cognitive calculability in regret space appears to predominantly drive this difference. We also show that this preference for regret minimization can be countermanded by changing the distribution of options presented to the respondent, posing a challenge to simple sequential accounts of strategy selection learning which sequence strategy selection and application in order.

Keywords: decision-making; cognitive heuristics; cognitive effort; regret minimization; utility maximization

Introduction

Regret is an important variable in humans' decision-making. Empirical investigations spanning psychology (Zeelenberg 1999; Connolly & Reb, 2005), neuroscience (Coricelli et al., 2005) and economics (Loomes & Sugden, 1982; Sarver, 2008) have demonstrated that in several decision contexts, humans behave as if they are trying to minimize *prospective* regret, rather than minimize *prospective* expected utility.

This distinction is of great significance for choice models that wish to track consequential human decisions. For instance, Chorus and colleagues have published a series of papers showing that a discrete choice model designed assuming regret minimization as the underlying choice strategy outperforms conventional random utility models (RUM) style discrete choice models in predicting future travel demand (Thiene, Boeri & Chorus, 2012).

At the same time, conventional RUM models, assuming implicit utility maximization have proved their value in modeling human choices in a large array of applications (Small & Rosen, 1981), suggesting that utility maximization is a useful approximation for peoples' intentions in such situations. Consequently, it is important to attempt to characterize situations wherein decision-makers are likely to prefer either of these decision-making strategies. Zeelenberg & Pieters (2007) have suggested, on theoretical grounds, that regret-minimization is more likely to be used:

(a) when choices are perceived to be important and difficult,

(b) when the decision-maker expects to be held accountable for their choice and

(c) when the decision-maker anticipates receiving feedback about options in the near future.

There is also some empirical evidence supporting the basic premise that domain unfamiliarity may drive the use of regret minimization strategies, a mechanism that is substantially congruent with the theoretical factors identified by Zeelenberg & Pieters (2007). Boeri, Scarpa & Chorus (2014) have showed using discrete choice modeling on a transport choice dataset that the behavior of respondents unfamiliar with the choice context was better explained by regret minimizing models.

A common thread between such theoretical and empirical observations is the notion that regret is explicitly *calculated* by the respondent (Zeelenberg & Pieters, 2007). It is because of this commitment to explicit psychological calculation that the role of prospective feedback and accountability etc. become important in predicting the use of regret minimization as a strategy. Since regret is arrived at via comparison with alternative outcomes, no possibility of feedback would imply no possibility of experiencing regret, which could shift respondents' behaviors towards other strategies.

This commitment to explicit psychological calculation differentiates regret from utility, for which no such commitments are necessary. It is common to observer proposals suggesting direct reward encoding in human observers' brains (Padoa-Schioppa & Assad, 2006). At a minimum, the idea that utilities may be constructed is not yet consensual in the corresponding literature at the interface between psychology and economics (Slovic, 1995; Srivastava & Schrater, 2015).

The centrality of explicit calculation for regret is the focus of the work we report in this paper, wherein we sought to characterize the effect of cognitive ease of calculation of regret on decision-makers' meta-decision to use it as a choice strategy. Our hypothesis was that observers would switch away from use of a regret minimization strategy as the cognitive costs of calculating regret increased. To test this hypothesis, we designed a simple choice task wherein expected regret minimization and expected utility maximization yield clearly divergent choice behaviors, and manipulated the choice stimuli to make explicit comparison of items in regret space easier or harder.

We obtained empirical results substantially supporting our hypothesis. Specifically, we found that participants preferred regret minimizing choices when the choice set was a set of monetary labels, but preferred utility maximizing choices when it was a set of product photos, albeit

associated with money labels. A chronometric assessment of difficulty in judging valuation differences between stimuli of the same category was used to establish that regret calculations for the former stimuli category were relatively easier than for the latter. Challenging simple sequential accounts of strategy selection in decision-making, a final experiment demonstrated that decision-makers' stimulus-category specific bias could be countermanded by changes in the distribution of stimulus valence at the time of presentation. We conclude with a discussion contextualizing our findings within existing formal accounts of strategy selection in decision-making.

Discriminating between choice strategies

Some econometric research in the past has sought to discriminate between the use of utility maximization and regret minimization strategies by fitting different varieties of discrete choice models to data (Thiene, Boeri & Chorus, 2012). However, such models have several free parameters and idiosyncrasies in estimation procedures, and their result interpretations are frequently susceptible to validity challenges. To avoid such complications, we sought to design a simple experimental task in which utility maximization and regret minimization would predict clearly divergent choices.

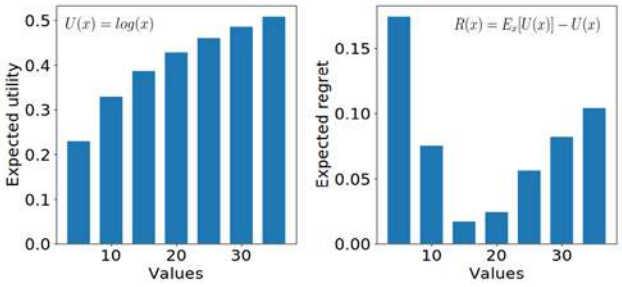

Figure 1: Expected utility (left) and expected regret (right) for nominal x values plotted on the x-axis. A logarithmic form is assumed for the utility function.

This took the form of a choice problem where respondents are told that the correct choice is one of N positive integer-valued options, that each of the options has an equal chance of winning, and that if they guess the correct option, they get the amount of money, or a product of equivalent cost, indicated by the integer value indexing that option[1].

Our interest was to contrast the relative performance of utility maximization and regret minimization strategies in this setup. Formally, given a set of alternatives X, and some estimate or direct measurement of the utility of alternatives a utility maximizer would select according to the choice rule

$$\arg\max_x U(x) \quad (1)$$

It is trivial to see that the expected utility maximizing choice in this problem is to always select the option with the highest integer value.

A regret minimizer, on the other hand would calculate the potential *regret* for choosing each one of the outcomes

$$R(x) = |U^* - U(x)| \quad (2)$$

where U* is some counterfactual comparative benchmark utility, and then use the choice rule

$$\arg\max_x R(x) \quad (3)$$

The choice of benchmark utility differentiates regret calculations into different categories. Minimax regret computations take the benchmark utility to be the utility from the best possible outcome (Savage, 1951), and is commonly used in game-theoretic settings to model behavior. Such a criterion is reasonable for when the decision-maker is expected to know the correct option, a common premise in game-theoretic settings. For decision-makers operating with little domain knowledge, average or expected utility is frequently selected as the benchmark utility, as is common in reinforcement learning settings (Kaelbling, 1996). Since our task falls in the latter category, we use expected utility to perform our regret calculations.

Assuming a linear relationship between utility and regret as defined in Equation (3), we see that the regret minimizing choice in this problem is to pick the option in the middle of the range of available options, calculating U(x) as the *prospective* utility of x should it win and treating U(.) as a logarithmic map of x, a classic micro-economic assumption. This pattern is, in fact, inevitable since the benchmark expected utility occurs in the middle of the value range given equi-probable outcomes and draws the regret minimum towards itself. Figure 1 illustrates this intuition quantitatively, showing that prospective regret is lowest when selecting in the middle of the range.

Thus, this simple decision problem potentially gives us a straightforward way of empirically differentiating the use of utility maximizing versus regret minimizing strategies. Assuming even spacing of choice set options, respondents selecting options towards the extreme large values of the offered range are expected utility maximizers, while respondents selecting options in the middle of the offered range are expected regret minimizers.

Given this premise, we next designed a simple experiment to test it. We designed two sets of choice stimuli, one for which regret calculation should be easy, and one for which it should be hard, and asked two different set of respondents to choose between them using the paradigm described above.

[1] The inspiration for this problem design is drawn from an unpublished draft by Oleg Urminsky & Adele Yang, which in turn derived this problem from a common radio station contest - the jackpot guessing game.

Experiment: easy money and hard pens

Our basic prediction is that decision-makers prefer a regret minimization strategy for option sets wherein comparing the value of options is relatively easy, and prefer utility maximization (or other strategies) when such comparisons are hard. To test this, we designed a between participants' experiment, with one cohort making decisions using a stimuli set that permits *easy* regret calculations and the other using a stimuli set that does not. As a precursor to this, we ran another study to quantitatively identify which stimuli categories are, respectively, easy and hard for respondents to calculate regret.

Precursor study

Regardless of whether comparisons are utility function-wise, feature-wise or heuristic-based, it appears natural that the presence of more features should make regret calculations harder. Therefore, we designed choice option sets to have either just one feature (a money amount) or multiple features (money amounts plus other features), corresponding to easy and hard regret calculation settings.

Design. Specifically, we selected two categories of stimuli to test for relative difficulty vis-à-vis a baseline of simple numerical comparisons. These were

(A) two-digit money amounts, and

(B) images of pens, presented alongside their actual market price.

Each participant completed two blocks of 35 trials each for either category of stimulus, with the block presentation order (ABAB/BABA) counter-balanced across participants. Within a block all participants saw a stream of 36 stimuli from a single category (ITI = 500ms), and had to successively respond to the cue, "Is this one much better or worse than the last one?" prompting 1-back comparisons with the stimulus currently on the screen. The sequence of stimuli presentation was pseudo-randomly generated in each category using sampling with replacement from a set of 7 unique stimuli (described in the main experiment for both categories), with the constraint that the new stimulus had to be different from the previous two stimuli in the sequence. "Yes" and "no" responses were coded to the "left" and "right" arrows of a regular QWERTY keyboard. Responses were disabled for the first stimulus in each block since it had no valid comparison. Participants were asked to take as much time as needed to respond, and the trial number within the block was shown alongside the total number of trials in the block on the screen.

Before these four stimuli-specific blocks were presented, participants' response time baselines for numeric distance calculations were established by presenting them with a stream of 36 three digit numbers (ITI = 500ms) sampled from a uniform distribution on [10,99], successively asking the question, "Is this number much larger or smaller than the last one?" The presentation and response interface used for this block was identical to the one used for the subsequent stimuli-based blocks.

Sample and analysis. For this precursor study, we recruited 10 volunteers (2F, age = 24 +/- 2.3 years, 0 left-handed) using convenience sampling.

The regret calculation conditions (easy vs. hard), in the form of different stimuli sets, were empirically validated on the premise that the critical step in regret calculation is the utilitarian comparison of the outcome received with an alternative. Adopting a mental chronometric approach, the relative time taken in performing this calculation for different categories of stimuli was used to operationalize our sense of relative *difficulty* of regret calculations. For all our calculations we report below, we excluded outlier RTs (> 2S.D. from category mean). These constituted 1.5% of all trials (21 out of 1400 total trials), but occurred primarily in the *pens* category trials. The exclusion of these outliers in fact deflates the size of primary result we report below. Therefore, we do not report results including them.

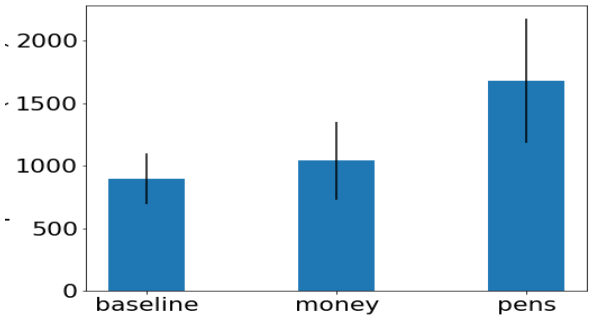

Figure 2: Mean Response times for pair-wise difference judgments within different categories of stimuli for all 10 participants of the precursor study. Errors bars represent +\- 1 S.D.

Results. Figure 2 displays average response times category-wise, combining trials across participants and category blocks. Clearly, respondents found the monetary comparisons of value approximately as easy as numeric comparisons of magnitude (Cohen's d = 0.40), demonstrating the intuitive mapping of number to value in the monetary domain. Equally clearly, respondents took longer to respond to comparisons involving images of pens alongside their prices (Cohen's d = 1.39), implicating multi-dimensional considerations in estimating the value of these objects.

Thus the precursor study objectively established that respondents take longer to assess whether two pens offered at different price points are significantly different from each other than to assess this for just two money amounts. Granted the chronometric assumption that RT predicts task difficulty, this result validates our consideration of choice stimuli drawn from the former category as *harder* than the latter. This distinction, in turn, permits the design and conduct of our main experiment.

Main study

Design. Volunteers for the main experiment were recruited from the general university population. However, participants from our precursor study were excluded. All consenting volunteers were randomly assigned to *easy* (N = 54, age 20.4 +/- 1.4 years, 31 F) and *hard* (N = 53, age 19.8 +/- 1.0 years, 25 F) regret calculation conditions respectively.

Both sets of respondents participated in the experiment in a classroom setting separated spatially from each other, transmitting their responses via text messages. The *easy* group respondents were presented with the following instructions, "Consider this hypothetical scenario. I have a bowl of seven paper tokens, each one with one of the first seven multiples of five written on them. Every number is written on at least one token, and no token has more than one number on it. At the end of the class, I will draw a token and whoever can text me (response number) the number on the token I will draw will win the amount of money written on that token."

Figure 3: Choice stimuli presented to respondents in the *hard* condition. Numbers in parentheses represent pen codes. Money amounts are true prices of the corresponding pens. Pens are arranged in randomized order with respect to money amounts to prevent positional bias in responses

The *hard* group respondents were presented with the visual display shown in Figure 3 accompanied by the instructions, "Consider this hypothetical scenario. I have a bowl of seven paper tokens, each one with a number between 1 and 7 written on it. Every number is written on at least one token, and no token has more than one number on it. At the end of the class, I will draw a token and whoever can text me (response number) the number on the token I will draw will win a pen of the type listed under that number on this display."

Analysis and results. Figure 3 summarizes the responses from both groups of respondents as a histogram of the number of respondents that selected each response option. The difference between the response patterns is visually apparent in the modes of the two distributions in Figure 3, and a two-sample T-test of the individual responses from the two cohorts also indicates a significant difference (t_{105} = 2.18, p = 0.03). An effect size calculation yielded a Cohen's *d* of 0.41, again consistent with a significant difference between the two response patterns.

A comparison with the predictions from Figure 1 clearly suggests that respondents from the *easy* group, who were significantly biased towards responding in the middle of the proffered range, were likely using a regret minimization strategy, whereas respondents from the *hard* group, who preferred the pricier pens, were likely using a utility maximization strategy.

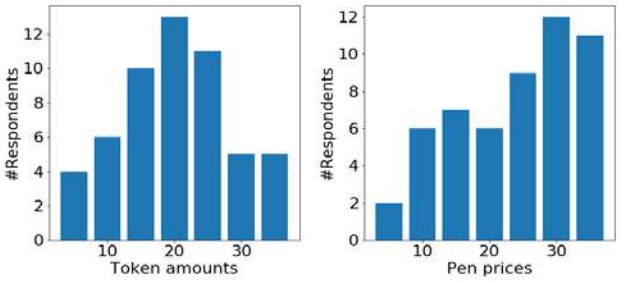

Figure 4: Histogram of respondents' selections for choices where regret calculation is designed to be (left) easy and (right) hard.

This finding is not easily explicable by alternative hypotheses. Previous theoretical proposals have suggested that respondents prefer to decide based on prospective regret when choices are difficult or consequential (Zeelenberg & Pieters, 2007). If anything, it appears intuitive that choosing in pen space is more difficult than choosing in money space. Results from our precursor study establish, at the very least, that estimating value differences between pens in our display is harder than estimating value differences between money amounts. If the pens are harder to choose from, then Zeelenberg & Pieters (2007) would predict the opposite pattern of results than what is seen. Similarly, arguments explaining regret minimization being preferred in unfamiliar domains should also predict it being used when selecting between pens than between money amounts, since choosing between money amounts is unlikely to be more unfamiliar than choosing between idiosyncratic stimuli like pens. Thus, this result appears to clearly favor an ease of calculation explanation for preferring a prospective regret minimization strategy.

Input or enabler?

While the difference in responding elicited by our manipulation does suggest a role for the ease of regret calculation entering into respondents' decision about which strategy to use, it does not clarify how this variable enters this reasoning.

We conducted a variant of the original experiment to differentiate between two potential roles for this cognitive effort variable: (i) as an input to hierarchical decision

process, where the strategy is selected first, then implemented, followed further by assimilation of feedback, or (ii) as a mechanistic enabler, in the sense that quicker regret calculation makes results from the use of a regret minimization strategy available sooner to participants, and hence more likely to be used.

As we discuss further below, the first possibility would fit this cognitive effort variable within formal hierarchical models of strategy selection and learning, such as Rieskamp & Otto's influential SSL model (Rieskamp & Otto, 2006). The latter would be more compatible with heuristic accounts of the effect of availability and accessibility on decision-making (Carroll, 1978), which are yet to be successfully formalized to the same extent (Gigerenzer & Gaissmaier, 2011).

Design. If strategy selection precedes outcome evaluation, then we would expect changes in the range of outcomes used for our decision problem to not affect the choice of decision strategy. Conversely, if changing the range of outcomes for the decision problem reveals differences in the pattern of responding, it is clear that some aspects of outcome evaluation must precede the decision of which strategy to use.

To test this hypothesis, we again used a between-subjects design. The decision problem and setup was identical to the one used in the *easy* condition of the main experiment, with two different groups of respondents making choices using two different sets of money amounts. The first set used the same stimuli as the original experiment. The second set used the stimulus set {5,10,15,20,25,30,**105**}, replacing the largest stimulus in the original set with a much larger value. All participants received the same instructions as in the main experiment's *easy* condition in a classroom setting, and transmitted their selections using text messaging as before.

Sample. Volunteers for the experiment were recruited from the general university population. We screened the recruited sample for previous participation in either our precursor study or the main experiment. A total of 90 participants (23F, Age = 20.3 +\- 1.8 years) were finally selected for participation in the experiment, and randomly assigned to two equally-sized groups for this study.

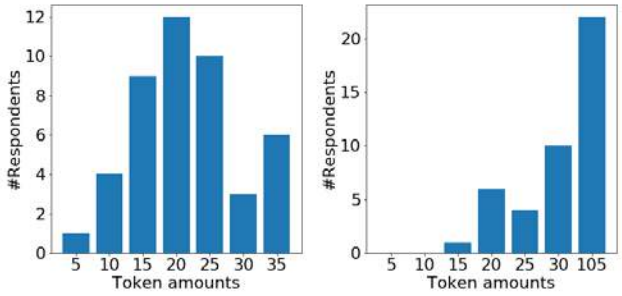

Figure 5: Histogram of responses for groups responding to (left) original stimuli set and (right) changed stimuli set

Analysis and results. As is evident from Figure 5, the response patterns in both groups were starkly different. A two sample T-test for the individual responses returned strongly statistically significant $t_{88} = 6.00$, $p < 10\text{-}6$ and an effect size calculation yielded a large effect (Cohen's d = 1.08). Further, the response pattern elicited from the 45 participants who were presented with the same stimuli as in the *easy* condition in the main experiment were not statistically different from the 54 participants' responses obtained during the former experiment (two sample t-test p = 0.40), suggesting that the original result was robust.

This result shows that changing the set of choice options by adding an extremely valuable alternative makes respondents substantially more likely to prefer the expected utility maximizing strategy, suggesting that a sequential view of strategy selection followed by application cannot faithfully reflect how participants use information available from the choice set before making their decision. Thus, the present evidence suggests that the expected different costs of regret computation for different stimuli sets does not enter explicitly into participants' strategy-selection calculations, but rather enables regret-based determinations to be emitted preferentially by virtue of being generated quicker, in line with the bag of heuristics view of decision-making strategies (Gigerenzer & Gaissmaier, 2011). However, we discuss below how our findings could potentially be reconciled with a hierarchical view of strategy selection further below.

Discussion

Summary of results. In this paper, we have proposed a novel characterization of when human decision-makers are likely to prefer minimizing prospective regret over alternative decision-making strategies like expected utility maximization. Our proposal is that decision-makers prefer to minimize regret when the cognitive cost of calculating regret is low, and switch to alternative decision strategies when this cost is high.

To test this hypothesis, we designed a simple decision problem which permits a clear empirical differentiation between the use of either of these two decision-making strategies. We conducted a chronometric assessment of two stimuli sets, for which relative value judgments had distinctly different difficulty levels. Although other measures of effort have been proposed in the literature, drawing upon information-theoretic considerations (Huber, 1980), the validity of these measures is ultimately assessed using reaction time data (Johnson & Payne, 1985). Thus, while alternative operationalizations of effort are certainly possible, our response time-based definition appears reasonable.

Using this observation to establish the relative difficulty of regret calculations using options selected from these two stimuli sets, we asked two separate groups of participants to make decisions that were formally identical, except for the stimuli identity difference. We found that the pattern of responses for choices made using stimuli that were hard to

evaluate comparatively was more consistent with the use of an expected utility maximization strategy, whereas for stimuli that were easier to compare, the pattern of responses was more consistent with the use of an expected regret minimization strategy. It is, of course, impossible to verify that these were the only two strategies possible for participants to use in the choice problem. Ad hoc heuristic approaches such as 'bias towards the middle of the range' etc could, in principle, be potentially confounded with the regret minimizing predictions for this choice problem. Such ad hoc proposals, however, are not parsimonious, in the sense that they fail to explain the shift to expected utility maximization for the same choice problem using different stimuli, whereas the cost of calculation explanation does.

A more significant question is how well the result demonstrated in this somewhat arbitrary choice problem generalize to richer experimental settings and real-world decisions. We consider this an important consideration for future work.

Related work. There is a large literature on strategy selection, anchored in contemporary times by Rieskamp & Otto's powerful SSL theory (Rieskamp & Otto, 2006). The basic outline of this theory is that observers select a strategy to tackle each instance of a decision problem stochastically, guided by their preference for each of the possible strategies. This strategy-preference in SSL has three components, (i) the maximum reward possible in a trial, (ii) an initial strategy-specific preference, and (iii) a learning-based association of strategy to the choice problem, based on the long-run trend of the use of that strategy resulting in a higher reward. The basic intuition underpinning SSL is that observers adapt to choice contexts by gradually learning to prefer strategies that prove more rewarding in them. Notably, Rieskamp & Otto (2006) explicitly consider the possibility that the cognitive costs of applying a strategy may enter observers' calculations for strategy preference. However, how such strategy-specific costs would enter their model's calculation has remained an open question.

The results in this paper provide useful constraints on the potential development of such a cost-sensitive model. Our main experiment strongly suggests a role for cognitive cost of applying a strategy in determining observers' preference for it. A naïve approach might be to subtract some notional *cost* of calculation from the reward term in the SSL prior on strategy preference. However, our follow-up experiment demonstrates that strategy preference can be affected by complex informational aspects of the choice problem, such as the distribution of options in value space.

Such a complex interaction does not appear to be possible in the baseline two-step algorithmic specification of SSL, wherein first the strategy is selected based on existing strategy preferences, and then information from the current trial updates the strategy preferences. We conjecture that a drift-diffusion based (Ratcliff & McKoon, 2008) extension of the SSL model, wherein the evidence for the utility of options accumulates competitively and becomes available to assist in strategy evaluation depending on how soon this competition terminates, could accommodate our results.

Abstract

There has been little cross-fertilization between research on active learning and teaching, despite extensive conceptual similarities. The current study aims to bridge the gap by showing that engaging in active learning can influence subsequent teaching performance. In a one-dimensional boundary teaching task, participants who first took the role of an active learner went on to become better teachers than participants who did not. In order to disentangle the effect of active selection of samples from their information content, the performance of active learners was compared to that of yoked passive learners. While prior passive learning also significantly boosted teaching performance, it did so to a lesser extent. However, in paired comparisons, teachers with active learning experience did not differ significantly from their yoked-passive learning counterparts. Based on the current results we cannot argue for a teaching benefit specific to active learning as opposed to a more general improvement caused by experiencing the task from the learner's perspective. However, we suggest that this is a promising line of inquiry using more complex learning and teaching tasks.

Keywords: teaching; active learning; evidence selection

Introduction

Perhaps the most enduring debate in the education literature, as well as around kindergartens and classrooms, concerns the virtues of exploratory play in contrast to the canonical, largely passive mode of teacher-led instruction (Bruner, 1961; Mayer, 2004). The discussion has been naturally phrased in terms of the relative benefits and disadvantages that the learner incurs when learning from self-guided discovery compared to direct instruction. However, the complementary, and equally important, link between efficient self-guided learning and good teaching has remained largely unexplored.

The common thread running between teaching and active learning is easy to identify when comparing their formal descriptions. Recent rational-agent models have conceptualized teaching as a recursive process in which the teacher and the learner reason about each other. Specifically, the teacher selects training samples for the learner such that, given the learner's prior knowledge and inference making mechanisms, these samples would lead the learner to the desired conclusion efficiently, i.e. by requiring the smallest number of samples (Shafto, Goodman, & Griffiths, 2014). Conversely, the learner interprets the observed samples assuming they were generated by this pedagogical process (as opposed to randomly). Similarly, an ideal active learner will also sample the environment strategically. However, they will do so by directing their information gathering (e.g. by moving their eyes to explore a visual scene or choosing interventions on the environment) in order to maximize their expected information gain (Yang, Wolpert, & Lengyel, 2018). There are two ways in which active learning can be advantageous. First, observations collected in a strategic way will be more informative for any learner (not just the one sampling information); for instance, by avoiding irrelevant or redundant evidence. Second, and more importantly, there is an added advantage specific to the active learner stemming from the fact that they sample information in light of their prior knowledge and the hypotheses that they wish to test. This effect was demonstrated in experiments in which the data selected by an active learner was also presented to a yoked "passive" learner, and, despite the observations being matched, active learners performed better than their yoked passive counterparts (Markant & Gureckis, 2014).

Thus, both being a good teacher and a good active learner rest on the same general ability to evaluate the potential value of a new piece of evidence relative to a current state of knowledge and a task. Nonetheless, there are important differences. First, teaching brings the added complexity of selecting data for the use of another agent, who might differ widely from the teacher in their state of knowledge and inference making. In line with this, Bass, Shafto, and Gopnik (2017) have linked Theory of Mind (ToM) development to children's pedagogical sampling ability. Second, the active learner does not have access to the target hypothesis, and thus can only select data that minimize uncertainty. However, Yang, Vong, Yu, and Shafto (2019) recently proposed a reconceptualization of active learning as self-teaching by envisioning a learner who simulates an uninformed teacher whose task is limited to providing queries. In this framework, the self-teacher does not optimize for expected information gain, although this will often be the collateral result. Thus, despite differences, it is still feasible to think about teaching and active learning as two highly related cognitive processes.

Given the computational similarity of teaching and active learning, is it possible that they are also integrated through linked processes in human behavior? In other words, would it be possible to hone teaching skills through active learning?

Figure 1: Example image array from the teaching task. In this trial, food items were sorted from left to right in ascending order of their vitamin B content. The black vertical bar represents the daily recommended dose of vitamin B, which is the boundary the participant had to teach. In this case, the participant clicked on the two images closest to the boundary, which were automatically labelled.

Intuitively, taking the perspective of the learner prior to teaching should be a useful experience. It could allow the teacher to better understand, even if implicitly, how a learner would make inferences to solve the task at hand based on the data provided, which in turn would help refine the data selection process.

Taking this reasoning one step further, having the experience of being an active learner prior to teaching should generate robust insights about how to select good examples for teaching in similar tasks. Additionally, if both tasks rely on a core ability to sample environmental data efficiently, the transfer could occur automatically during learning, without the knowledge or expectation that the acquired information will need to be used for teaching in the future. Furthermore, active learning should improve teaching performance beyond passive learning (even when the same information content is acquired) if the active selection of data was the crucial driver of the learning effect, rather than the benefit of familiarity with the teaching task or taking the perspective of a learner.

Experiment

In order to test the hypothesis that active learning improves teaching performance, we designed a simple task in which participants were required to both learn a one-dimensional categorization boundary, and teach it, in counterbalanced order. Thus, there were two independent groups of participants in our design, those who learned actively first and then taught, and those who first taught and then performed active learning. In addition, to probe whether the effect learning on teaching performance was specific to active learning, a yoked control group performed the same teaching task after learning passively from watching the active learners labeled queries.

Method

Participants Eighty-eight participants (54 female, M_{age} = 24 years, range = 18 - 42 years old) were recruited from the local population through the university online research participation system and the student union. Ethical approval was obtained from the United Ethical Review Committee for Research in Psychology (EPKEB) in Hungary.

Tasks All tasks (active learning, passive learning, and teaching) consisted of three trials. In each trial, participants were shown eight images in a horizontal array such as the one displayed in Figure 1. Participants were told that the images were sorted left-to-right according to a given "key" feature. For instance, animals were sorted according to their speed relative to body size or the average amount of time they sleep, or foods were sorted by their carbon footprint or their vitamin content. Images belonged to one of two categories (which were clearly marked at the extremes of the image array) according to whether their key feature was below or above a "boundary" (threshold value) which lied between two adjacent images (i.e. at one of seven possible locations). Unknown to the participants, the true boundary locations which dictated the category membership of the images were uniformly sampled in each trial from all the possible locations. [1]

The categories used for the learning and teaching tasks were randomly selected for each participant. Images and category cover stories were only presented once throughout the entire experiment.

In **active learning trials**, participants first saw the image array alongside the description of the categories and the boundary, following which they were told that their task was to find the boundary by querying two images. An image could be queried by clicking on it, which immediately revealed its category membership through the color of the frame drawn around it. After the second query, participants were asked to pinpoint where they thought the boundary was located, again by clicking on one of the seven possible boundaries. Participants received feedback on whether they were correct, un-

[1] Participants were provided with a description of a seemingly objective classification boundary (e.g. that slow and fast animals were separated by the speed of the average human scaled by size). These descriptions were intentionally chosen such that the participants were unlikely to have any strong priors about the location of the boundary. Knowing the participants' prior was essential because it determined the optimal query choice in active learning. The six categories and boundary descriptions used in the experiment were chosen based on a pilot in which participants were asked to select the boundary location by relying merely on their prior knowledge. The distribution of chosen boundaries (across participants) for the items included in the current experiment was not significantly different from the uniform distribution.

lucky (they selected a boundary compatible with the labelled images that was not the true boundary) or incorrect (selected an incompatible boundary).

The **passive learning trials** had the same structure, except that the labels of two images were sequentially revealed to the participants before they had to make their decision about the location of the boundary. Crucially, for each passive learning participant, the images labelled corresponded to the queries of a previous active learning participant.

In **teaching trials**, participants were shown the boundary separating the two categories and were asked to teach it to another participant who they were told would take part in the experiment at a later time. It was made explicit that the other participant would be presented with the same set of sorted images. The participant only needed to click on an image to mark it as an example, and it was automatically labelled. Mirroring the learning tasks, participants were only allowed to provide two examples, which is the number of examples sufficient to fully specify the correct boundary. Intuitively, selecting two adjacent images with different labels is sufficient to identify the boundary in this task.

Materials All the images were selected from the MultiPic databank of standardized color drawings of concrete concepts (Duabeitia et al., 2018).

Procedure Participants were pseudo-randomly assigned to one of three groups: active learning followed by teaching (N = 29), passive learning followed by teaching (N = 29), and teaching followed by active learning (N = 30). The experiment was presented on a 27inch screen in a quiet room and lasted for an average of 20 minutes (unspeeded). Following the experiment, participants completed an open-ended questionnaire about the strategies that they used to solve the tasks.

Quantifying performance Teaching performance was measured by the information gain, $\mathrm{IG}_{\mathrm{teach}}$, which is the amount of entropy by which the teacher reduced the imagined learner's prior entropy $\mathbb{H}(b)$ by labelling two images:

$$\mathrm{IG}_{\mathrm{teach}} = \mathbb{H}(b) - \mathbb{H}(b|s_1, s_2, l_1, l_2)$$

where s, l, and b respectively denote image stimuli, category labels, and potential boundary locations. $\mathbb{H}$ is the Shannon entropy over the possible hypotheses, the prior entropy is $\mathbb{H}(b) = -\sum_{b\in\mathcal{B}} \mathrm{P}(b)\log_2 \frac{1}{\mathrm{P}(b)}$, where $\mathrm{P}(b)$, the learner's prior over the boundary locations, is assumed to be uniform. The optimal teaching strategy is to label the examples immediately preceding and following the boundary as this will eliminate any uncertainty about the location of the boundary, thus reducing all of the original entropy. On the other hand, selecting an example set that will leave the learner uncertain about the true hypothesis because many potential boundaries compatible with the example set will translate into a lower information gain.

Using the observed information gain to evaluate active learning performance would introduce arbitrariness since it cannot distinguish a learner's well-planned query from a lucky one. An ideal learner should choose a query in light of their uncertainty about the labels that will be observed. First, learners should compute the expected information gain of the queries by weighing the posterior entropy by the probability of observing the given labels for the query made and then choose the query that maximizes the expected gain. Therefore, $\mathrm{EIG}_{\mathrm{learn}}$, the sum of the expected information gain of the first and second queries, was used instead of observed information gain. The expected information gain of the first query is:

$$\mathrm{EIG}_{\mathrm{learn}}(s_1) = \mathbb{H}(b) - \sum_{l_1\in\mathcal{L}} \mathbb{H}(b|s_1, l_1)\cdot \sum_{b\in\mathcal{B}} \mathrm{P}(l_1|s_1, b)\,\mathrm{P}(b)$$

After observing the first label, the prior over the boundary locations is updated, and the expected information gain is computed again relative to the entropy remaining after the first labelled sample:

$$\mathrm{EIG}_{\mathrm{learn}}(s_2|s_1) =$$
$$= \mathbb{H}(b|s_1, l_1) - \sum_{l_2\in\mathcal{L}} \mathbb{H}(b|s_2, l_2, s_1, l_1)\cdot \sum_{b\in\mathcal{B}} \mathrm{P}(l_2|s_2, s_1, l_1, b)\,\mathrm{P}(b)$$

Unless otherwise specified, statistical analyses of participants' responses were performed based on the average measures of $\mathrm{IG}_{\mathrm{teach}}$ and $\mathrm{EIG}_{\mathrm{learn}}$ in the three trials of each task.

Decisions about the boundary location In learning trials, after observing two labelled stimuli, participants marked the location of the categorization boundary. Their choice could be assessed based on whether or not the selected boundary was compatible with the labelled images they had seen. However, simply using the proportion of compatible answers (across the three trials) to assess their performance ignores the fact that trials differed in the number of remaining compatible boundaries. To control for this and characterize performance appropriately, we fitted a model that captured the intuition that participants behaved optimally and selected (randomly) from among the remaining compatible boundary locations in some r fraction of trials, while in the rest of the trials they "lapsed" and selected a boundary randomly among all locations:

$$\mathrm{P}(\text{choice} = b_i|s_1, s_2, l_1, l_2) =$$
$$= r\cdot \mathbb{1}\{b_i \in \mathcal{B}^{(i)}_{\text{compatible}}\}\cdot \frac{1}{\left|\mathcal{B}^{(i)}_{\text{compatible}}\right|} + (1-r)\cdot \frac{1}{|\mathcal{B}|}$$

Thus, $r = 1$ indicates optimal behavior, while $r = 0$ indicates chance performance. We estimated r for each participant by maximum likelihood (under the assumption that trials were *i.i.d*).

Data analysis Predictions were tested using planned independent t-tests to compare the teaching information gain in the teaching first and learning first conditions. Paired comparisons were used for the two groups who experienced being learners first, the active learners and passive learners.

Post-hoc analyses were conducted to ensure that variables extraneous to the predictions did not have a meaningful impact on performance or modulate the reported effects. The design of the experiment lends itself naturally to mixed model analysis, since it allows fitting trial level data (without aggregation) and can describe variation arising from the experimental design. Starting from a baseline fixed effects only model with the experimental condition as a predictor of teaching performance, we sequentially fitted and compared models using two additional fixed factors, learning performance and trial number (and their interactions with the condition), as well as random intercepts for participant and trial identity (i.e. dimension used for classification of the objects). Fixed effects were tested using log-likelihood ratio tests for nested models with the same random effects structure. Non-nested models were compared using the Bayesian Information Criterion (BIC) and Aikaike Information Criterion (AIC). Similarly, random effects (fitted via maximum likelihood) were tested using log-likelihood ratio tests while keeping the fixed effects model identical. Given that the mixed-effects analysis confirmed the results of the planned comparisons on the aggregated trial data, we will focus on these comparisons in the Results section for brevity and clarity.

Results

Descriptives Despite the surface level simplicity of the teaching task, a large proportion of participants ($\approx$ 60 %) did not perform it optimally (i.e. did not choose the two images on either side of the boundary as the teaching samples). However, prior active learning made it easier to gain insight into the optimal solution for teaching. More than half of active learners, 17 out of 29 participants, performed at ceiling level by consistently providing example sets compatible with only one categorization boundary. In contrast, only 11 of 29 participants in the yoked passive learning group, and 7 out of 30 of the participants who did not complete a learning task before teaching managed to select the optimal example sets.

Teaching performance across conditions As predicted, participants who were active learners before being teachers outperformed those who started directly with teaching, on average providing .63 bits, 95% CI [.22, 1.05], of additional information to their (fictitious) learners (see Figure 2). The group difference was highly significant in an independent t-test, $t(57) = 3.04$, $p = .01$, Bayes Factor (BF) [2] = 10.81 in favor of the alternative hypothesis.

Learning passively before teaching conferred a smaller, but still significant, benefit relative to foregoing learning. Passive learning increased teaching information gain by an average of .45 bits, 95% CI [.05, .85], $t(57) = 2.26$, $p = .03$, $BF = 2.16$ in favor of the alternative.

While we found strong evidence in support of the differences between the groups completing the learning and teaching tasks in different orders, a possible concern was that these differences were not induced by the experimental manipulation *per se*. Specifically, if there are prior differences in learning performance favoring the group that completed the active learning task first, and learning performance is correlated with teaching performance, then the condition effect could be just an artifact. In order to eliminate this possibility, a regression was performed on teaching performance with both the group (active learning before / after teaching[3]), learning performance, and their interaction as predictors. The group difference remained significant, $\beta = .62$, $p = .01$, when controlling for expected information gain in learning, which was not a significant predictor of teaching ability, $\beta = .08$, $p = .81$, nor did it interact with the group effect, $\beta = .68$, $p = .3$. Figure 2 shows, for each condition, the estimated (non-significant) slopes for information gain from teaching as predicted by ex-

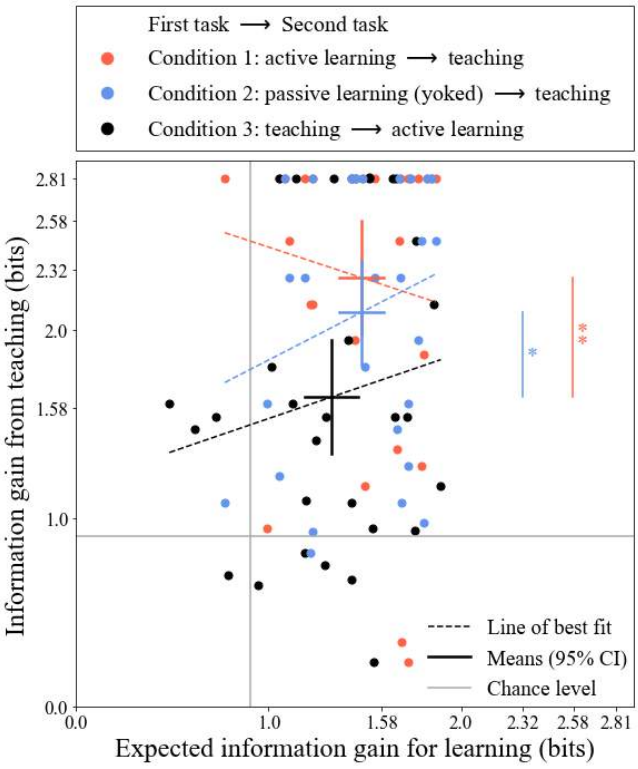

Figure 2: Teaching and learning performance across the three conditions. Each dot represents the information gain for one participant, averaged across the three trials of each task. Crosses represent the 95% confidence intervals for the group means. Dotted lines represent the expected mean information gain from teaching as a function of expected information gain. The maximum information gain for the task is 2.81 bits. The asterisks mark significance levels in independent t-tests (* $p < .05$, ** $p < .01$).

[2]Bayes Factors were calculated for a null model that assumes a zero standardized difference between groups, and a Cauchy alternative with a prior scaled to an effect size of .7, following Rouder, Speckman, Sun, Morey, and Iverson (2009).

[3]The same pattern of results was found for the difference between the group learning passively and then teaching, and the one teaching before active learning.

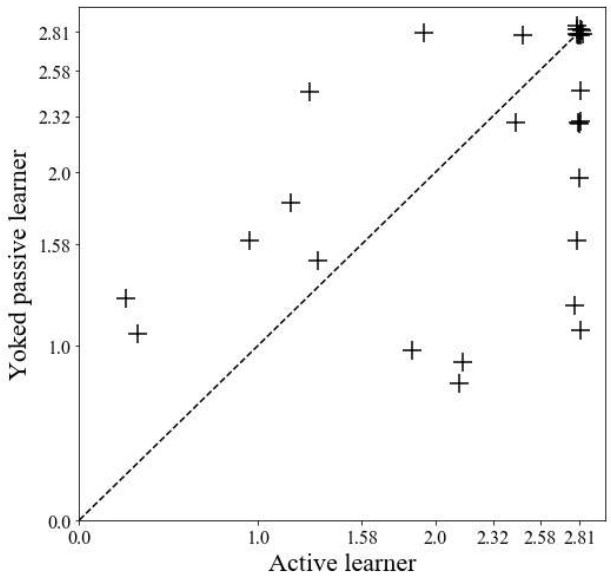

Figure 3: Teaching performance for the active-passive learning dyads. Each dot represents the information gain from teaching for one dyad. In dyads situated under the diagonal identity line, the active learner was the better teacher. A small Gaussian scatter was applied to make overlapping dots visible.

pected information gain for learning. Coupled with the fact that the difference in active learning performance between the two groups was not significant, $t(57) = 1.77$, $p = .08$, $BF = 1.28$ in favor of the null hypothesis, this suggests that the effect of the manipulation was not mediated by prior differences in active learning performance. To investigate this issue further, the two groups were repeatedly resampled with replacement such that the learning performance between groups could be matched and fixed at different levels. Comparing the teaching performance across these resampled groups confirmed the advantage of those who completed the learning tasks prior to the teaching task (the 95% CI of the mean of the resampled groups' differences did not include a null effect).

The second prediction of the study was that active learners would gain a larger benefit from learning before teaching than the yoked passive controls. Active learners fared on average only slightly better in the teaching task than their passive learning counterparts who were shown the same labelled data, with an average difference of .18 bits, 95% CI [-.11,.47]. The dyads' performance is illustrated in Figure 3. The difference was not significant in a paired t-test, $t(28) = 1.29$, $p = .21$, $BF = 2.39$ in favor of the null. It should be noted though that the paired comparison was underpowered (post-hoc power = .24) given the magnitude of the effect size observed.

While there was no significant difference in teaching performance in the planned, marginal comparison between the dyads, Figure 2 suggests that differences may potentially be present conditional on learning performance. There was no interaction between the three-level condition and learning performance, however, this analysis does not account for the dependence in the active learning and passive learning dyad data. As pairs of active and yoked passive learners had, by design, the same expected learning information gain, we regressed the within dyad difference in teaching performance against learning expected information gain. Learning performance was not a significant regressor of the difference in teaching, $\beta = -.86$, $p = .07$. On the one hand, the predicted within-dyad difference, conditioned on low values of learning performance, was significant (see Figure 4). For instance, the predicted within-dyad teaching difference was .60 bits, p=.03, at a one bit expected learning entropy. On the other hand, there was no discernible difference for dyads with high expected information gain. While this is not a strong result, given the low number of dyads and the small effect, it might suggest a potential modulation of the relative benefit of active learning.

Mixed effects analysis The best-fitting model contained the condition, $F(2,85) = 4.30$, $p = .02$, and trial number, $F(2,174) = 6.93$, $p = .01$, as fixed effects, alongside a participant level random intercept ($SD = .70$). The addition of the random intercept was judged meaningful based on the magnitude of the variance at the participant level (SD =.70). It also led to a reduction in BIC, from 796.6 for the fixed effects only model to 749.7.

The previous results regarding the condition effect hold, with a significant estimated difference of .63 bits, $se = .22$, $t(85) = 2.94$, $p = .01$, between the active learning first and teaching first conditions. Similarly, no significant difference was found between active and passive learners, estimated difference of .32 bits, $se = .22$, $t(85) = 2.94$, $p = .01$. Additionally, teaching performance improved from the first to the third trial by an estimated .38 bits, $se = .11$, $t(174) = 3.30$, $p = .01$. However, performance improvement from the first to the second trial was not significant, .02 bits, $se = .11$, $t(174) = .17$, p= .87.

Decisions about the boundary location In the active learning first condition, the mean of the best-fit individual r values was .79 (SD = .35), whereas for those completing the active learning following teaching it was lower, .58 (SD = .42). Yoked controls has the smallest average r, .51 (SD = .38). Active learners made better inferences about the boundary location than their matched controls as the average within-dyad difference in estimated probability r was .28, $t(28) = 2.99$, $p = .01$, $BF = 7.29$. The order of the active learning task led to marginally significant differences in an independent t-test, $t(57) = 2$, $p = .05$, $BF = 1.37$ in favour of the alternative.

The difference in r within active-passive learning pairs did not correlate significantly with differences in teaching performance, $r(26) = -.28$, $p = .13$.

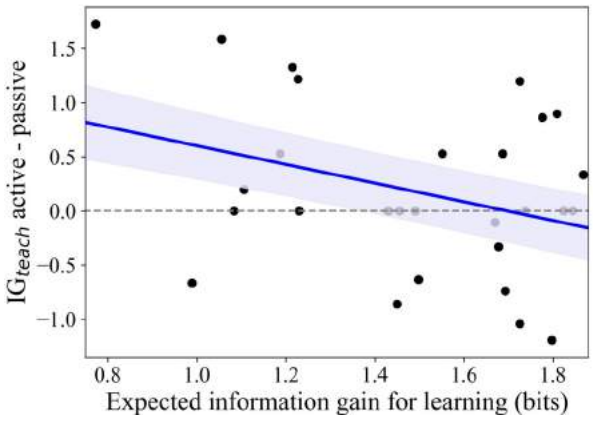

Figure 4: The difference in teaching information gain within dyads of active and passive learners as a function of the expected information gain for (active) learning. The fitted OLS regression line is shown alongside its 95% confidence bound.

Discussion

It has been proposed that humans have a likely innate sensitivity to pedagogical guidance (Csibra & Gergely, 2009) and a propensity for teaching others. From a normative standpoint, the prevalence of teaching in social groups is to be expected given that learning from others who are knowledgeable, well-intentioned and attuned to the learner is more efficient than self-guided learning. Experimental evidence is also accumulating to suggest that, at least in constrained laboratory settings, the behavior of human teachers matches the predictions of normative models (Shafto et al., 2014). However, while we know that humans are effective and keen teachers, we don't know much about the underlying abilities enabling teaching and how it relates to performance in other tasks, specifically active learning.

In the current study we observed an improvement in teaching performance for participants who engaged in active learning prior to teaching. Three active learning trials, using different stimulus sets than those used for teaching, were sufficient for the majority of participants to gain insight into the optimal solution of the teaching problem on the first attempt. Furthermore, they were able to draw on their experience as learners even though at the time of learning they had not been aware that the teaching task would follow.

The poor performance of participants with no learning experience resonates with previous findings of Khan, Zhu, and Mutlu(2017), who used a boundary teaching task as well, but did not constrain the example set size by their design. It seems that simply asking teachers to generate the minimally sufficient number of examples for optimal teaching was not enough to solicit the optimal solution.

The fact that the active learning benefit, relative to teaching first, was not modulated by the initial active learning performance suggests that active learning can improve teaching across the board, for poor and good active learners alike. However, prior active learning performance may play a role in differentiating teachers in a more complex teaching scenarios. Indeed, the surprising lack of a significant correlation between active learning performance and subsequent teaching performance can be explained by ceiling effects.

The impact of passive learning on teaching, relative to the baseline teaching first group, was smaller than that observed for active learning. However, we did not find a significant effect in the matched comparison between active and yoked passive learners. It is important to note here that the current task can be thought of as an insight problem, which means that there was less scope for observing gradual differences in performance. Further, once insight was achieved in the learning task, the solution was easy to verbalize, allowing the optimal strategy to be explicitly transferred to the teaching task.

On the other hand, for poor performing learning dyads, we observed a difference in the predicted direction. This suggests that in a more complex and ecological task in which the learning is more gradual, and the optimal solution is explicitly unknown to participants, active and yoked passive learners are likely to diverge more in terms of teaching performance. This would provide evidence for a more automatic, implicit link between active learning and teaching. In such a future teaching task it would also be interesting to examine whether the differences between active and passive learners, matched for information content, are moderated by the quality of the queries they both observe. Specifically, it should be tested whether the negative linear trend we observed generalizes to non-insight tasks.

Lastly, it is surprising that those who performed the teaching task prior to the active learning task did not differ in their expected information gain in the learning task, and, if anything, performed poorer than their counterparts who started by active learning. This resonates with previous experimental evidence from the developmental literature that has also highlighted more subtle ways in which being taught can hinder learning, for instance by limiting subsequent exploration (Bonawitz et al., 2011). It is an intriguing idea that, perhaps, not just the experience of being taught, but also teaching itself, can have an effect on exploration. Alternatively, if we assume that the teaching task is more cognitively demanding as it has a meta-cognitive component engaged in reasoning about the learner's knowledge and inference making, results can be explained by the known effect that an easier-to-harder progression of tasks is beneficial for learning, while the opposite order does not provide an appropriate stepping stone for active learning. On the other hand, Yang et al. argue that active learning can be re-formalized to also include a meta-cognitive aspect, reasoning that is applied reflexively to one's own reasoning.

To conclude, active learning proved to be a reliable intervention to improve teaching performance. It is important to investigate if the effect of active learning generalizes to more

complex and more ecologically valid tasks, or even between different learning and teaching tasks. If it does, it will open the way for quantitative inquires about whether successful teaching benefits from the ability of taking the perspective of an active learner and as such can be improved by prior active learning.

Children's Generalization of Novel Object Names in Comparison Contexts: An eye tracking analysis

Abstract

A common result is that comparison settings (i.e., several stimuli introduced simultaneously) favor conceptualization and generalization. In a comparison setting, we manipulated the semantic distance between the two training items (e.g., two bracelets versus a bracelet and a watch), and the semantic distance between the training items and the test items (e.g., a pendant versus a bow tie). We tested 5- and 8-year-old children's generalization of novel names for objects. This study is the first one to study the temporal dynamics of comparison in a generalization task with eye-tracking data. The eye movement data revealed clear patterns of exploration in which participants first focused on the training items and compared them with each of the choice options. We also compared the search profiles for correct answers and errors. The results show that participants first found commonalities in the learning items, which they compared with each items in the solution set. This pattern is consistent with an alignment view of generalization.

Key words: comparisons; conceptual distance; generalization; strategies; eye tracking measures

Introduction

Children usually learn the reference of novel words with a limited number of stimuli which are associated with these words. Which learning stimuli lead to accurate generalizations and which mode of presentation would be optimal to achieve this goal are crucial issues for concept learning. A large set of recent studies have shown that comparison settings lead to better generalization results than no-comparison learning conditions. In the latter case, young children tend to generalize novel words to objects that are perceptually similar to the learning items rather than to conceptually related ones (Imai, Gentner, & Uchida, 1994). By contrast, comparison settings favor conceptually based generalizations because they enable children to neglect irrelevant perceptual dimensions and highlight non-obvious properties that need to be identified to choose a taxonomic match (e.g.,(Augier & Thibaut, 2013; Gentner & Namy, 1999; Namy & Gentner, 2002).

However, still little is known of the solving strategies used to process comparison settings and generalize novel words, or of the steps that lead to generalization. In the present study we use eye tracking data to identify these strategies and get a better understanding of the cognitive processes that undergo comparison and generalization during learning.

Comparison and generalization

A large body of research demonstrates the benefits of comparison settings for learning novel object names (e.g., (Graham, Namy, Gentner, & Meagher, 2010), adjectives (e.g., Waxman & Klibanoff, 2000), action verbs (e.g., (Childers & Paik, 2009), objects (Thibaut, 1991; 1995) relational nouns (Gentner, Anggoro, & Klibanoff, 2011; Thibaut & Witt, 2015; see (Alfieri, Nokes-Malach, & Schunn, 2013). For example, Gentner and Namy (1999) presented 4-year olds with familiar objects with an imaginary name and asked them to extend the name. Children had to choose between two pictures, a taxonomic match and a perceptual match. Results showed that children preferred the perceptual match when they had only seen one object during the learning phase but preferred the taxonomic match when they had the opportunity to compare two objects with the same name, introduced simultaneously during the learning phase. The conditions under which comparisons lead to better learning and generalization have received much attention in recent years.

One crucial point is that comparisons generate cognitive costs (e.g., Richland, Morrison, & Holyoak, 2006; Thibaut, French, & Vezneva, 2010b) in the field of analogical reasoning). The hypothesis is that comparing multiple items, and choosing a match, while neglecting irrelevant dimensions including salient dimensions such as perceptual similarities may generate cognitive coasts because of the inhibition, decision making and flexibility involved in the task. For example, Augier and Thibaut (2013) studied conceptualization of unfamiliar objects in a comparison paradigm and manipulated the number of exemplars shown during the comparison phase. They tested 4- and 6-year olds and compared a no comparison condition, a 2-item comparison condition and a 4-item comparison condition. Interestingly, all children benefited from the comparison conditions compared to the no-comparison conditions. However only older children benefited from the four-item comparisons compared to the two-item comparisons. This suggests that cognitive control is necessary to succeed the task as suggested by contributions in numerous domains involving comparisons and integration of multiple information (see (Wiebe & Karbach, 2018).

The semantic distance between the compared items might contribute to increase the cognitive costs of comparison. For example, Green, Kraemer, Fugelsang, Gray, and Dunbar (2010) have shown that analogies based on distant domains were more difficult than equivalent analogies connecting closer domains because distant analogies involved more creativity, which was related to the central role of the prefrontal cortex in cognitive control. In children, Thibaut, French, and Vezneva, (2010a) have shown that semantic analogies based on weakly associated

relations are more difficult than those based on strongly associated relations. The authors interpreted this result in terms of the necessity to inhibit strongly associated but irrelevant items in the context at hand or in terms of the necessity to generate new candidate relations, which requires cognitive flexibility in the case of distant semantic domains.

In this cognitive control framework, it is argued that aligning semantically distant training items might involve deeper conceptual encoding. Indeed, for semantically close items, perceptual similarities are aligned with conceptual similarities (e.g. two apples) whereas for semantically more distant items alignable perceptual similarities are less synonymous of conceptually alignable similarities: aligning surface similarities does not entail an alignment of conceptual similarities or surface similarities are less correlated with conceptual similarities (e.g. a bracelet might look like a watch, but the nature of a watch is strongly connected with a devise giving the time, which can have a low saliency). On the other hand, if alignable perceptual similarities are well correlated with deep similarities for close learning items, the fact that these deeper similarities are embedded in perceptual similarities might prevent them from being easily aligned with conceptually important features when the generalization items are perceptually dissimilar. In that case, generating conceptual similarities might be difficult because the conceptual space cannot be grounded on perception and thus requires more extensive conceptual analysis.

Exploring children's strategies with eye tracking movements in a learning-generalization task

The present study's aim is to analyze the temporal dynamics of a comparison task, from the study of learning items to the selection of a candidate generalization stimulus, which, to the best of our knowledge has never been done. We will use materials by Thibaut and Witt (2017). They manipulated the semantic distance between the learning items (e.g., two bracelets versus a bracelet and a watch), and the semantic distance between the learning items and the generalization items (e.g., a jewel, near distance, versus a bow tie, far distance), and analyzed which combination of conditions would lead to more taxonomic choices. Four-year-old children made less taxonomic choices in the far generalization condition than the close generalization condition whatever the learning distance, whereas only six-year-old children got better results in the far learning distance, a condition in which participants had to coordinate information coming from very different domains. In the above cognitive control context, the authors argued that, as executive functions develop, children are able to compare stimuli from remote conceptual spaces more systematically. Indeed, the common features between two items may be found more easily with semantically close items than with semantically distant items. In the latter case, these features might be less salient and require more comparisons to be noticed. Also, in a broader conceptual space, the set of irrelevant properties to inhibit is likely to be larger than in a close domain.

Recent eye-tracking research on analogical reasoning tasks (another generalization task) have shown that during development younger children's solving strategies differ from older children's and adults' strategies (J.-P. Thibaut & French, 2016). They confronted two main hypotheses to the data, the projection first and the alignment first strategies. Projection-first refers to an initial analysis of the learning domain, in search of a relation connecting A and B. Once a relation is found it is projected on the generalization domain (which generalization item goes with C with the same relation). The alignment-first strategy refers to the alignment of equivalent stimuli (i.e., that play the same role) in the learning and the generalization domains (A with C, and B with D in a A:B::C:D proportional analogy). The authors showed that adults and children followed different search strategies.

In the type of comparison task we use, successful learning requires the learning items (L1 and L2) to be compared and conceptually aligned. Generalization requires switches (witnessing comparisons) between L1-L2 and the Ta(xonomic) target. How one reaches the taxonomic solution (or fails to) will be reflected in the transitions between L1-L2 and the set of the available options (taxonomic, thematic, and perceptual). The set of transitions and the time spent on each item will illustrate the search-construction of a solution.

Among the potential strategies, the projection-first strategy predicts early L1-L2 transitions (finding commonalities between L1 and L2), followed by comparisons between the three generalization options in terms of the features they actually share (either thematic, or perceptual, or taxonomic) with the common feature they have discovered for L1 and L2. The alignment-first hypothesis predicts early comparisons between learning items but also between the learning items and the generalization items, in order to find conceptually analogous items in the transfer set. One additional prediction is that participants compare each learning stimulus with each of the options

Another strategy contrast exists between constructive matching or response elimination (Bethell-Fox, Lohman, & Snow, 1984). Constructive matching predicts early L1-L2 comparisons followed by comparisons between generalization items that may reveal a careful construction of a solution and the application of the solution to the generalization set. This hypothesis makes similar predictions to those from the projection-first hypothesis. Response elimination predicts L1-L2 comparisons followed by back and forth switches between L1-L2 items and generalization options that may reveal a systematic response elimination strategy until a final choice is made. A difference between alignment first and response elimination, is that alignment-first predicts a progressive convergence towards the solution whereas the response elimination predicts no systematic search pattern.

The present study's main goal is to describe the strategies used by children to generalize correctly in a comparison setting, by analyzing eye movement data from two groups of children (5- and 8-year olds). We selected these two age

groups because previous research has shown that participants eye-tracking methods can be used with complex tasks with 5-year olds. Also, (J.-P. Thibaut et al., 2010b) showed that five-year olds might adapt their search strategy to the difficulty of the task in a less systematical way than 8-year olds. Thus, a priori, these two age groups were good candidates for studying strategy differences (if any exist). Also Thibaut and French (2016) showed that reliable results could be obtained with 5-year olds in an eye-tracking task.

We will confront our data with the strategies mentioned above. One hypothesis is that age matters: younger participants should use the response elimination strategy more often than the older group because it is cognitively less demanding: participants compare each transfer with the learning items, one by one, rather than store the found dimensions in working memory and compare all the transfer items in a row. They should also produce less systematic search patterns. For example, correct trials should start with L1L2 transitions less often for young children. There should also be differences depending on the difficulty of the task: easier conditions should elicit less transitions than difficult ones. Far generalization should be more difficult and should result in a larger proportion of comparisons between the options compared to the learning items.

Of particular interest are the differences, if any, between correct and error trials. Do strategy differences between errors and correct trials appear at the onset of the trial (thus, with significant differences in the first slices) or do they result from a wrong decision at the end of the trial (i.e. differences in the last slice), once all the options have been considered.

Methods

Participants 109 French speaking children were tested individually in a quiet room at their school. Two age groups were tested, five year olds, and eight year olds. Forty-nine younger children were recruited (mean age = 5;3; range: 4;11 to 5;9), and 60 children for the older age group (mean age = 8;4; range: 7;11 to 9;4). Informed consent was obtained from their school and their parents.

Materials Fourteen experimental sets of pictures were built, plus three warm-up trials. Each set was associated with a category *(e.g., clothing, food, tools, accessories, animals)*, and was composed of 7 pictures. Two learning objects, either from the same basic level category (close learning, L1 and $L2_C$) or from the same superordinate category (far learning, L1 and $L2_F$) (see Figure 1). The test pictures subsets were composed of three pictures: a taxonomically related generalization object (Ta), either near Ta_N, or distant, Ta_D, see Figure 1), an object perceptually similar to the initial learning object (P) and an object thematically related to the category (Th) (see Figure 1). This design worked as follows. For each object category (e.g., clothing accessories), the close learning objects (L1, $L2_C$) were composed of perceptually and semantically close items (e.g., a bracelet - a curb chain), while the far pairs (L1, $L2_F$) were composed of perceptually similar but conceptually more distant items (e.g., a bracelet – a watch). The three test pictures consisted of three objects in both the near and the distant generalization conditions. The perceptual match (P) was perceptually similar but semantically unrelated to the two training items (e.g., a tire in our bracelet case), the taxonomic choice (Ta) was perceptually dissimilar but taxonomically related to the learning objects and a thematically related object that was not perceptually related but thematically related (Th, e.g., a hand). Depending on the generalization condition, near or distant, the taxonomic choice was semantically near (Ta_N) or more distant (Ta_D) to the learning items (e.g., a jewel pendant in the near generalization case, or a bow tie in the distant generalization case). See Figure 1 for the "clothing accessories" category. Thus, a trial was composed of 5 pictures, L1, L2 ($L2_C$ or $L2_F$) , Th, Ta (Ta_N or Ta_D) and P, resulting in four possibilities (Close learning - Near or Distant generalization; Far learning - Near of Distant generalization.

Independent similarity ratings were obtained from fifty-four university undergraduate students. They are described in Thibaut and Witt (2017). They revealed that the close learning objects in a pair were conceptually closer one to the other than the objects composing the far learning pairs ($p < .01$, see Thibaut & Witt, 2017, for details) and that close generalization stimuli were semantically more similar to the two learning stimuli than far generalization stimuli were (see Thibaut & Witt for details $p < .01$). The same is true for perceptual similarity ratings which also revealed that the perceptual choices were more perceptually similar to the learning material than the objects used to instantiate taxonomic choices, ($p < .01$). For example, for the accessories category, a jewel pendant (near generalization object) or a bow tie (distant generalization object)

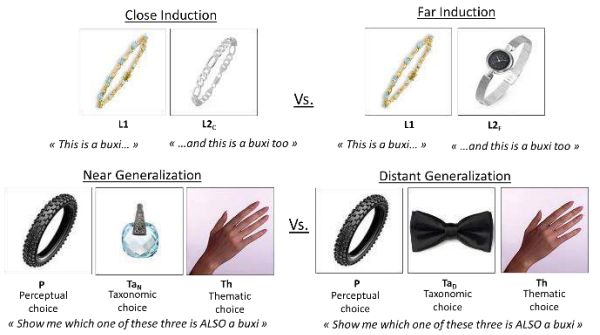

Figure 1: Example of a stimulus set and instructions adapted for the fourteen experimental conditions resulting from crossing Learning distance (Close vs. Far comparison) and Generalization distance (Near vs. Distant generalization) factors.

We forged 14 different bisyllabic labels (pseudo-words) which are, as shown by Gathercole and Baddeley (1993), easier to remember than monosyllabic pseudo-words (e.g., buxi, dajo, zatu, xanto, vira). Syllables were of the CV type which is the dominant word structure in French (from Lexique.org, New, Pallier, Brysbaert, & Ferrand, 2004).

The pictures were displayed on a Tobii T120 eye-tracker device with a 1024x768 screen resolution. The five pictures

of a trial were displayed simultaneously until the answer was chosen. Between each trial a standard fixation cross was shown for 3 seconds. Each experimental session started with a standard calibration phase, after the three warm-up trials. The experiment was run with E-prime®.

The five areas of interest (AOI, L1, L2 , Ta, Th or P) of a trial had a size of 500 by 500 pixels regardless of the object size inside the frame. The frame was chosen as the AOI's outline instead of the picture's outline, to standardize the AOI size.

Procedure The learning pair was displayed at the top of the screen and the test objects at the bottom. First the experimenter introduced the experiment as a game, using the following instructions. "Hello, we are going to play together, and we are going to play with a bear called Sammy. Look, this is Sammy, he lives far away from here and speaks a different language, we are going to learn his language" Then the children saw all three warm-up sets, with the trial instruction, which were followed by eye-tracking calibration. The experimenter then showed the fourteen trials, with the following instructions: "See Sammy's mummy says this is a buxi. And this is a buxi too. Sammy must find another buxi. Can you show which one is also a buxi, to help Sammy? Can you point to the other buxi?". Children chose one of the three test objects by pointing to it on the screen and the experimenter selected it with the mouse.

The presentation order of the fourteen experimental trials, the learning pair objects' position and the generalization objects' position were randomly assigned by the program (e.g., L1 L2, left right or right left, on the top of the screen; Th Ta P, Ta Th P for generalization objects). The names were assigned randomly to each trial. Participants were supposed to know the items. Indeed, these items were calibrated for knowledge by Thibaut and Witt (2017) and, in their experiment, were used with younger children. In their case, the percentage of unknown items was very low.

Design: Five and eight-year-old children were compared. Children were randomly assigned to one of the two experimental conditions (*close* comparison, 55 children or *far* comparison, 54 children). Age was crossed with Learning distance (*close* vs. *far* comparison, between-subject factor) and Generalization distance (*near* vs. *distant*, within-subject factor).

Results

Our first point of interest was the strategies used by the participants to compare and generalize the novel word to the taxonomic item.

Performance data We ran a three-way ANOVA on the percentage of correct taxonomic answers with Age (5, *8 years*), Learning distance (*close*, *far*) as a between factor, Generalization distance (*Near*, *Distant*) as a within factor. This ANOVA revealed a significant main effect of Age $F(1,101) = 29.41$, $p < .01$, $\eta_P^2 = .23$ (5-y-o., $M = 70.91\%$; $SD = 3.31$; 8-y-o, $M = 44.37\%$; $SD = 3.61$). The main effect of the Generalization Distance was significant, $F(1,101) = 31.04$, $p < .01$, $\eta_P^2 = .24$. Age and Generalization Distance interacted, $F(1,102) = 6.61$, $p < .05$, $\eta_P^2 = .06$ (Figure 2). A posteriori Tukey analyses showed that both generalization levels did not differ significantly in the younger group ($p = .18$ $M_{Near} = 45.9\%$ $M_{Distant} = 38.9\%$) whereas 8-year olds had better results for near generalization stimuli ($p < .001$ $M_{Near} = 76.1\%$; $M_{Distant} = 58.6\%$). Both age groups answered significantly above chance (5-year olds, $p < .001$; 8-year olds, $p < .001$).

A one sample t-test revealed that the majority of errors were perceptual matches, (5-year olds: $t = 5.18$ $p < .001$ $M_P = 5.7$ $M_{Th} = 2.42$; 8-year olds: t=2.81 $p < .01$ $M_P = 3.12$ $M_{Th} = 1.49$)

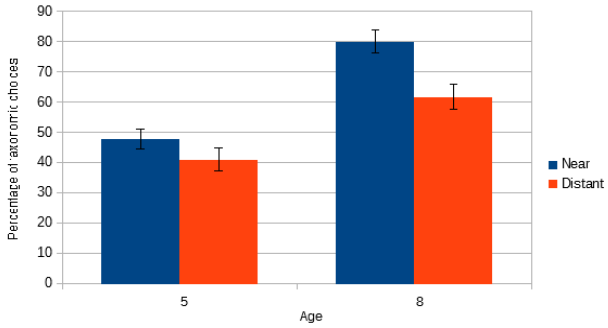

Figure 2: Percentage of taxonomic choices as a function of Age (5 and 8 years) and Generalization Distance (Near, Distant). Error bars are SEM.

We ran the same 3-way ANOVA on reaction times for the items that were correctly answered (see Thibaut & French, 2016). This ANOVA revealed the effect of Age, $F(1,101) = 13.35$, $p < .01$, $\eta_P^2 = .12$, the older children made faster choices ($M = 9539.83$ ms) than the younger children ($M = 11\,618$ ms). Age interacted with Learning distance $F(1,101) = 4.01$, $p < .05$, $\eta_P^2 = .04$ (Figure 3), and with Generalization distance $F(1,101) = 9.62$, $p < .01$, $\eta_P^2 = .09$ (Figure 4). As shown by Figures 3 and 4, the interactions resulted from an opposite pattern in the two age groups, longer RTs in the close and near conditions for the

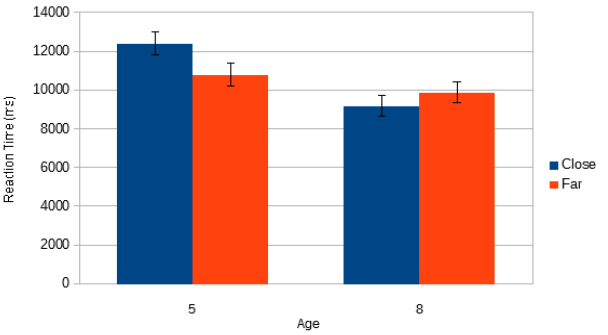

Figure 3: Reaction times (in ms) as a function of Age (5 or 8 years) and Learning Distance (Close or Far). Error bars are SEM.

younger group, and the opposite in the older group.

One interpretation of this pattern of results is that 8-year olds had a high level of performance in all conditions, but that the distant generalization condition was more difficult than the near generalization condition. The higher RTs reflect this higher level of difficulty. For younger children,

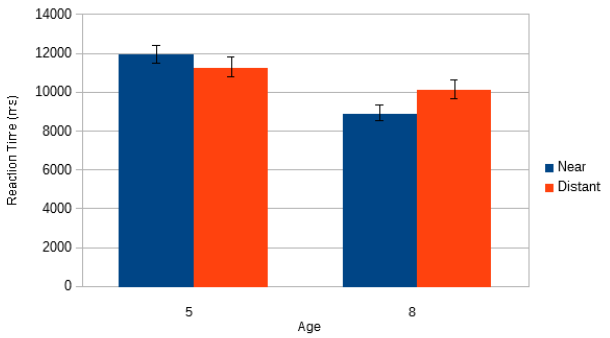

Figure 4: Reaction times (in ms) as a function of Age (5 or 8 years) and Generalization Distance (Near or Distant). Error bars are SEM.

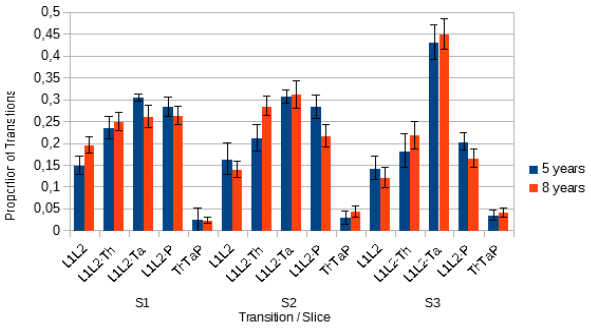

Figure 5: Proportion of transitions as a function of the Slice (S1, S2 or S3) and the Transition type (L1L2, L1L2-Th, L1L12-Ta, L1L2-P, ThTaP) for correct trials. Note: L1L2 are transitions between Learning1 and Learning2; L1L2-Th, between L1 or L2 and Thematic; L1L2-Ta, between L1 or L2 and Taxonomic; L1L2-P, between L1 or L2 and Perceptual; ThTaP, between Th, Ta and P) (Error bars are SEM)

the level of performance was close to chance, and lower RTs might reflect a tendency to answer quickly when the answer was difficult to find, or was less obvious, resulting in shorter RTs

Eight-year-olds had a higher level of performance in both conditions compared to 5-year-olds. Younger children's RTs are lower than the 8 year-old's RTs. However, the younger group does not significantly differ from chance. Chance performance might reflect a tendency to answer too quickly whereas the 8-year-olds RTs are likely to reflect the time necessary for the children to perform a more systematic analysis of a trial before giving an answer.

Eye tracking analyses on transitions (saccades)

The design of the analysis is complex. Since we focus on the temporal dynamic of the search for a solution, interactions involving transitions and time slices are central. A transition (or switch) was defined as a saccade between two stimuli. Each trial was decomposed into 3 time slices (S1-beginning, S2-middle, S3-end) of equal size. We ran a five-way analysis of variance (ANOVA) on the proportions of transitions for *correct* answers, with Age (5 and *8 years*), Learning Distance (*Close*, *Far*) as between factors, Generalization distance (*Near*, *Distant*), slice (S1, S2, S3), and Transition type (L1L2, L1L2-Ta, L1L2-P, L1L2-Th, Ta-P-Th) as within factors. There was a main effect of the Transition type factor, $F(8,640) = 111$, $p < .01$, $\eta_P^2 = .58$. Transition type and Slice interacted, $F(8,640) = 22$, $p < .01$, $\eta_P^2 = .21$. The ANOVA revealed two three-way interactions. The most interesting was the interaction between Slice, Transition type, and Age: $F(8,640) = 2.19$, $p < .05$, $\eta_P^2 = .03$ (see Figure 5). Slice, Transition type, Learning distance also interacted: $F(8,640) = 2.41$, $p < .05$, $\eta_P^2 = .03$, an interaction that we will not analyze here.

Figure 5 shows that all the transition types appeared in the first slice, at the same level, except transitions Th-Ta-P (i.e., between Thematic, Taxonomic and Perceptual generalization items) which are virtually absent in the threeslices. This absence of between-solution transitions is important because it shows that the alignment hypothesis is confirmed (ie. back and forth transitions between learning and generalization items). Second, overall, the general search profile was similar in both age groups. They compared L1 with L2 and each option with L1 and L2 in the first slice and then progressively converged on the correct solution. The large proportion of saccades between L1-L2 and each option is a bit unexpected, since we expected more L1-L2 transitions than any other type. However, it might mean either that from the onset of the trial participants actually looked at all the options at the same rate or that participants looked at L1 and L2 first, and very slightly later transitioned between generalization options and L1-L2 during the first time slice.

In order to disentangle these two possibilities, we ran an ANOVA on the fixation times towards the five AOIs in the first time slice, for correct trials. The analysis revealed a significant effect of AOI, $F(4, 388) = 28.864$, $p < .0001$, $\eta_P^2 = .22$, M = L1 = 27%, L2 = 27%, Th = 15 %, Ta = 15,5%, P = 16%. Tukey HSD revealed that L1 and L2 looking times were significantly larger than the other three AOIs. These results show that children gazed more at L1 and L2 than at the other stimuli at the beginning of the trial, but switched to the options quite early in the trial.

Correct answers and errors profile A last analysis compared the search profiles for correct answers and errors in the younger group only (5-year olds), because the number of errors was low for 8-year olds. An error was either a thematic or a perceptual choice. Two options are possible. First, errors and correct answers have similar search profiles: errors would be the result of a correct search, but followed by a wrong decision. Second, errors might result from different search patterns, which would differ from the onset of the trial. We ran a five-way ANOVA with Learning distance (Close, Far) as a between factor, and Accuracy (Correct, False), Generalization Distance (Near, Distant), Slice (S1, S2, S3), Transition type (L1L2, L1L2-Th, L1L12-Ta, L1L2-P) as within factors. Time slices were defined as the 1st, 2nd, and 3rd thirds of a trial. We excluded the transition Th-Ta-P from the analysis, because its frequency was close to 0. The ANOVA revealed a main effect of Transition type $F(6,162) = 19$, $p < .01$, $\eta_P^2 = .41$; an interaction between Accuracy and Transition type $F(6,162) = 6.64$, $p < .01$, $\eta_P^2 = .19$; an interaction between Generalization distance, Slice and Learning distance,

$F(6,162) = 3.65$, $p < .05$, $\eta_p^2 = .12$. The main result was the interaction between Accuracy, Slice and Transition type: $F(6,162) = 6.70$, $p < .0001$, $\eta_p^2 = .19$ (Figure 6). It shows that the main difference between errors and correct answers takes place during the third slice of the trial, participants focusing on the selected option, error or correct. Note that there were two peaks for errors, on Th and P. This can be related to the predominance of perceptual errors, in the 3rd slice. This suggests that participants studied both incorrect options but, eventually, went for the most salient one. Another interesting feature of this interaction is that the first two slices of the error trials had a flatter pattern than the

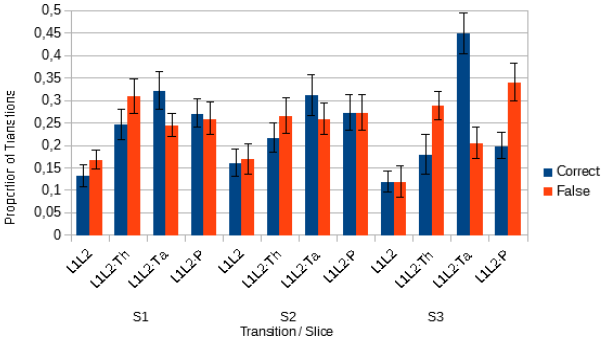

Figure 5: Proportion of transitions as a function of Accuracy (Correct, False), Transition type (L1L2, L1L2-Th, L1L12-Ta, L1L2-P) and Slice (S1, S2, S3). Error bars are SEM

correct answers. This might suggest that errors take hold in the 1st and 2nd slice, that is earlier than at the decisional stage. A priori contrasts between correct answers and errors revealed significantly more L1L2-Th transitions in error patterns rather than in correct trials in slice 1 and significantly more L1L2-Th and L1L2-P for error than for correct trials in slice 3, and significantly more L1L2-Ta in correct than in errors.

Discussion

First, we assessed which learning and generalization conditions would give the best generalization results as a function of conceptual distance between learning items and between learning items and generalization items. Second, we characterized the temporal dynamics of a solution, as a function of age and learning and generalization conditions with eye tracking movements. Generalization was better for near items than for distant items, with a larger difference in older children. This was confirmed by the higher RTs in the distant generalization case, in the 8-year-old group (younger participants results are difficult to interpret since they were at chance). These results might seem straightforward, at first glance. However, we predicted that the difference between near and distant trials should decrease for older children, because they should have a deeper conceptual understanding in the far learning case. Older children's performance significantly differed from chance in the two generalization conditions whereas younger children were at chance in the four conditions. This pattern of results suggests that some of the younger children encountered difficulties to integrate the information resulting from the comparisons, but does not mean that younger children answered randomly, as shown by the difference between error-correct gaze patterns.

The other main contribution, the eye-tracking analysis, revealed a consistent pattern of results across ages. All the comparisons were between learning items (L1-L2) and each of the three types of options, with virtually no comparison of the three options (i.e., no Th-Ta-P transitions). In the 1st slice, the remaining four transitions were equally distributed. However, the looking times on each of the five AOIs in the 1st slice showed that both age groups spent significantly more time on the training items than on the three generalization items, which is consistent with an initial search of commonalities between the learning items before considering the options.

Overall, in terms of the compared solving strategies, the results are consistent with an alignment view rather than with a projection view: participants first compare the learning stimuli, that is align each one with the other. Then comparisons between the learning pair and each option show that participants align commonalities found in L1-L2 with each of the options. A projection interpretation would be compatible with a high number of Th-Ta-P transitions, with participants comparing the three solution options one with the other in terms of the commonalities initially extracted from L1-L2, which occurred very rarely. In a similar way, results are not compatible with a constructive matching strategy. Indeed, as Figure 4 and 5 show, and the discussion above suggests, participants keep on looking at L1-L2 during the entire trial, while testing each option, the latter occurring very early.

There was no interaction between generalization distance and the transitions and slices. The significant interaction between learning distance, transitions and slices, though significant had a small effect size, and seemed to result from small differences, essentially in slice 1. This seems to suggest that generalization distance did not affect the search strategy in a systematic way.

The anatomy of errors Do search patterns for correct answers differ from those for errors? Much of the triple interaction between accuracy, slice and transitions seems to be explained by the distribution of taxonomic, thematic and perceptual choices in correct trials and errors in the 3rd slice (see Figure 5). This pattern would mostly reflect decisional processes at the end of the trial rather than early differences. However, the flatter profile in slice 1 for errors together with the significant difference between errors and correct trials for thematic answers suggest that errors might be prepared early on. This would be consistent with Thibaut and French (2016) who, in their eye-tracking study of analogical reasoning, showed that children's errors differed from correct answers in significant respects even at the onset of the trials.

In sum, younger children had difficulties across conditions whereas the older group could reliably extract the relation in most conditions, especially in the close generalization cases. The eye-tracking measures revealed similar search patterns in both groups of children, with early transitions between L1 and L2 and L1-L2 towards each solution option. Errors seemed to result from an incorrect decision but seemed to be prepared early on, maybe by a less systematic analysis of the taxonomic choice. A more extensive analysis of AOIs looking times and of the order

of the initial gazes should give us a more refined picture of early search steps. We might also analyze the response evaluation processes, for example with an analysis of the distribution of the backward transitions from the options towards L1-L2 separately. These transitions might reflect evaluation of participants' choices.

Using eye gaze data to examine the flexibility of resource allocation in visual working memory

Abstract

Computational models of visual working memory (VWM) generally fall into two categories: slots-based models and resources-based models. Slots-based models theorise that the capacity of memory is defined by a finite number of items. Each slot can only contain one item and once an item is in memory it is remembered accurately. If an item is not in memory, however, there is no memory of the item at all. By contrast, resources-based models claim that all items, rather than just a few enter memory. However, unlike the slots model they are not necessarily remembered accurately. On the surface, these models appear to make distinct predictions. However, as these models have been developed and expanded to capture empirical data, they have begun to mimic each other. Further complicating matters, Donkin, Kary, Tahir and Taylor (2016) proposed that observers were capable of using either slot- or resource-based encoding strategies. In the current experiment, we aimed to test the claim that observers adapt their encoding strategies depending on the task environment by observing how participants move their eyes in a VWM experiment. We ran participants on a standard colour recall task (Zhang and Luck, 2008) while tracking their eye movements. All participants were asked to remember either 3 or 6 items in a given trial, and we manipulated whether the number of items was held constant for a block of trials, or varied randomly. We expected to see participants use more resource-like encoding when the number of items to remember was predictable. Contrary to these expectations, we observed no difference between blocked and unblocked conditions. Further, the eye gaze data was only very weakly related to behaviour in the task. We conclude that caution should be taken in interpreting eye gaze data in VWM experiments.

Keywords: visual working memory; eye gaze; hierarchical modelling

Introduction

In recent years, there have been a number of attempts to describe visual working memory (VWM) using computational models. These models attempt to address fundamental questions such as whether VWM has a strict capacity limit and how likely a stimulus is to be remembered. Broadly speaking, these models fall into two categories: slots-based and resources-based models.

Slots-based models propose that memory functions like a finite set of slots with each slot able to hold one item. The slots-based model proposed by Luck and Vogel (1997) is the prototypical account of this type. If an item is in a slot then it will be remembered. Critically, this account states that if an item is in a memory slot it will be remembered with a very high precision. If it is not in memory, no information is retained about the item. Therefore, if asked to recall an item that is not in memory, a slots-based account assumes that person – having no information about the item – will be forced to guess. Zhang and Luck (2008) expanded on this basic model to create their slots plus averaging model that makes the additional assumption that when the observer has more slots than items to remember, then items are stored in multiple slots. The information in multiple slots can then be combined to produce a more accurate response, thus leading to better performance when set sizes are small.

The resources-based model, on the other hand, conceptualises memory as being more flexible than does the slots model. Memory is described as a resource that is allocated to different items. This memory resource determines the quality of the memories. The more memory resource an item is allocated, the more precise the memory. According to the standard resources model (Frick, 1988) memory is divided equally between all items in the display. Since the amount of memory resource is constant, the more objects there are in a display, the less memory each item is allocated. Unlike the slots model, all items are remembered however, they are remembered with less accuracy as the number of items increases. Beyond the standard model, a variety of resources-based models exist that allow resources to be distributed more flexibly, or models that favour selecting a few items to focus most resources on (Alvarez & Cavanagh, 2004; Bays & Husain, 2008).

The mimicry problem

Zhang and Luck (2008) compared their slots-plus-averaging model to a slots model and a resources model and found that their model provided a better account of the data in a colour recall task. They concluded that the slots-plus-averaging model provided a favourable account of their VWM data. However, this model was challenged by Van den Berg et al. (2012), who developed the resources-based, variable-precision model. Unlike the standard resources model, the variable-precision model assumed that memory resources could be distributed unequally between items in memory. Van den Berg et al. (2012) compared the resources, slots-plus-averaging and variable-precision models and found that the variable-precision model had a better account of the data. Furthermore, in a large scale study, Van den Berg, Awh, and Ma (2014) tested a host of computational models of VWM against the variable-precision model. Using data from multiple experiments across multiple sites it was found

that versions of the variable-precision model tended to provide the best account of the data.

Due to its flexible allocation of memory, the variable-precision model can produce many memory states that closely resemble what is predicted by a slot based model. For example, it is possible that in a 6 items display the mnemonic resource could be allocated equally between four items with no memory resource allocated to the other two. The result of such a memory state would be that four items are remembered with high precision and two are remembered with very low precision. If these very low precision memories are probed, the predictions of the model are indistinguishable from guessing. Such a memory state appears very much like a slots model. On the one hand, such overlap between models is problematic, due to model mimicry. Despite making the same predictions, the interpretations from the slots and resource models are very different. The variable-precision model states that "random" responses are caused by extremely low precision memories, while a slots model says that such responses are not based on memory. At our current level of understanding it is not possible to distinguish between these models. On the other hand, it could be that the mimicry between models represents what is actually shown in individuals. That is, perhaps observers do alternate between slot- and resource-like encoding of VWM displays.

A slot and resource model of encoding in VWM

A recent finding from Donkin, Kary, Tahir, and Taylor (2016) suggested that participants may be able to change their memory "strategy" in VWM tasks. Specifically, they argued that if people know how many items they will be required to remember, they are more likely to use a resource-like encoding, attempting to remember information about all items in the display, compared to if they don't know the set size of the next trial.

In their study, Donkin et al. (2016) analysed data from old and two new experiments with a model that used a mixture of slots-based and resources-based memory processes. The experiments were change detection experiments in which participants were tasked with recalling 2, 4, 6 or 8 items. In one experiment, set size varied from trial to trial, with an equal number of each size in each block of trials (the 'unblocked' condition). In the other experiment, set size was constant within each of four one-hour sessions (the 'blocked' condition). Compared to the experiments with unblocked set size, participants in the blocked experiment appeared more likely to use resource-like encoding (Figure 1). By contrast, participants in the unblocked condition were better accounted for by a slot-like encoding.

The authors suggest that VWM may be more flexibly applied than previously thought. It is possible that the task environment affects how people apply their memory. Perhaps if people know the number of items presented in a trial they will attempt to remember all items instead of focusing on a few. This would increase the chance of an item being in memory, but lower precision on blocked trials relative to unblocked trials and thus following a more resources-like pattern. While the behavioural data in a change detection task appear consistent with this suggestion (when analysed with these particular models), such a claim warrants more evidence to its support.

Here, we present data from a continuous production task in which participants were presented with items in either a blocked or unblocked conditions. To replicate the general results in Donkin et al. (2016), we expect that the number of items remembered should increase in the blocked compared to the unblocked condition (with a corresponding decrease in the precision of memory). As a further test of this prediction, we also use eye tracking to see whether eye movements differ between blocked and unblocked trials, thus suggesting endogenous attention is able to change the strategy used in VWM. We expect that participants in the blocked condition would move their eyes to more items in the display, presumably spending less time fixating on any given item.

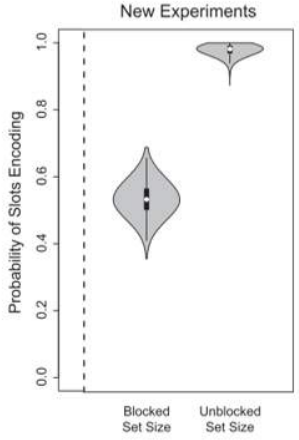

Figure 1: Results from Donkin et al. (2016) depicting the likelihood that participants used slots-like compared to resources-like encoding in the blocked and unblocked (new) experiments.

The current experiment

This experiment aimed to examine Donkin et al.'s (2016) claims that participants may be able to change their memory strategy depending on task environment. We wanted to determine whether 1) flexible memory allocation could be seen in a continuous report task, and 2) eye gaze could provide evidence of a change in memory strategy.

The task used was an adaptation of the colour recall task used by Zhang and Luck (2008), with the addition of eye tracking as well as a between-subjects condition of blocked or unblocked trials. The colour stimuli used in the standard production experiments are very simple to encode (Eng, Chen, & Jiang, 2005). As a result, a participant may be able to encode items quickly. We thought that more complex stimuli would encourage longer fixations and thus provide more data to assist our analysis. While more complex stimuli were desirable, it was also necessary to have stimuli that could be reproduced from a continuous range (the key benefit of colour stimuli). To this end, we used a "ring" set of stimuli. Shown in Figure 2a, these stimuli consisted of a coloured ring

with a "bead" placed randomly on the ring's circumference. Participants were asked to place the bead on the ring as it appeared during study (Figure 2b). The stimuli were presented in set sizes of N = 3 or 6 for 1000ms.

By introducing eye gaze to this task, we hope to observe some differences in attention between our blocked and unblocked conditions. In tasks in which participants can move their eyes freely – such as a visual search task – there is little evidence that participants utilise peripheral attention (Findlay & Gilchrist, 2001; Rayner, 2009). As such, where participants fixate their gaze provides a proxy for what they are attending. If participants are able to change their memory strategy it seems likely that there would be differences in attention allocation as well. In order to see every item on a trial, a participant must move their eyes faster for a 6-item trial than for a 3-item trial. In the blocked condition the participant knows the set size of the next item. With this knowledge, it is possible that they prepare to move their eyes more quickly in the 6-item blocks. In the unblocked condition, participants are unsure of the set size on the next trial. While they might encode set sizes of 3 fairly easily, without additional preparation they may not able to see every item when the set size is 6.

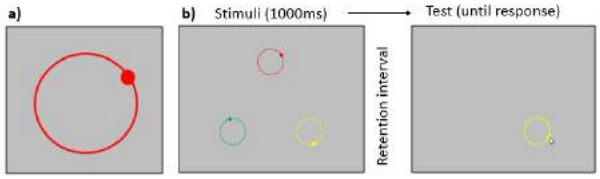

Figure 2: a) An example of the stimuli used. Stimuli varied in colour and location of the bead. b) The trial sequence. 3 or 6 stimuli were presented on a grey background for 1000ms followed by a retention interval (mask then blank screen) of 700ms. Participants were presented with a ring at the study location and were asked to place the bead on the ring as it appeared during study.

It was predicted that 1) similar to Donkin et al.'s (2016) results, we would find an increased probability resources-like encoding in the blocked condition of this experiment. This would be measured by higher chances on an item being in memory and lower precisions when compared to an unblocked condition. 2) We predicted we would see eye gaze data that supported more resources like encoding in the blocked condition. Specifically, more fixations but lower fixation durations compared to the unblocked condition.

Method

Participants 40 participants were recruited from the UNSW sign-up system SONA to complete a single one-hour session. Participants received $15 in exchange for participating.

Apparatus A Tobii TX300 eye-tracker, with 300 Hz temporal and 0.15° spatial resolution, mounted on a 23-inch widescreen monitor (1920 x 1080 resolution, refresh rate 60 Hz) was used. Participants' heads were positioned in a chinrest 60 cm from the screen.

Stimuli The stimuli (Figure 2a) were coloured rings with a filled circle placed on the ring's circumference. They could be one of eight distinct colours (red, yellow, green, cyan, blue, magenta, brown or salmon pink) and were presented on a grey background. All rings had a fixed diameter of 120 pixels (visual angle = 3.03°) and a thickness of 2 pixels (visual angle = 0.05°). Beads had a fixed diameter of 20 pixels (visual angle = 0.51°). Stimuli were presented randomly around the circumference of an invisible circle at the centre of the screen (diameter 600 pixels, visual angle = 15.1°). The angle between items was equal. Beads were randomly placed on the ring for each item, on each trial. The target was indicated by presenting just the ring of the stimulus in the location it had appeared in during study.

Design This recall task followed Zhang and Luck's (2008) design. 420 trials were divided into 14 blocks of 30 trials. Either N = 3 or 6 items were presented on each trial. In the unblocked condition, presentation was randomised per block with an equal number of 3 or 6 item displays per block. In the blocked condition, the first half of the experiment consisted of trials of all one set size and the second half consisted of only the other set size (counter balanced between participants).

Procedure A fixation cross was presented for 500ms at the start of each trial, followed by a blank screen for 400ms. The study array of N rings were presented for 1000ms. This was followed by a mask for 200ms then a blank screen for 500ms. The participant was then presented with a ring they saw at study (same location and colour) and was asked to place a bead on the ring where it appeared during the trial. The participant indicated where they believed the bead was with the mouse and confirmed their selection with the spacebar. Participants received feedback on their selection for 1000ms. Their deviation from the correct bead location was given in degrees alongside verbal feedback ("OUTSTANDING!" for deviations less than 10°, "Very good!" between 10° and 20°, "Good" between 20° and 35°, "OK" between 35° and 45° and deviations greater than 45° were labelled "Poor"). Figure 2b depicts the trial sequence. After each block, participants were given a break for a minimum of 20s before continuing.

Model procedure We used a model to allow us to compare the probability of an item being in memory (P_m) and the precision of memories (Prec) between the blocked and unblocked conditions. The model was a Bayesian hierarchical version of the Zhang and Luck (2008) mixture model (Oberauer, Stoneking, Wabersich, & Lin, 2017). The model assumed that the deviation between given response and the correct response either came from memory or from a separate guessing process. Responses based on memory were associated with Von Mises distributions with a mean that was centred on the correct response and a precision that varied depending on condition (blocked and unblocked), set size (3 and 6) and individual participant. Responses based on guessing were uniformly distributed around the circle for all conditions and all participants. The model allocated responses to either memory or guessing process by taking a value from a Bernoulli distribution with a probability of using

memory equal to P_m. The parameters P_m, like Prec, also varied with condition, set size and individual participant. Thus, four values were estimated for each participant, P_m and Prec for set sizes 3 and 6 (remembering that blocked and unblocked conditions are between subjects). Rather than estimating parameters separately for each participant, we instead constrained individual-participant level parameters such that they came from their own population-level Normal distributions (i.e., one for each parameter in each set size and blocked/unblocked condition). We focus our analysis on the population-level posterior distributions of P_m and Prec across the four conditions of our experiment.

Results

Prior to analysis, trials with no eye gaze data collected were removed (544 trials or 3.24% of trial data). Trials with more than 10 fixations during the presentation window were also removed (964 trials, 5.74% of the data) as were trials where the average fixation duration was less than 125ms (2703 trials, 16.09% of the data).

Behavioural results For each trial, the deviation between the participant's answer and the true bead location was recorded. Since the range of answers varied around the circumference of the circle, the deviation was expressed in radians (π radians = 180 degrees). Figure 3 shows the frequency distribution of deviations for set sizes 3 and 6 (green and red lines respectively) for unblocked and blocked set sizes. Both conditions displayed the typical response pattern for this task (e.g. Zhang and Luck, 2008) with most responses clustered around the correct response for both set sizes but with more accurate responses for set size 3.

Modelling results Figure 4 shows plots of the population-level posterior distribution for P_m and Prec across condition and set size. There was no visible difference in P_m values for set size 3 between the blocked and unblocked conditions. There was a slight indication of a difference between the unblocked and blocked conditions for set size 6, with smaller P_m values in the blocked compared to the unblocked condition. Note that this pattern is the opposite of what we expected. Prec values appear to differ across set size, with higher precision in set size 3 compared to 6. However, there was no observable difference between the blocked and unblocked conditions.

The differences in Pm and Prec values between conditions for set size 6 only are presented in Figure 5. The difference between the posterior distributions for Prec centres on zero, suggesting no difference between conditions in precision for set size 6. The plot of P_m difference shows higher values for P_m in the unblocked condition compared to the blocked condition. However, this difference is small. Since an appreciable mass of the posterior distribution surrounds zero, there is little evidence of a difference between the conditions.

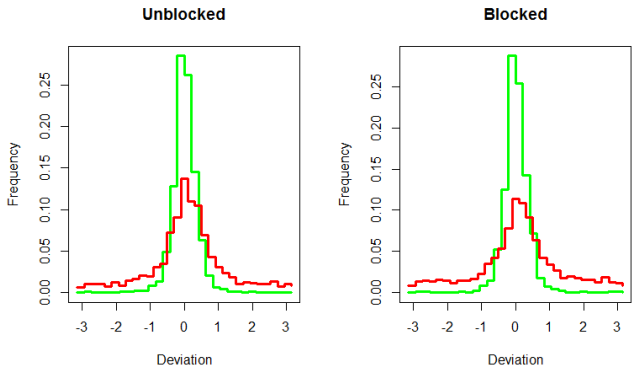

Figure 3: The frequency of responses by deviation from actual bead location for the unblocked and blocked conditions. The green line represents set size 3 the red line represents set size 6.

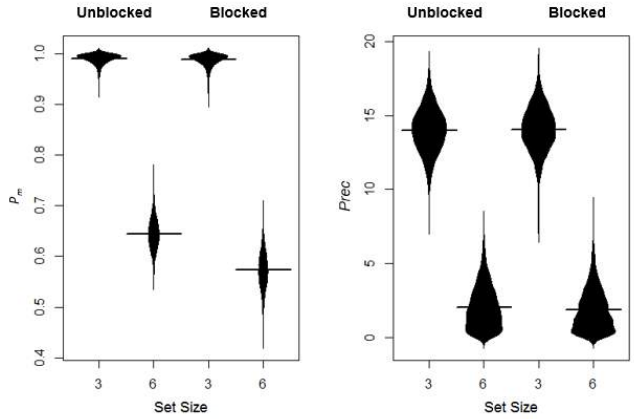

Figure 4: Posterior distribution for Pm and Prec parameters in blocked and unblocked conditions for both set size 3 and 6. Horizontal lines show the mean of the distributions.

Eye gaze results We now compare unblocked and blocked conditions using the average fixation duration per trial and the average number of fixations for each set size. The mean values of each measure in each condition are plotted in Figure 6. On average, the unblocked condition had more fixations and less fixation duration compared to the blocked condition. Again, the qualitative pattern, if present, is in the opposite direction of what was expected.

An analysis of variance (ANOVA) on average number of fixations and average fixation duration yielded no significant effect of condition ($F(1,37) = 1.441$, $p = 0.238$; $F(1,37) = 1.443$, $p = 0.237$ respectively) or set size ($F(1,37) = 0.337$, $p = 0.543$; $F(1,37) = 0.170$, $p = 0.682$ respectively) on either measure. We find no strong evidence for a difference between the average number of fixations or average fixation duration between trials of different set size or condition.

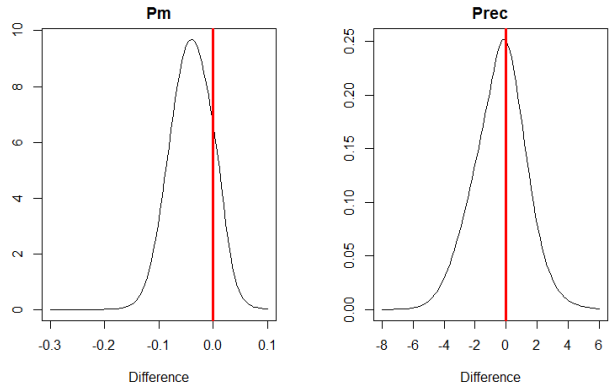

Figure 5: Difference in the posterior distributions of Pm and Prec between the unblocked and blocked conditions (set size 6 only).

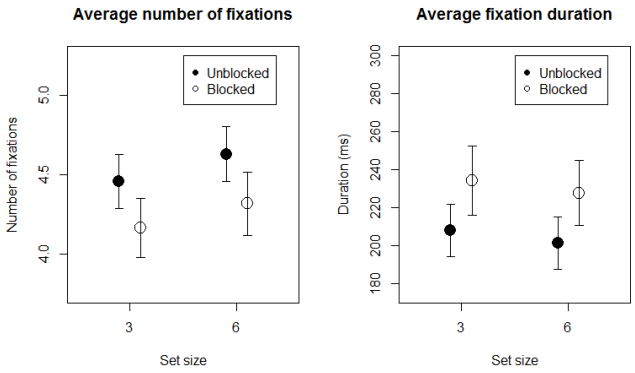

Figure 6: Average number of fixations and average fixation duration per trial for blocked and unblocked conditions for set sizes 3 and 6. Error bars indicate the standard deviations.

Discussion

The behavioural results for both the blocked and unblocked conditions were similar. The modelling results indicated very little difference in the memory strategies between conditions. For each condition, similar values for the probability of an item being in memory and for precision were found. Similarly, there was little difference in eye gaze patterns. There was a suggestion that there was a higher probability of an item being in memory in the unblocked condition. However, there were more fixations with lower durations in this condition as well. This trend is counter to our prediction, that the blocked condition would have a higher probability of items in memory, more fixations and lower average fixation duration.

Overall, these results are not consistent with what we expected based on Donkin et al.'s (2016) finding that memory can be flexibly allocated based on task environment. There were a number of differences in the experimental design between the Donkin et al. experiments and those reported here. The largest difference seems to be that here we used a continuous production task. It may be that participants are less able or willing to adapt their mnemonic resources in production tasks. On the face of it, production tasks require a more precise response than in a recognition/change detection task (in which there are only two responses). In the change detection experiments reported in Donkin et al., it was the blocked condition that was unlike previous experiments. It may have been that participants in our blocked condition did not spread their resources more diffusely in an attempt to remember more items because of the resultant cost to the precision of their memories. Future experiments could encourage participants to accept more error in their response, giving positive feedback whenever a response falls within a particular region around the correct response. Perhaps participants would adjust their mnemonic allocation in blocked conditions (where the number of items to remember is predictable) in such lenient environments. That said, such an explanation is obviously post-hoc, and so we do interpret this data as problematic for a model of VWM that proposes that mnemonic allocation is flexible and under strategic control.

In future work, we aim to connect the eye gaze data and the behaviour of individuals on individual trials. We have conducted preliminary analyses in which we see a weak correlation between fixation duration and the deviation between the correct response and the response given by the participant. We also see that whether an item was fixated during study is a weak predictor of deviation accuracy. These results were much weaker than we had anticipated, and so we will follow up these analyses with more refined methods. In particular, we will use summary statistics from eye gaze data as predictors for the parameters of the Zhang and Luck (2008) mixture model. For example, we might expect that an item not fixated during study would be more likely to come from a guessing process in the mixture model. We would also expect the fixation duration to affect the precision parameter of the memory process in the model. We have carried out versions of these analyses that we are not yet confident enough to report here, but were again very surprised by the lack of relationship between the eye gaze data and the behaviour of participants in the task.

Some of the flaws in the current design need to be addressed to convincingly link eye gaze and memory in this task. For example, one of the problems with the eye gaze data is perhaps that there is not enough distinction in where people are looking (their fixation locations) and their fixation durations. In this task, we suspect it is possible for participants to encode more than one stimulus in a single fixation as these relatively simple stimuli can be encoded quickly. We anticipate that either spatially separating items or more complex stimuli would therefore help distinguish which items a participant has looked at and thus attended and encoded.

Conclusions

Given participants did not move their eyes as much as anticipated, this seems to have impacted the collection of eye gaze information. In turn, the value of using eye gaze as our proxy for attention was thus diminished. As a result, we did not observe the difference in memory strategy between

unblocked and blocked conditions as seen by Donkin and colleagues (2016).

Logically, vision must be helpful in encoding visual items into memory. The lack of a connection between memory and eye gaze in this study is likely due to methodological reasons. As mentioned, it might be necessary to make items more complex or make the display array more separated. However, to what extent alterations need to be made in order to observe an effect of eye gaze on memory remains to be seen. Future experiments could include gaze contingent presentations. Such a paradigm could require participants to fixate on a stimuli for a set period of time within a study array. As a result, there would be more certainty in what participants have looked at and perhaps encoded.

Presently, the current experiment serves as a caution to those interested in investigating VWM tasks using eye gaze.

Abstract

Choice blindness is a cognitive phenomenon describing that when people receive false feedback about a choice they just made, they often accept the outcome as their own. Little is known about what predisposes people to correct manipulations they are subjected to in choice blindness studies. In this study, 118 participants answered a political attitude survey and were then asked to explain some of their responses out of which three had been manipulated to indicate an opposite position. Just over half (58.4%) of the manipulations were corrected. We measured extremity, centrality and commitment for each attitude, and one week prior to the experiment we assessed participants' preference for consistency, need for cognition and political awareness. Only extremity was able to predict correction. The results highlight the elusiveness of choice blindness and speak against dissonance and lack of motivation to engage in cognitively demanding tasks as explanations why the effect occurs.

Keywords: choice blindness; attitude change; attitude strength; need for cognition; preference for consistency; political awareness.

Introduction

Choice blindness (CB) is a cognitive phenomenon indicating a dissociation between making a choice and its later justification. It highlights the limitations of our introspective capacity when reasoning about past choices. CB occurs when people receive false feedback about a choice they just made accepting the outcome as their own and reporting seemingly introspective (albeit confabulated) reasons for having made that choice (see Johansson et al., 2005 for details). CB has been reported for many domains and modalities, ranging from taste and smell preferences (Hall, Johansson, Tärning, Sikström & Deutgen, 2010) to eye-witness testimony (Cochran, Greenspan, Bogart & Loftus, 2018), and has been shown to affect both later memories and preferences (e.g. Strandberg, Sivén, Hall, Johansson & Pärnamets, 2018; Pärnamets, Hall & Johansson, 2015; Johansson, Hall, Tärning, Sikström & Chater, 2014). CB has also been applied to the study of attitudes and attitude change, an area of research where deliberation and introspection are often seen as important ingredients. In Hall, Johansson and Strandberg (2012) about 60% of manipulations to a survey on moral dilemmas were accepted by the participants' as being their own attitudes. Hall et al., (2013) reported similar findings for salient political issues in the run up for a Swedish general election. In that study participants not only changed their attitudes on political issues, but their actual voting intention was also affected in the direction of the false feedback. Notably, Strandberg and colleagues (2018) found that when participants accepted the manipulations to political attitudes, these shifted congruently with the false feedback when re-elicited one week later. Although CB is ubiquitous, and undeniably relevant for the study of attitudes and decisions, little is known about what factors that predisposes people to correct the manipulated responses. So far, only a few studies have attempted to establish CB mediators, and thereby link the effect to other psychological constructs (e.g. Strandberg et al., 2018). However, no studies have focused purely on why people correct the false feedback. In this study, we aim to explore several factors that we have identified as meaningful for understanding why correction in the CB paradigm occurs, particularly in the domain of attitudes.

Subjective experience of attitude strength

One possible key to CB susceptibility could be in the relationship between the individual and the attitude itself. This is supported by the literature describing strong attitudes as "resistant to change, persuasion, and contextual influence" and weak attitudes as "unpredictable, malleable, and created in the moment" (Krosnick & Petty, 1995). Given this definition, it seems reasonable that correction of manipulations to attitudes should correlate with attitude strength. Here we tested three self-report measures adopted from Bassili's (1996) seminal work on attitude strength: extremity, centrality and commitment. Extremity directly estimates how strongly a person agrees with an issue on a bipolar scale. Extremity, which is basically just the response to the survey item, is what Bassili calls an operative measure based on first order cognitive processing. Extremity is operative because, for example, the

experienced valence of the extremity could be directly retrieved from memory and not the product of inference. Centrality and commitment, on the other hand, are so called meta-attitudes. These are second order impressions of attitudes that rely on people to report on psychological properties not necessarily represented in long-term memory. As such, meta-attitudes are often inferred from sources more or less relevant to the strength of which the attitude is held. Centrality is described as tapping into the importance of an attitude and how it relates to personal values. Studies show that central attitudes are often more memorable and resistant to persuasion and contextual influence compared to peripheral attitudes (Holland, 2003; Pomerantz et al., 1995). Commitment is described as tapping into the confidence in an attitude: the conviction that the attitude is correct and valid. Commitment has been shown to moderate self-perception and contextual influence in attitudes (Holland, 2003; Pomerantz et al., 1995). Since these measures are meant to capture attitude strength – with strong attitudes being defined by their "resistance to change, persuasion, and contextual influence" – they should also correlate with correction of CB manipulations.

Variation in cognitive style

Another possibility is that aspects of the CB task might be experienced as rather cognitively demanding, such that some individuals may be more susceptible to CB than others due to being less motivated to perform them. Previous studies have shown that individuals with a larger set of general analytic skill are more prone to correct the manipulations (Strandberg et al., 2018). Hence, measures capturing peoples' motivation to engage in cognitively demanding task, such as the *Need for Cognition* (NC; Cacioppo, Petty & Kao, 1984; Cacioppo, Petty, Feinstein & Jarvis, 1996) might also correlate with correction. NC is commonly used in attitude change research, where studies have shown that people with high NC tend to form attitudes that are more resistant to persuasion compared to people with low NC (Haugtvedt & Petty, 1992). CB could also be affected by a consistency motive, which is the case for dissonance phenomena such as cognitive dissonance, cognitive balance, foot-in-the-door etc. These phenomena show that people often change either their behavior or their attitudes to appear consistent (cf. Festinger, 1957). One measure for estimating peoples' need to have consistent cognitions is *Preference for Consistency* (PFC; Cialdini, Trost & Newsom, 1995). Further, PFC has also been shown to predict if people change their attitudes due to social pressure or external demand (Bator & Cialdini, 2006). Thus, if CB share properties with cognitive dissonance phenomena; or if participants accept manipulations due to demand from the experimental situation, correction may correlate with the PFC score.

Variation in political awareness

We would also like to consider variation in political awareness, since much research in political science highlights political awareness as one of the most important factors when forming strong and resilient political attitudes (Zaller, 1992). Interestingly, recent CB studies involving political attitudes have yielded mixed results. In Hall et al. (2012) politically involved participants were more likely to correct the manipulations, and this was not found in Strandberg et al. (2018). However, since political awareness is supposed to determine how people select, interpret and internalize political information (Sidanius, 1988; Lusk & Judd, 1988) we continue to explore the relationship between various measures of political awareness and participants' behavior in a CB study involving political issues.

Thus, we set out to test if susceptibility to correct manipulated responses in CB could be predicted by any of the attitude strength measures, variation in cognitive style, or political awareness described above.

Method

Participants

A total of 128 (70 female) participants, with ages ranging from 18 to 64 years (M = 23.5, SD = 16.8), were recruited to answer a political survey. Sample size was predetermined based on previous CB studies (e.g. Johansson et al. 2005). Ten participants were excluded due to malfunctions with the experimental equipment. Thus, 118 participants remained for the final analysis. The participants were recruited through posters and flyers distributed at the university campuses of Lund and Malmö and compensated with a cinema voucher. At the start of the experiment, we described the general purpose of the study, but without telling the participants that some of their answers would be manipulated. Participants were informed that they could quit the experiment at any time, request their data to be erased, and still receive the cinema voucher. Participants were fully debriefed at the end of the experiment, before consenting to their anonymized data to be used by signing a consent form. All but six participants allowed their interviews to be recorded (leaving a total of 112 verbal recordings to be analyzed). The study was approved by the Lund University Ethics board, D.nr. 2008–2435.

Materials and design

Pre-test One week before the main experiment, participants completed an online questionnaire assessing their demographics, political awareness, PFC and NC. PFC was assessed using the abbreviated 9-item version (Cialdini et al., 1995) with scales ranging from 1 (low consistency) to 9 (high consistency). The PFC questionnaire assessed the participants' internal and external consistency and included items such as: "It is important to me that my actions are consistent with my beliefs". For NC, we used the 18-item version (Cacioppo, Petty & Kao, 1984) with scales ranging from 1 to 9 where a nine gave four points and a one subtracted four points (five gave zero points, and so on).

The NC questionnaire assessed the participants' attitudes towards effortful thinking, and contained items such as: "I usually end up deliberating about issues even when they do not affect me personally". Further, political awareness was established by assessing the participants' political interest with a scale ranging from extremely uninterested (1) to extremely interested (9), and whether they were involved in any political party or organization (yes/no). Visit *https://osf.io/zsy47/* for a list of all measures and items.

Main experiment After the pre-test, participants scheduled to partake in the main experiment being held one week later. It consisted of a questionnaire running on a tablet with a touch-based interface that the participants interacted with using a tablet pen. The experiment consisted of two parts: (1) responding to political issues, (2) explaining the responses, and ended with a full debriefing.

Procedure

Part 1 – responding to political issues During the first part, participants responded to 12 sets of political issues with each set containing a political statement and corresponding six meta-attitudes; three centrality, such as "how important is this issue to you?", and three commitment, such as "how confident are you about your attitude towards this issue?" (visit *https://osf.io/zsy47/* to see all centrality and commitment items). The political issues were selected together with leading political scientists, and represented 12 of the most salient and important issues in Sweden at the time of the study (Table 1). As such, we believe that the vast majority of our participants were familiar with them. This was also confirmed by the verbal reports: most participants were able to intelligibly and knowingly discuss the various issues. Below each item were visual analog scales with endpoints at 0 and 100 (completely disagree to completely agree for the political statements and for example extremely unimportant to extremely important for the centrality item "importance"). The participants were instructed respond to each item by drawing a mark using the pen. They could change their responses as many times as they wanted by clicking a change icon located to the left of each scale, as well as toggle freely between the 12 sets of issues. The participants were left to complete the questionnaire at own, and told to inform the experimenter when finished.

False feedback and correction When going over and explaining the responses, participants had received false feedback on three of the six trials. Trials 2, 4 and 6 had been manipulated by the tablet application to indicate a position opposite to the original (Figure 1). Trials 1, 3 and 5 were non-manipulated controls. The manipulation had two rules: move the participants' rating across the midline of the scale (with a minimum of 5 mm from the middle, i.e. ratings 45 or 55), and then randomly positioned on the opposite axis. If participants in any way indicated that their responses did not correspond with their views, or indicated that something was wrong, the experimenter would tell them that they could change their response if they wanted to, after which they could base their explanation on that response instead. Correction was operationalized when change was clicked and a new response drawn.

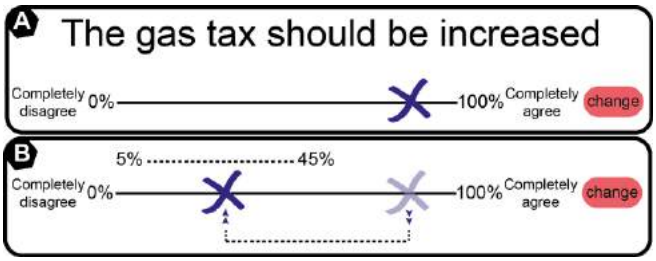

Figure 1: To respond, participants drew an X on a scale going from completely disagree to completely agree (A). On manipulated trials, participant's X was surreptitiously moved from one side of the scale and then randomly placed on the other side (B). Participants could change their X as many times as they wanted by clicking 'change' (A-B).

Table 1: The political issue statements.

1.	The gas tax should be increased
2.	A wealth tax should be reinstated
3.	The labor taxes should be lowered
4.	The monarchy should be abolished
5.	The government should run all elementary schools
6.	The punishment for violent crimes should be stricter
7.	The subsidized service for homework assistance should be abolished
8.	High schools should offer more applied and fewer theoretical courses
9.	Women should be recruited to company boards through affirmative action
10.	Private health care companies should be allowed to make profits in the welfare sector
11.	Copyright protected material from internet should be free to download for personal use
12.	The government should be allowed to monitor telephone conversations and internet traffic

Analysis

Consistent with Bassili (1996) extremity was calculated by taking the absolute value of the deviation between a rating on the 100 point scale and the midpoint. All other variables are reported using their averages. Since attitude extremity, and the difference between the original rating and the manipulated rating, labeled 'manipulation length', are core features in CB studies using rating scales; we first tested how well these would predict correction. In our dataset, extremity and manipulation length were highly correlated, r = .73, $t_{(333)}$ = 19.6, p = 2.2*10^{-16}. To address this we performed our analyses using decorrelated variables by transforming manipulation length to be the distance on the scale the manipulated attitude was moved *beyond* the midpoint. The resulting variables were independent, r = -.028, $t_{(333)}$ = -0.52, p = .61. We then used these two variables to fit a baseline for the other predictor variables (i.e. meta-attitudes and cognitive style). We analyzed our data using mixed regression models including by participant varying intercepts and slopes. Models were estimated in a Bayesian framework using the brms package in R (Bürkner, 2016). Weakly regularizing priors were used for all parameters.

Results

On average participants were moderately interested in politics (M = 6.0, SD = 2.1) and about one fifth identified as politically involved (M = 22.9, SD = 42.2). As we can see in Table 2, extremity, centrality and commitment was rated fairly strong, averaging between 60 to 65 points of 100. The PFC score in our sample was similar to the 48.9 (SD = 10.7) that Cialdini et al. (1995) reported, and the NC score was similar to that reported in a recent meta-analysis of the NC scale (M = 33.2, SD = 10.2 (de Holanda & Wolf, 2018)).

Table 2: Means and SD for the main predictor variables.

Predictor	Mean	SD
Extremity	29.2	13.9
Centrality	63.9	18.2
Commitment	65.0	20.1
NC	29.1	17.8
PFC	44.8	12.6

False feedback correction

Participants corrected 58.4% of the total 347 manipulations. Each participant was exposed to three manipulations and the average correction rate was 1.66 (SD = 0.98), with 15 participants accepting all manipulations and 27 participants correcting all. After correcting a manipulation participants were instructed to replace it with a new response. This corrected rating was on average placed within 9.43 points (SD = 11.7) of their original rating; or -4.45 points (SD = 14.4) when taking the direction of the corrected rating into account (defining a weakened new rating as a negative quantity and a strengthened new rating as a positive quantity). As in previous CB studies, correction did not vary as a function of sex, gender, age, or political party.

Predictors of correction

To test for predictors of correction we conducted mixed-effects logistic regression analyses using standardized variables. We first fit a baseline model consisting of extremity and manipulation length. This model (LOO = 402.77, SE = 14.86) indicated a large effect of extremity on correction (β = 1.77, SD = 0.32, *95% CI* = [1.17, 2.43], BF_{10} > 1.0*10^5), but only a smaller, uncertain effect of manipulation length (β = 0.53, SD = 0.28, *95% CI* = [-0.0043, 1.09], BF_{10} = 1.67), with the intercept estimated as β = 0.46 (SD = 0.19, *95% CI* = [0.10, 0.84]). See Figure 2 for the marginal posterior predictions of the attitude extremity and manipulation length.

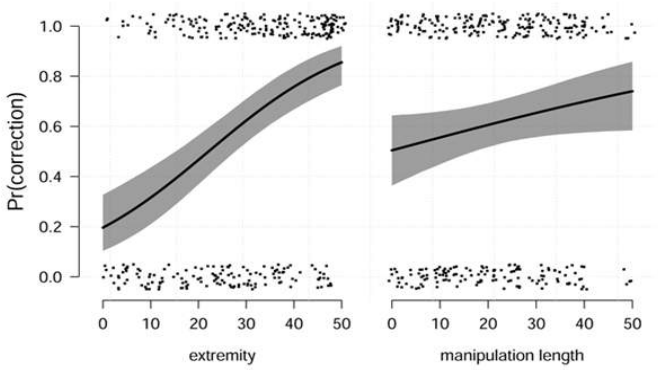

Figure 2: Marginal posterior predictions from the baseline model. Predictions assume other variable held at its average value (0 for standardized predictors). X-axes renormalized to increase interpretability. Shaded regions indicate 95% posterior intervals.

We next fit a full model with all our candidate predictors: extremity, centrality, commitment, preference for consistency (PFC), need for cognition (NC), political involvement, political interest and manipulation length (LOO = 401.65, SE = 17.03). The estimated coefficients, their credible intervals and associated Bayes Factors can be found in Table 3. Marginal posterior predictions are depicted in Figure 3. Notably, when comparing the baseline and full model using LOO we found that the baseline model and the full model did not differ, with a difference of 1.12 (SE = 6.23), this is also mirrored in the estimates where there is little evidence that any of the added predictors are particularly successful at estimating correction.

Predictors of correction types

On an exploratory note, we tried to better capture participants' subjective experience of correcting a manipulation. We conducted a simple classification of the reasons participants reported for wanting to correct.

Table 3: Estimates and Bayes Factors from the full model.

Predictor	Est (β)	SD	95% CI	BF_{10}
(Intercept)	0.51	0.21	[0.12, 0,94]	-
Extremity	1.34	0.38	[0.06, 2.10]	333.69
Centrality	0.44	0.39	[-0.31, 1.23]	0.71
Commitment	0.69	0.39	[-0.06, 1.46]	1.78
NC	-0.07	0.40	[-0.86, 0.72]	0.40
PFC	-0.12	0.37	[-0.85, 0.59]	0.38
Pol.Involvement	0.71	0.47	[-0.21, 1.62]	1.45
Pol.Interest	-0.22	0.43	[-1.06, 0.65]	0.49
Manip.Length	0.59	0.31	[-0.0013, 1.20]	1.94

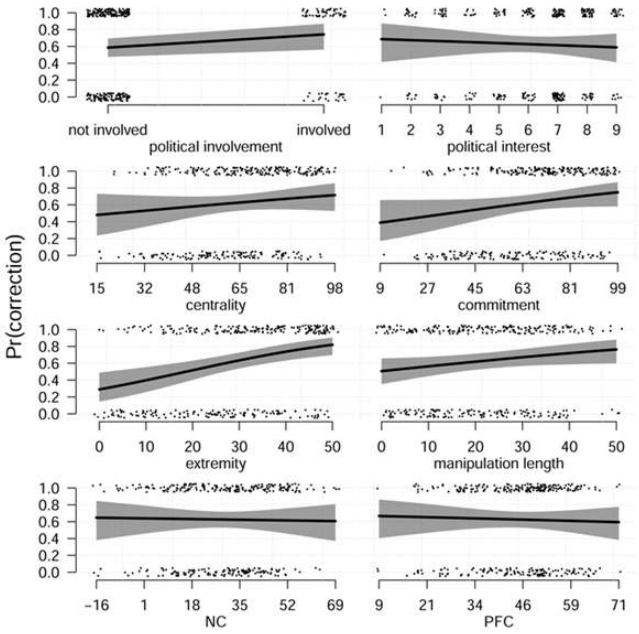

Figure 3: Marginal posterior predictions from the full model presented with the same properties as Figure 2.

One independent rater listened to all the 112 recorded interviews and coded the different reasons participants gave when correcting a manipulation. We identified three distinct types distributed evenly among the corrections: *internal attribution* (36.8%), when participants claimed to have misinterpreted the question, the scale, or something in the task; *external attribution* (33.9%), when participants blamed the experimental equipment; and *change* (29.2%), when participants felt they had spontaneously changed their minds about the issue. Only for a few trials did participants report suspicion that their responses had been manipulated; these were categorized as external attribution. A second rater then classified a subset of 40 interviews; the raters agreed on 90% of the classifications. To test for determinants of the correction types we conducted a hierarchical multinomial logistic regression analysis using correction type as dependent variable and the predictors used in previous analyses. Since we were mainly interested in whether people attributed the wish to correct internally or externally, the change category was used as the reference level in the analysis. Consistent with previous findings, most variables were unable to predict whether participants would attribute correction internally (e.g. feeling that they had made a mistake) or externally (e.g. blaming the experimental equipment). However, we did find that the larger absolute difference between the original response and the manipulated response the more likely participants were to attribute correction internally (β = 2.40, *SD* = 0.57, *95% CI* = [1.03, 3.57], BF_{10} = 1017.52). We also found a small negative effect of political involvement, meaning that participants that were uninvolved politically were more likely to attribute correction externally (β = -1.15, *SD* = 0.77, *95% CI* = [-2.63, 0.37], BF_{10} = 2.36). However, the effect size of this latter finding was very small, but could potentially be a subject for future research.

Discussion

To summarize, we first assessed participants' preference for consistency, need for cognition, and political awareness; and one week later measured attitude extremity, centrality and commitment on a questionnaire containing 12 political issues. Participants were then asked to explain their responses to six of these issues out of which three had been manipulated to indicate the opposite position using the Choice Blindness Paradigm. Just over half of the manipulations were corrected by the participants, meaning that the remaining was accepted by the participants as being their own attitudes. This is similar to previous CB studies on political attitudes (Strandberg et al. 2018; Hall et al. 2012).

Attitude strength

In this study we were particularly interested in testing potential underlying factors that predisposes participants to correct the manipulations. We found that correction was mainly predicted by attitude extremity; meaning that the stronger participants agreed with an issue on the bipolar scale, the more likely they were to correct it. That attitude extremity correlates with correction is also in line with previous CB research (Strandberg et al. 2018; Hall et al. 2012; 2013) and corresponds with for example Bassili's (1996) findings on the relationship between extremity and attitude stability. However, surprisingly, the two meta-attitudes centrality and commitment did not contribute to the correction prediction. One possible explanation to this could be that operative measures of attitude strength, such as extremity, are more relevant to the task compared to second order impressions such as centrality and commitment. Bassili (1996) suggested that extremity is closely associated with the cognitive processing involved in attitude formation and retrieval which is two main components in a CB task. Centrality and commitment on the other hand rather tap into more abstract concepts of the attitude structure (Holland, 2003) not necessarily relevant for scrutinizing one's own survey responses. It could also be that higher extremity is the product of deeper and more involved elaboration,

making those responses more salient and memorable (Petty & Cacioppo, 1986). These results highlight the difficulties in assuming an attitude's strength and stability based on seemingly relevant self-report measures.

Individual difference and cognitive style

The two measures of cognitive style, preference for consistency and need for cognition, were also not able to predict correction.

Preference for consistency In the case of PFC (Cialdini, Trost & Newsom, 1995), we interpret this as an indicator that the correction of CB manipulations is not based on consistency motives or social influence. Further, PFC is mainly about people self-monitoring and being aware about their own consistency; whereas CB corrections tend to occur outside of the participants' awareness. This could be seen in the reasons people reported when wanting to correct: they were almost exclusively about having made a mistake, detected a glitch in the survey application, or having spontaneously changed their minds. Importantly this result also distinguishes CB from cognitive dissonance (Festinger, 1957) and other consistency phenomena that are typically highly correlated with PFC. This is useful when discussing CB and its consequences in a larger theoretical context.

Need for cognition NC (Cacioppo, Petty & Kao, 1984) is often used in social psychology research for its supposed implications to people's attitudes, judgments and decisions. In this literature, NC is described as associated to peoples' tendency to process information and form elaborated and coherent attitudes. Because of this, attitudes of individuals high in NC should be more resilient to change, persuasion, and context effects (e.g. Haugtvedt & Petty, 1992). This is not what we found in this study. However, while individuals high in NC tend to be more resistant to various biases, previous research argue that even these individuals can be influenced if the bias is very subtle (Cacioppo, Petty, Feinstein & Jarvis, 1996). The subtlety factor might help explain why NC and CB correction did not correlate. Further, people with low NC can perform at a comparable level to those with high NC given enough external motivators. One such motivator could be the perception of what participants believe to be their own survey response.

Political awareness The two political awareness measures (political interest and involvement) also did not correlate with correction. While there is nothing uniquely special to *political* awareness per se, the awareness part addresses a domain specific aspect that could determine the participants' understanding, knowledge, and vested interest about the current CB theme (Zaller, 1992). For example, one previous CB study did find that political involvement correlated with correction (Hall, Johansson & Strandberg, 2012), and in this study we found a tendency (albeit small) that politically involved participants were more likely to attribute the correction externally (e.g. believing that there was some error with the equipment). This tendency at least indicates that politically involved participants experienced the false feedback differently from the uninvolved. It could simply be that politically involved individuals have stronger convictions in the politically attitudes; so when they notice a discrepancy between their original and present response, their main explanation is that software application malfunctioned.

Limitations and future studies

The main limitation of this study was the small number of participants. While we only found a relationship between correction and attitude extremity, the lack of relationship between the other variables might at least be partially explained by the small sample size. Thus, one interesting avenue of future research would be to more systematically, and with more participants, test how a variety of attitude, personality, and performance measures affect correction rates and correction types. This would also allow us to examine subgroups within our sample; for example: what is it that makes some participants correct all the manipulations and some accept all? Importantly, while we found no relationship between correction and any of the two motivated cognition measures (NC and PFC), other more performance based variables might be relevant to CB and worth exploring. For example, in Strandberg et al. (2018) the Cognitive Reflection Test (CRT) correlated with correction, with participants having higher CRT score also being more likely to correct the manipulations. CRT is a performance based cognitive processing measure that captures peoples' ability to use reflective and deliberative thinking instead of gut feelings (Frederick, 2005). Thus, future research could try to link CB to performance based measures that taps into working memory, attention, or perhaps factual knowledge. Another potential shortcoming of this study was that the majority of the participants were students. Although we have no reason to believe, given previous studies, that a phenomenon such as CB would drastically differ between different demographics, it is always important to establish whether the experimental findings generalize across the public. However, similar levels of correction have been found in experiments with a more diverse and representative sample (Strandberg, Olsson, Hall, Woods & Johansson, in preparation).

Conclusion

Choice blindness is a cognitive phenomenon powerful enough to influence peoples' opinions and reasoning in important political issues. Still, it is difficult to pinpoint what disposes people to accept or correct the manipulations. It seems that the CB manipulation is so surreptitious that it sometimes flies under the radar even for people with strong convictions and motivations to engage in political reasoning. This study contributes to the understanding of CB, serving as both a backdrop for future research, and an important piece of a broader theoretical puzzle.

It's not the treasure, it's the hunt: Children are more explorative on an explore/exploit task than adults

Abstract

The current study investigates how children act on a standard explore-exploit bandit task relative to adults. In Experiment 1, we used child-friendly versions of the bandit task and found that children did not play in a way that maximized payout. However, children were able to identify the machines that had the highest level of payout and overwhelmingly preferred it. We also show that children's exploration is not random. For example, children selected the bandits from left to right multiple times. In Experiment 2, we had adults complete the task in Experiment 1 with different sets of instructions. When told to maximize learning, adults explored the task in much the same way that children did. Together, these results suggest that children are more interested in exploring than exploiting, and a potential explanation for this is that children are trying to learn as much about the environment as they can.

Keywords: cognitive development; explore-exploit; decision making

Introduction

Imagine that it is your second day at a new job. You are standing at the coffee cart outside your office building, considering the unfamiliar menu. Yesterday you had a cappuccino and enjoyed it; today you must decide whether to get the cappuccino again like yesterday, or try the matcha green tea latte, which you might not like. This is known as an explore/exploit problem, because you must choose between exploiting a familiar option (the cappuccino) or exploiting a new one (the matcha latte). Such problems arise all the time: Do you buy the same brand of hiking boots you just wore out, or try a new style? Make the same old macaroni and cheese that you know your kids will eat, or gamble on pasta puttanesca? Re-watch that Netflix movie that you enjoyed before, or try a new one?

Researchers studying the explore/exploit problem in adults have traditionally defined a good decision as one that maximizes payout and minimizes cost. The problem is commonly operationalized in bandit tasks named after the 'one-armed bandits' (i.e., slot machines) found in casinos. In a bandit task, participants decide between two or more bandits, each of which has an unknown rate of reward. The goal of the task is to maximize return by using a combination of exploration and exploitation. Formally, the optimal strategy is to explore the different bandits just long enough to learn which one pays out best, and then switch to exploiting that one (Mehlhorn et al., 2015). Indeed, that's what most adults do. The explore-exploit problem has been widely investigated in many different contexts, including reinforcement learning (Daw, O'doherty, Dayan, Seymour, & Dolan, 2006; Wilson, Geana, White, Ludvig, & Cohen, 2014), psychiatric populations (Addicott, Pearson, Sweitzer, Barack, & Platt, 2017), and animal behavior (Beachly, Stephens, & Toyer, 1995; Chen et al., 2016; Snell-Rood, Davidowitz, & Papaj, 2011). The present studies asked, What about children?

Very few studies have investigated how children approach explore-exploit tasks, and if they approach these tasks with similar strategies as adults do. A large number of studies suggests that children, and even infants, possess intuitive statistics and a basic understanding of probability (Xu & Kushnir, 2013). Further, there is substantial evidence suggesting that children are better at maximizing statistics in scenarios whereas adults are drawn towards probability matching (Derks & Paclisanu, 1967; Hudson Kam & Newport, 2005). Taken together, this suggests that children would indeed maximize reward on this type of task, perhaps at an even faster rate than adults would. However, Blanco & Sloutsky (2018) had children complete a 4-armed bandit task on a tablet. They found that children do not maximize payout as adults typically do. Instead, they visit each bandit equally across 100 trials.

The key question in this study is that in a bandit task, in its most simplistic form, will children follow similar strategies to adults and attempt to maximize payout. If we find that children do not maximize payout, what are the reasons for their suboptimal performance? Are children viewing the task in the same way as adults?

In Experiment 1, we conduct a simplified version of the bandit task with 159 children. Critically, we designed this task to be simplistic and minimize the memory constraints which other bandit tasks possess. In Experiment 2, we conducted the same bandit task used in

Experiment 1 with adults and give different motives: to learn or to win.

Experiment 1

One explanation for children's over-exploring in Blanco & Sloutsky (2018) could be that they simply cannot figure out which bandit pays out better. In this task, we made it easy for children to see the payouts. To do this, we showed children all of the previous results from each bandit.

We also changed the task structure so that there were three machines: One that paid off every time, one that paid off half the time, and one that never paid off.

Methods

Participants. We tested 159 children between the ages of 3 and 9 (mean 5 years, 7 months; range 2 years, 11 months to 8 years, 11 months). Of those, 69 were girls, 90 were boys. Children were recruited from science museums and preschools in an urban area. An additional 11 participants were tested but excluded because they did not answer both control questions correctly. Participants were given a small toy upon sign-up (e.g., a plastic slinky).

Procedure. Participants were presented with three "Mystery Machines," each with a different proportion of winning (green) and losing (red) balls (see Figure 1). One box dispensed only winning balls, one dispensed only losing balls, and one alternated between winning and losing. The machines associated with different payoffs were counterbalanced across participants. Green balls contained a sticker that the child was allowed to take home; red balls contained no sticker.

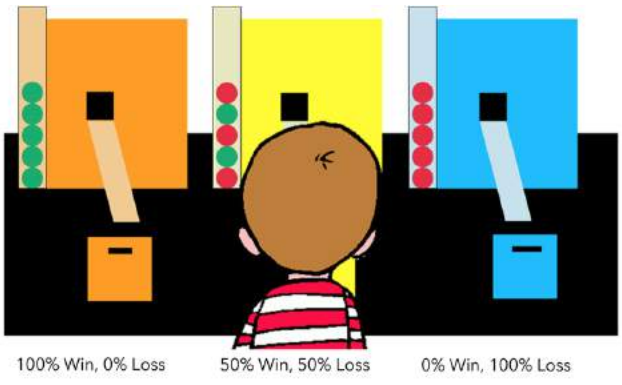

Figure 1: An illustration of the machines at the end of the study for a participant who chooses each machine equally. Green balls have stickers inside, red balls are empty. The tubes are empty at the beginning of the task.

Children were told, "These are Mystery Machines. When you put a coin in the orange box, a ball rolls down the orange slide. When you put a coin in the blue box, a ball rolls down the blue slide. When you put a coin in the yellow box, a ball rolls down the yellow slide. Balls can be green or red. A green ball, like this one, [shows green ball] has a prize that you can take home inside. See? [Opens ball and shows sticker] A red ball, like this one, [shows red ball] has no sticker in it. See? [Opens ball and shows inside.] Some machines have more green balls, some machines have more red balls."

Afterward, children were asked whether they would win any stickers if they received one green ball and one red ball. Those who were unable to correctly answer this question were excluded. Children were then given fifteen coins to put in the coin slots corresponding to the machines of their choosing. When the child put a coin in one of the three coin slots, a machine sound played, and a ball rolled down the slide of the machine corresponding to the coin slot that the child chose. Before the experiment started, a machine operator hid underneath the table at which the children were tested and crawled out from under the table once the child was seated on the other side of the table and thus could not see this person.

The machine operator used a noise maker to make the machine noise and rolled a ball down the slide each time the participant made a selection by dropping a coin in a coin slot. Empty balls were placed in the tube corresponding to the machine that they came from, in order to reduce the number of things that the participant needs to keep track of. This clearly showed the distribution of wins and losses that the participant encountered from each machine (See Figure 3).

After participants completed the task, they were asked the following questions: 1) Which machine was your favorite? 2) Why was the "xxx" colored machine your favorite? 3) Which machine has the most green balls? And 4) How do the machines work?

Results

Few children maximize, many explore each box equally. Children on average pick the winning box 44.72% of the time, a value a Wilcoxon-signed rank test finds as significantly above chance ($V = 6338.5$, $p < 2.2e\text{-}16$). However, this value is still significantly below what maximizing would look like ($V = 297$, $p < 2.2e\text{-}16$). Figure 2B shows each individual child's choice.

Children's behavior is neither random nor optimal. To better understand children's behavior, we simulated two different strategies: a random strategy where the boxes were chosen from a uniform distribution and the optimal policy (from Steyvers, Lee, & Wagenmakers, 2009). We sampled 1000 instances from each strategy so we could compare how children acted to these datasets (See Figure 2 and Figure 3).

Children often explored the machine in a Left to Right pattern as if they were reading a book (see Figure 4) and therefore deviated from a pure random strategy of picking a

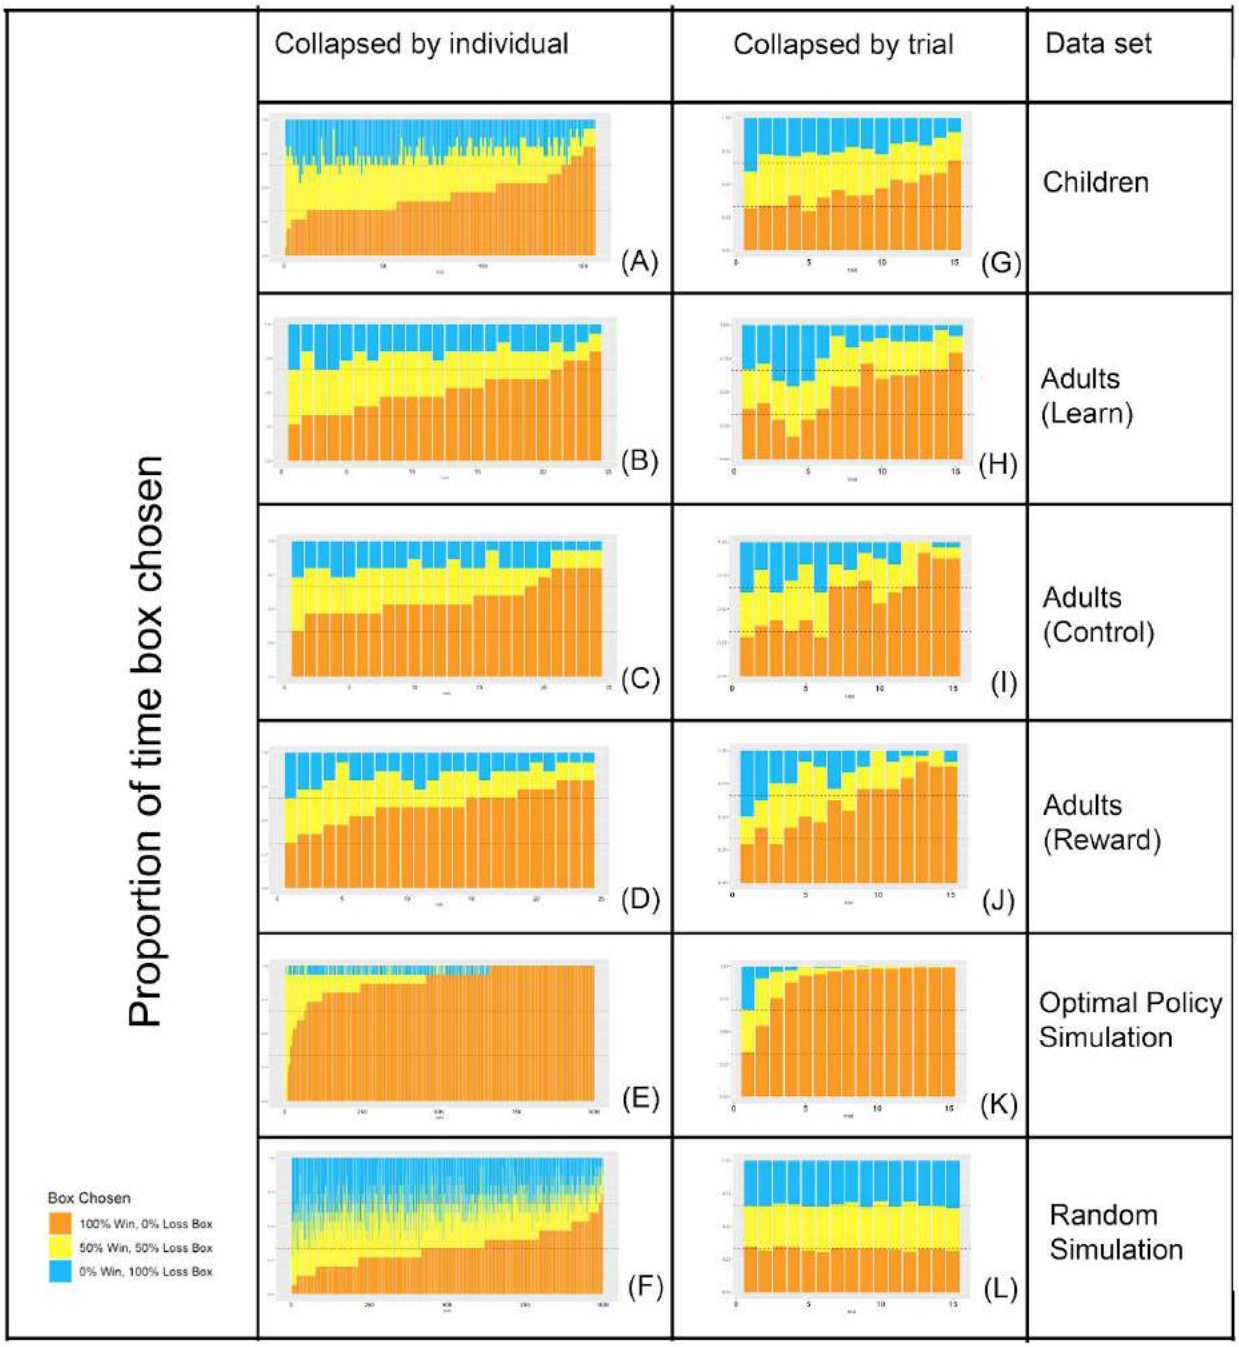

Figure 2: The proportion of choices for each box. The dotted red line indicates chance (.3333 and .6666). Orange indicates the proportion of time choosing the 100% win box, yellow indicates the proportion of time choosing the 50% win box, and blue indicates the proportion of time choosing the 0% win box. Adults in the control, reward, and the optimal policy data chose the winning box significantly more than children. Child data was collected as part of Experiment 1. The adult data were collected as part of Experiment 2. Optimal Policy data was simulated following the optimal policy in Steyvers, Lee, & Wagenmakers (2009). (A-F) Each line is a participant or simulated data point from a particular group. The red dotted line indicates chance (.3333) and (.666). Participants are ordered in increasing levels of picking the winning box. (G-H) Each line represents the proportion of participants that choose each box on a given trial.

machine at chance regardless of the previous machine chosen. For example, they would choose the orange machine, the yellow machine, and then the blue machine. Some children continued with this strategy throughout the entire task. A chi-square test of independence was performed to examine the relationship between the frequency of children going from left to right, and the frequency of this occurring in our randomly generated data set. This relationship was significant. $X^2(5, N = 1159) = 105.52$, $p = < 2.2e\text{-}16$. This suggests that children moving from left to right between boxes would not be plausible under random chance. Children could be acting in this way to strategically explore their environment, and are not necessarily acting purely randomly.

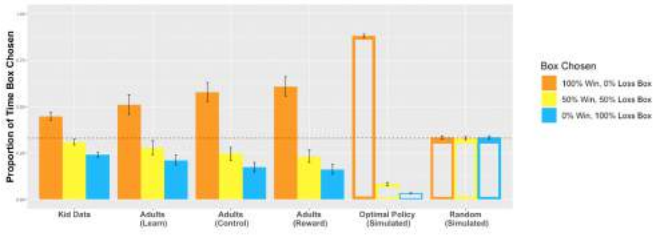

Figure 3: The proportion of times choosing each box. The dotted red line indicates chance (.3333). The error bars indicate 95% confidence intervals. Adults in the control, reward, and the optimal policy data chose the winning box significantly more than children. Child data was collected as part of Experiment 1. The adult data were collected as part of Experiment 2. Optimal Policy data was simulated following the optimal policy in Steyvers, Lee, & Wagenmakers (2009).

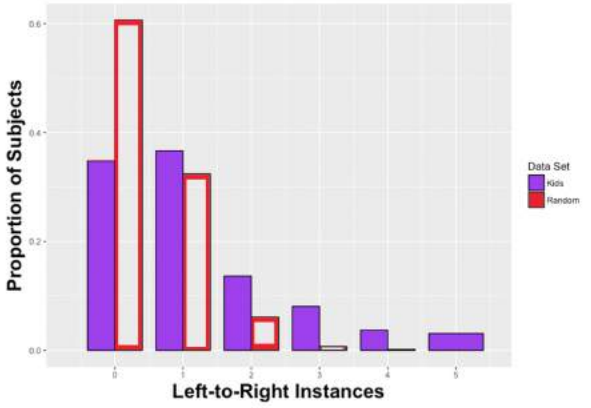

Figure 4: Histogram comparing the Left-to-Right instances made by children (purple columns) and the data set we generated where the choice of machine was random (red-outlined columns).

Children prefer the 100% win box. 128 children (83%) said their favorite box was the one that had 100% winning balls. 15 children (9.7%) prefer the box which alternated between winning and losing balls, 8 children (5.2%) preferred the box that always dispensed losing balls, 5 children (3.2%) said they liked all of the boxes, 2 children (1.3%) said they liked two of the boxes, and 1 child (.06%) said they didn't like any of the boxes (see Figure 5). We performed a proportion test to see if this number was significantly above chance (.3333). We found that this was unlikely due to chance $X^2(1, N = 159) = 159.2$, $p < 2.2e\text{-}16$. Of the 128 children who said their favorite box was the one that had the highest payout, we asked the children why the box they chose was their favorite, 105 children (97.2%) said it was because it gave the most green balls. The other explanations included that they liked the color of the box, or they gave an unrelated answer such as, "because rainbow."

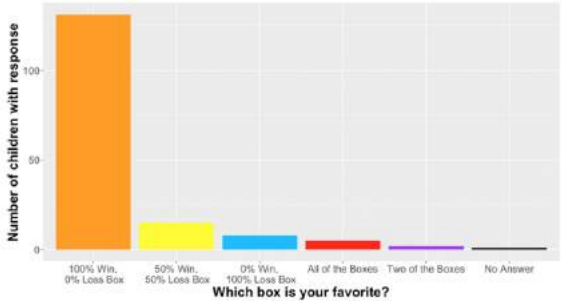

Figure 5: Children's responses to, "Which box is your favorite?"

Age is not related to the proportion of max choices. We looked for a correlation between age and number of max choices made. We found that age and number of times choosing the max box were not correlated. We found evidence in favor of the null ($r(159) = .086$, $BF_{01} = 5.17$).

Experiment 2

In Experiment 1, most children did not maximize stickers. However, at the end of the task, 83% of the participants stated that their favorite machine was the one that always won. This suggests that perhaps children knew, and preferred the winning machine, but chose to explore anyways. Additionally, we found that children were making their choices in a sequential pattern that would not be predicted by chance. While it is plausible that children have not learned the distributions yet and that is why they are exploring more, in Experiment 1, children were able to identify the machine or side that had the highest payout. Children might be approaching this task with a different motive than adults.

As adults, we have more experiences with gaming and decision making. We have learned that often times, the best thing to do is maximize reward. Maybe children, who have

less experience with decision-making tasks of this nature, could just be trying to pick up as much information about the environment as possible. This would mean exploring even when you are fairly confident about the stability of an environment. Perhaps this difference in goals is what can account for differences in behavior.

To test this hypothesis, we had adults complete the protocol outlined in Experiment 1 with one of three sets of instructions: a control scenario, a reward scenario, and a learning scenario. In the control scenario, adults were told exactly what the children were told. In the reward scenario, adults were told that they would be evaluated on how many stickers they won. In the learning scenario, adults were told they would be evaluated based on how well they learned the different distributions of the three machines.

Methods

Participants. We recruited and tested 72 adults from the University of California, Irvine SONA system. Our participants were primarily female (55 females, 17 males) and between the ages of 18-21 (57). 15 other participants were between the ages of 22-30. Participants were compensated with course credit.

Procedure. We followed the procedure outlined in Experiment 1. Adults were randomly assigned to one of three scenarios: Control, Reward, or Learning. In the Control scenario, adults were told exactly what the children were told in Experiment 1. In the Reward scenario, adults were told that they would be evaluated on how many stickers they won. In the Learning scenario, adults were told they would be evaluated based on how well they learned the different distributions of the three machines.

Results

Comparing adult data to children's data Adults in the Control & Reward conditions picked the winning box significantly more than the children and the adults in the Learn condition (See Figure 2, Figure 3, & Table 1).

Using an ANOVA, we found that there was a significant relationship between the instruction condition and the number of times the winning box was chosen ($F(3,229) = 15.41$, $p < .001$, $\eta = .168$). When comparing the children data, adult data, random strategy, and optimal policy, using an ANOVA there is an even larger effect and a significant relationship between condition and number of times the winning box was chosen ($F(5, 2227) = 1570$ $p < .001$, $\eta = .779$). We found that children picked the winning box significantly less than adults in the Control condition & Reward condition, but not the Learning condition.

Table 1: Pairwise Comparison using t-tests with pooled standard deviation. t-value (p-value)

	Control	Children	Learn
Children	-4.274 (1.0e-04)	---	---
Learn	-1.652 (0.197)	2.09 (0.109)	---
Reward	10.519 (0.449)	5.273 (8.7e-07)	2.409 (0.064)

Children switch between boxes more than adults do. A way of quantifying exploration is through looking at the proportion of switch trials participants made. If a participant is exploring, they would have a high proportion of switch trials. A participant who never makes the same choice twice in a row would have a switch proportion of 1. A participant who always chooses the same box would have a switch proportion of 0. On average, child participants had a switch proportion of .8051, whereas adults had an average switch proportion of 0.5962. Conditions that adults were in did not influence their switching behavior. A Wilcoxon rank sum test with continuity correction showed that children switched significantly more than adults did ($W = 2400$, $p = 1.527e-12$).

Trial level analysis. When looking at the data at the trial level (See Fig 2G-L), children and adults do choose the winning box more frequently near the end of the task. We did a logistic regression looking at trials as a predictor of choosing the winning box. For children, we found that trial number was an indicator of choosing the winning box ($\beta = 0.094$, $p < 2e-16$). However, for adults, the coefficient was higher ($\beta = 0.181$, $p < 2e-16$). This shows that while children are more likely to chose the maximal option as the task goes on, the change at a much slower rate than adults.

Discussion

In this paper, we presented two bandit experiments had no memory constraints. The first was with children, who did not play in a way that maximized payout and explored more than would be optimal. Uniquely, our paper showed that children were able to identify the machines that had the highest level of payout and overwhelmingly preferred the bandit with the highest payout. We also show that children's exploration is not random. For example, children moved across the bandits from left to right over and over again, as if they were reading a book.

In Experiment 2, we instructed adults to either maximize payout or learn the distributions of the 3-armed-bandit task. Experiment 2 showed that adults maximized payout, but when they are asked to maximize learning, they explore more -- like children.

Together, these results suggest that children are more interested in exploring than exploiting, and a potential explanation for this is that children are trying to learn as much about the environment as they can. There are several possible explanations for our findings.

Explanation 1: Children don't maximize payout because they don't know which machine pays out the best. One potential explanation for our data is that children spend longer than adults exploring the environment of the game because it takes children longer to figure out which machine has the best payout. This is plausible, given that children have much poorer working memory than adults do (Gathercole, Pickering, Ambridge, & Wearing, 2004), as well as less experience with this type of task.

But the children in our study did know which machine gave the most stickers -- at least, they knew this by the time they finished playing. And children overwhelmingly preferred the machine with the best payout.

Moreover, despite their poorer working memory, there are some domains of learning where children come to the correct answer faster than adults do. In language learning, for example, 6-year-old children outperform adults by maximizing probability whereas adults tend to match probability (Hudson Kam & Newport, 2005). Children also outperform adults in a simple probability guessing game (Derks & Paclisanu, 1967).

Explanation 2: Children don't maximize payout because they would rather explore the game environment. In any explore/exploit task, participants must explore to find the resources before they can shift to exploiting those resources. But it is possible that the shift from exploring to exploiting is not only seen over the course of an individual task, but over many timescales. Just as all participants explore in the early stages of a task, perhaps people explore more (in general, across domains) in the early years of life -- that is, in childhood. the time scale of one human life. Perhaps children are more 'exploring' than adults in general, meaning that they seek information about the environment in a broad sense rather than in just the narrow sense needed to maximize immediate payout (in this case, stickers).

According to this explanation, children sacrifice payout in order to get more information. But presumably, if children could get that information, either way, they would still want to maximize payout. And indeed, in bandit tasks where children are given all of the information that they would have gained from each of the different choices, they do maximize payout (Plate, Fulvio, Shutts, Green, & Pollak, 2018; Starling, Reeder, & Aslin, 2018).

We hypothesize that the optimal time to shift from exploring to exploiting depends on (A) how well you know the environment, and (B) how likely it is that the environment will change. When you don't know the environment well and/or the environment is likely to change, then more exploring is beneficial because it provides more information about all aspects of the environment (addressing Problem A) and it provides information that may be helpful if something in the environment changes (Problem B.) We hypothesize that children typically are in a situation where (A) is low and (B) is high, so they naturally explore, whereas adults know the environment better and also have fewer years left ahead of them, meaning that the amount of change they must prepare for is lower.

Our results are consistent with the idea that children develop flexible knowledge through exploration and broader search (Gopnik et al., 2017). From a child's point of view, the world is constantly changing. It makes sense to prioritize gathering data rather than maximizing immediate payouts. As our Experiment 2 showed, adults do the same when they are told to focus on learning, rather than on immediate rewards.

Abstract

Slang is a common device for expressivity in natural language. While slang has been studied extensively as a social phenomenon, its cognitive bases are not well understood. We formulate the processes of slang generation as a categorization problem. We explore a set of cognitive models of categorization that recommend slang words based on intended referents of the speaker beyond the existing senses of words. We test these models against a large repertoire of slang sense definitions from the Online Slang Dictionary and show that the categorization models predict slang word choices substantially better than chance, without explicit consideration of external social factors. We also show that words similar in existing senses tend to extend to similar novel slang senses, reflecting a process of parallel semantic change. Our work helps to ground theories of slang in cognitive models of categorization and provides the potential for machine processing of informal natural language.

Keywords: informal language; slang; generative model; categorization; language and cognition

Introduction

Slangs—a representative form of informal language—are ubiquitous in natural language, making up approximately 52% of words in all English books written in the past two centuries (Michel et al., 2011). Slang is a common device for enhancing expressivity in human language, allowing us to express a multitude of ideas beyond the standard lexicon. Slang also adds stylistic richness to language, often allowing the identification of social groups (Millhauser, 1952). Although slangs are prevalent and accountable for language expressivity, the cognitive processes that give rise to slangs are not well understood.

Previous work has characterized slang as a social phenomenon. For instance, Labov (1972, 2006) studied how informal language emerges as a result of differing ethnicity and social-economic status. More recent work has also suggested how slang might be influenced by multiple social factors including ethnicity (Blodgett, Green, & O'Connor, 2016), gender (Bamman, Eisenstein, & Schnoebelen, 2014), and geography (Eisenstein, O'Connor, Smith, & Xing, 2010). Although it is undeniable that slang is a social phenomenon, recent work on social media analysis has suggested that slangs are more likely to catch on if they are also linguistically appropriate (Stewart & Eisenstein, 2018). We extend these work by exploring the bases of slang from a cognitive perspective, complementary to the social factors that could influence slang formation.

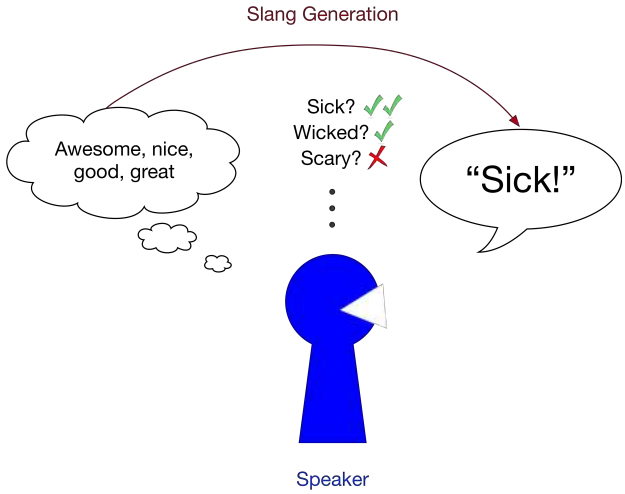

Figure 1: Illustration of the slang generation problem.

Recent work in cognitive science has explored related topics in the context of non-literal language, particularly the comprehension of metaphors (Kao, Wu, Bergen, & Goodman, 2014; Kao, Bergen, & Goodman, 2014). While slangs can often emerge from metaphorical relations, there exist many cases suggesting otherwise. For example, the slang word *sick* has the existing sense "ill" while its slang sense refers to "awesomeness". In this case, the link between the slang and existing senses are not metaphorical, but instead accounts to a polarity shift in sentiment from the existing sense.

Here we consider the general problem of slang generation by asking what cognitive processes can give rise to slang word choices for novel senses. Specifically, given a new intended slang referent one wishes to convey, how does the speaker choose an appropriate word for expressing that sense? Figure 1 illustrates this problem of *slang generation*.

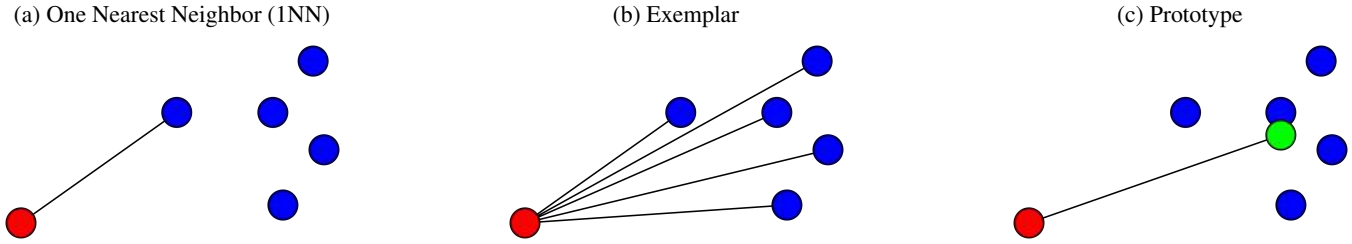

Figure 2: Illustration of categorization models for slang generation. Red (bottom-left) dot denotes novel slang sense. Blue dots denote existing senses of a candidate word. Green dot denotes prototype (or mean) of the existing senses.

Given a slang sense such as "awesome/nice", we wish to predict the word choice made by the speaker among possible alternative candidate words. In the illustrated case, the target word *sick* might be chosen if its existing senses relate to the novel slang sense, and words similar to the target word *sick* such as *wicked* might also have a good chance of being chosen. We formalize these intuitive notions of slang generation in terms of lexical choice via categorization, where we consider each candidate word as a category of existing word sense definitions. For this study, we focus on the problem of slang generation from words that are part of the existing lexicon, so we do not consider out-of-vocabulary or novel word forms for slang (e.g., Kulkarni & Wang, 2018).

We explore slang generation based on two key ideas from recent work on lexical semantic change, particularly historical word sense extension: 1) Words that bear closely related senses to a novel sense are likely to be extended to express that novel sense, a process known as semantic chaining (Lakoff, 1987; Malt, Sloman, Gennari, Shi, & Wang, 1999; Ramiro, Srinivasan, Malt, & Xu, 2018); 2) Words that begin with similar senses tend to extend to similar novel senses, a process also known as the law of parallel semantic change (Lehrer, 1985; Xu & Kemp, 2015). We formalize these ideas along with classic proposals of categorization in a simple computational framework and test them against a large online dictionary of slang.

To preview our findings, we show that cognitive models of categorization predict slang word choices substantially better than chance, and these models can be enriched by a mechanism of collaborative filtering that accounts for parallel semantic change.

Computational formulation

Models of categorization

We formulate slang generation as a categorization problem. Given a set of candidate words as categories $\{w_1, w_2, \cdots, w_N\}$ with sets of existing senses as exemplars $\{\mathcal{E}_1, \mathcal{E}_2, \cdots, \mathcal{E}_N\}$ associated with those words, we wish to find the word w_s that is most appropriate for expressing a novel slang sense s, where we represent word senses by embedding their dictionary definitions into a high-dimensional vector space (see details in the next section). For a given slang sense s, a categorization model specifies a distribution over the space of candidate words based on similarities between s and existing senses of the candidate word w_j in $\mathcal{E}_j$.

We recommend a slang word choice based on the probability distribution $p(w_j|s)$ via Bayes' rule:

$$p(w_j|s) \propto p(s|w_j)p(w_j) \tag{1}$$

Here $p(s|w_j)$ is the likelihood of the novel slang sense s given the word w_j or equivalently the collective set of its existing senses E_j, and $p(w_j)$ is the prior on the candidate word. Because we constrained our analyses to words with slang senses, we used a uniform prior on the set of candidate words. We thus estimate $p(w_j|s)$ using the maximum likelihood formulation:

$$p(w_j|s) \propto p(s|w_j) = p(s|E_j) \tag{2}$$

We specify the likelihood by considering similarity relations between existing senses of the word w_j in E_j and the slang sense s. Given a set of existing senses $E_j = \{e_1, e_2, \cdots e_M\}$, we compute its similarity with the slang sense s by considering how individual exemplars in E_j are similar to s:

$$p(s|E_j) = f(s, E_j) = f(\{sim(s, e_i); e_i \in E_j\}) \tag{3}$$

We consider the specific forms of the similarity function based on three existing models of categorization: One Nearest Neighbor (1NN), Exemplar, and Prototype. We illustrate these models in Figure 2.

One Nearest Neighbor (1NN) model. Motivated by work on semantic chaining (Ramiro et al., 2018), this model predicts that a novel word sense is attached to an existing sense of a word that is closest in semantic space. We test this hypothesis in slang generation by postulating that a novel slang sense would be attached to the most similar existing sense of a word:

$$f(s, E_j) = \max_{e_i \in E_j} sim(s, e_i) \tag{4}$$

Exemplar model. Motivated by the exemplar theory (Nosofsky, 1986), this model evaluates similarities between the novel sense s and all existing senses of a word. Here we postulate that slang choice depends on the aggregated similarities of existing senses of a word to the slang sense:

$$f(s,E_j) = \sum_{e_i \in E_j} sim(s,e_i) \quad (5)$$

Prototype model. Motivated by the prototype theory (Rosch, 1975), this model predicts that category membership is established by similarity between the slang sense and a representative or prototypical existing sense:

$$f(s,E_j) = sim(s,E_j^{prototype}) \quad (6)$$

Because we do not have an accurate estimate of sense frequencies, we consider the simple version of this model where the prototypical sense is taken as the average of the existing senses, i.e., by assuming senses are equally frequent:

$$E_j^{prototype} = \frac{1}{M} \sum_{e_i \in E_j} e_i \quad (7)$$

Where M is the set size of E_j.

Similarity. To estimate individual similarities between s and e_i, we consider vector-based embeddings that transform word sense definitions into a high-dimensional vector space. We then compute the similarity as follows:

$$sim(s,e_i) = \exp(-\frac{d(s,e_i)^2}{h_s}) \quad (8)$$

Here $d(s,e_i)$ is the Euclidean distance between the vector representations of senses and h_s is a parameter controlling the degree of sense specificity that we fit to data.

Collaborative filtering

We consider an enriched version of the categorization models by taking into account parallel semantic change, cast as a variant form of collaborative filtering (Goldberg, Nichols, Oki, & Terry, 1992) that is commonly used in recommendation systems. The rationale is that words similar in existing senses may extend to label similar novel slang senses. For example, *massive* and *stellar* both refer to *large* in their existing senses, but both of them can refer to *impressiveness* in the slang context. We capture parallel semantic change by considering the influence of neighboring words to candidate words w_j's by nested likelihoods:

$$p(w_j|s) \propto \sum_{w' \in \mathcal{L}(w_j)} p(w_j,w'|s) = \sum_{w' \in \mathcal{L}(w_j)} p(w_j|w')p(w'|s) \quad (9)$$

Here $\mathcal{L}(w_j)$ indicates a small neighborhood around the word w_j in word embedding space. We estimate $p(w_j|w')$ by computing similarity between w_j and its neighboring words:

$$p(w_j|w') \propto sim(w_j,w') = \exp(-\frac{d(w_j,w')^2}{h_w}) \quad (10)$$

For the word itself, $sim(w_j,w_j) = 1$. h_w is a free parameter that controls the strength of influence from the neighbors. This nested model estimates $p(w'|s)$ using the same likelihood functions described in the previous section. The resulting collaborative filtering model effectively provides a weighted average of the likelihoods corresponding to words in the neighborhood $\mathcal{L}(w_j)$.

Materials and methods

We collected lexical data from the freely available Online Slang Dictionary (OSD; `http://onlineslangdictionary.com`) and WordNet (Miller, 1998) for novel slang and existing word sense definitions respectively. In OSD, we considered all available slang word forms with at least one available example usage. We removed words that do not exist in WordNet and extracted all word-definition pairs from the remaining words, resulting in 4,805 slang definitions from 2,357 distinct slang words. We also extracted existing definitions from WordNet by first querying the slang word and then extracting definition sentences from all retrieved *synsets*, resulting in 11,780 existing definitions. On Average, each candidate word in our dataset has 2.00 slang definitions (SD: 1.74) and 5.54 existing definitions (SD: 6.82).

We excluded acronyms because they do not extend to new senses. We removed all slang definitions containing the word 'acronym' and words that have fully capitalized spellings. Finally, we excluded slang definitions that are already part of WordNet by performing two pre-processing steps: 1) Remove a slang definition if one of the corresponding existing definitions in WordNet has at least 50% overlap in the set of content words. 2) Remove WordNet definitions that contain the token 'slang' and remove slang words that no longer have corresponding WordNet definitions. We performed a manual sanity check on 100 randomly sampled slang definitions and only 6 of them have close definitions in WordNet. After preprocessing, there are $N = 4{,}256$ slang definitions from $V = 2{,}128$ slang words. We used these words as the vocabulary for candidate slang words. We partitioned the data of sense definitions by randomly splitting into a 90% training set and a 10% test set for model evaluation.

To represent the sense definitions in a vector space, we used distributed word embeddings from fastText (Bojanowski, Grave, Joulin, & Mikolov, 2017) pretrained with subword information on 600 billion tokens from Common Crawl (`http://commoncrawl.org`). To obtain a fixed dimensional representation for the definition sentence, we take the average word embedding of all content words within the definition sentence (Landauer, Laham, & Rehder, 1997). The average pooling scheme has been shown to be a competitive sentence encoder in machine learning literature (Wieting & Kiela, 2019) and has consistently achieved better results in our experiments compared to pre-trained deep sentence encoders. We apply the same encoding method to both existing and slang definitions with no distinction. We estimated the free model parameters (h_s, h_w) using L-BFGS-B (Byrd, Lu, Nocedal, & Zhu, 1995), a quasi-newton method for bound constrained optimization, to minimize negative

log-likelihood of the posterior:

$$\min(-\log \mathcal{L}) = \min(-\sum_{s} \log p(w_s|s)) \tag{11}$$

Here w_s is the ground truth word corresponding to the slang sense s. We estimate the free parameters on the training set while keeping them fixed in testing. For all analyzed models, we set the initial h values to 1 with bounds $[10^{-2}, 10^{2}]$. For the collaborative filtering models, both free parameters were jointly optimized.

Results

We evaluate our approach by first examining prediction of slang word choices from the three categorization models: 1NN, Exemplar, and Prototype. We then examine how collaborative filtering influences these basic categorization models on the same predictive task.

Evaluation of models of categorization

We assessed our models by ranking all candidate words according to the posterior distribution $p(w_j|s)$ from the categorization models that we described. For each slang sense definition s in the dataset, we assigned a rank to all candidate words in the vocabulary for a given model.

We first present receiver-operater curves (ROC) of model accuracy: How probable is each model to predict the correct target slang word in the first n guesses? We computed the standard Area-Under-Curve (AUC) statistics to compare cumulative precision of the models. The top row of Figure 3 shows both the ROC curves and AUC statistics of the three categorization models. All three models perform substantially better than chance. In particular, 1NN and Prototype perform better than exemplar on average in both training and testing data, which suggests that slangs are unlikely to be generated based on aggregate similarities between the existing senses and the slang sense.

Differing from previous findings on historical word sense extension where the 1NN model outperforms Prototype (Ramiro et al., 2018), we observed no substantial difference between the two models in predicting slang choices. We also considered a k-nearest-neighbor extension of the 1NN model, but we did not find any improvement in performance. We observed little difference between training and testing performances from all models, which suggests that the models did not overfit to free parameters.

For the same set of models, we also computed the expected rank of the ground-truth target words over all slang defini-

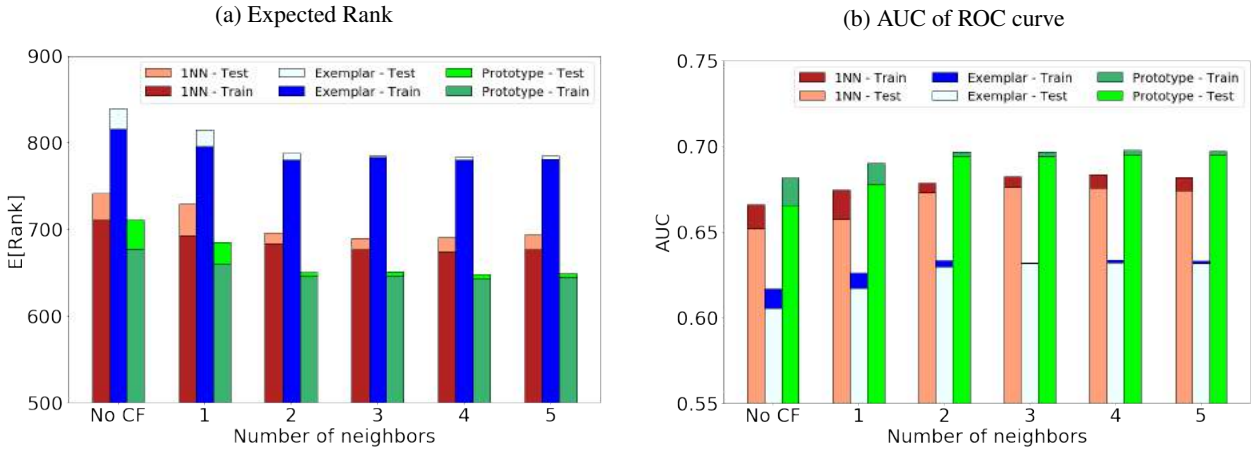

Figure 4: Summary statistics of collaborative filtering models. a): Expected Rank, b): Area-Under-Curve of ROC curves (AUC)

Table 1: Expected ranks from the categorization models.

Model	E[Rank] - Train	E[Rank] - Test
Random	1064.0	1064.0
1NN	710.89	741.29
Exemplar	815.54	839.71
Prototype	677.44	711.30

tions, based on both training and testing data. A lower expected rank indicates better predictive power. Table 1 summarizes the results. We observed similar findings with results based on AUC: All three models perform better than chance, while 1NN and Prototype models both perform better than the Exemplar model. Although these models perform above chance, the predicted expected ranks are quite high. Although some predicted words differ from the ground truth word, they may still be valid candidates for slang given sufficient social popularity. How to improve and better evaluate these model predictions will be topics of future research.

The bottom row of Figure 3 visualize the expected ranks via binning the slang definitions by degree of polysemy of their respective ground-truth candidate words w_s. We observed that all three categorization models generally perform better on more polysemous words. In particular, all three models perform better than chance when the target word has at least three existing senses. This behavior is the most prominent on the Exemplar model. Although the Exemplar model performs worse than the other two models on average, it tends to perform better on highly polysemous words. However, the Exemplar model has a natural tendency to favor those words by construction because it computes a sum of similarities instead of averaging. Both 1NN and Prototype also perform better as the number of existing senses increases. With more existing senses, it is more likely for one of them to have a close match with the slang sense, thus the improvement on 1NN. The prototypical senses would also become more accurate due to a larger sample for estimation. Compared to 1NN, the Prototype model performs slightly worse when the target word has few senses, but it outperforms 1NN as the degree of polysemy increases.

In sum, these results show that slang word choices are predictable without considering external social factors and provide evidence that simple models of categorization can capture non-arbitrariness in the generative processes of slang.

We provide examples of model success and failure in Table 2. In the *wicked* example, our models captured polarity shift in slang generation, indicated by low expected ranks from all models. The second example shows how our model can have limited predictability when the slang and existing senses are cognitively distant. In both examples, the Exemplar model consistently gave low ranks to candidate words *broken*, *play*, and *cut* because they are some of the most polysemous words in our vocabulary with more than 50 existing senses each.

Evaluation of collaborative filtering

We next examined the influence of collaborative filtering on each of the three categorization models. For each model, we considered variants of these models with up to five neighboring words.

Figure 4 summarizes the results. All collaboratively filtered models achieve better AUC and expected rank on both the training set and testing set compared to their respective basic categorization models. The improvement is most prominent on the test set, lowering expected rank by more than 50 and improving AUC by over two percent for all three models. In particular, collaborative filtering improved model prediction most substantially when two closest neighboring words were considered. Consideration of more neighbors did not improve model prediction further, suggesting that information about slang word choice is sufficiently encapsulated in a small set of neighboring words.

Table 3 illustrates collaborative filtering with two examples. In both cases, the basic categorization models perform poorly because existing senses of the ground-truth words do not have strong similarity with the slang senses. The neighboring words however, contain senses that are more rele-

Ground truth target word [w]:	*wicked*
Slang sense in OSD [s]:	impressive.
Corresponding WordNet senses [E]:	(1) morally bad in principle or practice; (2) having committed unrighteous acts; (3) intensely or extremely bad or unpleasant in degree or quality; (4) naughtily or annoyingly playful; (5) highly offensive; arousing aversion or disgust.
Model expected rankings [E(Rank)]:	(1NN): 93/2128; (Exemplar): 369/2128; (Prototype): 33/2128
Top ranked words:	(1NN): *bonzer, spot, point, tall, grand*; (Exemplar): *broken, play, cut, point, heavy*; (Prototype): *bonzer, good, tall, grand, hot*
Ground truth target word [w]:	*breezy*
Slang sense in OSD [s]:	an unimportant girlfriend or girlfriend on the side.
Corresponding WordNet senses [E]:	(1) fresh and animated; (2) abounding in or exposed to the wind or breezes.
Model expected rankings [E(Rank)]:	(1NN): 1977/2128; (Exemplar): 1829/2128; (Prototype): 1762/2128
Top ranked words:	(1NN): *man, buddy, pal, beard, associate*; (Exemplar): *broken, play, cut, run, line*; (Prototype): *front, mate, face, joker, associate*

Table 2: Examples of model success and failure.

Ground truth target word [w]:	*icky*
Slang sense in OSD [s]:	gross, unappealing.
Corresponding WordNet senses [E]:	(1) very bad; (2) soft and sticky.
5 neighboring words used in collaborative filtering [$\mathcal{L}(w)$]:	*yucky, nasty, stinky, freaky, dirty*
Ground truth target word [w]:	*scary*
Slang sense in OSD [s]:	ugly, weird.
Corresponding WordNet senses [E]:	provoking fear terror.
5 neighboring words used in collaborative filtering [$\mathcal{L}(w)$]:	*freaky, crazy, nightmare, awesome, stupid*

Table 3: Examples that illustrate how collaborative filtering helps predicting slang word choice.

vant to the probe slang sense, hence informing the model better about the ground-truth words. We also observed that the neighboring words used in collaborative filtering have strong semantic correlations, which explains the diminishing effect in performance when introducing additional neighboring words.

Conclusion

We have presented slang generation as a categorization problem. Our formulation relies on few free parameters and sheds light on the cognitive processes that give rise to slang word choice. Although the full slang generation processes are beyond the models we have explored, our framework was able to capture substantial predictability without explicitly modeling external social variables. Furthermore, we incorporated parallel semantic change in slang generation using collaborative filtering and found that it improves slang prediction beyond the basic categorization models. Future work should explore richer semantic representations of slang and extend the current framework to novel slang word forms.

Abstract

There has been a great deal of interest in how generalizations and exceptions are learned, with particular interest in how speakers learn to avoid overgeneralizations. Do overgeneralizations disappear only because exceptions become more strongly represented or does the generalization itself become suppressed? Novel labels were constructed by combining 56 syllables with one of two prefixes, and each label was assigned a unique image. Most labels with the first prefix were paired with images from a generalization category, whereas exceptional labels were paired with images from a different semantic category. All labels with the second prefix appeared with a third category ("baseline"). Participants used a computer mouse to choose one of two images for each label. Mouse-tracking results show that the generalization itself became suppressed over time in the context of exceptional labels. A post-test demonstrated that exceptions were learned with item-specific precision.

Keywords: language acquisition, generalization, exceptions, overgeneralization, mouse-tracking

Introduction

In order to speak a language fluently, it is critical to learn subclasses of exceptions within otherwise broad generalizations. For instance, in Spanish, words ending *–a* are generally grammatically feminine, but roughly half of the words that end in *–ma* are masculine (e.g., *el drama*). The present work investigates how these sorts of generalizations and exceptional subclasses interact with one another during the learning process. In particular, we investigate whether competition between a generalization and a subclass of exceptions persists to the same degree throughout learning.

Competition between generalizations and exceptions is widely recognized to affect language processing (Bates & MacWhinney 1987; Christiansen & Chater 1999; McClelland, & Rumelhart 1986; Goldberg 2019). However, less attention has been focused on how the process of learning exceptions might affect memory for the generalization. One possibility is that the generalization and exceptions are represented independently, and learning the exceptions has no effect on memory for the generalization. According to this perspective, the generalization and exceptions may operate in parallel and race to provide the correct form during production (Pinker 1999), or they may operate as sequential rules (Yang 2016). Both of these proposals are consistent with the idea that speakers learn to avoid overgeneralizations because exceptions become more strongly represented. No change in the representation of the generalization is required.

A third possibility we investigate here is that the generalization becomes suppressed in the context of exceptions. Support for this hypothesis comes from the literature on how competition between memories drives learning. Numerous studies have found that, when memories (semantic or episodic) compete, the "losing" memories (i.e., memories that are partially activated, but less than the memory that is fully retrieved) become harder to subsequently access, compared to memories that do not undergo competition. (Anderson et al., 1994; Anderson et al., 2000; Bäuml, 1998; Bäuml 2002; Johnson & Anderson, 2004; Levy et al., 2007; Murayama et al., 2014; Lewis-Peacock & Norman 2014; Kim et al., 2014).

For example, in Anderson et al. (1994), participants memorized a set of word pairs, some of which shared a semantic category (*fruit: orange; fruit: apple*) while other items were part of an unrelated category (*tool: hammer*). During the retrieval practice phase, participants were given a semantic cue and asked to recall a subset of the items (*fruit: ap___*). Note that the semantic category fruit can be expected to activate *orange*, but *orange* would lose in competition to *apple* because it is inconsistent with the partial cue "*ap___*".

That is, the cue ensures that *apple* wins in a competition with *orange* (and other prototypical fruits). At the final test phase, unsurprisingly, participants recalled practiced items (*apple*) best. Critically, items in the same category which were not themselves practiced (e.g., *fruit: orange*), had a lower recall rate than unrelated baseline items (*tool: hammer*), an effect known as retrieval-induced forgetting (RIF).

Anderson et al., (2000) emphasized the role of competition during retrieval in RIF. They found that simply repeating an item (e.g., *apple*) without the semantic cue (*fruit: ap____*) that could be expected to partially activate competitors such as *orange,* did not result in the subsequent suppression of *orange*. In this case where there was no competition-inducing cue, the repeated item (i.e., *apple)* was strengthened but the other word from the same category (i.e., *orange*) was not less likely to be recalled than words from other categories (like, *hammer*). These results demonstrate that it is not merely the strengthening of the more activated memory that resolves the competition. Rather, competition also leads to suppression of the less activated memory.

In the domain of language learning, we hypothesize that exceptions serve to delimit the domain of a generalization, suppressing its activation and carving out a space of their own so that the generalization and exceptions become more differentiated over the course of learning. The alternative hypothesis is that exception learning is the strengthening of the exception alone, with no change to the generalization. We aim to evaluate these hypotheses by exposing participants to a mini-artificial language that contained a generalization and a subclass of exceptions. We then used a mouse-tracking design, as it provides a sensitive way to detect competition between two alternatives in a forced choice task.

The mini-artificial language consisted of two prefixes and 56 syllables and images. One prefix appeared with 40 syllables paired with images of one semantic category (the generalization) and 8 other syllables paired with a second semantic category (the exceptions). The second prefix consistently appeared with 8 instances of a third semantic category and served as a baseline. For example, as presented in Figure 1, a subset of participants witnessed the prefix, *abber,* paired with 40 unique syllables and unique faces and 8 different syllables and unique scenes. The other prefix, *belling*, was then paired with 8 unique syllables and unique objects. The combination of semantic category (faces, scenes, objects) and prefix (*abber, belling*) was counterbalanced across participants, and additionally, the pairing of each syllable and image was randomized for each participant. However, for ease of description, we refer to the assignment of categories and prefixes represented in Figure 1 throughout the paper.

Participants were first exposed to all 56 <prefix+ syllable> pairs (hereafter, labels) and images. In the main task, participants heard each label and decided which of two images on the screen matched that label (vs. the other "lure" image) by using a computer mouse to move from the bottom of the screen to the chosen image (Spivey, Grosjean, & Knoblich, 2005; Spivey & Dale, 2006). These mouse-tracking trials were repeated over 8 blocks in order to investigate learning over time. Only correct trials are included in the main analysis. But the dependent measure used was deviation toward the distractor image (the "lure"), weighted by time, which captures the degree to which participants were lured by the *incorrect* category (Figure 2).

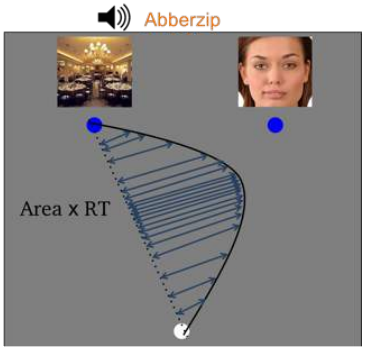

Figure 2: Example mouse-tracking trajectory sampled every 30 ms to determine the strength of the lure category (here, the face image).

Specifically, the distance between the cursor's position and a straight line to the correct response was measured at 30 millisecond intervals. To the extent that participants drew a relatively straight line from the start to the correct target, the deviation measure was low, indicating that the lure was not active in their minds. On the other hand, if participants drew an arc that trended toward the lure, we can conclude that the lure was activated by the label to some degree

Since our interest was in the relationship between a generalization and a subclass of exceptions, it might be tempting to focus on trials that included both an image from the generalization category and an image from the exception category. However, it would be impossible to determine in that case whether the trajectory was due to being lured by one image or by avoidance of the other. Specifically, an overgeneralization may be captured by a strong pull towards the generalization lure image or a lack of pull towards the correct exception image.

Therefore, in order to investigate how generalization activation changes without contamination from the lure of an exception image, a second trial type was introduced, "Scrambled-Image" trials (Figure 3). On these trials, participants were told to always select the scrambled image, regardless of what label was heard or which other image was available. For these

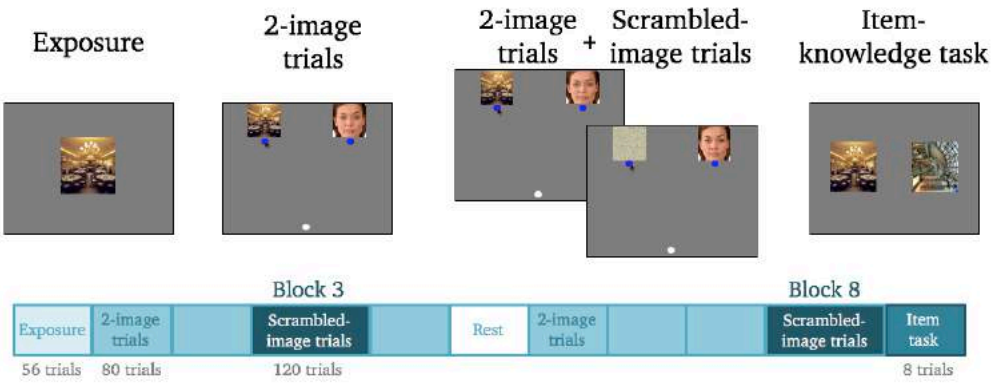

Figure 3: Exposure phase, followed by 8 blocks of 2AFC trials. Blocks 3 and 8 also contained scrambled-image trials in order to measure the strength of lures as directly as possible. Lastly, there was an item-knowledge task.

scrambled-image trials, the trajectory indicated how much participants activated the lure image category without the confound of preference toward the chosen image, since this was held constant across all scrambled-image trials. In order to avoid over-learning of the scrambled-image task (i.e., participants becoming good at going straight to the scrambled image without consideration of the lure), this type of trial was only included in blocks 3 and 8.

Blocks with two intact-image trials (blocks 1,2, & 4-7) each had 80 trials per block. Blocks 3 and 8 had two intact-image trials intermixed with scrambled-image trials for a total of 120 trials (Figure 3). Thus, in total, there were 720 trials, 11.11% of which were scrambled-image trials. Participants were not given any indication of the block structure of the task, except that they were given a rest after block 4, half way through the experiment.

By comparing performance on scrambled-image trials in blocks 3 and 8, the activation of lures over the course of learning can be detected. See Figure 3 for experimental design.

The scrambled-image trials, along with the mouse-tracking measure, allowed us to home in on the activation of a particular category for a particular label and how it changed over the course of learning. This enabled us to test the following hypothesis: a generalization becomes suppressed over time in the context of exception labels.

Method

The sample size and the main analysis were preregistered on Aspredicted.org, prior to data collection.

Participants

42 undergraduate students from Princeton University were compensated with course credit and up to an additional $5, depending on task performance.

Stimuli

The 2 prefixes (*abber* and *belling*) and 56 syllables (e.g., *zip, ber,* and *za)* were all phonotactically regular. The labels (prefix + syllable) were presented auditorily without pauses between the prefix and the syllable, and each lasted approximately 800 ms. Each scrambled image was created by scrambling the pixel locations of the lure image used in the same trial.

Procedure

Participants were given general instructions at the beginning as well as 6 practice trials for the 2AFC mouse-tracking task. They were told to pay attention to the pairing of the labels and images, but were not told about the structure of the stimuli (i.e., that the labels were a combination of a prefix and a syllable, nor the general distribution of categories). They were instructed to make their choices as quickly as possible and to move the cursor as directly to the target as possible while trying to avoid errors. The entire experiment lasted 1.5-2 hours, including a short rest period.

Initial exposure phase: Each label-image pair was presented once, for a total of 56 trials (40 generalization items + 8 exception items + 8 baseline items), with order of presentation randomized for each participant.

Mouse tracking task: Blocks 1-8: Participants were instructed to choose the image that matched the label they heard, except on scrambled-image trials in which they were instructed to always choose the scrambled image. For the intact-image trials, the two images always came from different categories, so participants could perform at ceiling by recognizing which category each label belonged to, without necessarily learning which face, scene or object each label corresponded to. For the scrambled-image trials, one of the images was created by scrambling the pixel

location of the other intact image. All other procedures were equal between intact image trials and scrambled-image trials.

The label was played through headphones. Once it was finished, participants could click the white button at the bottom of the screen, causing 2 images to be displayed. Participants then moved their cursor to the image that was associated with the label and clicked on the blue button underneath that image. In order to encourage participants to respond as quickly as possible, a score appeared on the center of the screen, calculated according to the trajectory of the mouse and speed of response. When the score was displayed, the incorrect image would disappear, leaving the correct image only. If participants had chosen incorrectly, they had to move their cursor to the correct image and click, before continuing to the next trial. After block 4, participants were given a mandatory 5-10-minute break before continuing with block 5.

Item-knowledge task: After the 8 blocks of the 2AFC task, participants performed a short task designed to test whether they had incidentally learned to associate particular exception labels with particular images within that category. The 2 images in this task were both instances of the exception category (e.g., 2 different scenes), requiring participants to identify the item-specific association of label and image. Participants were unaware they would be tested on item-specific knowledge for this task.

Results

All 42 participants exceeded the preregistered threshold of 75% accuracy on the mouse-tracking task ($M = 87.14$, $SD = 0.0085$), and none were excluded ($N = 42$). 3.25% of all trials were excluded because participants took > 2 seconds to click the start button or > 5 seconds to make a choice between images.

Accuracy on intact image trials

For trials in which participants decided which one of the two intact images matched the label they had heard, we can look at their accuracy against chance (50%) to see how well they knew the label-image pairings. Participants were above chance on all trial types in the first block after exposure ($t = 22.95$, $p < 0.0001$, $M = 0.89$), except for exception-label trials. On exception-label trials, participants heard an exception label and had to choose between an image from the exception category (e.g., scene, the correct choice) and the generalization category (e.g., face, the incorrect choice). Initially, accuracy on exception-label trials was significantly below chance (block 1), indicating that participants were systematically choosing the generalization image ($t = -2.13$, $p = 0.039$, $M = 0.43$). Accuracy for exception-label trials quickly rose, however, becoming significantly above chance in block 2 ($t = 2.43$, $p = 0.020$, $M = 0.59$). By block 8, accuracy for exception-label trials was as high as that for other trial types ($t = 1.30$, $p = 0.20$, $M = 0.93$ for exception trials, $M = 0.96$ for other trials).

Trajectory toward lure

The dependent measure for each trial was the area underneath the trajectory weighted by reaction time (area x RT). To calculate the area x RT, we compared the trajectory against the most direct, straight line connecting the starting point and the end point. The starting point was the position the participant had to click at the start of the trial and the end point was where the participant clicked when they made a choice (one of two blue circles). We measured points on the actual trajectory every 30 ms and calculated the distance between each of these points from the straight line. The sum of these distances is the area x RT. Note that the farther participants moved their cursor away from the straight line and the longer it stayed there, the higher the area x RT was. We had preregistered the dependent measure to be the maximum distance from the straight trajectory, and the result of the preregistered main analysis does not qualitatively differ when the maximum distance is used. However, after preregistering, we decided that area x RT was more appropriate and sensitive, allowing us to take both speed and deviation into account.

We report the results from the trajectory of the scrambled-image trials because it is the most direct measure of the activation of a category (i.e., the lure image category) given a label. For all analyses we used a maximal multilevel model with trial type or an interaction of trial type and block as the fixed effects and random intercepts and slopes for subjects and items where convergence would allow (Barr, Levy, Scheepers, & Tily 2013), using the lmerTest library (R Development Core Team 2008).

First, to confirm that highly activated lure images would indeed yield greater deviation and thus higher area x RT measures, we compared trials in which the label matched the lure image (e.g., the label was paired during the training phase with a specific scene and the lure image is that specific scene) and trials in which the label did not match the lure image or its category (e.g., the label was paired with a scene and the lure image is a face). As expected, we found that matched trials had a higher area x RT than unmatched trials ($\beta = -0.69$, $t = -11.06$, $p < 0.0001$).

Recall our hypothesis: that generalization activation (e.g., face image activation) would decrease over time for exception items (e.g., for labels that are paired with scenes). Thus, the critical preregistered comparison

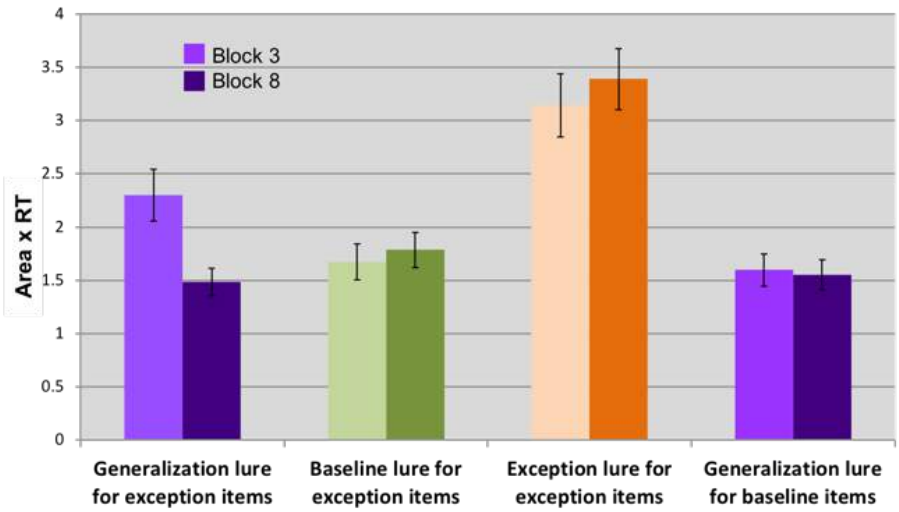

Figure 4: Deviation measure toward lure in block 3 (lighter color) and block 8 (darker shade), for exception-label trials with generalization image lures (left purple), exception-label trials with baseline lures (green), exception-label trials with exception lures (orange), and baseline-label trials with generalization lures (right purple). The correct choice in all cases was a scrambled image.

was the change of activation of the lure from block 3 to block 8 on trials when an exception-label was heard. We compared trials in which the lure image was the generalization (e.g., the label was paired with scene and the lure was a face image) against the baseline (e.g., the label was paired with a scene and the lure was an object image). The model found a significant interaction of trial type and block (β = 0.23, t = 2.66, p = 0.010). In other words, for exception items, the generalization activation became suppressed over time, more so than did baseline activation. In Figure 4, the far-most left panel shows the key generalization suppression from block 3 (light purple) to block 8 (dark purple). There is no suppression over blocks for baseline activation (green). Thus, generalization suppression cannot be attributed to general improvement over time or to general improvement on scrambled image trials.

Another critical part of the hypothesis is that the generalization was suppressed due to competition from learned exceptions. For exceptions to compete with the generalization, exceptions must be activated to some degree. In other words, exception-labels must be identified as exceptions and activate the correct exceptional category (scene) for competition to occur. Results additionally provide evidence that, as early as block 3, participants had learned which labels were exceptional. In particular, when an exception-label was heard, the matched exception image (scene) exerted a strong pull away from the scrambled image (third panel, light orange bar). In fact, the area x RT for matched exceptional images was higher than that for generalization images (face images) at block 3 (β = 0.42, t = 2.10, p =0.038). This means that the generalization suppression we observe occurred after participants had already learned the exceptions to some degree.

An alternative explanation for generalization suppression over time for exception-label trials could be that the generalization (e.g., face images) became less of a lure across the board, for exception items as well as baseline items. To investigate this possibility, we compared area x RT towards generalization lure images for exception-label trials against baseline-label trials. If (as hypothesized) generalization suppression is unique to exception labels (because of the competition from sharing a prefix), there should be no generalization suppression for baseline labels (where a prefix was never shared, and thus no competition took place). We again found a significant interaction of trial type and block (β = 0.19, t = 2.37, p = 0.018). In other words, generalization suppression over time was evident only in the context of exception items, not baseline items. In Figure 4, the far-most right panel shows no change of generalization activation over time for baseline items (purple bars). This also rules out the possibility that generalization suppression for exception items was specific to an image category (e.g., generally disliking faces over time).

Item-knowledge task

Despite high accuracy in the main task being achievable based purely on recognition that certain labels were exceptional (i.e., were associated with the non-dominant category for the prefix), the final task demonstrated that participants nevertheless learned with near-ceiling level accuracy which specific scene was paired with which specific label (M = .9494; t = 29.19, p < 0.0001).

Discussion and Conclusion

This experiment assessed how the activation of a generalization changed in the context of exceptions

over the course of learning. By using mouse-tracking to measure lure activation, we were able to isolate the activation of the generalization from the activation of the exception for a given label. Results demonstrate that the competing probabilistic generalization was a strong lure for the exceptions early on, but the generalization became suppressed over time in the context of exceptions. That is, the suppression of the generalization over time was evident only for exception labels. Because accuracy on exceptions was already high and exception lures were already even stronger lures early on, we suggest that the suppression was caused by competition from learned exceptions. Results of a post-test demonstrated that exceptions were learned with item-specific precision even though ceiling performance was possible by reliance on category membership only.

Importantly, our claim is not that learning eliminated all competition between generalizations and exceptions in this study. We know that comprehension is incremental, so we fully expect that listeners activated multiple options that were consistent with the input they witnessed until the point of disambiguation (Jurafsky, 1996; McQueen, 2007; Rayner & Clifton, 2009; Swinney, Prather, & Love, 2000); hearing *abber* should trigger a competition between exceptional items (e.g., *abber zip*) and other items that begin with the same prefix (e.g., *abber fep*), even after learning takes place. Rather, our main hypothesis pertains to what happens after the disambiguating syllable (*zip*) is heard: Would learning of exceptions affect the activation of the generalization, specifically in the case of exceptions like *abber zip*? We found that it did: the generalization became a less powerful lure as exceptions became more easily identified.

This work was motivated, in part, by the effects of competition on memory observed during studies of *retrieval-induced forgetting* (RIF). Consistent with RIF findings in the memory literature, the linguistic generalization became suppressed ("forgotten") in the context of exceptions. At the same time, it is important to point out a key difference between our study and the way RIF is usually tested. Most RIF studies look at final recall to measure memory performance. Our study, on the other hand, considered the change in activation over the course of learning. This difference led us to use a different baseline for determining whether suppression occurred. In standard RIF studies, suppression is measured by how much lower the memory for competing items is, compared to baseline items which had not been in competition with the practiced items. In our studies, suppression was measured by how much lower the activation for the generalization became over time. We found that generalization activation significantly decreased over time for exception items, much more than it did for baseline items. However, we did not find that activation levels of the generalization fell below baseline activation; as such, we did not find RIF in the classic sense. Nonetheless, our results are consistent with the idea that competition leads to suppression of the less activated memory.

We selected the "prefix plus syllable" structure for the labels to allow for prediction of the category given the prefix. The prefix plays the role of a classifier (i.e., a grammatical element that selects for nouns of certain semantic categories; Dixon 1986) As noted in the introduction, linguistic categories, including classifier categories, often have subclasses of exceptions, as in the present experiment. However, the finding in this study is not, in principle, specific to words. For example, similar competitive mechanisms may serve to suppress grammatical overgeneralizations through what has been called *statistical preemption* (e.g., Goldberg, 2019; Perek & Goldberg 2017; Robenalt & Goldberg, 2015). Future work will build on these results to explore how generalizations and exceptions compete in other domains, how the underlying neural representations change, and how these competition-driven changes relate to behavior.

Redundant morphological marking facilitates children's learning of a novel construction

Abstract

The presence of redundant marking in languages raises interesting questions about the balance of different pressures in language learning and use. Speakers tend to avoid redundant elements in production: omitting (or reducing) more predictable elements. At the same time, languages maintain different types of redundant marking, such as encoding thematic assignment by both word order and case marking. Why is redundancy found in languages even though speakers seem to avoid it? Here, we propose that redundant cues can facilitate learning. We test this hypothesis in an artificial language learning study with children, where either word order alone or both word order and case marking serve as cues for thematic assignment in a novel construction. Results show that children learned the redundant language better despite having to learn an additional morpheme. We discuss implications for the effect of different cognitive pressures on language change.

Keywords: redundancy; artificial language learning; language acquisition; language evolution

Introduction

It has long been claimed that languages exhibit an optimal trade-off between two competing pressures: minimizing effort and maximizing understandability (Givón, 1991; Haspelmath, 2008; Jäger, 2007; Jaeger & Buz, 2017; Piantadosi, Tily, & Gibson, 2012; Zipf, 1949). Under this view, redundant cues will be dispreferred in language use (because they increase effort without increasing understandability), eventually leading to their reduction in language structure (Fedzechkina, Newport, & Jaeger, 2016; Gibson, Piantadosi, et al., 2013; Givón, 1991; Jaeger, 2013). In line with this view, speakers seem to avoid redundant marking in production: more predictable messages are more likely to be omitted or reduced (Aylett & Turk, 2004; Cohen Priva, 2015; Frank & Jaeger, 2008; Jaeger, 2010; Kurumada & Jaeger, 2015; Levy & Jaeger, 2007). For example, speakers tend to omit optional case marking when the meaning it encodes is more predictable from context (Kurumada & Jaeger, 2015; Lee & Kim, 2012).

At the same time, redundant marking is attested, in different forms, in multiple language systems. For instance, a number of typologically diverse languages are documented as redundantly marking a single meaning using multiple morphological markers (defined as *multiple exponence*, Caballero & Harris, 2012; Harris, 2017). In Choguita Rarámuri, for example, words containing an inner derivational marker for causatives and applicatives can have a second, optional marker suffixed to the noun (Caballero & Kapatsinski, 2015). Languages can also redundantly mark the same grammatical information by more than one means: one such example is the encoding of thematic assignment (who is doing what to whom) by both word order and case marking (e.g., Icelandic, see Siewierska, 1998). That is, morpho-syntactic redundancy—where two linguistic cues are used to mark the same function—is found across language systems.

How can we reconcile the presence of redundancy in language structure with speakers' tendency to avoid it in production? One way is to examine the possible functions of redundancy: why does it come about in the first place and what advantage can it confer? Here, we propose that the answer may lie in the impact of redundancy on learning. In particular, we suggest that (a) redundancy can facilitate learning under certain conditions, and (b) if this is so, speakers may increase (or maintain) the use of redundant cues when conversing with learners, supporting their continued presence in language. This proposal is compatible with the principles of efficient communication: the balance between effort and understandability can change depending on the comprehension ease or difficulty within a conversation (Gibson, Bergen, & Piantadosi, 2013; Kurumada & Jaeger, 2015; Levy & Jaeger, 2007). Speakers may allow (or even prefer) more redundancy when the listener is seen as having more difficulty in comprehension, as in the case of learners. The two predictions—the facilitative effect of redundancy on learning and its increased use with learners—are related, but theoretically independent. In the present study, we focus on the first prediction: Does redundancy facilitate language learning? Our focus here is on morpho-syntactic redundancy: cases in which different morpho-syntactic cues encode the same information. In line with previous work, we treat the omission and reduction of linguistic material as reducing redundancy (Aylett & Turk, 2004; Jaeger, 2010; Kurumada & Jaeger, 2015).

The advantage of multiple cues in learning has been demonstrated for different domains, such as vision (Sloutsky & Robinson, 2013) and category formation

(Yoshida & Smith, 2011). Recent computational evidence suggests that multiple cues can also facilitate language learning (Monaghan, 2017). Monaghan (2017) examined learning new mappings between forms and meanings with multiple cues. The cues were probabilistic in the learning phase (appeared only some of the time), and were absent during testing (where only the labels appeared). In line with our prediction, the computational model showed that words were learned better from multiple cues (pointing, prosody, and distributional cues) compared to single cues. Importantly for the present research question, the multiple cues used in these studies involved the combination of linguistic and non-linguistic cues (e.g., pointing) where the non-linguistic cues did not have to be learned in and of themselves (they did not carry information beyond increasing attention to the label). Here, we go beyond this work to ask whether redundant *linguistic* cues can also facilitate language learning. If redundant morphological marking is facilitative, we should see improved learning despite the added complexity of having to learn an additional cue. We focus on the morpho-syntactic redundancy of word order and case marking and use the transitive construction as a test case.

The Transitive Construction

Languages use different cues to indicate who-did-what-to-whom in the transitive construction. Two prominent cues are word order and case marking[1]: looking at learning when both cues are used lets us examine the possible advantage of redundant marking. The contribution of different cues to sentence interpretation has been studied extensively within The Competition Model (MacWhinney, 1987). Stemming from this theoretical framework, studies in various languages have tested how children utilize these two cues to comprehend transitive constructions. Dittmar, Abbot-Smith, Lieven and Tomasello (2008) examined the relative reliance of German-speaking toddlers on word order and case marking. They found that 2;6-year-olds could comprehend transitive sentences only when there was redundant marking of agent and patient (both cues were used). These findings were replicated across several languages (Cantonese: Chan, Lieven, & Tomasello, 2009; Japanese: Matsuo, Kita, Shinya, Wood, & Naigles, 2012; Warlpiri: O'Shannessy, 2010), and are in line with the predictions of The Competition Model, according to which a convergence of cues should facilitate comprehension of thematic assignment (Bates, McNew, MacWhinney, Devescovi, & Smith, 1982; Bates & MacWhinney, 1989; Ibbotson & Tomasello, 2009). However, in many of these cases, the redundant form is also the prototypical and the most frequent form in child-directed speech (Dittmar et al., 2008; Ibbotson & Tomasello, 2009). Therefore, it is not clear whether comprehension was facilitated because of the redundant cues, or because of the greater frequency of the prototypical structures (which happened to also have redundant cues). These explanations are hard to tease apart using natural language data, since individual cues are often correlated with one another (Ibbotson & Tomasello, 2008), and confounded with frequency.

[1] There is typological and historical debate about the relation between those two cues (with many languages showing a trade-off between the two), we return to this in the discussion.

The Current Study

In the current study, we use an artificial language to assess the impact of redundant morpho-syntactic cues on children's learning of a novel language. We compare the learnability of transitive constructions in two artificial languages: one with fixed OSV word order and no additional cues to thematic assignment (the non-redundant language), and the other with the same fixed OSV word order but with additional redundant case marking on objects (the redundant language). We used OSV word order because it differs from the dominant word order of Hebrew (SVO) - the language of the children in our study. Following exposure, we tested both comprehension and production of sentences in the novel language. Although the language without the case marking is simpler, in the sense of having fewer elements to learn, we predict that the redundant language will lead to better comprehension of thematic assignment because it contains redundant cues to indicate who-did-what-to-whom. Our prediction about the effect of redundancy on prediction is less clear-cut. On the one hand, if redundant markers indeed facilitate learning in general, this could aid production as well. Alternatively, the need to produce an additional element could make the sentences harder to produce. Such a dissociation between comprehension and production pressures is documented in other linguistic domains (e.g., Harmon & Kapatsinski, 2017).

Method

Participants

60 children participated in the experiment (age range: 7;0-9;0y, mean age: 7.10y, 41 boys and 19 girls). All children were visitors at the Bloomfield Science Museum in Jerusalem. They were recruited for this study as part of their

Figure 1: A trial example in the Sentence comprehension test phase.

Trial number	0.03324	0.03046	1.091	0.275
Age	-0.36756	0.32724	-1.123	0.261

visit to the Israeli Living Lab in exchange for a small reward. Parental consent was obtained for all children. All children were native Hebrew speakers, and none of them had known language or learning disabilities.

Materials

In both language conditions, participants were exposed to the same lexicon, which was composed of 6 semi-artificial Hebrew nouns (Hebrew nouns with nonce suffixes) and two Hebrew verbs. All nouns corresponded to masculine human characters, that were differentiated by their profession (e.g., clown, chef). The verbs were the Hebrew translations of "kick" and "touch". The constituent order of the language in both conditions was the non-Hebrew like OSV. In the redundant language (henceforth R-language) a nonce case marking ("patz") followed all objects, while in the control language (C-language) there was no such case marking. This cue was also non-native-like: Hebrew doesn't have post-nominal case-marking on objects. Participants saw and described the exact same drawings in both conditions[2].

Procedure

Participants were told they were going to meet some aliens who "say things differently from us" and that they would learn to speak like these aliens. Children were randomally assignmed to one of the two language conditions. Children sat with headphones in front of a computer next to a research assitant that provided them with verbal instructions. They saw drawings and heard recorded descriptions of these drawings in the alien-language (concatenated from recordings of the individual words spoken by a female Hebrew speaker). The experiment had several stages. First, a noun exposure phase, in which children saw each character, heard its name in the alien language, and had to repeat each name outloud (6 trials, one per noun). In both conditions, only the noun label was presented (without case marking). This was followed by a noun comprehension test (12 trials, two per noun) where participants saw two drawings, heard one label and had to match the label to the correct drawing. Feedback was provided after each trial. The following phase was sentence exposure (12 trials) where children saw a drawing of a transitive action (involving two of the characters, all characters could appear as agents and patients), heard a transitive sentence, and had to repeat it. The position of the agent and the patient in the drawing (left vs. right) was counterbalanced. The next stage was a sentence comprehension test (12 trials) where children saw two drawings of events, heard a sentence, and had to match the sentence to the correct drawing (see Figure 1). All the sentences here involved previously unheard combinations of agents and patients. The children had to use the mouse to choose the matching drawing. No feedback was given. The next phase was sentence production (12 trials) where chlidren saw previously unseen drawings of a transitive actions and had to describe them in the alien-language. Children's descriptions were recorded. Children in the R-language condition had one additional sentence forced-choice phase (12 trials) where they saw a previously unseen drawing, heard two descriptions of it, and had to choose the correct one. One option had case marking (like the sentences they heard before) and one was without case marking (as in the C-language). Children had to say which was a better way to describe the drawing by pressing on "1" or "2", corresponding to the order in which the options were presented. This phase was added to ensure that children in the R-language condition noticed the case marking cue.

Results

Comprehension

Children successfully learned the language (better than chance) in both conditions (C-language: M=65%, SD= 26%, t-test (29) = 3.1, p=0.004; R-language: M=91%, SD= 12%, t-test (29) = 26.8, p<0.0001). We used a mixed-effect logistic regression model to examine the effect of language condition on sentence comprehension (using the glmer function in R software, Bates, Maechler, Bolker, & Walker, 2015), and the maximum random effect structure justified by the data that converged, Barr, Levy, Scheepers, & Tily, 2013). The dependent variable was accuracy on each trial (as a binary variable). The model included fixed effects for condition (R-language vs. C-language, effect coded), age and trial number as centered continuous factors, and random intercepts for participants (see Table 1 for full model). As predicted, children showed better learning in the R-language condition (91% vs. 65%, β=1.04, SE=0.2, p<0.0001, Figure 2). Importantly, the difference in sentence comprehension

[2] The drawings were drawn by Sara Rolando from the University of Edinburgh, courtesy of Kenny Smith and Jennifer Culbertson

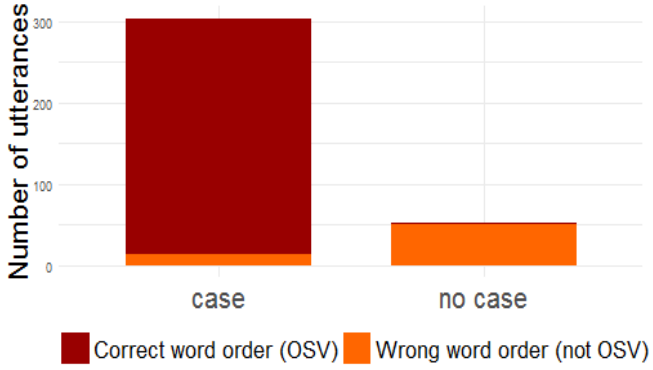

Figure 3: Production of correct word order (OSV) by production of case marking for children in the R-language condition.

did not stem from differential learning of the lexicon, both groups learned the nouns equally well (99% vs. 97%, t(58)=0.88, *p*=0.38).

Production

Children's productions were transcribed and coded for word order and vocabulary accuracy. Both measures were binary, and were scored by a research assistant blind to the condition and the experimental hypothesis. We used a mixed-effect logistic regression model to examine the effect of language condition on these production measures. The dependent variable was word-order accuracy on each trial (as a binary variable). The model included fixed effects for condition (R-language vs. C-language, effect coded), age and trial number as centered continuous factors, and random intercepts for participants. We found no significant difference in word order accuracy between the two conditions, although the trend was in favor of the R-language (82% vs. 69%, β=0.42, SE=0.86, *p*>0.6). We used the exact same model with lexical errors as the predicted variable and found no effect of condition here as well (0.1% vs. 0.07%, β=0.2, SE=0.18, *p*>0.2). Production did not seem to be facilitated in the R-language condition.

To further look at the possible facilitative effect of the redundant case marking, we looked only at the productions of children in the R-language condition (since only learners of the R-language had the potential to use both cues in production). We noticed several interesting patterns. First, children produced case marking in the majority of their productions (M=85%, SD=35%), indicating that they treated the cue as an inherent part of the system, despite its redundancy and the additional effort involved in producing it. Second, children produced the correct word order in most of the sentences (M=82%, SD=32%), indicating they managed to learn the non-Hebrew order. Interestingly, word order accuracy was impacted by the production of case marking: word order was more accurate when case marking was produced (291 correct utterances vs. 13 incorrect utterances) and was less accurate when it was not produced (only 1 correct utterance vs. 51 incorrect ones). To quantify this effect, we ran an additional model in which word-order accuracy on each trial was the dependent variable. The model included fixed effects for case marking on each trial (presence or absence, effect coded), age and trial number as centered continuous factors, and random intercepts for participants (see Table 2 for full model). In line with our hypothesis, case-marking had a significant effect on word order accuracy β=10.35, SE=2.7, *p*=0.0001, Figure 3).

Finally, we looked at participants' responses in the forced-choice part to sentences with and without case marking (note that only participants that learned the R-language had this additional part). Participants generally preferred the sentences with the case marking (M=88%, SD=19%), indicating, again, that they noticed the cue and learned it as part of their language.

Trial number	1.0889	0.7204	1.512	0.130652

Discussion

The presence of redundancy in languages is puzzling: if speakers are driven by a bias for efficient communication (Aylett & Turk, 2004; Cohen Priva, 2015; Jaeger, 2010; Kurumada & Jaeger, 2015; Levy & Jaeger, 2007), why do languages use more than one cue to convey the same information? Our study set out to test the prediction that redundant marking could be facilitative in learning circumstances. Our results show that having a redundant morpheme facilitates children's learning of thematic assignments. Although the R-language was more complex than the C-language, since it contained an additional cue to attend to and learn, children learned a non-native like word order better in this condition. The redundant morpheme benefited not only comprehension, but also production of the correct word order: despite the additional effort involved in producing it, word order was more accurate when case marking was produced. Taken together, these findings suggest that redundancy can be functional in learning circumstances. This is in line with previous work on the effect of learning from multiple cues (Monaghan, 2017; Sloutsky & Robinson, 2013; Yoshida & Smith, 2011). It further suggests that redundant cues can help language learning even when these cues need to be learned themselves.

These findings are of relevance for a recent influential proposal about the impact of different kinds of learners on the morphological complexity of a language. The Linguistic Niche hypothesis (Lupyan & Dale, 2010) proposes a causal link between the proportion of L2 speakers in a community and the degree of morphological complexity of the language. The prediction is that languages with more L2 speakers will have less complex morphology, a prediction that is supported by a large-scale study of over 2000 languages. Importantly, the proposed mechanism rests on the assumption that children and adults differ in the impact of redundancy on learning: whereas child learners benefit from redundant cues (leading to their existence in language), adult learners do not (leading to their simplification). While intuitively appealing, there is no direct evidence that children and adults differ in their response to redundant cues in learning. Building on the current findings, we are currently running a version of this study on adults to see if they indeed differ from children in the impact of redundant cues on learning. The Linguistic Niche hypothesis predicts that adult learning should be less facilitated by redundant cues. On the other hand, adult learners benefit from repetition (e.g., Jensen & Vinther, 2003; Onnis, Waterfall, & Edelman, 2008), and therefore may benefit from redundant cues as well.

Our findings document an effect of morpho-syntactic redundancy on learning, but they need to be extended in several ways. First, children in the R-language were exposed to the redundant morphome in both exposure and test. We are currently running additional versions of the study to better understand the impact of the redundant cue on exposure/testing. Second, we want to know if similar faciliatitve effects can be found for other linguistic domains beyond the learning of thematic assigment. Finally, the current study did not examine the prediction that redundancy is found more when conversing with learners. In an additional line of work, we investigate whether learning interactions are in fact characterized by more redundant marking, and whether this, in combination with their facilitative role can give rise to patterns of redundant marking in language.

Finally, the current findings are informative for our understanding of how languages are shaped by different cognitive pressures. Although in many languages the input children hear contains multiple cues for thematic assignment (Dittmar et al., 2008; Ibbotson & Tomasello, 2009), different typological studies suggest languages tend to trade off between these cues. In particular, languages that rely on word order to encode thematic assignment often lack productive case marking (Blake, 2001; Koplenig, Meyer, Wolfer, & Mu, 2017; Siewierska, 1998). Furthermore, several historical studies document this trade-off overtime in some Latin languages (e.g., Old English, Marchand, 1951, though see Detges, 2009; Pintzuk, 2002 for challenges to this claim). Recent experimental work suggests that this trade-off reflects speakers' bias for efficient communication (Fedzechkina et al., 2016; Roberts & Fedzechkina, 2018): When participants learned a novel language with fixed word order and optional case marking, they tended to decrease the use of case marking relative to their input. On the surface, these findings seem to contrast with our own: learners reduced the use of a redundant morpheme. However, this highlights the differential impact various pressures can have on language. First, case marking was deterministic in our design (case marking in the R-language was present on 100% of the objects), therefore, it is likely that participants were trying to faithfully reproduce it (see discussion in Fedzechkina et al., 2016). More importantly, we saw facilitation in comprehension: the impact of communicative and learnability pressures may differ for production and comprehension (e.g., Harmon & Kapatsinski, 2017). While redundancy may facilitate comprehension, it is costly in production (Zipf, 1949). These competing pressures (ease of production vs. understanding) may be weighted differently depending on the conversational situation: learning circumstances (or conversing with learners) may benefit from redundancy while other situations will not, leading to the observed trade-off between case-marking and word order seen in languages.

In sum, we have shown that children learn thematic assignment better from a language that has both word order and case marking, despite having to learn an additional morpheme. The present study serves as an important first step for understanding the functionality of having both cues.

Bayesian Inference of Social Norms as Shared Constraints on Behavior

Abstract

People act upon their desires, but often, also act in adherence to implicit social norms. How do people infer these unstated social norms from others' behavior, especially in novel social contexts? We propose that laypeople have intuitive theories of social norms as behavioral constraints shared *across* different agents in the same social context. We formalize inference of norms using a Bayesian Theory of Mind approach, and show that this computational approach provides excellent predictions of how people infer norms in two scenarios. Our results suggest that people separate the influence of norms and individual desires on others' actions, and have implications for modelling generalizations of hidden causes of behavior.

Keywords: Social Norms; Social Cognition; Bayesian Theory of Mind; Intuitive Theories

Introduction

Imagine entering a cafeteria in a foreign country that you know little about. There are but a handful of individuals in the cafeteria; you notice a tray-return receptacle at the far end, but you do not notice any signage on the walls detailing the expectations governing tray returns. If you observe someone carry their tray to the far end in order to return it, what inferences might you make? Does that person *like* returning trays, incurring the cost of walking across the room to do so? Or, is there an implicit social norm at play? A second person leaves without returning their tray. What might you now infer about them or about the potential social norm? Lastly, a third person approaches the second and loudly chastises them for not returning their tray, what would you then infer about everybody's preferences and the social factors at play?

Social norms are ubiquitous features of human societies, and as the example above suggests, we are able to rapidly infer their presence in novel situations. Children as young as three (Schmidt, Butler, Heinz, & Tomasello, 2016) demonstrate the ability to learn and generalize these rules of social behavior (Rakoczy & Schmidt, 2013). Not surprisingly, this ability continues into adulthood, allowing us, for example, to travel to new countries and then learn through observing others whether one is obliged to tip at restaurants, what the appropriate manner of greeting is, or what topics of conversation are considered impolite. In other words, we seem to possess not just an intuitive Theory of Mind (ToM) which allows us to infer the beliefs and desires of individuals, but also a corresponding ability to efficiently make inferences about shared norms that drive behavior *across* individuals. Furthermore, we appear naturally capable of disentangling the influence of social norms and individual desires: when we see someone picking up trash on the sidewalk, we infer that this is more likely due to an obligation to keep the streets clean rather than enjoyment of the act itself.

Despite (or perhaps because of) its ubiquity, how people *infer* social normativity is relatively understudied. The philosophical literature on social norms has generally focused on characterizing the precise nature of such norms—whether they are best understood as social practices, preferences conditioned upon shared expectations of behavior, or commonly-held normative attitudes (Bicchieri, 2005; Brennan, Eriksson, Goodin, & Southwood, 2013). Across philosophy, economics and psychology, there has also been an emphasis upon understanding the conditions and mechanisms for the emergence of norms (Hawkins, Goodman, & Goldstone, 2018)—whether they arise, for example, as Nash equilibria (Axelrod, 1986; Young, 2015), correlated equilibria (Gintis, 2010), or through maximization of cultural values (Bölöni, Bhatia, Khan, Streater, & Fiore, 2018). Other studies investigate how norms influence decision making (Chang & Sanfey, 2011), and how they are enforced (Fehr & Fischbacher, 2004). However, apart from a few simulation-based studies (Savarimuthu, Cranefield, Purvis, & Purvis, 2010; Cranefield, Meneguzzi, Oren, & Savarimuthu, 2016), research into how social norms are *inferred* remains scarce.

How then to explain our ability to infer social norms? In recent years, Bayesian models of cognition have begun to establish a computational basis for how people make social inferences. The Bayesian Theory of Mind (BToM) approach is perhaps the most prominent example, allowing researchers to formalize how people make graded judgments about unobservable mental states by observing the actions of others (Baker, Jara-Ettinger, Saxe, & Tenenbaum, 2017). This approach to social cognition has been extended to model reasoning about others' emotions (Ong, Zaki, & Goodman, 2015), inferring others' beliefs and desires from observed actions and emotional expressions (Wu, Baker, Tenenbaum, & Schulz, 2018), reasoning about how others balance costs and rewards in deciding how to act (Jara-Ettinger, Gweon, Schulz, & Tenenbaum, 2016), learning how people value the welfare of others (Kleiman-Weiner, Saxe, & Tenenbaum, 2017), and inferring the presence of co-operation or competition from the behavior of multiple individuals (Shum, Kleiman-Weiner,

Littman, & Tenenbaum, 2019). Related work modelling human concept learning as Bayesian rule inference (Goodman, Tenenbaum, Feldman, & Griffiths, 2008) has also been used to develop theories of why people tend to learn act-based moral rules rather than outcome-based ones (Nichols, Kumar, Lopez, Ayars, & Chan, 2016).

We build upon this tradition of computational cognitive modelling, and hypothesize that people intuitively understand social norms as factors of behavioral influence which are shared across agents in a particular social context. These shared norms influence behavior alongside the individual desires of agents, and can generally be understood as injunctions or constraints on behavior, i.e., they prescribe, recommend, or prohibit certain kinds of actions[1]. We propose that people include these norms in their lay theories of social behavior, and we model these theories as Bayesian networks which include both norms and desires as possible causes of action. Judgments about the presence of a norm can thus be modelled using Bayesian inference conditioned upon observed actions, which can be made alongside desire inferences. Furthermore, since social norms are shared, inferences about them can be made from observations of multiple agents, unlike those for desires. We discuss several of these models, each of which captures a plausible intuitive theory of how norms influence both desires and actions. We then describe an experiment to test which model provides the best explanation of lay people's judgments in two social scenarios.

Computational Models

In order to study how people make inferences about social norms given observations of behavior, we choose to model situations where norm-driven actions are likely to be salient. In such situations, agents can take the role of **actors**, who are in the position to comply with a potentially applicable norm, or they can take the role of **judges**, who are in the position to enforce that norm after observing non-compliance. For simplicity, we restrict ourselves to the smallest multi-agent setting, with only one actor and one judge. The actor takes an action A_1, which corresponds to compliance or non-compliance with a potential norm. We also assume that the actor has some latent (binary) desire D_1 over action A_1 and its associated outcome. If the actor decides not to comply with the norm, the judge may take an action A_2, which corresponds to enforcement or non-enforcement of the potential norm. The judge also has a (binary) desire D_2 over the space of outcomes of A_1 (note however that D_2 is conditionally independent of A_1, since the judge's desires exist whether or not A_1 is taken). D_2 influences the enforcement action A_2 because A_2 can rectify the outcome produced by A_1. We denote the norm by N, which either exists ($N = 1$) or does not ($N = 0$) in the modelled situation.

[1]Here we are not interested in modelling descriptive norms—statistical regularities—since they can be directly learned through observation, though it is an interesting but separate research question as to how people might infer injunctive norms from descriptive ones.

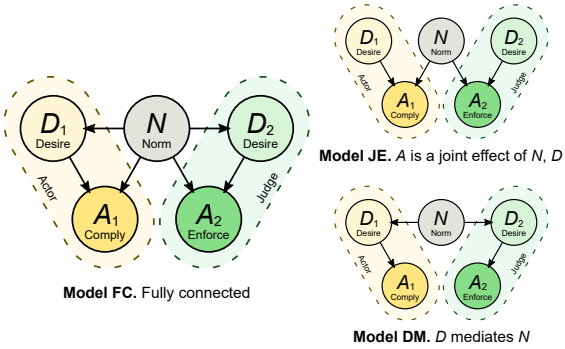

Figure 1: Possible intuitive causal models of how social norms influence behavior. We consider two agents, an Actor (on the left of each model, with nodes in yellow) and a Judge (on the right, with nodes in green). In Model FC, norms influence desires, and both norms and desires jointly influence actions. In Model JE, desires are independent of norms, while in Model DM, desires are the sole mediators of norms upon behavior.

We consider three plausible models of laypeople's intuitive theories of norm-driven behavior (Fig. 1). In the **Fully Connected (FC)** model, we posit that social norms influence the desires of each agent, reflecting the idea that norms can be (partly) internalized, such that norm compliance becomes part of one's desire. We also assume that norms and desires jointly affect an agent's actions. This corresponds to the notion that whether or not a norm is internalized, it continues to directly influence actions, whether by imposing an expected social cost to non-compliance, or simply by having a normative force that is separate of individual desire.

In our second candidate model, the **Joint Effect (JE)** model, desires and norms still jointly influence actions, but agent desires are independent of norms. That is, lay people's notions of what agents 'want' to do are separate from what they 'should' do, mapping roughly to the Kantian distinction between desire and duty. Lastly, the **Desire Mediation (DM)** model assumes that norms do not influence actions directly, but only when mediated by desires. This assumption corresponds to the Humean notion that desires are the sole motives for action—that 'shoulds' cannot influence action unless they also become 'wants'—a notion which might plausibly feature in lay intuitions about norms. In addition to these three 'complete' models, we also tested two lesioned models: a desire-only model (**D-only**) and a norm-only model (**N-only**).

It is worth emphasizing that in proposing these models, we are *not* attempting to give a rigorous philosophical account of the relationship between norms, desires, and actions, nor are we attempting to argue that social norms cannot be explained in terms of desires, or for that matter, other cognitive variables such as shared beliefs or expectations. Rather, our intention is to propose models of how people *intuitively* understand norms and norm-driven behavior.

Experiment

We conducted an experiment through Amazon's Mechanical Turk (AMT) to elicit lay people's likelihood judgments about norms, desires and actions in two different social scenarios: one involving an obligative norm—the norm that people should return their trays after eating—and another involving a prohibitive norm—the norm that people should not litter. Given widespread intuitive acceptance of the act-omission distinction (Kahneman & Sunstein, 2005), we expected that people might also respond differently to obligations and prohibitions. We also chose common, but not universal, social norms, so that we could better observe how people adjusted their certainty about the existence of each norm.

Methods

We provide a sample of our experiment, our data, and analysis code at `https://github.com/ztangent/norms-cogsci19`.

Scenario Structure. Both scenarios were identical in structure—participants were introduced to an actor in a position to comply with a potentially applicable norm, and asked to make various likelihood judgments. They were then shown the actor not complying with the potential norm, introduced to a judge who (unknown to the actor) had observed the actor's action, and made another round of judgments.

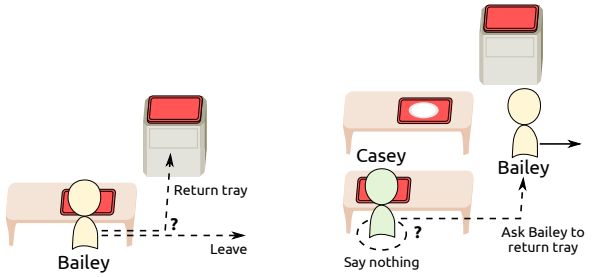
Experimental Conditions. To measure how well our proposed models predict lay people's inferences, as well as determine which model best captures intuitions about norms, we divided each each scenario into five conditions, each querying for different sets of likelihood judgments:

A. Norm and desire priors, and desires given norms:
   $P(N)$, $P(D_1)$, $P(D_2)$, $P(D_1|N)$, $P(D_2|N)$.
B. Actions conditioned on desires only: $P(A_1|D_1)$, $P(A_2|D_2)$.
C. Actions conditioned on norms only: $P(A_1|N)$, $P(A_2|N)$.
D. Actions conditioned on both: $P(A_1|D_1,N)$, $P(A_2|D_2,N)$.
E. Norm and desire posteriors:
   $P(D_1|A_1)$, $P(D_2|A_1,A_2)$, $P(N|A_1)$, $P(N|A_1,A_2)$

Data from conditions A–D were used both to calibrate the models and to investigate people's intuitions about the relationship between norms, desires and actions, e.g., by comparing $P(D_1|N)$ (condition B) to $P(D_1)$ (condition A) to see if people judge desires to be dependent upon norms. After calibrating the models, data from condition E was compared against the models' posterior inferences to see if they predicted participants' inferences about norms and desires.

Participants. We recruited 200 US participants (mean age 35.6, SD 11.2; 104 male, 95 female, 1 unreported) via AMT, restricting to those with a HIT approval rate of 99% and above. All participants went through both scenarios in random order, and each participant was randomly assigned to a different condition within each scenario (i.e. assigned conditions for Scenario 1 and 2 were independent). For Scenario 1, conditions 1A through 1E, sample sizes were n =51, 24, 25, 51 and 49 respectively. For Scenario 2, conditions 2A through 2E, sample sizes were n =49, 25, 25, 50 and 51 respectively. Assuming a large effect size (Cohen's $f = 0.5$), these sample sizes give $> 93\%$ power for one-way ANOVA between sub-conditions at the 5% significance level (e.g. comparing $P(A_1|N=1)$ and $P(A_1|N=0)$ in condition C).

Scenario 1: An Obligative Norm



(a) Actor's choices (b) Judge's choices

Figure 2: Returning one's tray as an obligative social norm.

Details. Participants were presented with a vignette with two phases, with text descriptions accompanied by illustrations. In the first phase (Figure 2(a)), Bailey, the actor, has finished a meal served on a tray in a restaurant. The restaurant has a tray return station, and Bailey can choose to either return ($A_1 = 1$) or leave ($A_1 = 0$) the tray. Since the norm at play was obligative ('People should return their trays after eating.'), $A_1 = 1$ corresponds to compliance with the norm (if it exists, i.e, if $N = 1$). In the second phase, participants are told that Bailey decides to leave the tray, and are introduced to Casey, who, unknown to Bailey, has watched this occur (Figure 2(b)). Casey now has the option of either asking Bailey to return the tray ($A_2 = 1$) or saying nothing ($A_2 = 0$), where $A_2 = 1$ corresponds to enforcement of the potential norm.

Questions were presented after *each* phase was introduced, asking participants to make judgments depending on the condition they were assigned. When queried for priors (condition A), participants were directly asked how likely they thought a certain state of affairs was true (e.g. "How likely do you think Casey *wants* the tray to be returned?" for $P(D_2)$, "How likely do you think the following norm exists?" for $P(N)$). When queried for conditional likelihoods, including the posteriors, participants were first asked to suppose a certain state of affairs (e.g. "If you saw Casey ask Bailey to return the tray," for $P(\cdot|A_1=0,A_2=1)$ or "Suppose that Bailey does not want to return the tray." for $P(\cdot|D_1=0)$), and then asked to give likelihood judgments given those suppositions. To make these counterfactuals more concrete in the case of the posterior inferences (condition E), we also provided corresponding illustrations of the counterfactual actions.

Results. To determine if participants intuitively judged desires to be independent of norms, we first analyzed the data from condition A to see if $P(D_i)$, $P(D_i|N=1)$ and $P(D_i|N=0)$ ($i \in \{1,2\}$) exhibited significant differences. As can be

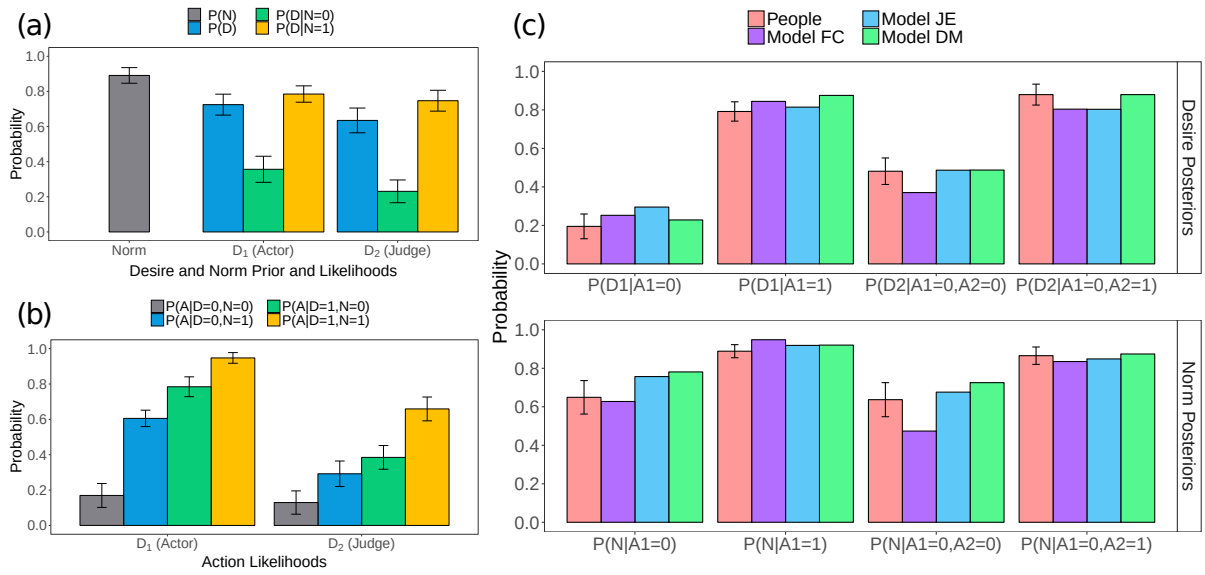


Figure 3: Scenario 1 Results. (a) Empirical norm and desire judgments from condition 1A. (b) Empirical action likelihoods, from condition 1D. (c) Comparing empirical posteriors from condition 1E with posterior judgments from our proposed models.

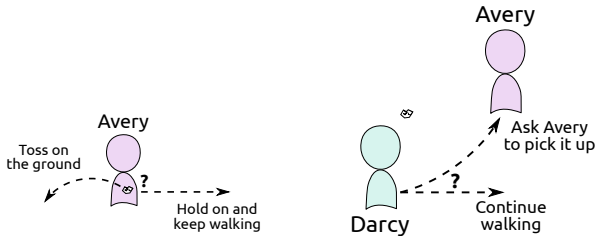
seen in 3(a), this was indeed the case, with one-way ANOVA giving $F(2,150) = 55.13$, $p < 0.001$, for the actor's conditional and prior desires (D_1), and $F(2,150) = 66.95$, $p < 0.001$, for the judge's (D_2) conditional and prior desires. This provides evidence against Model JE, which assumes that desires are independent of norms.

Next, to determine if desires and norms jointly influence behavior, we analyzed the conditional action likelihoods from condition D. As Figure 3(b) shows, given a fixed value of desire, there were significant differences between action likelihoods when the norm was either absent or present (all ts > 5.77, all ps < 0.001, df$= 50$, paired test). That is, regardless of whether the agent *wanted* to act, the presence of the tray-return norm ($N = 1$) led people to judge both norm compliance ($A_1 = 1$) and norm enforcement ($A_2 = 1$) as more likely. This provides evidence against Model DM, which assumes norms have no direct effect on actions. (For brevity, we omit comparisons between $P(A_i|D_i,N)$, $P(A_i|D_i)$ and $P(A_i|N)$, $i \in \{1,2\}$ using the data from conditions B and C, but these display significant differences as well.)

Finally, we computed the desire and norm posteriors under the FC, JE and DM models, then compared them against participants' posterior judgements, as shown in Figure 3(c). All three models displayed high correlation with the empirical data (FC: $r = 0.944$, JE: $r = 0.974$, DM: $r = 0.981$). The correlations of the lesioned models were worse by comparison (D-only: $r = 0.944$, N-only: $r = 0.384$). Both norm and desire posteriors increased when compliance ($A_1 = 1$) or enforcement ($A_2 = 1$) were observed, and decreased otherwise. The three models also captured people's ability to integrate information across multiple agents to infer the presence of norms—when non-compliance by the actor ($A_1 = 0$) is observed, the likelihood of the norm's existence decreases ($P(N) > P(N|A_1 = 0)$), but when enforcement by the judge (A_2) is subsequently observed, the likelihood of the norm increases again ($P(N|A_1 = 0) < P(N|A_1 = 0, A_2 = 1)$).

Despite the desire and action likelihoods providing strong evidence against the JE and DM models, these models were surprisingly more correlated with participants' posterior judgements than the FC model. The results for Scenario 1 are thus hard to interpret conclusively. Plausibly, this was due the high degree of inter-subject variance in likelihood ratings, suggesting that people's intuitive models of social normativity have substantial heterogeneity.

Scenario 2: A Prohibitive Norm



(a) Actor's choices (b) Judge's choices

Figure 4: Not littering as a prohibitive social norm.

Details. As in Scenario 1, participants were presented with a two-phase vignette. In the first phase (Figure 4(a)), Avery, the actor, is walking along a city street while holding on to some crumpled paper. Avery can choose to either toss the paper ($A_1 = 1$) or continue holding on ($A_1 = 0$). Since the norm at play was prohibitive ('People should not discard their belongings on the ground.'), $A_1 = 1$ corresponds to violation of

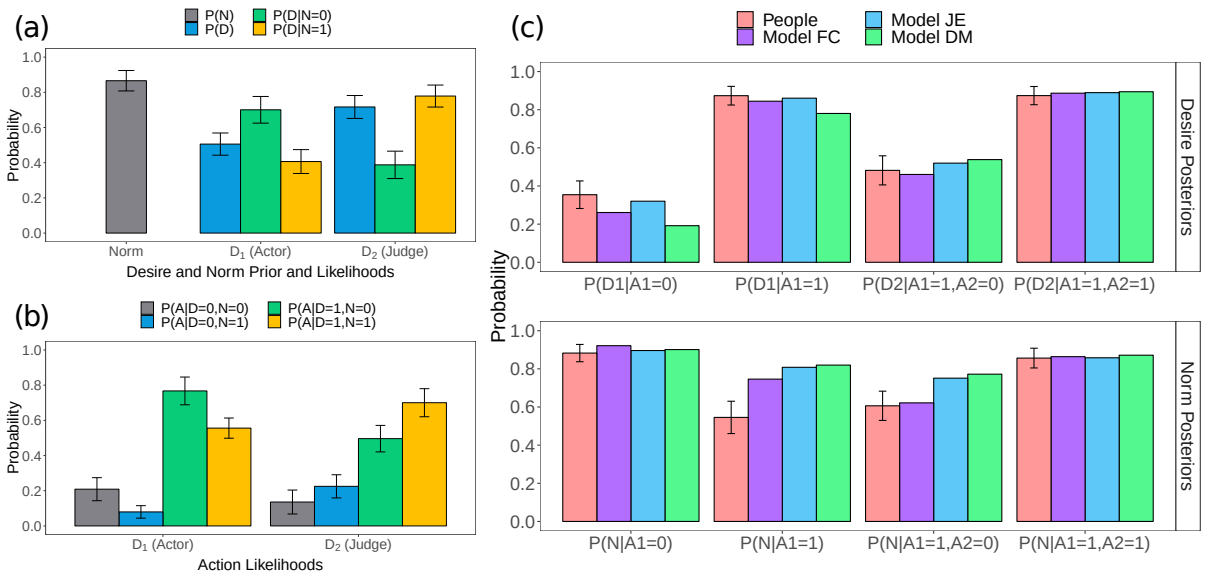


Figure 5: Scenario 2 Results. Figure is similar to Fig. 3 except for the fact that Scenario 2 involved a prohibitive norm, where $A_1 = 1$ (littering) contravenes the norm. This explains the different patterns for the likelihood of Actor variables (D_1, A_1).

the norm, unlike in Scenario 1. In the second phase, participants are told that Avery decides to toss the crumpled paper on the ground, and are introduced to Darcy, who, unknown to Avery, has watched this occur (Figure 4(b)). Darcy now has the option of either asking Avery to pick up the crumpled paper ($A_2 = 1$) or saying nothing ($A_2 = 0$), where again $A_2 = 1$ corresponds to enforcement of the potential norm. After each phase was introduced, participants were asked to make likelihood judgments depending on the condition they were assigned, using the same question formats as in Scenario 1.

Results. First, we analyzed the data from condition A to see if participants judged desires to be norm-dependent. As 5(a) shows, this was once more the case, with one-way ANOVA giving $F(2,144) = 18.02$, $p < 0.001$, for the actor's conditional and prior desires (D_1), and $F(2,144) = 35.86$, $p < 0.001$, for the judge's (D_2) conditional and prior desires. We then analyzed the conditional action likelihoods from condition D, and found similarly that there were significant differences when the norm was either absent or present (all ts > 3.10, all ps < 0.005, df$=49$, paired test). To be clear, the influence of the norm here was in the *opposite* direction—$N = 1$ led to littering $(A_1 = 1)$ being less likely.

Lastly, we computed the desire and norm posteriors under the various models and compared against the empirical data, as shown in Figure 5(c). Compared to Scenario 1, more pronounced differences could be observed between models. In particular, Model DM significantly over-estimates the norm's likelihood when a norm-violating or non-enforcing action is taken (see Figure 5(c) $P(N|A_1 = 1)$, $P(N|A_1 = 1, A_2 = 0)$), because it attributes the cause of the action primarily to the desire not to comply with or enforce the norm. In contrast, Model FC better predicts that the norm's likelihood should decrease when norm violation is observed. This is because there are multiple causal pathways that lead from the norm to the actions in Model FC—norm-violating actions directly imply that the norm is unlikely to exist, but they also imply that the desire for the norm-violating action exists, which indirectly implies the non-existence of the norm. Model JE over-estimates the norm's likelihood slightly less than Model DM, but still more than Model FC, because it has only one causal pathway from the norm to the action.

Nonetheless, all three models still correlated highly with the data (FC: $r = 0.934$, JE: $r = 0.887$, DM: $r = 0.828$), and the lesioned models again performed worse (D-only: $r = 0.772$, N-only: $r = 0.461$). Both norm and desire likelihoods increased when compliance $(A_1 = 0)$ or enforcement $(A_2 = 1)$ were observed, and decreased otherwise. We similarly observed that people integrated information from multiple agents: the likelihood of the norm decreases after observing norm violation $(P(N|A_1 = 1) < P(N))$, but increases again after subsequently observing enforcement $(P(N|A_1 = 1, A_2 = 1) > P(N|A_1 = 1))$.

Unlike in Scenario 1, Model FC displayed the highest degree of correlation out of our three proposed models. This, combined with the analysis showing that both actions and desires are directly norm-dependent, provide strong evidence for model FC over the other two models. One reason this might have been the case for Scenario 2 is that a prohibitive norm tends to *conflict* with the direction of desire—people are more likely to act how they believe they *should*, whatever they happen to *want* for themselves. This would disfavor Model DM (hence its over-estimation of the norm's likelihood) but favor Model FC, because it betters captures the restraining effect of norms on both desires and actions.

General Discussion

We experimentally investigated how laypeople infer norms from behavior, and showed that a Bayesian model provides excellent predictions of people's posterior inferences of both obligative and prohibitive norms. We tested several plausible theories, and found strong evidence that people understand norms to directly influence both desires and actions. This suggested that the JE and DM models should be ruled out, leaving the FC model. While our analysis of the model's posterior inferences in Scenario 1 did not unambiguously support this conclusion, the corresponding analysis for Scenario 2 did so, with the FC model showing the highest correlation when averaged across both scenarios (FC: $r = 0.939$, JE: $r = 0.931$, DM: $r = 0.905$). Furthermore, comparison with lesioned models showed that accurate inferences cannot be made by omitting either desires on norms.

Our results lend support to our hypothesis that people understand social norms as behavioral constraints shared *across* agents, in contrast to preferences that are idiosyncratic to individual agents. In this way, people are able to observe different actions made by individuals in different roles, integrating that information and allowing them to rapidly make inferences about the presence of social norms in a given context. This ability is highly useful, for it allows us navigate unfamiliar social environments without deducing the preferences of every stranger about how one should act.

Of course, not all environments are unfamiliar—people spend their whole lives with a familiar set of norms. Thus, one might expect a person to bring strong expectations to bear when making inferences about norms in a new, but familiar, situation. Indeed, this was the case for many participants in our experiment—while we constructed scenarios with common but not universal norms, participants were often *certain* that the norm in question was present, even before observing any actions. These priors made it harder for our experiment to detect whether people deemed a norm *more* likely to exist after observing norm compliance, but made it easier to detect when people deemed a norm less likely to exist after observing a norm violation. Future experiments should introduce participants to a more alien environment where they have no sense of what the norms might be, and see if they can infer the presence of a norm through a few observations.

Participants not only came in with varied priors, but also varied likelihood judgements, with some participants giving more weight to the influence of norms than others. This heterogeneity may help explain why our results for Scenario 1 were not conclusive—participants' internal models might have diverse parameters, and some might even have different model structures altogether. As such, while the results clearly showed that the models predicted average judgments with high correlation, the ability to distinguish the exact model type may have been lost. Still, it is interesting that even with such diversity, people are still able to rapidly learn and converge upon the same set of norms. How exactly this convergence occurs is a topic worth exploring further.

In conclusion, we have demonstrated a principled, computational framework for how people infer the shared drivers of behavior that we call social norms. In addition, our results give us insight into people's intuitive theories of norms as influencing *both* our desires and our actions. This builds upon previously studied models that infer the beliefs, desires, and intentions of single agents, extending their inferential capacity to large groups of agents constrained by shared context. By laying the groundwork for how we make these inferences, our work elucidates one way in which we make sense of the full richness of social life—and how we *ought* to live it.

Abstract

Exposure to Inconsistent message has been demonstrated as a useful method to alleviate belief in false rumor. However, the data from previous research included unexplained variation in response to inconsistent message. Existing research also included the possibility that participants skipped out on reading and therefore they were not exposed to a message. We used an eye tracker to eliminate the possibility. Eye tracking data revealed that participants not only did not skip but they paid more visual attention to inconsistent messages comparing with consistent messages. Despite the overall effectiveness of inconsistent message, some responses showed continued belief in rumors even after the exposure. Eye-tracking analyses demonstrated that when participants had positive pre-belief for a rumor, more visual attention to inconsistent message predicted strengthened the belief. We discuss when exposure to inconsistent message does not work well as a way for harnessing belief in false rumor.

Keywords: rumor; belief change; eye tracking; social media

Introduction

The recent exponential growth of social media, such as Twitter and Facebook, has been affecting how rumors spread. Once a rumor is posted on social media, it can be shared widely in a very short time. In this sense, social media can be a salient rumor mill. Additionally, while prior eras included the spread of rumors by word of mouth, online rumors never go away completely online. Accumulation of rumors can increase the risk of misunderstanding, miscommunication, and potential social problems.

Several researchers have provided definitions for rumors. One popular definition is, "public communications that are infused with private hypotheses about how the world works" (Rosnow, 1991). Although other definitions emphasize aspects that include circulation in contexts of ambiguity, danger, or potential threat (e.g., DiFonzo & Bordia, 2007), we should not ignore the risk of spreading rumors within normal everyday interactions. As misinformation, propaganda, and "fake news" are diffused every day under the semblance of rumors, the risk for rumor belief should be acknowledged more broadly.

How we handle rumors in the digital age? Past studies have demonstrated that exposure to inconsistent messages, including denial, rebuttal, and criticism, was effective to mitigate belief in various types of rumors, such as an alleged misdemeanor (Koller, 1993), organizational rumors (DiFonzo & Bordia, 2000), disaster related rumors (Tanaka, Sakamoto, & Matsuka, 2013), ill effects of smoking (Iyer & Debevec, 1991), and a computer virus (Bordia, DiFonzo, Haines, & Chaseling, 2005). Bordia et al. (2000) revealed that exposure to a denial message mitigated belief in a rumor. In reality, recent studies have reported that while many people spread rumors through social media, others try to stop the spread of false rumors by posting inconsistent messages(Mendoza & Poblete, 2010; Starbird et al., 2016).

Despite the overall effectiveness of inconsistent message exposure, previous studies have shown the variation in the effect. For example, an experiment reported by Bordia et al. (2005) showed that an average belief in a rumor was reduced from 5.10 to 3.60 (1 = not at all believable to 7 = totally believable) after inconsistent message exposure. Although this is a significant belief reduction the result indicates that participants evaluate the rumor as moderately believable even after exposure to an inconsistent message. The same patterns emerged in another study by Tanaka et al. (2013) where some participants did not change their belief in rumor after they were exposed to an inconsistent message and even decided to spread the rumor. To consider the practical application of rumor control to real life, it is necessary to understand the responses of continual believing rumor despite inconsistent messages.

The present study examined the mixed effectiveness of inconsistent message exposure on belief change in rumors. We measured eye movements of participants when they were exposed to an inconsistent message with a rumor. The reason for this is to check whether participants are genuinely exposed to an inconsistent message. Even if a participant was asked to read an inconsistent message on a traditional

questionnaire or a computer screen, the possibility that he or she skipped reading the message still remains. Recent eye-tracking research demonstrated that people tend to skip reading posts on social media when they look uninteresting (Bode, Vraga, & Troller-Renfree, 2017). Thus, to examine the effect of inconsistent message exposure, it is important to eliminate the possibility of participants skipping out on reading and not actually being exposed to the message.

We focus on fixation duration and fixation frequency as eye movements. Fixation is defined as the periods when an eye is close to immobile and distinguished from rapid movement termed saccades (Rayner, Pollatsek, Ashby, & Clifton, 2012, p.91). A reader extracts printed visual information during fixation. Fixation duration tends to be longer when text becomes conceptually difficult (Rayner, 1998) and unpredictable (Ehrlich & Rayner, 1981; Rayner, Slattery, Drieghe, & Liversedge, 2011).

Based on earlier research, we hypothesize that exposure to an inconsistent message with a targeted rumor will cause belief change in the rumor by reducing pre-belief when compared with the control response to a targeted filler after consistent message exposure (Hypothesis 1). If an effect was found, eye movement record can help determine whether it was caused by exposure to, or skipping an inconsistent message. We expect that eye movement record will show that participants were exposed to an inconsistent message because belief change would not occur if they are skipping the inconsistent message (Hypothesis 2). As for eye movements, we expect that fixation duration will be longer when participants are reading an inconsistent message because the inconsistent message is not predictable based on prior experience of reading a rumor (Hypothesis 3). Predictability effect was observed not only in alphabetic scripts such as English but also in a logographic script (Rayner, Juhasz, & Yan, 2005), therefore, it is reasonable to apply this hypothesis to Japanese which uses logographic characters. This kind of research has implications for understanding what makes people stop believing or keep believing rumors.

Method

Participants

The participants were 46 college undergraduate and graduate students in Japan (32 males, 14 females, M_{age} = 20.8, SD_{age} = 1.89). They received 1,000 Japanese yen (about 9.00 USD) for their participation in an approximately 50-minute session. They all reported having Japanese as their native language and 72% reported attending a psychology class.

Materials

Stimuli For rumor tweets, 12 false rumors related to popular psychology topics were selected from the Japanese translation of Lilienfeld, Lynn, Ruscio, & Beyerstein (2010), including topics such as "*Subliminal messages can persuade people to purchase products*" and "*People use only 10 % of their brain power*" (see Appendix for stimulus materials). All rumors were written in Japanese horizontally and the number of characters was controlled to fall within the range of 46 to 48. Each rumor was transformed into a Twitter PNG image tweet. The user name associated with each tweet was randomly generated.

For each rumor, an inconsistent message with the rumor was developed based on the criticisms against the rumors (Lilienfeld et al., 2010). An inconsistent message was operationally defined as a message including inconsistent or contradictory information against a target rumor. For example, an inconsistent message for the rumor regarding "*subliminal messages*" mentioned above was "*An analysis of research from a Canadian television station revealed that the subliminal message 'please telephone us right away' was aired 352 times. However, there was no increase in the incoming telephone calls. Likewise, people cannot be made to buy things in this manner"*. For each of the 12 false rumors, an inconsistent tweet was developed. The number of characters was controlled to fall within the range of 70 to 75.

In order to prevent the participants learning the characteristics of the inconsistent message stimuli and acting strategically, filler stimuli were added. Twelve tweets were created from psychological knowledge based on textbooks and made into filler stimuli. For each filler, a consistent message was developed. There were no significant differences in the number of characters between rumor and filler tweets, and inconsistent and consistent messages.

Figure 1. A slide image on the eye-tracking computer. It presents a set of a rumor tweet (target: upper left) and its inconsistent message (bottom-left).

Apparatus

Eye movements were recorded only in the following inconsistent message exposure phase by a Tobii Pro Nano, which samples eye position at 60 Hz. All images were presented on a 17.3-inch display with a screen resolution of 1920 × 1080 pixels. Participants were seated ~60cm from the display. For each participant, the system was calibrated before the experiment using a set of 5 calibration points covering the whole screen area. Informed written consents

from participants were obtained. A 23.8-inch display was used except in the eye-tracking phase.

Procedure

Each participant was tested individually. Participants were told that the experiment concerned understanding students' knowledge about psychology, and it was not revealed that the research was interested in false rumors and the inconsistent message exposure until the debriefing period at the end of the experiment. The experiment was administered in the following order.

1. Pre-belief measurement The rumor tweets and the filler tweets were presented one at a time on a computer screen. Presentation of the stimuli was randomized for each participant. Participants were not informed that some stimuli were false. They were asked to answer the following three questions about each tweet: (1) Familiarity – How much do you know about this information? (*Well, Slightly, Not at all*); (2) Accuracy – How accurate do you think this information is? (1 *Not at all*, 5 *Highly accurate*); (3) Importance – How important do you think this information is? (1 *Not at all*, 5 *Highly important*).

2. Inconsistent/consistent message exposure Inconsistent message was a message including inconsistent or contradicting information. For example, the inconsistent message for the "*subliminal messages*" rumor refers to research which showed that the subliminal effect was not observed. On the other hand, consistent messages for fillers mentioned supportive examples and did not include any inconsistent or contradict information (see Appendix). After a five-point calibration for each participant using Tobii Pro Lab software (Tobii Technology), the 12 sets of a rumor tweet and an inconsistent message were presented one at a time mixing with the 12 sets of a filler tweet and a consistent message. The order of presenting the 24 sets was counterbalanced. Figure 1 shows a slide which presents one of the sets. Participants were instructed that each message was referring to the message of the target tweet. They were asked to read each set of tweets silently at their own pace and to judge the message interesting or not interesting. They were required to press 4 on the numeric keypad if the message was not interesting and 6 if the message was interesting.

3. Post-belief measurement The same set of target tweets from the pre-belief session were shown a second time. Participants evaluated accuracy and importance for each tweet.

After completing all tasks, participants were debriefed as to the purpose of the study. It was emphasized that some tweets were false. Participants provided another informed consent.

Data analyses

Eye-movement type and eye coordinates were recorded per millisecond (ms) with Tobii Pro Lab software throughout the message exposure phase. Direct visual attention (fixated) was extracted from the raw eye-tracking data using a minimum fixation duration of 100ms. To identify visual attention per tweet, we calculated fixation duration for target and message regions respectively. For each region, fixation frequency and total fixation duration were calculated. As the number of characters in each tweet was different between target tweets and messages, fixation duration rate was calculated per tweet, for both target tweet and message, by dividing the total fixation duration by the number of characters. We also calculated fixation frequency rate by dividing the total frequency of each tweet by the number of characters.

Results

Table 1 shows the means and standard deviations for pre-belief and post-belief. For pre-belief, there was a significant difference in accuracy perception between rumor and filler tweets. The accuracy perception for rumor tweets was lower than filler tweets, whereas there were no significant differences in importance between rumor and filler tweets.

Table 1. Pre- and post-beliefs for target tweets

Target Tweet	Accuracy		Importance	
	Pre-belief	Post-belief	Pre-belief	Post-belief
Rumor	3.14 (0.47)	2.67 (0.50)	3.52 (0.49)	3.23 (0.57)
Filler	3.53 (0.44)	3.46 (0.46)	3.56 (0.47)	3.57 (0.51)

Note. The numbers in parentheses are standard deviations.

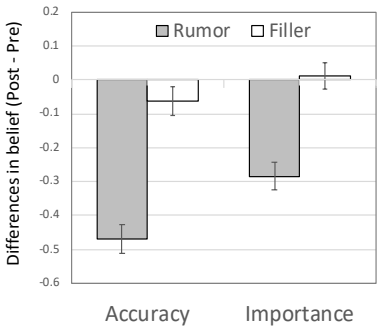

Figure 2. Means and standard errors for belief change after message exposure. Participants were exposed to inconsistent message for rumor and to consistent message for filler.

To test the effects of inconsistent message exposure, belief change after inconsistent message exposure was compared with the responses after the filler consistent message exposure. An analysis of variance (ANOVA) test with message type (inconsistent vs. consistent) was

conducted on belief change in accuracy of target tweets. The main effect of message type was significant, F (1, 45) = 24.28, $p < .001$, $\eta^2_G = .22$. The belief change in accuracy for rumor tweets exposure was bigger (M = -0.47, SD = 0.98) than that for filler tweets (M = -0.06, SD = 0.99) (Figure 2). We also performed a one-way ANOVA with message type on belief change in importance. Result showed a significant effect of message type, F (1, 45) = 12.26, $p < .005$, $\eta^2_G = .11$. The belief change in importance for rumor tweets exposure was bigger (M = -0.29, SD = 1.00) than that for filler tweets (M = 0.01, SD = 0.94) (Figure 2).

To examine eye movement, we performed a one-way ANOVA with message type on fixation duration rate on target tweets and messages, respectively. There were no significant differences in fixation duration rates between rumor and filler target tweets. However, the result of a one-way ANOVA on fixation duration rates on the message region showed that the main effect of message type was significant, F (1, 45) = 38.77, $p < .001$, $\eta^2_G = .04$. The fixation duration per character on inconsistent message (M = 85.76, SD = 64.14) was longer than consistent message (M = 71.30, SD = 50.40)(Figure 3, left figure). The same pattern emerged for fixation frequency rate. There was no significant difference between rumor and filler target tweets, whereas the result of a one-way ANOVA revealed a significant main effect of message type, F (1, 45) = 33.67, $p < .001$, $\eta^2_G = .04$. The fixation frequency rate on inconsistent message (M = 0.34, SD = 0.21) was higher than consistent message (M = 0.29, SD = 0.18) (Figure 3, right figure).

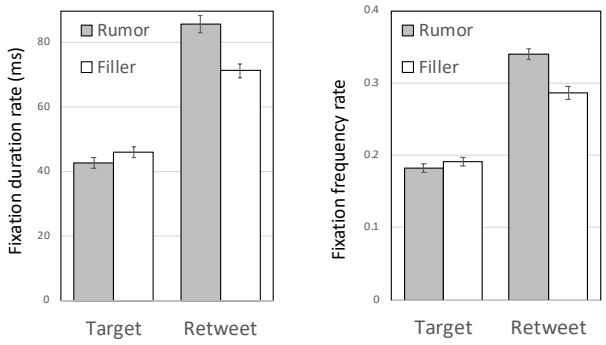

Figure 3. Means and standard errors of fixation duration rate and fixation frequency rate (per character).

To examine the relationship between eye-tracking data and belief, we used 'lme4' package (Bates, Maechler, Bolker, & Walker, 2015) in R (R Core Team, 2012). As fixed effects, we entered tweet type (inconsistent vs. consistent), pre-belief on accuracy and importance into the model. As random effects, subjects and multiple stimuli for each tweet type were added into the model.

We constructed a generalized linear mixed model (GLMM) of fixation duration rate. The inconsistent message affected fixation duration rate ($\chi^2(1) = 31.36$, $p < .001$), increasing it by about 14.5 ms ± 2.56 (standard errors)[95% CI: 9.44, 19.48]. Pre-belief and post-belief in a target tweet were not related to fixation duration rate on the message. As for fixation frequency rate, a GLMM revealed the same pattern. The inconsistent message affected it ($\chi^2(1) = 34.15$, $p < .001$), increasing it by about 0.05 ± 0.01 (standard errors) [95% CI: 0.04, 0.07]. There were no other factors related to fixation frequency rate.

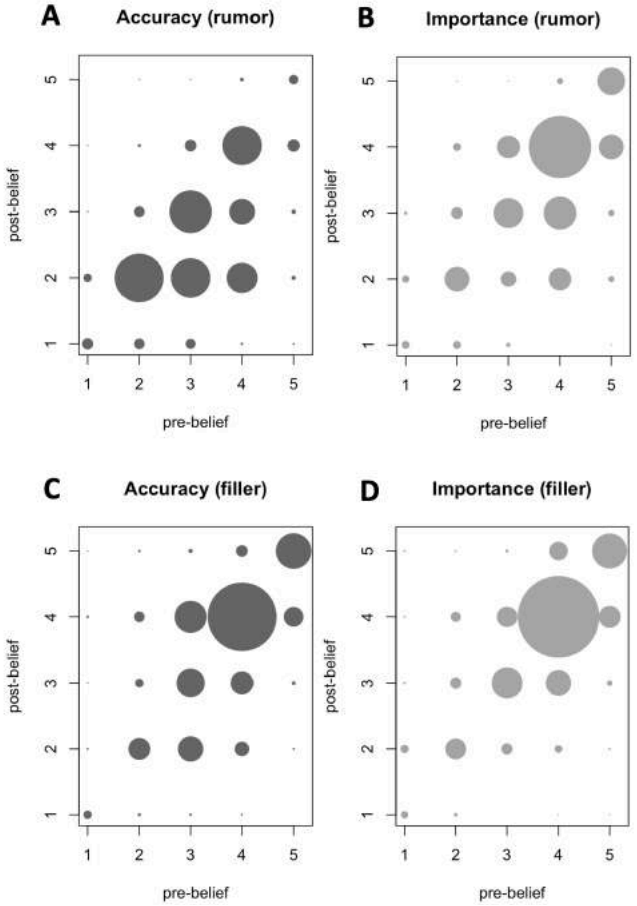

Figure 4. Belief change after exposure to inconsistent message associated with rumor tweets. The circle size represents the number of data points. Belief changes on rumor tweets in accuracy (A) and importance (B) after inconsistent message exposure. Belief changes on filler tweets in accuracy (C) and importance (D).

Figure 4 shows the distributions of the relationship between pre-belief and post-belief in rumors and fillers. Comparing with pre-belief in fillers that tended to be stable after consistent message exposure (Fig.C and D), pre-belief in rumors tended to be weakened after inconsistent message exposure (Figure A and B). However, the distributions of rumor tweets include not a few responses that did not change their belief and kept believing rumors after inconsistent messages.We examined predictor of the

difference in responses after inconsistent message exposure. As our focus here was especially on the belief change in the responses which had positive pre-belief (rated 3, 4, or 5) for rumor tweets, other responses which had negative pre-belief (rated 1 or 2) were excluded from the following analysis. This is an attempt to avoid a floor effect. That is, there is very little or no room to show a decrease in belief after inconsistent message exposure for the responses which had negative belief towards the bottom of the graph. Among all 552 responses associated with rumors (46 participants × 12 rumor tweets), 396 (71.7%) and 439 (79.5%) responses were analyzed in terms of accuracy and importance, respectively.

We constructed a GLMM to predict belief change (pre – post) in accuracy on the rumor with the responses with positive pre-belief. Fixation duration rate on inconsistent message increased belief change of accuracy positively ($\chi^2(1) = 4.91$, $p = .03$), that is, strengthening pre-belief of accuracy by about 0.002± 0.001 (standard errors) [95% CI: 0.0002, 0.003]. Fixation frequency rate on inconsistent tweet also affected belief change in accuracy ($\chi^2(1) = 3.85$, $p = .05$), strengthening pre-belief of accuracy by about 0.47± 0.23 (standard errors) [95% CI: 0.005, 0.92]. A GLMM to predict belief change of importance for rumor tweet revealed no significant relationship between eye movements and belief change.

Discussion

The present study investigated the effects of inconsistent message exposure on belief change in rumor and relationship between the belief change and eye movement.

First, we examined whether inconsistent message exposure changes the belief in rumor target message. Results showed that inconsistent message exposure tends to reduce pre-belief associated with rumors. Both perceived accuracy and importance associated with rumors were significantly reduced after inconsistent message exposure, whereas pre-belief of filler target did not significantly change after consistent message exposure. Thus, Hypothesis 1 was supported. These results support previous findings on the exposure of readers to denial messages being helpful to mitigate their false belief in rumors (Bordia et al., 2005; Bordia, DiFonzo, & Schulz, 2000; Koller, 1993).

Eye tracking data demonstrated that participants paid more visual attention to inconsistent messages associated with rumors than consistent message associated with fillers. Both fixation duration rate and fixation frequency rate associated with inconsistent messages were higher than consistent messages. This result provides support for Hypothesis 2, eliminating the possibility that participants skipped reading an inconsistent message. This result indicates that the inconsistency of the message attracted visual attention. These results provide support for the literature indicating that fixation duration becomes longer when text becomes more unpredictable (Rayner et al., 2011) and when it includes inconsistency (Rayner, Chace, Slattery, & Ashby, 2006). When people encounter inconsistent message, they need to consider the relationship between pre-belief and the inconsistent message and to update the pre-belief if needed. This cognitive procedure could result in longer visual attention. Taken together with a rumor study which demonstrated that people tend to spread false rumors because of novelty (Vosoughi, Roy, Aral, 2018), one explanation is that inconsistent messages were unpredictable and novel, thus, resulting in a relatively decrease in the novelty of rumors. This explanation is corroborated by the result that there were no significant differences in visual attention to the target tweets between rumor and filler. Participants have read the target tweets prior to eye measurement, that is, both types of target tweets were predictable. This prior experience resulted in no significant differences in eye movements between rumor and filler.

Next, we focused on the variation in the effect of inconsistent message exposure. Although the exposure to inconsistent message tends to devalue the accuracy and importance of rumor, the distribution of the relationship between pre- and post-belief in rumor showed that some responses showed a continued belief in rumors even after the exposure to inconsistent messages. Further examination focusing on the belief change of the responses with positive pre-belief in rumor tweets demonstrated that the belief change of accuracy was predicted by eye movement. Longer fixation duration and higher fixation frequency on inconsistent message predicted that the accuracy of rumors would be strengthened. These results can be interpreted in line with the previous findings (Espino, Santamaria, & Garcia-Madruga, 2000; Masson, 1983; Rayner et al., 2006): that the difficulty of text can lead a longer reading duration. Our findings indicate that the effect of inconsistent message exposure became limited for the participants having positive pre-belief in a rumor when they did not fully comprehend the inconsistent message.

There are some limitations in the current study. This study did not measure the level of comprehension of inconsistent messages. It is unclear whether longer fixation was related directly to low comprehension. Additionally, fixation predicted belief change in accuracy but it was not related to belief change in importance. Further research is needed to clarify these relationships.

In conclusion, the current study demonstrated the overall effect of exposure to inconsistent messages to reduce false belief in rumors, supporting previous research on rumor control. Our findings demonstrated the relationship between eye movement and belief change after inconsistent message exposure. The effectiveness of inconsistent message exposure was limited when the inconsistent message was difficult to process, resulting in as slightly strengthened pre-belief.

Appendix

Example of stimulus set (translated from Japanese into English). The numbers in brackets under each rumor or filler are means and standard deviations for pre- and post-belief of accuracy.

Rumor #1 The brain weighs approximately 1.2-1.5 kg, but in actual fact, most of us use only 10% of that. [M_{pre} = 3.41 (0.96), M_{post} = 2.85 (1.19)]

Inconsistent message for Rumor #1 When even a part of the brain is damaged by an accident or illness, it affects physical exercise, perception, language, and thought. These kinds of effects would be strange if 90% of the brain was not being used.

Rumor #2 People can be broadly divided into left-brained and right-brained, where left-brained people are logical and

analytical, while right-brained people are artistic. [M_{pre} = 3.30 (1.05), M_{post} = 3.07 (1.10)]

Inconsistent message for Rumor #2 Language is necessary for both logical and artistic activities, but both sides of the brain are working when language is used. The left side of the brain is superior in producing grammar and vocabulary, and the right side of the brain, responsible for intonation.

Rumor #3 Because one's personality appears in their handwriting, experts can understand a person's character by judging their letters and lines. [M_{pre} = 3.35 (1.06), M_{post} = 2.63 (1.01)]

Inconsistent message for Rumor #3 Handwritten application documents include information like one's work experience and criminal record in addition to just handwriting. When these indirect clues were regulated, handwriting analysts' predictive abilities were at coincidental levels.

Filler #1 Comics are funnier read when holding a pencil between your teeth so as not to touch your lips than when holding a pencil between puckered lips. [M_{pre} = 2.70 (1.11), M_{post} = 3.15 (1.23)]

Consistent message for Filler #1 When you hold a pencil in your teeth without touching your lips, your mouth spreads from side to side and makes an expression like when laughing. The laughing expression influences the way you read or perceive the comics.

Filler #2 When people repeatedly experience that their situation does not improve whether they work hard or resist, they learn the feeling of powerlessness. [M_{pre} = 3.96 (1.07), M_{post} = 3.96 (0.99)]

Consistent message for Filler #2 People must be tormented by feelings of powerlessness in companies where they are scolded "not to do whatever they feel like" if they independently think and take action, but scolded "not to be passive and to think for themselves" if they wait for instructions.

Filler #3 As in the case of things studied at home being easier to remember at home than in the classroom, circumstances influence memory. [M_{pre} = 4.07 (0.93), M_{post} = 3.80 (1.07)]

Consistent message for Filler #3 I have heard the same kind of thing about feelings — it is apparently easier to remember sad events when feeling sad and easier to remember happy events when feeling happy.

Predicting the Appreciation of Multimodal Advertisements

Abstract

Creativity is an essential factor in successful advertising where catchy and memorable media is produced to persuade the audience. The creative elements in the visual design and in the slogan of an advertisement elevate the overall appeal providing a perceptually grounded attractive message. In this study, we propose the exploitation of creativity cues in textual and visual information for the appreciation prediction of multimodal advertising prints. Moreover, as a novel dimension space of multimodality, we propose using the human sense (i.e., sight, hearing, taste, and smell) information embedded in the language. Our findings show that sensorial information is an invaluable indication of whether the advertisement is appreciated or not. Furthermore, combining linguistic and visual models significantly improves the unimodal appreciation detection performances.

Keywords: advertising creativity; human senses; multimodal creativity

Introduction

Creativity in advertising is an entangled, multi-dimensional phenomenon that reflects the complex structure of human creativity. A catchy and memorable advertisement is coherent and captivating. It is carefully designed with a diverse range of approaches including the ways of visualizing concepts, the use of rhetorical devices, such as exaggeration, paradox, metaphor and analogy, and taking advantage of shock tactics and humour (Pricken, 2008). In case of the advertising prints, visual and textual contents are designed to have a complementary and coordinated meaning. Advertising makes use of sensory and linguistic sensorial information heavily in order to reach the customers and persuade them. Elder and Krishna (2009) propose that multi-sensory ads induce higher taste perceptions than ads focusing on taste alone. They also state that using multiple senses in slogan increases the positive thought about the advertised food product. As a way of improving advertising communication, Percy (1982) suggests the use of concrete and high imageary words and concepts to stimulate better recall, better comprehension of the advertised message leading to an easier and more accurate understanding of the ad. Another creativity infusion strategy in ad production is using sensory words especially generating linguistic synaesthesia as an imagination boosting tool (Pricken, 2008). The slogans '*The taste of a paradise*' (Bounty bar commercial), where the sense of *sight* is combined with *taste*, and '*Hear the big picture*'(CBC Radio One commercial), where *sight* and *hearing* are merged, can be considered as the examples of linguistic synaesthesia.

As a topic being on the rise in computational linguistics, multimodality is mostly exploited by adding other modalities on top of the linguistic models to perceptually ground the current tasks. For instance, semantic representations benefit from the reinforcement of linguistic modality with visual (Bruni, Tran, & Baroni, 2014) and auditory (Kiela & Clark, 2015) modalities. In the same manner, we propose devising visual modality in collaboration with linguistic modality in the appreciation detection task. To our knowledge, this is the first study aiming to identify multimodal appreciation in a computational manner. Moreover, the multimodality of the dataset stands out amongst the others since the linguistic channel of an ad is complementary to the visual channel instead of being a scene description or an image label. This study focuses on the appreciation of the advertising print by the advertising professionals and communities instead of the appreciation by the audience/customer of the advertised product.

In this paper, we investigate the appreciation level of multimodal advertising prints focusing on the creativity cues in the slogan and in the corresponding image. We use a set of fundamentally creative artworks; an advertising dataset which is composed of 4265 images and corresponding slogans. The objective of this paper is twofold: i) to capture the potency of sensorial dimension of semantics as a creativity cue in the language along with various creative properties both in visual and linguistic modalities, ii) to develop a multimodal appreciation detection model. We utilize a random forest model trained on a dense feature set extracted from the slogans, ad categories and product types for the linguistic modality. For the visual modality, we employ a fine-tuned convolutional neural network model and a random forest model trained on the observable features of the images to determine whether the appreciated images display common visual characteristics and whether these characteristics have a distinctive effect on the overall appreciation of a multimodal ad.

Related Work

Considering that the essential focus of this study is computational creativity and multimodality, we summarize the most relevant studies conducted on these topics. Elgammal and Saleh (2015) quantify the creativity in paintings within the context of historical creativity where creative paintings adequately differ from the antecedent paintings and influence the subsequent. They present a computational framework that is

based on a creativity implication network.

Regarding the linguistic creativity, Özbal, Pighin, and Strapparava (2013) present a creative sentence generation framework, BRAINSUP, on which several semantic aspects of the output sentence can be calibrated. The syntactic information and a huge solution space are utilized to produce catchy, memorable and successful sentences. Kuznetsova, Chen, and Choi (2013) focus on identifying creativity in lexical compositions. They consider two computational strategies, first investigating the information theoretic measures and the connotation of words to find the correlates of perceived creativity and then employing supervised learning with distributional semantic vectors. Alnajjar, Kundi, Toivonen, et al. (2018) propose a methodology to automatically create slogans for a target concept and its adjectival property by first generating metaphors, based on a metaphor interpretation model. They produce a semantic space with the generated metaphors and use the semantic space to fill the slogan skeletons extracted from the existing slogans. They evaluate the slogans through crowd-sourcing with respect to the relatedness of the slogan to the concept and property, the correctness of the language, the metaphoricity, the catchiness, attractiveness and memorability, and the overall appropriation of the expression as a slogan.

Concerning the multimodality, Bruni, Boleda, Baroni, and Tran (2012) analyze the affect of different types of visual features such as SIFT and LAB on semantic relatedness task, and present a comparison of unimodal and multimodal models. Sartori et al. (2015) experiment on a complementary multimodal dataset similar to ours. They explore the influence of the metadata (i.e., titles, description and artists statement) of an abstract painting for the computational sentiment detection task. For the combination of modalities, they propose a novel joint flexible Schatten p-norm model exploiting the common patterns shared across visual and textual information. Shutova, Kiela, and Maillard (2016) exploit visual modality to improve the metaphor detection performance while Zadeh, Chen, Poria, Cambria, and Morency (2017) apply multimodal input to sentiment analysis.

Creativity in Advertising Prints

The creativity elements and dimensions in advertising have been investigated thoroughly. Ang and Low (2000) explore the influence of dimensions of creativity such as novelty (expectancy), meaningfulness (relevancy), and emotion (valence of feelings) to the effectiveness of the advertisement. While novelty could be identified as the unexpectedness and out-of-box degree of an advertisement, meaningfulness is the relevancy of the advertisement to the message aimed to be conveyed. The third dimension, emotional content, focuses on the feelings awakened in the audience. These three dimensions should manifest themselves in a creative advertising media. Smith, MacKenzie, Yang, Buchholz, and Darley (2007), on the other hand, elaborate on the divergence, which is the encapsulation of novel, different, or unusual elements, in ads proposing that the most significant characteristic of creative ads is their divergence. In addition to the above-mentioned general dimensions of advertising creativity, we specifically focus on the sensorial elements and their effect in the objective creativity level. Sensorial language makes use of multiple senses to induce higher taste perceptions (Elder & Krishna, 2009). Multiple senses in the advertising text trigger the positive thinking in the audience. Using highly imageable, in other words highly sensory words, helps to convey the advertised message better and easily. Finally, linguistic synaesthetia is a specific but a very significant way of effective advertising. Furthermore, for visual creativity in advertising, we focus on capturing the divergence factors through a transfer learning mechanism built on top of a deep learning image classification model and artistic values by taking advantage of the observable visual features in the image.

Multimodal Advertising Creativity Dataset

To investigate the appreciation of a multimodal advertising print, we first need to identify a dataset that reflects relatively upper and lower levels of appreciation from human subjects. To this respect, we chose AdsOfTheWorld[1], which has a wide range of coverage of ads considering its characteristic of being a social network that aims to inspire the advertising professionals. The members of the website can share their advertisement artwork, rate and discuss the ads created by others. The published advertising prints are diverse in terms of the level of creativity and ratings such that some ads are award-winning while some are highly disfavored by the community. We collected the ad images, their slogans and meta-data from AdsOfTheWorld[2]. The meta-data of an ad includes the average user rating, which is an integer within the range from 1 to 10, the number of raters, brand name and category.

While constituting the appreciated and unappreciated classes, namely *AP* and *UNAP*, we considered the opposite endings of the rate scale to distinguish the appreciation levels of advertisements as much as possible. We also paid regard to the number of instances that we obtained after filtering in order to have sufficient data for generalization of the *AP* and *UNAP* classes for training a classifier. In order to avoid feeding noise to our models, we empirically determined a minimum number of votes to postulate an average rating as reliable. To this end,we incorporated an ad into our final dataset if it is voted by at least 20 users and if it has an average rating in the range from 1 to 4 for *UNAP* class, or in the range from 7 to 10 for *AP* class. Finally, we eliminated the improper image styles, such as photographs of the billboards or images containing only textual content, from the dataset so that we can guarantee each image and its respective slogan contribute to the targeted message. From the final dataset that contains 4265 images-slogans, we sampled 3265 instances for training, 100 instances for development and 900 instances for testing. While the development and test sets are perfectly balanced for both classes, the training set includes

[1] http://adsoftheworld.com

[2] AdsOfTheWorld has recently changed its interface, no more showing the user ratings.

1470 *UNAP* and 1795 *AP* instances. During the sampling, we paid attention to putting the ads from the same brand into the same set since a slogan for a brand can be paired with various visual designs leading to more than one instance with the same linguistic input. As an additional meta-data, we collected the type of the products since category labels are considerably high-level. For instance, the category *House, Garden* includes a great variety of product types, such as furniture, laundry detergent, or insect killer. Utilizing product type and category labels as reference points allows us to appraise the meaningfulness of a slogan which affects its appreciation level notably. Advertisement 1[3] and Advertisement 2[4] exemplify highly appreciated and highly unappreciated samples in the final dataset, respectively. Although these advertising images seem to be very similar at the first glance with an object in the middle of the frame and in front of a blurred background, the subtle and creative details in the pictures, such as perplexing design of an octopus and sailboat made of pages of a book in Advertising 1 aims to immediately draw the attention of the audience. It holds an average rating of 10, which is the highest appreciation score, and is rated by 23 users. On the other hand, the obvious irrelevance of the main object in the image to the advertised message is a sign of an unappreciated design. Advertisement 2 with the slogan "Can't sleep?" promotes a tea brand that helps with sleeping problems by using a clearly irrelevant main object in the image. It has an average rating of 1 and its unappreciated label is trusted considering that it is rated by 171 users.

Appreciation Prediction Experiments

We design the appreciation prediction experiment of multimodal advertising prints exploiting the creativity dimension cues in the slogan and in the corresponding image, considering the studies done on the dimensions of creativity (Smith et al., 2007; Ang & Low, 2000; Elder & Krishna, 2009). To be more precise, we intend to capture surprisal, novel, meaningful, emotional, unusual and perceptual properties in an advertising slogan. Moreover, we aim to extract artistic components in the visual elements along with the latent visual descriptions and patterns.

Appreciation Detection on Slogans

For the textual model, we hypothesize that the creativity elements in the ad slogan can be mapped to features that are useful to detect the appreciation of an advertisement.

Surprisal (Self Information), as contributing to novelty/expectancy (Ang & Low, 2000) and surprisal(Smith et al., 2007) dimensions of creativity, can be interpreted as the information load of a specific outcome of an event. We calculate the self-information s of a bigram B by $s(B) = -log(p(B))$ exploiting the conditional probability distribution of bigram model trained on the corpus. We obtain the slogan self information as the average s of the bigrams extracted from the sentence.

Domain Relatedness features for the slogan are generated to address the meaningfulness (relevance) dimension (Ang & Low, 2000) of creativity. We expect that a meaningful slogan could contain words that are mapped to the same semantic domain with the product type and product category. On the other hand, a surprising effect could be achieved by injecting words from different domains. The ads dataset contains 24 categories, such as fashion or food. We obtain the domain information for each category as a noun, from WordNet Domains (Magnini, Strapparava, Pezzulo, & Gliozzo, 2002). Similarly, for each lemma-POS in the slogan and for the product type, we collected the related domains. The categories, product types and lemma-POS pairs are associated with the first sense from WordNet. In addition, we exploit a smaller set of domains that is constructed by normalization with respect to the middle level of WordNet hierarchy. The normalization of the domains provides a higher level of abstraction (Ozbal, Strapparava, Tekiroğlu, & Pighin, 2016) and could allow us to capture whether indirect concepts or ideas are employed for expressing the targeted message.

Semantic Similarity features also allow us to capture the meaningfulness dimension (Ang & Low, 2000) of ad creativity. We exploit ad category and the product type to calculate similarity scores with respect to the lemmas in the sentence. We employ 300 dimensional word representation vectors from GloVe (Pennington, Socher, & Manning, 2014) pretrained embeddings trained on Wikipedia 2014 articles and English GigaWord 5 (LDC). The similarity scores between a category/product type and a lemma are obtained by calculating the cosine similarity of their embedding vectors. The average score of a slogan is encoded as a real valued feature for category and another for product type.

Emotion as a creativity dimension focuses on the feelings awakened in the audience(Ang & Low, 2000). We also generated the emotion features as suggested by Özbal et al. (2013).

Sentiment scores are estimated and used as a part of the emotion(Ang & Low, 2000) dimension features. A word with a highly negative or positive sentiment can induce a positive or negative feeling and might alter the effectiveness and appreciation of the sentence. For instance, an environmental awareness slogan would intend to evoke negative sentiment intensifying the feeling of danger in order to be more striking. Thus, we determined the highest values of positive and negative sentiments in the slogan by checking each lemma-POS and encode them as real valued features. We use the sentiment scores of SentiWordNet (Esuli & Sebastiani, 2007).

Unusual Words contribute to the creativity as the unusual elements dimension suggested by Smith et al. (2007), also as a suprisal factor. We generated unusual words features following the study by Özbal et al. (2013).

Variety can be mapped to the flexibility dimension (Smith et al., 2007). We employ variety scores to detect whether creative and appreciated language displays a particularly different word variety than a less-creative and unappreciated lan-

[3] http://www.adsoftheworld.com/media/print/anagram_sea

[4] http://www.adsoftheworld.com/media/print/gryphon_slippers

guage in a similar way with Özbal et al. (2013).

Phonetic scores can be considered as contributing to the artistic value dimension (Elgammal & Saleh, 2015; Smith et al., 2007; Fichner-Rathus, 2011). The exploitation of phonetic features in creative and persuasive sentence analysis has been deeply explored by Özbal et al. (2013). Following them, we explore the alliteration, rhyme and plosive scores generated by using the HLT Phonetic Scorer[5].

Sensorial features are created regarding the sensory dimension of ad creativity (Elder & Krishna, 2009). A slogan aims to trigger a sensory activation in the mind of the audience. For instance, to evoke the sense of taste for an ad in the food category, certain sensorial information, such as the 'warmness' of a soup or the 'sweet aroma' of a cake, should be transmitted through the language. To identify the sensorial load of the sentences, we obtain the word-sense associations from Sensicon (Tekiroğlu, Özbal, & Strapparava, 2014) and Voted Norms, which we generated as a new set of sensory modality association norms through a voting mechanism and labeling the words with the senses that receive the majority of the votes from 4 different sensorial lexicons (Lievers & Winter, 2017; Tekiroğlu et al., 2014; Lynott & Connell, 2009, 2013; Winter, 2016). Sensicon embodies 22,684 and Voted Norms Lexicon includes 3890 English lemmas together with their part-of-speech (POS) information that have been linked to one or more of the five senses. For each sensory modality, we encode the average sensorial associations of the lemma-pos tuples in the slogan. In addition, we explore how the sensorial trait of a product interacts with the sensorial information in the slogan. Therefore, we create a binary feature indicating whether the sensorial modalities with the highest value of the product type and the slogan are identical. We also add the sensorial association relation of the product type and the slogan as a feature set by taking the mean of the slogan associations and product associations with respect to Sensicon and the Voted Norms. As another hypothesis, we expect that sensory experience ratings (Juhasz, Yap, Dicke, Taylor, & Gullick, 2011) can provide a second channel of sensorial information since *SER* resource estimates the sensory experience triggered in human mind instead of the sensorial information that one word carries. We extracted sensory experience ratings by averaging the SER values of the words in the slogan. Based on the category and sensorial modality correlations provided by Tekiroğlu et al. (2014), we propose a set of sensorial features encoding whether the sensorial information in the slogan conforms to the predetermined sensorial structure of its category.

We generated category conformity scores utilizing Voted Norms. For each sense, we set a binary flag indicating if the average association value of the slogan and the sensorial value of the category are both positive. As an example, the feature set of an ad from the food category contains the binary features *conforms_taste=1* and *conforms_hearing=1* if the average sensorial association value of the slogan for these modalities are over 0.0. In addition, we checked the sensorial association peak of the slogan which shows the modality of the highest sensorial association among the lemma-POS tuples in the slogan. We created a binary feature if the peak modality of the slogan and its category are identical. Contrary to our hypothetical assumption, the peak sensorial conformity is observed to be an indicator of a lower level of appreciation (Mann-Whitney $p < 0.001$) in the training set. A possible explanation for this can be that the unexpected sensorial elevation contributes to the appreciation level of a slogan and a less-appreciated slogan is associated to the senses in a more conventional manner. For instance, a less-appreciated toothpaste slogan "For brighter smiles"[6], which is from the *health category*, has the sensorial peak conformity since both the sensorial peak, i.e. *brighter*, and the ad category are associated with the sense of sight. Using an overly well-known effect of the product to describe a stereotypical metonymic replacement, i.e. *brighter smile* for *whiter teeth*, might be one of the causes of a lower level of appreciation of the ad.

Model	# Feat	Training F1	Testing F1
L	62	0.573	0.577
$L \setminus Sensorial$	34	$*$0.542	$\star$0.496
$L \setminus V \cup U \cup SI$	62	0.585	0.558
$L \setminus Similarity$	61	0.573	0.560
$L \setminus Domain$	55	0.580	$*$0.548
$L \setminus Phonetic$	59	0.573	0.561
$L \setminus Emotion \cup Sentiment$	45	0.568	$^{\#}$0.552

Table 1: The linguistic modality ablation study results. $\star$ denotes $p < 0.001$, $*$ denotes $p < 0.01$, $^{\#}$ denotes $p < 0.05$ for the McNemar significance test between L and ablated models.

Linguistic Experiment Results

We investigated the performances of linguistic features with a classification task employing Random Forest algorithm implemented within the *scikit-learn* package. To fine tune the hyper-parameters of the classifier, we perform a grid search over the number of the generated trees (between 100 and 500, with a step size of 100), the maximum depth of the tree (as [5, 10, 20]) using 10-fold cross validation on the training data. To guarantee the same slogan being only in the training folds or only in the validation fold, we divided the training set into 10 folds by taking into consideration the brand information. Since the training data is unbalanced, we selected the best model by using the weighted average of F1 values.

The results of the full model with all the implemented features and the ablation study are summarized in Table 1. The first row labeled 'L' shows the micro F1 scores for the cross validation and test phases using all the linguistic features. Each row in the rest of the table shows the ablation of the indicated feature. We marked statistical significance in terms of the drop of the performance during ablation in comparison to all features L according to McNemar's test.

In the linguistic experiment, we found out that all the fea-

[5] hlt-nlp.fbk.eu/technologies/hlt-phonetic-scorer

[6] http://www.adsoftheworld.com/media/print/colgate_hide_and_seek

tures contribute to the performance of the final linguistic model even if they cause a slight increase in the F1 scores. By utilizing all the features, we obtain an average training cross-validation F1 score of 0.573 and testing F1 score of 0.577. The linguistic model without *Sensorial Information* yields an F1 test score of 0.496 that is significantly lower ($p < 0.001$) than the model *L*. We obtain a significantly lower ($p < 0.01$) F1 score of 0.548 on the absence of *Domain* features in the linguistic feature set. Removing the *Emotion* and *Sentiment* features from the model decreases the score down to 0.552 on the test set causing a statistically significant loss of performance ($p < 0.05$). The contributions of the strongest features point out that the relevance of a slogan to the product category and type, the positive or the negative feeling that a slogan induces and most importantly the sensorial structure of the slogan and its sensory impact in the audience are indeed essential for a creative and *AP* slogan which is in line with the creativity dimension analysis.

Appreciation Detection on Images

The message of an advertising print is conveyed through both linguistic and visual channels. In this experiment,we utilize the raw sensory input in the form of embedded representations of the image and visual surface features.

Transfer Learning (CNN) Deep learning approaches are proven to be successful in multimodality tasks yielding the state of the art performances on Computer Vision studies such as image classification (Krizhevsky et al., 2012) or object detection (Ren et al., 2015). Considering the promising strength of the convolutional neural networks in image recognition, we hypothesize that certain characteristics of an image, such as objects and patterns, can tamper with its appreciation level as a creative artwork. For instance, marketing images mostly encode cultural and historical stereotypes of masculinity and femininity in order to invoke the feeling of gender identity in the customers (Schroeder & Zwick, 2004). We conjecture that such patterns can be utilized to predict the appreciation level of an ad image if we can capture them automatically.

Since our dataset is not large enough to train a deep network from scratch, we employ transfer learning where we fine-tune Inception V3 image recognition model(Szegedy et al., 2016) as an appreciation predictor. Inception V3 is a deep convolutional neural network that significantly improves the state of the art ILSVRC 2012 1000-class ImageNet classification benchmark. It is trained using stochastic gradient on Tensorflow. Although, the object classification on ImageNet and the appreciation classification task on carefully designed ads are fundamentally dissimilar, Yosinski et al. (2014) state that transferring features from a distant task is still better than randomly initialized variables. Therefore, it would be feasible to boost a network by transferring deeply trained features to overcome the scarcity of the advertising data.

While conducting a transfer learning on Inception V3, first, we only retrained the top 2 layers, labeled as Inception-V3/Logits and Inception-V3/AuxLogits, and kept the earlier layers frozen. In this phase, we obtained a checkpoint after 1000 steps. We exploited Tensorflow Slim[7] implementation to train the new layers and we set the *learning rate* to 0.01. The last layer of the network is a softmax layer that provides posterior probabilities as normalized prediction values for *AP* and *UNAP* classes. In the second phase, we fine-tune all trainable weights in the whole network only for 500 steps and with a learning rate of 0.001. We keep the learning rate small in order to protect the powerful weights of the original Inception V3 model from changing too quickly and loosing their representation ability.

Observable Visual Features (OVF) Together with the implicit properties and patterns belonging to *AP* and *UNAP* classes, we also utilize the explicit elements such as lines and their properties found in the images. In addition, we seek the impact of the color information per se in the creativity detection by encoding the dominant colors as another feature. These features are mostly related to the artistic dimension of the creativity. We extract top 10 dominant colors in the images by k-means clustering on the color values of the pixels and map the center values of the clusters to 16 colors. In addition, we extracted lines in an image through Hough Transform (Duda & Hart, 1972). This feature set contains the normalized length of the longest line and average line length; 3 binary flags indicating whether the longest line is horizontal, vertical or diagonal. We also encoded an interpretation of the "Rule of Thirds", which is a well-known rule of photographic composition[8] and mainly states that the center of interest in images should be on the intersection points or along the lines when an image is divided into 9 equal sections by 2 horizontal and 2 vertical lines. We generated a binary feature indicating if the longest line in the image starts from an outer area and crosses over only 2 sections horizontally and/or 2 sections vertically. Our intuition is that cutting the continuum of the line close to "Rule of Thirds" interest areas can guide the eye of the viewer to the center of focus and contribute to the message and aesthetic value of the image.

Visual Modality Experiment Results

We trained the CNN models on 3265 images from the training set. Using the trained models, we performed the testing on 900 images from the test set. At the end of the test phase, we obtained *AP* and *UNAP* scores for each test image. We employed a straightforward decision process with a 0.5 cut-off where the labeling is conducted by finding the higher value among the *AP* and *UNAP* scores. The performances of the CNN models are summarized in Table 2. The validation accuracy shown in the table is calculated by evaluating the model over the randomly sampled 265 images as the validation set during the training phase. We observe that fine-tuning all the network after the retraining the last 2 layers provide a clear boost to the classifier performance of CNN-1K. The F1 score on the test set significantly ($p < 0.05$) increases from 0.561 to 0.596.

Visual Model	Validation Acc	Testing F1
CNN-1K	0.608	0.561
CNN-1K+500	0.626	$^{\#}$0.596

Table 2: The CNN visual modality experiment results. $^{\#}$ denotes $p < 0.05$ for the McNemar significance test between the models.

Model	#Features	Training F1	Testing F1
OVF	22	0.547	0.560
Colors	17	$\star$0.517	$*$.0.515
Lines	5	0.533	$^{\#}$ 0.508

Table 3: The OVF model visual modality experiment results. $\star$ denotes $p < 0.001$, $*$ denotes $p < 0.01$, $^{\#}$ denotes $p < 0.05$ for the McNemar significance test between *OVF* and Colors or Lines.

For the *OVF* model, we performed the same training strategy that we employed in the linguistic experiment. The model yields relatively poor training (F1:0.547) and testing (F1:0.560) results as they are shown in Table 3. During the ablation study, we observed that a significant performance change occurred when we removed the *Lines* (F1:0.517, $p < 0.001$) for the training cross-validation results. Through the analysis on testing results, we found out that both *Colors* (F1:0.515, $pval < 0.05$) and *Lines* (F1:0.508, $p < 0.01$) contribute to the final model significantly. Although the results of the whole *OVF* model suggest that these aesthetic features are indeed indicating factors of image creativity, we can imply that the overall visual appreciation of an ad is affected by more subtle properties to be discovered than the aesthetic features that we implemented.

Multimodal Fusion

We embraced the late fusion (score level) strategy (Kiela & Clark, 2015) to obtain the multimodal appreciation score. To combine the scores from each model for a class by soft voting approach, we employed Equation 1 where s_n denotes the appreciation score for the ad x by the model m_k and α_n denotes the weight for the model m_k.

$$ms(x) = \sum_{n:m_k} \alpha_n \times s_n \quad (1)$$

We obtained the peak points for α values by running a grid search on the multimodal fusion of model outputs for development set. In this search, all α values are positive and their sum equals to 1.0. After calculating the multimodal appreciation scores, namely *ms*, we labeled the instance *a* by finding the maximum value among the class scores. We evaluate the multimodal experiment results by averaging (Equal α) and soft voting in terms of the F1 scores on the test set and we present the results in Table 4. The α values that we employ during the fusion are shown in the last column. While calculating the multimodal fusion results, we employ the unimodal models; *L*, *OVF* and *CNN-1K+500*. We chose to use the model *CNN-1K+500* since it yields the highest validation accuracy and has a significant improvement for the testing in comparison to its predecessor. Regarding the uni-modal results of linguistic and visual models, the lowest performance is obtained by using OVF while the highest F1 score is yielded by the CNN model. As shown in Table 4, the *ALL* model significantly outperforms the linguistic and observable visual features models. *ALL* model surpasses *CNN*, which is the best unimodal model, by increasing the performance from 0.596 to 0.625 for the soft fusion and to 0.620 for the equal α fusion. This outcome can be considered as conforming with our initial anticipation that the different modalities play complementary roles in expressing the creativity and appeal of an advertising print. The highest contributor of the complete model *ALL* is the *CNN* model and when we remove it from the fusion, the Equal α F1 score drops to 0.587.

Model	Eq. α F1	Soft α F1	α values
ALL	0.620	0.625	L:0.18,C:0.24,O:0.58
$L \cup OVF$	0.587	$*$0.573	L:0.11, O:0.89
$L \cup CNN$	0.605	0.606	L:0.74, C:0.26
$OVF \cup CNN$	0.618	0.612	C:0.25, O:0.75
CNN	0.596	0.596	C:1.0
OVF	$*$ 0.560	$\star$0.560	O:1.0
L	$^{\#}$0.577	$^{\#}$0.577	L:1.0

Table 4: Multimodal fusion results and comparisons to the uni-modal experiments. $\star$ denotes $p < 0.001$, $*$ denotes $p < 0.01$, $^{\#}$ denotes $p < 0.05$ for the McNemar significance test between *L* and ablated models.

Discussion and Conclusion

For the example in `www.adsoftheworld.com/media/print/act_tv_numbers_insects_vs_frog`, which is an *AP* sample resolved by the model *ALL* but not by the visual models, although the visual channel is highly expressive too, the lack of straight lines and dull color palette decreases the prediction performance of *OVF* model. *CNN* model also mislabels the image with a very low confidence since it possibly fails to recognize the peculiar focus elements. Therefore, a wider range of training samples for advertising images would be necessary to identify the style marks of creative and appreciated compositions.

Our quantitative results show that the sensorial structure of the relation between the slogan, and the product category/type is a strong indicator of the creativity appreciation level. When we analyze the feature importance of the final model *L*, we detected that especially the sensorial relation features between the product type and slogan become prominent among the implemented sensorial features. To better illustrate the contribution of the sensorial information to the final model, we fused the visual models with the model $L \setminus Sensorial$ in which we removed all sensorial features from the linguistic model. The Equal-α F1 score of the fusion model decreases to 0.594 without the sensorial features. In the ad `www.adsoftheworld.com/media/print/febreze_french_fries`, we show an *AP* test sample resolved by the contribution of sensorial features. In fact, the example epitomizes the usage of the olfactory disadvantage of the language as a creativity inducing tool. We believe

that smell related words, such as the word "odor" in the example, possibly contributes to the surprisal dimension of the creative and *AP* advertising since olfactory words tend to be less expected by the audience. Indeed, our analysis on the training set reveals that the smell association of the words are inclined to be higher in the *AP* samples in comparison to the *UNAP* samples (Mann-Whitney $p < 0.001$). On the other hand, *taste* association tends to denote the opposite behaviour in our training set (Mann-Whitney $p < 0.001$) while we cannot observe any significant difference for the other senses w.r.t. the Sensicon association values.

Although the automatic assessment of the appreciation level of advertising is a substantially compelling challenge, our findings suggest that sensorial information along with the other linguistic, semantic, cognitive and, finally visual aspects establish a starting point to tackle its complexity.

Abstract

In everyday life, people see, describe and remember motion events. We tested whether the type of motion event information (path or manner) encoded in speech and gesture predicts which information is remembered and if this varies across speakers of typologically different languages. We focus on intransitive motion events (e.g., a woman running to a tree) that are described differently in speech and co-speech gesture across languages, based on how these languages typologically encode manner and path information (Kita & Özyürek, 2003; Talmy, 1985). Speakers of Dutch (n = 19) and Turkish (n = 22) watched and described motion events. With a surprise (i.e. unexpected) recognition memory task, memory for manner and path components of these events was measured. Neither Dutch nor Turkish speakers' memory for manner went above chance levels. However, we found a positive relation between path speech and path change detection: participants who described the path during encoding were more accurate at detecting changes to the path of an event during the memory task. In addition, the relation between path speech and path memory changed with native language: for Dutch speakers encoding path in speech was related to improved path memory, but for Turkish speakers no such relation existed. For both languages, co-speech gesture did not predict memory speakers. We discuss the implications of these findings for our understanding of the relations between speech, gesture, type of encoding in language and memory.

Keywords: Motion events; Memory; Cross-linguistic differences; Co-speech gesture

Introduction

People frequently perceive, remember and communicate about events. The relations between these different cognitive processes are not well-understood. In this study, we ask whether the way a visually perceived event is described relates to how it is remembered. How exactly an event is described, varies across typologically different languages. In addition, within languages there is also variation: two speakers of the same language may perceive the same event, but describe it differently. Importantly, in describing events people not only use speech but also co-speech gestures that describe main components of events. These gestures also vary both across and within languages. How does the way one speaks and gestures about events predict one's memory for various aspects of events?

Many of the events people see in their daily lives involve motion, because the world around us is constantly moving. Two crucial components of motion events are the manner of motion (e.g., running) and the path that the motion follows (e.g., to the tree). Whether people mention the manner or path during a motion event description is strongly affected by the language they speak. Verb-framed languages (e.g., Turkish, Greek, Spanish) typically encode path in the main verb and can optionally add manner of motion, for example in subordinate verbs or in adverbial phrases (see example sentence (1) from Turkish below; Talmy, 2000). By contrast, satellite-framed languages (e.g., Dutch, English, Russian) typically encode manner in the main verb and path in a variety of other structures, such as prepositional phrases (see example sentence (2) from Dutch below). A crucial difference between verb-framed and satellite-framed languages is that speakers of satellite-framed languages typically mention both path and manner information, while speakers of verb-framed languages regularly omit manner information (Slobin, 2003).

If speakers of different languages describe the same motion event differently, do they also remember the event differently? Prior work found no cross-linguistic differences in how speakers of verb-framed and satellite-framed languages remember manner and path (Engemann et al., 2015; Gennari et al., 2002; Papafragou et al., 2002; Papafragou, Hulbert, & Trueswell, 2008, but see Filipović, 2011 for differences using complex motion events). However, these studies simply compared speakers of verb-framed and satellite-framed languages at the group level, without considering the variation within languages in terms of which motion event information is described. It remains unknown whether which information a speaker mentions in a particular motion event description may predict their later memory for that information, regardless of their native language. For example, if a speaker described the path of a motion event, do they remember that path better? In addition, how these specific descriptions might interact with native language to predict memory also remains unclear. For example, does describing path have a different effect on path memory for speakers of verb-framed languages compared to speakers of satellite-framed languages?

It is plausible that the information encoded in linguistic descriptions predicts memory performance for two reasons. First, it could be that the description is a window into the mental representation of the event: if a speaker describes the path, this might indicate that the speaker has mentally represented the path of the event. Therefore, the speaker may be more likely to remember the path (Papafragou et al., 2002). Second, it could be that the verbal description functions as an additional format in which the event is encoded in memory. This way, the description itself might be remembered and thus aid memory for the components encoded in the description (Papafragou et al., 2002). Indeed, it appears that what exactly is said in a motion event description is important for memory: speakers who described a path of motion later remembered this path better (Billman, Swilley, & Krych, 2000).

When investigating the link between descriptions and memory, it is important to keep in mind that language is multimodal (Vigliocco, Perniss, & Vinson, 2014). In fact, descriptions of events are often accompanied by iconic co-speech gestures. For example, while saying "The woman ran to the tree", a speaker might wiggle one's index and middle fingers in an inverted V-shape across space from left to right. Co-speech gestures can represent path, manner, or both in one gesture (Figure 1). Importantly, co-speech gestures accompanying motion event descriptions differ both across and within languages. In terms of cross-linguistic differences, the *form* of motion event co-speech gestures differs between speakers of verb-framed and satellite-framed languages (Kita & Özyürek, 2003). However, it is yet unknown whether there are cross-linguistic differences between speakers of verb-framed and satellite-framed languages in terms of *how often* they gesture about path and manner, and whether this relates to their memory for path and manner. In addition, co-speech gesture production also differs within languages. Within speakers of a language, one element of motion might be gestured more often than another element for different events. Therefore, both speech and co-speech gesture need to be taken into account to see how differences within and across languages in motion event descriptions relate to motion event memory.

Figure 1: Gestures can represent only path (A), only manner (B) or both manner and path (C)

Indeed, prior work shows that gestures are related to event memory. For example, producing co-speech gestures when describing motion and action events leads to better memory for these events (Cook, Yip, & Goldin-Meadow, 2010). In addition, the specific action event information conveyed in gesture predicts the information later remembered (Koranda & MacDonald, 2015). These results are in line with research on the enactment effect, which shows that reading descriptions of action events and performing these actions leads to better memory for the descriptions that does only reading (for review, see e.g., Cohen, 1989). The involvement of the motor system could lead to richer memory representations, or to stronger memory representations (Madan & Singhal, 2012). These studies point to the importance of taking co-speech gestures into account when investigating the relation between motion event descriptions and memory.

The Present Study

The main aim of the present study was to investigate whether the speech and co-speech gestures that speakers use to describe motion events predict their memory, and whether cross-linguistic differences in speech and gesture lead to cross-linguistic differences in memory. To test these questions, Dutch and Turkish speakers watched and described motion events, after which their surprise

recognition memory for manner and path was tested. We had the following predictions:

(a) In general, we expected that encoding a motion event component in speech would predict better memory for that component.
(b) Similarly, we expected that encoding a motion event component in gesture would predict better memory for that component.
(c) Cross-linguistically, we expected Dutch speakers to encode manner more often in speech and gesture than Turkish speakers, due to the optional encoding of manner in Turkish. As a result, we expected Dutch speakers to have better memory for manner.

Method

Participants. Data were collected from 19 adult native speakers of Dutch (15 females, M_{age} = 23) and 22 adult native speakers of Turkish (16 females, M_{age} = 21). Dutch speakers received monetary compensation for their participation. Turkish speakers received course credit for their participation.

Materials. Target events presented in the study phase consisted of 16 silent video clips that depicted a female actor moving with respect to a landmark object along a particular path with a particular manner (e.g., a woman hopped to a cactus). Each clip was 2500ms long. Each clip was created by combining four spontaneous manners of motion (run, hop, twirl, tiptoe) with four motion paths (to, into, from, out of). Sixteen additional video clips of transitive events served as fillers (e.g., a woman biting an apple).

In the memory phase, half of the events had a change to either the manner (e.g., a woman tiptoed instead of hopped to a cactus) or the path (e.g., a woman hopped from instead of to a cactus) of motion (Figure 2). The other half of the events remained the same. Of the 15 filler events, half remained the same and half involved an object change (e.g., a woman biting a banana).

Procedure. Each participant was tested in a quiet room at their university campus in their native language by a native speaker together with a confederate who served as an addressee.

In the study phase, participants saw 16 target and 16 filler events. Each trial started with a fixation screen of 1000ms, followed by the event shown for 2500ms. Then a gray screen appeared, during which participants described "what happened in the video" to the addressee. Participants' speech and gestures were videotaped for later coding. The memory task was presented immediately after the study phase. The memory task was a surprise for the participants, because this way the prospect of the memory task could not affect the production results. During the memory task, participants saw another set of events and for each event indicated whether they had seen this exact video before by pressing a button. In both study and memory phases, each participant saw the events in different randomized order.

Figure 2: Example of a manner change (hop became tiptoe; left panel) and a path change (to became from; right panel)

Coding. Descriptions of target events were coded for the presence of path and manner information in speech and gesture using ELAN software (Lausberg & Sloetjes, 2009) by a native speaker of the relevant language. In speech, manner information was coded as present if how the motion was performed was encoded with a manner verb (e.g., rennen; running – mostly in Dutch) or a manner verb subordinated to a path verb via a connective (e.g., koşarak; run-Connective – mostly in Turkish). Path information was coded as present if the change of location with respect to something was encoded with prepositions or spatial/directional nouns (e.g., naar (to), içine (inside)) or path verbs (e.g., gir (enter), yaklaş (approach)).

In gesture, manner information was coded as present if speakers produced a gesture representing the motion in a non-linear way. Gestures could represent the manner from a third person perspective (e.g., for twirling, a manner gesture could involve the index finger turning in circles) or could be an enactment of the figure's posture during the movement (e.g., for running, a manner gesture could involve moving the arms up and down). Path information was coded as present if speakers deliberately traced the change of location with a body part chosen to represent the figure. Path gestures could trace the change of location in the lateral axis (either with a correct or incorrect direction) or in the sagittal axis (moving towards or away from the body). Points to the location of the landmark were not coded as path gestures. Gestures could either include one motion element (manner-only or path-only) or a combination of both elements.

Results

Data were analyzed with generalized binomial linear mixed effects modelling (glmer) with crossed random intercepts for Subjects and Items using *lme4* package (Bates et al., 2015) in *R* (R Core Team, 2018). This mixed effects approach allowed us to take into account the random variability that is due to having different participants and different items.

Speech and gesture production

First, we tested whether there were cross-linguistic differences in how often path and manner components of motion events were mentioned in speech (Figure 3). We excluded three trials (two Dutch) in which the addressee talked and affected the speaker's speech production. A glmer model that tested the effects of Language (Turkish, Dutch) and Component (Path, Manner) on binary values for mention in speech (0 = no, 1 = yes) at the item level revealed only a main effect of Component (β = 3.41, *SE* = 1.50, *z* = 2.28, *p* = .02). Speakers mentioned Manner (*M* = 0.97) more often than Path (*M* = 0.72). No other effects or interactions were significant. Furthermore, the proportion of mention of path and manner components in speech by Turkish and Dutch speakers were similar per specific types of path or manner (Table 1).

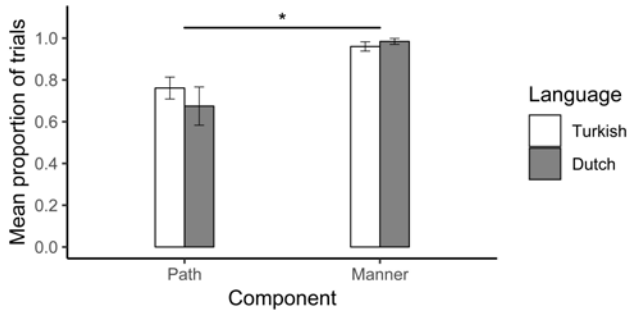

Figure 3: Event components encoded in speech. Error bars represent the standard error around the mean proportion of trials in which a component is mentioned per participant.

Table 1: Proportions of event components encoded in speech for each manner and path type, separated by language.

		Language	
		Turkish	Dutch
Manner	hop	0.99	0.98
	run	0.99	1.00
	tiptoe	0.91	1.00
	twirl	0.95	0.96
Path	to	0.67	0.56
	from	0.61	0.51
	into	0.95	0.90
	out of	0.80	0.73

Next, we tested whether there were cross-linguistic differences in how often speakers gestured about path and manner components while describing motion events (Figure 4). We excluded the same three trials that were excluded from the speech data analyses. A glmer model that tested the effects of Language (Turkish, Dutch), Component (Path, Manner) and their interaction on binary values for whether a component was encoded in gesture in an event description (0 = no, 1 = yes) revealed only a main effect of Language (β = -1.59, *SE* = 0.49, *z* = -3.24, *p* < .01). Turkish speakers (*M* = 0.48) gestured more often about both elements than Dutch speakers (*M* = 0.28). No other effects or interactions were significant. These patterns were replicated in a follow-up analysis that selected only the trials in which speakers gestured, and thus eliminated the possibility that differences in gesture rates hide cross-linguistic differences in what speakers of Dutch and Turkish prefer to gesture about.

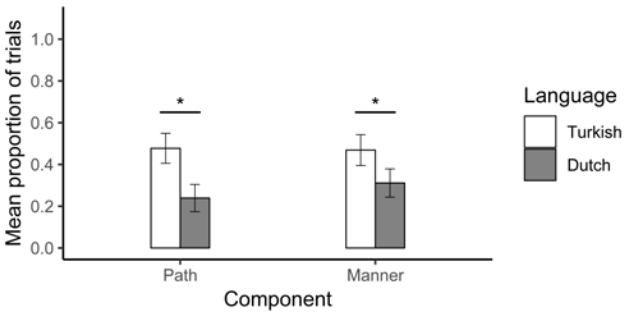

Figure 4: Event components encoded in gesture. Error bars represent the standard error around the mean proportion of trials in which a component is gestured per participant.

Memory performance

Beginning with filler events, Dutch (*M* = 0.99) and Turkish (*M* = 0.95) speakers had similar memory accuracy, indicating that the language groups were comparable in general memory performance. Furthermore, collapsed across language groups, memory for No change items (*M* = 0.78, *SD* = 0.15, *t*(40) = 11.98, *p* < 0.001) and Path changes (*M* = 0.68, *SD* = 0.26, *t*(40) = 4.29, *p* < 0.001) were significantly higher than chance level. However, memory for Manner changes (*M* = 0.40, *SD* = 0.26, *t*(40) = -2.39, *p* = 0.99) did not differ from chance level. This suggests that the participants may have simply been guessing when there was a Manner change. In addition, looking at the distribution of Manner change detection accuracy, it was clear that almost all participants had poor manner memory. It was thus not the case that some participants' memory was very poor, while other participants' memory was good. Therefore, we did not further attempt to predict manner memory using speech, gesture and language, because we did not want to predict guessing behavior.

For predicting path memory, path mentions in speech that only used unspecific verbs (e.g., to advance) that do not indicate or imply the spatial relation between the figure and the landmark were analyzed together with no mention trials and were contrasted to path mentions with prepositions, spatial/directional nouns or path verbs. Because these unspecific path verbs could be used regardless of the trajectory of motion we reasoned that they would not aid

memory. Following a similar reasoning for gestures, we analyzed path gestures in the sagittal axis together with no gesture trials and contrasted them to path gestures in the lateral axis with the correct direction. Path gestures in the lateral axis with the incorrect direction were excluded from the analyses because they might even hinder memory.

A glmer model tested the effects of Path in speech (0 = no mention, 1 = mention), Path in gesture (0 = no gesture, 1 = path gesture), Language (Turkish, Dutch) and Condition (No change, Path change) on binary values for whether an item was remembered (0 = no, 1 = yes). The best-fitting model revealed a main effect of Condition as well as an interaction between Condition and Path in speech (β = 1.26, SE = 0.51, z = 2.46, p = .01): for No change items, speakers had similar accuracy regardless of whether Path was mentioned in speech; for Path changes accuracy was higher if Path was mentioned in speech than if it was not. There was also an interaction between Path in speech and Language (β = 1.57, SE = 0.58, z = 2.71, p < .01): Dutch and Turkish speakers had similar accuracy when they did not mention Path in speech, but Dutch speakers had higher accuracy than Turkish speakers when they mentioned Path in speech (Figure 5). No other main effects or interactions were significant. Notably, there were no effects or interactions involving the factor Path in gesture. Thus, contrary to our expectations, gesturing about path did not predict better memory for path of motion. We turn to the significance of these findings below.

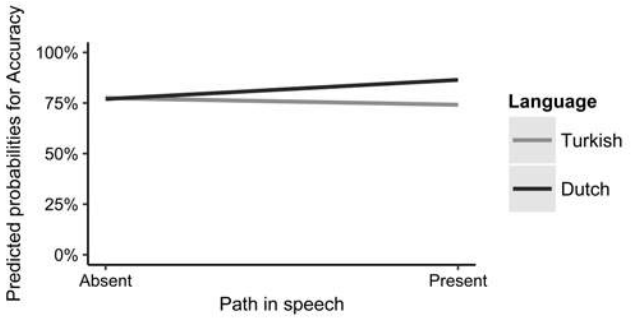

Figure 5: Interaction between Path in speech and Language for path memory accuracy, as predicted by the glmer model

Discussion

We tested whether the speech and gesture used to describe a particular motion event predicts memory for that motion event, looking at variation across and within languages. Our study has five key findings. First, speakers of Turkish did not omit the manner more often than speakers of Dutch. Second, speakers of both Dutch and Turkish had chance level memory for manner of motion. Third, speakers who mentioned path in their speech were later more accurate at detecting changes to this path. Fourth, path mention in speech was positively related to path memory for Dutch speakers, but not for Turkish speakers. Finally, we found that speaking but not gesturing predicts memory for path information.

Regarding the production results, we did not replicate the classic typological finding that speakers of verb-framed languages omit the manner more often than speakers of satellite-framed languages (Slobin, 2003). Instead, we found that speakers of both Dutch and Turkish almost always mentioned the manner of motion. A possible explanation can be found in the stimuli used in the present study. In an attempt to increase manner memory, we used manners that were rather salient (tiptoe, twirl, hop, run). It is plausible that because these manners were so salient, speakers of Turkish deemed it important to mention them. This interpretation is in accordance with the finding that speakers of Greek, a verb-framed language, mention the manner of motion much more often when it is not inferable for the listener compared to when it is inferable (Papafragou, Massey, & Gleitman, 2006). Although the cross-linguistic difference in manner omission has been reported many times, our findings show that within-language encoding flexibility makes it possible that under certain conditions (e.g., for some events), such cross-linguistic differences can be diminished.

Our study was the first to directly compare memory for manners and paths, where the path and manner changes did not involve object changes, but manner and path changes for intransitive events (unlike e.g., Bunger, Trueswell, & Papafragou, 2012 investigating instrumental motion). The finding that path is remembered better than manner is in accordance with a previously reported developmental path bias in terms of categorization (Konishi et al, 2016; Pruden et al., 2012, 2013). It is possible that path is remembered better than manner because it is related more to intentionality or goal-directedness of the motion (Pourcel, 2004). Such a relation between intentionality and memory of motion is also found when comparing memory for goal paths (e.g., to) versus source paths (e.g., from). Goals are remembered better than sources, possibly because they are more informative about the figure's intentions (Lakusta & Landau, 2012; Papafragou, 2010). Notably, this goal-source asymmetry exists only for animate figures, who can have intentions (Lakusta & Landau, 2012).

Interestingly, while speakers were not successful at remembering the manner, they did almost always describe the manner. This dissociation indicates that in terms of manner, there is no strong correspondence between speech and memory. However, this overall comparison is based on data that is averaged across different participants, items, and languages. It is still possible that when these factors are taken into account, one might find a subtle relation between mentioning manner in speech and remembering manner. In future research, this can be tested if manner memory accuracy is increased to above chance level. Nevertheless, this overall dissociation between manner mention in speech and manner memory is still quite striking. This suggests that there are at least partly different criteria for which motion event information is important to describe to another person and for which motion event information is important to remember.

For describing motion events to another person, manner of motion may be important when it is salient and not inferable. By contrast, for remembering motion events, path of motion may be important because it relates to the intentions of the figure.

In terms of the relation between descriptions and memory, we found that speakers who described a path in speech were more accurate at detecting changes to that path. This is consistent with a previous finding that speaking about path predicts better memory for path (Billman et al., 2000). It is also consistent with prior findings from other domains, demonstrating relations between how speakers describe and remember visual stimuli (e.g., eye-witness memory, Marsh, Tversky, & Hutson, 2005; picture recognition, Zormpa et al., 2018). Whether this relation between path speech and path change detection is causal is a question for further research.

In addition, the relation between path speech and path memory differed cross-linguistically: for Dutch speakers only, speaking about path predicted better memory for path. For Turkish speakers, path memory was similar regardless of whether path had been mentioned. This result might be due to cross-linguistic differences in how path was mentioned. For example, while Dutch speakers mentioned path in prepositions, Turkish speakers mentioned path mainly in verbs. Perhaps these are differentially related to memory. Another cross-linguistic encoding difference is that while Dutch speakers almost always used path prepositions that indicate the spatial relation between the figure and the landmark, Turkish speakers sometimes used unspecific verbs (e.g., to advance) to describe the path. Thus, if a Turkish speaker wants to mention path, specifically mentioning the relation to the landmark is optional. This greater optionality may have resulted in a weaker link between linguistically encoding the relation to the landmark in speech and remembering it. Further research is necessary to investigate these speculations. Either way, this interaction indicates that when linking typological differences to cognition, it is important to move from studying main effects of native language to investigating more subtle interactions of native language and descriptions.

Finally, we found no relation between co-speech gesture and memory. Importantly, path gestures typically co-occur with path speech. Therefore, this lack of a relation between gesture and memory can be interpreted to mean that path memory is equally accurate for speakers who speak and gesture about path, compared to speakers who only speak about path. The lack of a relation between path gesture and memory was surprising, given that previous research has shown a link between gesture production and event memory (Cook et al., 2010; Koranda & MacDonald, 2015). However, these studies differ from ours in one important respect: while we used motion events only, they either collapsed motion events with actions (Cook et al., 2010) or used actions only (Koranda & MacDonald, 2015). Perhaps the different memory results can be attributed to the differences between iconic co-speech gestures that describe actions versus gestures that describe paths of motion events. For example, action gestures might involve motor simulation more strongly than tracing path gestures (Hostetter & Alibali, 2008).

Either way, it appears that for the path of motion events, speech but not co-speech gesture predicts memory. There are two potential explanations of this finding. One possibility is that speech planning affects attention more than does co-speech gesture planning. Speech planning affects attention: while watching motion events to prepare for description, people look at the events in such a way that they can describe it later (Bunger et al., 2012; Flecken et al., 2015; Flecken, von Stutterheim, & Carroll, 2014; Papafragou et al., 2008; Trueswell & Papafragou, 2010). By contrast, because gestures do not follow such a strict system, their planning might have less of an impact on attention, and in turn have less of an impact on memory. Another possible explanation for why speech but not gesture predicts memory concerns the nature of speech and gesture representations. While speech is categorical and relies on discrete units, gesture is analogue and allows information to be conveyed imagistically (Cook, Yip, & Goldin-Meadow, 2012). Therefore, the verbal representation is an easier, more simplified version of the real event, compared to the gestural representation, and thus might be more useful as a memory cue.

In conclusion, the present study reveals differential contributions of speech and gesture in predicting motion event memory. Our findings underline that the relation between language and event memory is intricate and is influenced by subtle variations in how motion events are described within and across speakers of different languages.

Abstract

In real world contexts of reasoning about evidence, that evidence frequently arrives sequentially. Moreover, we often cannot anticipate in advance what kinds of evidence we will eventually encounter. This raises the question of what we do to our existing models when we encounter new variables to consider. The standard normative framework for probabilistic reasoning yields the same ultimate outcome whether multiple pieces of evidence are acquired in sequence or all at once, and it is insensitive to the order in which that evidence is acquired. This equivalence, however, holds only if all potential evidence is incorporated in a single model from the outset. Hence little is known about what happens when evidence sets are expanded incrementally. Here, we examine this contrast formally and report the results of the first study, to date, that examines how people navigate such expansions.

Keywords: sequential diagnostic reasoning; sequential causal structure learning; causal Bayesian networks; order effects.

Introduction

Tom wakes up one morning and notices a rash on his skin. He does not think the rash is a big deal, but after a couple of days the rash is still present so he decides to see a doctor. Before he visits a doctor he thinks that the rash is either caused by a bacterial or a viral infection or, perhaps, both. The doctor agrees with him that the rash could be caused by a bacterial and/or a viral infection. However, she additionally informs Tom that he also has a swelling he didn't notice, which can also be caused by a bacterial and/or a viral infection. Furthermore, she tells him that either type of infection is more likely to cause the swelling than the rash. How do (should) Tom and the doctor revise their beliefs about multiple independent causes given multiple pieces of evidence of different diagnosticity?

From a normative standpoint, many would argue that the answer is encoded in the causal Bayesian networks (CBNs): directed acyclic graphs with nodes representing variables (causes and effects) and arrows representing probabilistic and causal relations between the nodes (Pearl, 2009, 1988; Neapolitan, 2003). Here one would build a 4-node CBN with 2 common effects and 2 independent causes.[1] For instance, the CBN in Figure 1 would model the situation we described above: C_1 = viral infection, C_2 = bacterial infection, E_1 = rash, and E_2 = swelling.

To fully parameterize CBN from Figure 1, one needs to specify the following probabilities:

$$P_1(\mathrm{C}_1) = c_1 \quad , \quad P_1(\mathrm{C}_2) = c_2$$
$$P_1(\mathrm{E}_1 \mid \mathrm{C}_1, \mathrm{C}_2) = \alpha_1 \quad , \quad P_1(\mathrm{E}_1 \mid \mathrm{C}_1, \neg\mathrm{C}_2) = \beta_1$$

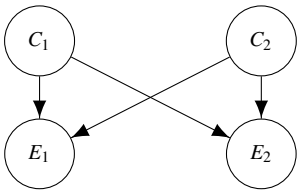

Figure 1: CBN with 2 independent causes and 2 common effects.

$$\begin{aligned} P_1(\mathrm{E}_1 \mid \neg\mathrm{C}_1, \mathrm{C}_2) = \gamma_1 \quad , \quad P_1(\mathrm{E}_1 \mid \neg\mathrm{C}_1, \neg\mathrm{C}_2) = \delta_1 \\ P_1(\mathrm{E}_2 \mid \mathrm{C}_1, \mathrm{C}_2) = \alpha_2 \quad , \quad P_1(\mathrm{E}_2 \mid \mathrm{C}_1, \neg\mathrm{C}_2) = \beta_2 \\ P_1(\mathrm{E}_2 \mid \neg\mathrm{C}_1, \mathrm{C}_2) = \gamma_2 \quad , \quad P_1(\mathrm{E}_2 \mid \neg\mathrm{C}_1, \neg\mathrm{C}_2) = \delta_2 \end{aligned} \tag{1}$$

$P_1(\mathrm{C}_1)$ and $P_1(\mathrm{C}_2)$ are usually referred to as the prior probability of the two causes and the remaining probabilities as being part of the conditional probabilities tables (CPTs) for the two effects. The doctor then could use this CBN to update her beliefs about the probability that Tom has a viral infection after learning that Tom has a rash by calculating $P_1(\mathrm{C}_1 \mid \mathrm{E}_1)$. After additionally learning that Tom also has swelling the doctor could further update her probability of Tom having a viral infection by calculating $P_1(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2)$ (similarly for the bacterial infection).

However, it is somewhat accidental that Tom first noticed the rash and not the swelling. He could have plausibly first seen the swelling and gone to the doctor and then noticed the rash. Would the CBN calculation be different in this scenario? It depends. If the rash and the swelling are not equally diagnostic of the two causes as is suggested by the example, then it is possible that $P_1(\mathrm{C}_1 \mid \mathrm{E}_1) \neq P_1(\mathrm{C}_1 \mid \mathrm{E}_2)$, in which case the doctor's degrees of belief about a viral infection after first learning that Tom has swelling would not be equal to those where she first leaned about the rash. However, after learning the second effect the order in which the effect appear no longer matters: that is, $P_1(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2)$ is always equal to $P_1(\mathrm{C}_1 \mid \mathrm{E}_2, \mathrm{E}_1)$.

It is then empirically interesting to investigate whether people are sensitive to these different orders of effects and whether they update the causes differently depending on the order in which the effects appear. Studies on sequential di-

[1] Hayes, Hawkins, Newell, Pasqualino, and Rehder (2014) have used a dynamic CBN to model these kinds of situations. However, in this paper we employ static CBNs as there are no significant differences in the formalism in this case.

agnostic reasoning have sought to tackle exactly these issues (see Meder & Mayrhofer, 2017b; Hogarth & Einhorn, 1992). They presented participants with a sequence of effects and asked them to reason from multiple effects to causes either with each effect they learned (step-by-step procedure) or after they learned about the whole sequence of effects (end-of-sequence procedure) (see Hogarth & Einhorn, 1992; Rebitschek, Bocklisch, Scholz, Krems, & Jahn, 2015). Their studies were primarily interested in investigating primacy effects (most of the evidential weight is given to the first piece of evidence) and recency effects (most of the evidential weight is given to the most recent pieces of evidence). Meder and Mayrhofer (2017a) investigated sequential diagnostic reasoning by providing participants with verbal information regarding the strengths of the causes instead of a more quantitative information (like the CPTs) and found that participants are remarkably accurate in their judgements. However, all these studies investigated only situations where the causes were mutually exclusive and exhaustive causes (which would be modeled as one node for all causes). Hayes et al. (2014) investigated a scenario where two symptoms could be produced by two independent causes. However, in their study both effects had exactly the same diagnosticity (i.e. the same CPT) and for that reason there are no order effects, i.e. it does not matter whether we learn first E_1 or E_2, $P_1(\mathrm{C}_1 \mid \mathrm{E}_1) = P_1(\mathrm{C}_1 \mid \mathrm{E}_2)$.

One of the goals of this paper is to empirically investigate people's ability to reason diagnostically from multiple effects with different diagnosticities (CPTs) to multiple independent causes. More specifically, we aim to test how people's judgements compare to the normative answer from CBNs such as the one in Figure 1 by manipulating the way in which multiple pieces of the evidence of different diagnosticity are presented (in a particular order or at the same time) and the way judgements about the causes are elicited from the participants (step-by-step (SbS) or all-at-once (AaO)).

Another interesting issue emerges when reasoning with independent causes. Not only can we learn the evidence sequentially, but we can sequentially learn about new variables that may influence our beliefs about the causes. In technical parlance, we may need to expand the algebra. Consider Tom from our example. Initially Tom only knew about his rash and, based on that knowledge, he updated his probabilities of the two causes. Unlike the doctor, Tom did not even know that the two types of infection could also cause swelling. It is only after he visited his doctor that he learned about the another potential effect and the occurrence of that effect. At the time he only knew about the rash he updated the probabilities of the two causes on the basis of a CBN model with only three nodes: two independent causes and one common effect while the doctor always had in mind the CBN from Figure 1. Despite operating with two different CBNs, both Tom and the doctor would arrive at the same probabilities (assuming the same priors and CPTs for the effect) at this first step. The next step is, however, crucial. After learning about the swelling, the doctor would simply learn the new piece of evidence and update the probabilities of the causes based on the CBNs from Figure 1. Tom, by contrast, might do one of two things: (1) forget about his original 3-node network and create a new 4-node one like the one in Figure 1 in which case he would arrive at the same estimates as the doctor; or (2) take his (and doctors) previous estimates of the two causes based on only one piece of evidence and take them as new priors in his new 3-node network with the second piece of evidence as a common effect (see Figure 2). In the latter case he would be 'splitting' the CBNs from Figure 1 into two 3-node networks.

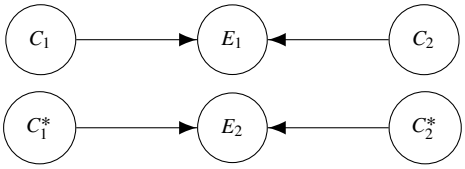

Figure 2: 'Split' CBN from E_1 to E_2

$$
\begin{aligned}
P_1(\mathrm{C}_1) = e_1 \quad &, \quad P_1(\mathrm{C}_2) = e_2 \\
P_2(\mathrm{C}_1^*) = P_1(\mathrm{C}_1 \mid \mathrm{E}_1) \quad &, \quad P_2(\mathrm{C}_2^*) = P_1(\mathrm{C}_2 \mid \mathrm{E}_1) \\
P_1(\mathrm{E}_1 \mid \mathrm{C}_1, \mathrm{C}_2) = \alpha_1 \quad &, \quad P_1(\mathrm{E}_1 \mid \mathrm{C}_1, \neg\mathrm{C}_2) = \beta_1 \\
P_1(\mathrm{E}_1 \mid \neg\mathrm{C}_1, \mathrm{C}_2) = \gamma_1 \quad &, \quad P_1(\mathrm{E}_1 \mid \neg\mathrm{C}_1, \neg\mathrm{C}_2) = \delta_1 \\
P_2(\mathrm{E}_2 \mid \mathrm{C}_1^*, \mathrm{C}_2^*) = \alpha_2 \quad &, \quad P_2(\mathrm{E}_2 \mid \mathrm{C}_1^*, \neg\mathrm{C}_2^*) = \beta_2 \\
P_2(\mathrm{E}_2 \mid \neg\mathrm{C}_1^*, \mathrm{C}_2^*) = \gamma_2 \quad &, \quad P_2(\mathrm{E}_2 \mid \neg\mathrm{C}_1^*, \neg\mathrm{C}_2^*) = \delta_2
\end{aligned}
\tag{2}
$$

Eq. (2) specify the priors and the CPTs of the two networks. Although one might intuitively think that Tom will arrive at the same probabilities as the doctor even in the case where he models the situation as in Figure 2, that turns out to be true only under very specific conditions, some of which may violate common assumptions in causal Bayesian reasoning (see Appendix A). Less technically, this is because once one learns evidence (E_1) and updates the probabilities of the two causes (C_1 and C_2) in a common-effect CBN, the two previously independent causes become dependent: although $P_1(\mathrm{C}_1 \mid \mathrm{C}_2) = P_1(\mathrm{C}_1)$, generally $P_1(\mathrm{C}_1 \mid \mathrm{C}_2, \mathrm{E}_1) \neq P_1(\mathrm{C}_1 \mid \mathrm{E}_1)$. This dependency is preserved in the full CBN network in Figure 1 even *before* one learns the second piece of evidence (E_2) and again updates the probabilities of the two causes. However, in the lower 3-node CBN in Figure 2 the dependency is lost since it is assumed that C_1^* and C_2^* are independent *before* observing E_2. Therefore, the final probability estimates of the two causes, i.e. their estimates *after* learning both pieces of evidence, will most likely diverge on the two different modeling strategies. More specifically, the final estimates of the two causes will always be higher according to the 'split' CBN in Figure 2 than those according to the full one in Figure 1 precisely because the full one accounts for the above-mentioned dependency and the 'split' one does not. Moreover, when the diagnosticity of the two pieces of evidence is different (as is the case in this study), the height of the final estimates in the 'split' CBN will depend on the order the evidence is observed: learning E_1 then E_2 will result

in the final estimates of the causes that are different to those that result from learning E_2 then E_1 (as previously mentioned, whether we learn E_1 first then E_2 or vice versa does not affect the final probability estimates of the causes in the full CBN). It is also worth pointing out that this divergence only happens when the causes are independent. If the causes are mutually exclusive and exhaustive, one can safely 'split' the full network into multiple ones without worrying about ending up with different estimates (see Appendix B).

To the best of our knowledge no study has yet investigated sequential diagnostic reasoning with sequentially learning the algebra. In the literature mentioned above participants were presented with all the variables and the causal/probabilistic information related to them before they started making judgements about the causes. Even in such contexts, it is worth looking at order effects because it has long been recognized that order effects may be particularly diagnostic with respect to the processes underlying the formation of a judgment. Specifically, there is a long literature concerned with order effects in contexts such as impression formation (Anderson, 1965) or numerical estimation (Jacowitz & Kahneman, 1995). However, our concerns in this paper go beyond this. We are interested in examining how reasoners fare in probabilistic reasoning contexts where they are faced with entirely new variables. This issue has, to the best of our knowledge, not been explored. In many scientific and everyday situations we must make judgements about potential causes given effects without being aware of other potential effects that could also inform our judgements. The main aim of this study was to examine how people reason with multiple pieces of evidence when they successively learn not just that some piece of evidence obtains, but also that there is another potential piece of evidence not known before. We compared participants' estimates to both the full network's predictions (Figure 1) and the 'split' networks' predictions (Figure 2).

Experiment overview

In the present experiment we investigated the influence of manipulating algebra and evidence learning on probabilistic judgements of the two independent causes. Participants were prompted to reason with either the full 4-node model (Figure 1) from the outset or they learned in stages that there is another possible effect of the two causes. Further, participants either observed the effects in one of the two sequences or they observed both effects at once. The prior probabilities of the cases and CPTs of the effects were the same in all conditions: $P(\mathrm{C}_1) = P(\mathrm{C}_2) = 0.15$; $P(\mathrm{E}_1 \mid \mathrm{C}_1, \mathrm{C}_2) = 0.99$, $P(\mathrm{E}_1 \mid \mathrm{C}_1, \neg\mathrm{C}_2) = P(\mathrm{E}_1 \mid \neg\mathrm{C}_1, \mathrm{C}_2) = 0.7$, $P(\mathrm{E}_1 \mid \neg\mathrm{C}_1, \neg\mathrm{C}_2) = 0$; $P(\mathrm{E}_2 \mid \mathrm{C}_1, \mathrm{C}_2) = 0.6$, $P(\mathrm{E}_2 \mid \mathrm{C}_1, \neg\mathrm{C}_2) = P(\mathrm{E}_2 \mid \neg\mathrm{C}_1, \mathrm{C}_2) = 0.2$, $P(\mathrm{E}_2 \mid \neg\mathrm{C}_1, \neg\mathrm{C}_2) = 0$. For simplicity the priors of the causes were the same and the CPTs of the effects reflected different diagnosticities of the two effects.

Methods

Participants and design

A total of 271 participants ($N_{\mathrm{MALE}} = 101$, $M_{\mathrm{AGE}} = 32.1$ years; one participant identified as neither male nor female) were recruited from Prolific Academic (`www.prolific.ac`). All participants were native English speakers who gave informed consent and were paid £1.25 for partaking in the present study, which took on average 13.9 minutes to complete. Participants were randomly assigned to one of the 2 (algebra: full or sequential) × 3 (evidence learning: all-at-once (AaO), step-by-step from E_1 to E_2 (SbS1), or step-by-step from E_2 to E_1 (SbS2)) = 6 between-participants groups (one group with 44 participants, 3 groups with 45 participants, and 2 groups with 46 participants).

Materials

All participants were given the same cover story wherein rain (C_1) and a lawn sprinkler (C_2) (two binary and independent variables) could cause a wet lawn (E_1) and/or a wet exterior house wall (E_2) (a version of the cover story can be found in Pearl, 1988). The participants in AaO condition completed an online inference questionnaire comprising of 10 comprehension questions (2 about the priors of the causes and 8 about the CPTs) and 2 test questions (one relating to $P(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2)$ and one to $P(\mathrm{C}_2 \mid \mathrm{E}_1, \mathrm{E}_2)$). Everyone else completed the same 10 comprehension questions and 4 test questions (relating to $P(\mathrm{C}_1 \mid \mathrm{E}_\mathrm{i})$, $P(\mathrm{C}_2 \mid \mathrm{E}_\mathrm{i})$, $P(\mathrm{C}_1 \mid \mathrm{E}_\mathrm{i}, \mathrm{E}_\mathrm{j})$, and $P(\mathrm{C}_2 \mid \mathrm{E}_\mathrm{i}, \mathrm{E}_\mathrm{j})$).

Procedure

In the full algebra condition, the participants were initially presented with a causal cover story (both in a textual and a visual form) which explained the relations between variables and probabilistic information relating to the priors of both causes (priors were textually communicated as a percentage chance). They were then asked 2 priors comprehension questions. Following that, participants were told the CPTs of the two pieces of evidence (also textually communicated as a percentage chance) and subsequently asked 8 comprehension questions regarding the CPTs (in a random order). After completing the comprehension questions, participants in the AaO condition learned that both pieces of evidence occurred and were prompted to answer 2 test questions (one for each cause) presented in the same order. Participants in the SbS conditions first learned about one piece of evidence and answered 2 test questions relating to the 2 causes and then learned that the second piece of evidence occurred and asked final 2 questions. When answering the test questions participants were reminded of the priors of the causes and the CPTs of each piece of evidence, as well as their previous estimates of the two causes (in the SbS conditions).

Participants in the sequential algebra condition were initially told a cover story (both in a textual and a visual form) including only two causes and one effect. As in the full algebra condition, they were told the priors of the causes (percentage chance) and asked 2 priors comprehension questions.

In contrast to the full algebra contention, they were then told CPTs (percentage chance) regarding only one piece of evidence and completed 4 comprehension questions related to CPTs (in both the AaO and the SbS conditions). This was followed by 2 test questions relating to the probability of the causes given that one piece of evidence was observed (only in the SbS conditions). Participants then additionally learned that there is another piece of evidence potentially relevant to the probability estimates of the two causes. They learned the CPTs for the second piece of evidence and completed 4 comprehension questions followed by 2 test questions prompting them to estimate their confidence in the causes happening given the additional piece of evidence obtained. Again, participants were reminded of the priors of the causes, CPTs (but only for the current piece of evidence), and their previous estimates of the two causes (in the SbS conditions). In the AaO, after completing the first 4 comprehension questions participants were not told that the evidence obtained. Rather, they went on to learn that there is another potentially relevant piece of evidence, completed additional 4 comprehension questions, and subsequently told that both pieces of evidence obtained. After that, participants were reminded of the priors, CPTs (for the both pieces of evidence) and completed 2 test questions regarding the probabilities of the two causes.

In all conditions the test questions prompted participants to provide percentage confidence (0–100%) of C_i given one or two effects. For example, after learning that E_1 occurred, they were asked (in SbS1 condition) a diagnostic reasoning questions: "How confident are you that it **rained** overnight now that you know that the lawn is wet?" After additionally learning E_2 occurred they were asked: "How confident are you that it **rained** overnight now that you know that *both* the lawn *and* the house wall are wet?" (the full algebra condition) or "How confident are you that it **rained** overnight now that you know that the house wall is also wet?" (the sequential algebra condition). All participants provided explanations for each answer to the test questions.

Results

All the participants' responses to the test questions are plotted in Figure 3. To test the effect of the algebra and the evidence learning conditions on participants estimates on the test questions, we built a linear mixed effects model using the lme4 package (Bates, Mächler, Bolker, & Walker, 2014). The model had two fixed effects, Algebra and Evidence learning, with a random intercept for each participant (there was no random slope for participant since algebra and evidence learning conditions vary between participants). We found a main effect of Evidence learning but no main effect of Algebra (see Table 1). We also found no interaction between Algebra or Evidence learning. However, likelihood ratio tests showed that including the predictors in the model does not improve model fit compared to just having an intercept as a predictor ($\chi^2(3) = 6.11,\ p = 0.11$). That is, the data grand mean fits the data no worse than the model which includes both predictors.

Table 1: Linear mixed effect model results

A=Algebra; EL=Evidence learning

	Estimate	95% CI	t-value	p
A	-6.51	[-17.76, 4.73]	-1.13	0.26
EL	-0.53	[-1.03, -0.03]	-2.1	0.04*
A$\times$ EL	3.28	[-17.76, 4.73]	1.29	0.2

A finer grained analyses on the data within each group showed a significant difference between $P(C_1 \mid E_i)$ and $P(C_1 \mid E_i, E_j)$ in the full algebra SbS1 condition ($t(44) = -4.04, p = 0.0002$); in the full algebra SbS2 condition both between $P(C_1 \mid E_i)$ and $P(C_1 \mid E_i, E_j)$ ($t(45) = -4.87 p < 0.0001$) and $P(C_2 \mid E_i)$ and $P(C_2 \mid E_i, E_j)$ ($t(45) = -2.98, p = 0.005$); as well as in the sequential algebra SbS2 condition between $P(C_1 \mid E_i)$ and $P(C_1 \mid E_i, E_j)$ ($t(45) = -5.57, p < 0.0001$) and between $P(C_2 \mid E_i)$ and $P(C_2 \mid E_i, E_j)$ ($t(45) = -6.13, p < 0.0001$). No significant differences in the sequential SbS1 condition.

Further analyses showed that none of the $P(C_1 \mid E_i, E_j)$ and $P(C_2 \mid E_i, E_j)$ are significantly different across the levels of the evidential learning condition whereas some $P(C_2 \mid E_i)$ are: in the full algebra condition $P(C_2 \mid E_i)$ in SbS2 and SbS1 are statistically different, $t(89) = -2.09, p = 0.04$, as well as $P(C_2 \mid E_i)$ in the sequential algebra condition SbS2 and SbS1 $t(88.5) = -2.51, p = 0.014$, with those in SbS1 having higher means. Combining these results from those above regarding participants estimates withing each group suggests that (i) people are sensitive to the different orders the pieces of evidence of different diagonsticity were presented and (ii) that their estimates go against both the full CBN and the 'split' CBNs (qualitative) predictions since the differences $P(C_1 \mid E_i, E_j) - P(C_1 \mid E_i)$ and $P(C_2 \mid E_i, E_j) - P(C_2 \mid E_i)$ are larger in SbS2 condition than in SbS1 condition whereas the full CBN and the 'split' CBN predict exactly the opposite (see Figure 3).

A closer look at the data distributions in Figure 3 reveals the driving force of the results; namely, that participants' responses are highly clustered. Three clustering points ('20%', '60%', and '70%') seem to correspond to the probability values one finds in the CPTs for the effects. One clustering point corresponds to the priors of the causes ('15%'). The largest clustering point seems to be around the '50%' mark. Table 3 shows a frequency of responses around ($\pm 2\%$) the clustering points. The data captured in Table 3 amounts to $\approx 67\%$ of all data.

Finally, to assess the fit of each model to the data, we calculated mean squared errors (MSEs) for each model across the two algebra conditions.[2] Given the above-mentioned cluster-

[2]Note that the 'split' CBN does not have a unique prediction for AaO condition (see Figure 3). In calculating the MSE for that model we included the prediction that has the lower MSE.

ing around particularly the '50%' mark, we additionally calculated the MSEs for a simple model that included the correct priors (same as in both the full CBN and the 'split' CBN modeling), but has 50% as a response to all test questions. The results are presented in Table 2.

Table 2: MSEs for the full CBN, 'split' CBN, and '50%' model in the full and sequential algebra conditions

	Full algebra	Sequential algebra
Full CBN	621.18	536.94
'Split' CBN	778.93	701.97
'50%' model	573.73	496.65

The best fitting model of the three was the simple '50%' model, further confirming the clustering effect around the '50%' mark and the results of the linear mixed effect model. The full CBN model was a better fit than the 'split' CBN model of both the full algebra condition data and sequential algebra condition data. All three models fit better the sequential algebra condition data than the full algebra condition data suggesting a difference between the two conditions. However, according to the linear mixed effect model that difference is not statistically significant.

Discussion

The general goal of the paper was twofold. First, we sought to explore new avenues in sequential diagnostic reasoning by investigating peoples causal judgements with multiple independent causes and multiple pieces of evidence of different diagnosticity. To this effect we found that people are sensitive to the order of presentation of the different pieces of evidence. However, although there was a trend in increasing the probabilities of the causes after finding out that the second piece of evidence obtained (in accordance with both the full and the 'split' CBN model), the (qualitative) predictions of both models regarding the amount of increase in each order go against the participants' mean estimates.

Second, we introduced the issue of the novel variables in sequential reasoning and the practical challenge it presents. In the first empirical study on this issue, we found that people update almost identically when they are presented with the full algebra and when the algebra is expanded sequentially. In principle, this lack of difference could mean either that people are very good at this expansion, or that they inappropriately treat the full model in a sequential, local fashion. The MSE analysis showed that the full CBN model is a better fit than the 'split' CBN model across board supporting the latter option. However, the significant clustering in our data and the fact that the '50%' model fitted the data better then either the full or the 'split' CBN model suggest that participants employed different strategies in answering our test questions. Some of these seem indicative of well-established errors in human causal/probabilistic reasoning such as 'the inversion fallacy' where people confuse $P(\mathrm{A} \mid \neg \mathrm{B})$ with $P(\mathrm{B} \mid \mathrm{A})$ (Nance & Morris, 2002) or more recently identified errors such as 'the zero-sum fallacy' where people treat evidence as a zero-sum game in which alternative independent hypotheses compete for evidential support which may lead to splitting the probability space between the hypotheses (Pilditch, Fenton, & Lagnado, 2019). The prevalence of such errors may mask other differences that would emerge across those contexts. In particular, systematic differences may yet be found in more naturalistic scenarios where there are no explicit numbers for people to hold on to. This should be pursued in future work.

Appendix A

We adopt the following convention: $\overline{a} = 1 - a$.

Theorem 1. *$P_1(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2) = P_2(\mathrm{C}_1^* \mid \mathrm{E}_2)$ if and only if (i) $\alpha_1\,\delta_1 = \beta_1\,\gamma_1$ or (ii) $\alpha_2 = \beta_2$ and $\gamma_2 = \delta_2$.*

Proof.

$$
\begin{aligned}
P_1(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2) &= \frac{P_1(\mathrm{C}_1, \mathrm{E}_1, \mathrm{E}_2)}{P_1(\mathrm{E}_1, \mathrm{E}_2)} \\
&= \frac{P_1(\mathrm{C}_1) \sum_{C_2} P_1(\mathrm{E}_1 \mid \mathrm{C}_1, C_2)\, P_1(\mathrm{E}_2 \mid \mathrm{C}_1, C_2)\, P_1(C_2)}{\sum_{C_1, C_2} P_1(\mathrm{E}_1 \mid C_1, C_2)\, P_1(\mathrm{E}_2 \mid C_1, C_2)\, P_1(C_1)\, P_1(C_2)} \\
&= \frac{A_1}{A_1 + A_2} \\
A_1 &:= c_1\,(\alpha_2\,\alpha_1\,c_2 + \beta_2\,\beta_1\,\overline{c_2}) \\
A_2 &:= \overline{c_1}\,(\gamma_2\,\gamma_1\,c_2 + \delta_2\,\delta_1\,\overline{c_2})
\end{aligned}
$$

$$
\begin{aligned}
P_2(\mathrm{C}_1^* \mid \mathrm{E}_2) &= \frac{P_2(\mathrm{C}_1^*, \mathrm{E}_2)}{P_2(\mathrm{E}_2)} \\
&= \frac{P_2(\mathrm{C}_1^*) \sum_{C_2} P_2(\mathrm{E}_2 \mid \mathrm{C}_1^*, C_2^*)\, P_1(C_2^*)}{\sum_{C_1^*, C_2^*} P_2(\mathrm{E}_2 \mid \mathrm{C}_1^*, C_2^*)\, P_2(\mathrm{C}_1^*) P_2(C_2^*)} \\
&= \frac{P_1(\mathrm{C}_1 \mid \mathrm{E}_1) \sum_{C_2} P_1(\mathrm{E}_2 \mid \mathrm{C}_1, C_2)\, P_1(C_2 \mid \mathrm{E}_1)}{\sum_{C_1, C_2} P_1(\mathrm{E}_2 \mid C_1, C_2)\, P_1(C_1 \mid \mathrm{E}_1) P_1(C_2 \mid \mathrm{E}_1)} \\
&= \frac{B_1}{B_1 + B_2}
\end{aligned}
$$

$$
\begin{aligned}
B_1 &:= c_1\,(\alpha_1\,c_2 + \beta_1\,\overline{c_2}) \cdot \\
&\quad \cdot [\alpha_2\,c_2\,(\alpha_1\,c_1 + \gamma_1\,\overline{c_1}) + \beta_2\,\overline{c_2}\,(\beta_1\,c_1 + \delta_1\,\overline{c_1})] \\
B_2 &:= \overline{c_1}\,(\gamma_1\,c_2 + \delta_1\,\overline{c_2}) \cdot \\
&\quad \cdot [\gamma_2\,c_2\,(\alpha_1\,c_1 + \gamma_1\,\overline{c_1}) + \delta_2\,\overline{c_2}\,(\beta_1\,c_1 + \delta_1\,\overline{c_1})]
\end{aligned}
$$

Let $\Delta_1 := P_1(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2) - P_2(\mathrm{C}_1^* \mid \mathrm{E}_2)$. Then

$$
\begin{aligned}
\Delta_1 &= \frac{A_1\,(B_1 + B_2) - B_1\,(A_1 + A_2)}{(A_1 + A_2)\,(B_1 + B_2)} \\
&= \frac{A_1\,B_1 + A_1\,B_2 - A_1\,B_1 - A_2\,B_1}{P_1(\mathrm{E}_1, \mathrm{E}_2)\,P_2(\mathrm{E}_2)} = \frac{A_1\,B_2 - A_2\,B_1}{P_1(\mathrm{E}_1, \mathrm{E}_2)\,P_2(\mathrm{E}_2)} \\
&= \frac{c_1\,\overline{c_1}\,c_2\,\overline{c_2}\,(\alpha_1\,\delta_1 - \beta_1\,\gamma_1)\,[G_1 + G_2]}{P_1(\mathrm{E}_1, \mathrm{E}_2)\,P_2(\mathrm{E}_2)}. \\
G_1 &:= (\gamma_2 - \delta_2)\,c_1\,(\alpha_2\,\alpha_1\,c_2 + \beta_2\,\beta_1\,\overline{c_2}) \\
G_2 &:= (\alpha_2 - \beta_2)\,\overline{c_1}\,(\gamma_2\,\gamma_1\,c_2 + \delta_2\,\delta_1\,\overline{c_2})
\end{aligned}
$$

■

Using a similar proof strategy one can show that: (a) $P_1(\mathrm{C}_2 \mid \mathrm{E}_1, \mathrm{E}_2) = P_2(\mathrm{C}_2^* \mid \mathrm{E}_2)$ if and only if $\alpha_1\,\delta_1 = \beta_1\,\gamma_1$ or (ii) $\alpha_2 = \gamma_2$ and $\beta_2 = \delta_2$; (b) $P_1(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2) = P_3(\mathrm{C}_1^* \mid \mathrm{E}_1)$ if and only if (i) $\alpha_2\,\delta_2 = \beta_2\,\gamma_2$ or (ii) $\alpha_1 = \beta_1$ and $\gamma_1 = \delta_1$; and (c) $P_1(\mathrm{C}_2 \mid \mathrm{E}_1, \mathrm{E}_2) = P_3(\mathrm{C}_2^* \mid \mathrm{E}_1)$ if and only if (i) $\alpha_2\,\delta_2 = \beta_2\,\gamma_2$ or (ii) $\alpha_1 = \gamma_1$ and $\beta_1 = \delta_1$ (proofs omitted).

It follows then that $P_1(\mathrm{C}_1 \mid \mathrm{E}_1, \mathrm{E}_2) = P_2(\mathrm{C}_1^* \mid \mathrm{E}_2) = \mathrm{P}_3(\mathrm{C}_1^* \mid \mathrm{E}_1)$ if (1) $\alpha_1\,\delta_1 = \beta_1\,\gamma_1$ and $\alpha_2\,\delta_2 = \beta_2\,\gamma_2$, or (2) $\alpha_1 =$

β_1 and $\gamma_1 = \delta_1$, or (3) $\alpha_2 = \beta_2$ and $\gamma_2 = \delta_2$. Similarly, $P_1(\mathrm{C}_2 \mid \mathrm{E}_1,\mathrm{E}_2) = P_2(\mathrm{C}_2^* \mid \mathrm{E}_2) = \mathrm{P}_3(\mathrm{C}_2^* \mid \mathrm{E}_1)$ if (1) $\alpha_1\delta_1 = \beta_1\gamma_1$ and $\alpha_2\delta_2 = \beta_2\gamma_2$, or (2) $\alpha_1 = \gamma_1$ and $\beta_1 = \delta_1$, or (3) $\alpha_2 = \gamma_2$ and $\beta_2 = \delta_2$. Therefore, the order is not important and one can decompose a full CBN in smaller ones while preserving the same probability distributions if (1) $\alpha_1\delta_1 = \beta_1\gamma_1$ and $\alpha_2\delta_2 = \beta_2\gamma_2$; or (2) $\alpha_1 = \beta_1$, $\gamma_1 = \delta_1$, $\alpha_2 = \gamma_2$, and $\beta_2 = \delta_2$; or (3) $\alpha_2 = \beta_2$, $\gamma_2 = \delta_2$, $\alpha_1 = \gamma_1$, and $\beta_1 = \delta_1$; or (4) $\alpha_1 = \beta_1 = \gamma_1 = \delta_1$; or (5) $\alpha_2 = \beta_2 = \gamma_2 = \delta_2$. (4) and (5) make E_1 and E_2 respectively fully undiagnostic with respect to C_1 and C_2, which violates the faithfulness condition (see Neapolitan, 2003). (1) implies that C_1 and C_2 are conditionally independent given E_1 and that they are also conditionally independent given E_2, that is, learning E_1 makes C_1 and C_2 independent and learning E_1 makes C_1 and C_2 independent. (2) and (3) both entail (1) and are more specific versions of (1).

Appendix B

Here we show that there are no order effects when the causes are mutually exclusive and exhaustive, i.e. when $P(C_1, C_2) = 0$ and $P(C_1) + P(C_2) = 1$. We model mutually exclusive and exhaustive causes with one node, C, that has two values: C_1 and C_2.

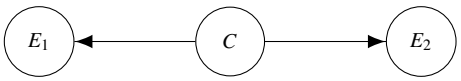

Figure 4: CBN with mutually exclusive and exhaustive causes

$$\begin{aligned} P_4(C = \mathrm{C}_1) = c \quad &, \quad P_4(C = \mathrm{C}_2) = \overline{c} \\ P_4(\mathrm{E}_1 \mid \mathrm{C}_1) = \alpha_1 \quad &, \quad P_4(\mathrm{E}_1 \mid \mathrm{C}_2) = \beta_1 \\ P_4(\mathrm{E}_2 \mid \mathrm{C}_1) = \alpha_2 \quad &, \quad P_4(\mathrm{E}_2 \mid \mathrm{C}_2) = \beta_2 \end{aligned} \tag{3}$$

Splitting the CBN from Figure 4 we get two CBNs:

$$P_5(C = \mathrm{C}_1) = c \quad , \quad P_5(C = \mathrm{C}_2) = \overline{c}$$

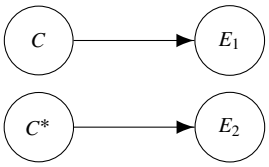

Figure 5: 'Split' CBN from E_1 to E_2

$$\begin{aligned} P_5(C^* = \mathrm{C}_1^*) = P_4(\mathrm{C}_1 \mid \mathrm{E}_1) \quad &, \quad P_5(C^* = \mathrm{C}_2^*) = P_4(\mathrm{C}_2 \mid \mathrm{E}_1) \\ P_5(\mathrm{E}_1 \mid \mathrm{C}_1) = \alpha_1 \quad &, \quad P_5(\mathrm{E}_1 \mid \mathrm{C}_2) = \beta_1 \\ P_5(\mathrm{E}_2 \mid \mathrm{C}_1^*) = \alpha_2 \quad &, \quad P_5(\mathrm{E}_2 \mid \mathrm{C}_2^*) = \beta_2 \end{aligned} \tag{4}$$

Theorem 2. *$P_4(\mathrm{C}_1 \mid \mathrm{E}_1,\mathrm{E}_2) = P_5(\mathrm{C}_1^* \mid \mathrm{E}_2)$ when $P_{4,5}(C_1^{(*)}, C_2^{(*)}) = 0$ and $P_{4,5}(C_1^{(*)}) + P_{4,5}(C_2^{(*)}) = 1$.*

Proof.

$$\begin{aligned} P_4(\mathrm{C}_1 \mid \mathrm{E}_1,\mathrm{E}_2) &= \frac{P_4(\mathrm{C}_1)\,P_4(\mathrm{E}_1 \mid \mathrm{C}_1)\,P_4(\mathrm{E}_2 \mid \mathrm{C}_1)}{\sum_C P_4(C)\,P_4(\mathrm{E}_1 \mid C)\,P_4(\mathrm{E}_2 \mid C)} \\ &= \frac{c\,\alpha_1\,\alpha_2}{c\,\alpha_1\,\alpha_2 + \overline{c}\,\beta_1\,\beta_2} \\ P_5(\mathrm{C}_1^* \mid \mathrm{E}_2) &= \frac{P_5(\mathrm{C}_1^*)\,P_5(\mathrm{E}_2 \mid \mathrm{C}_1^*)}{\sum_{C^*} P_5(C^*)\,P_5(\mathrm{E}_2 \mid C^*)} \\ &= \frac{P_4(\mathrm{C} \mid \mathrm{E}_1)\,P_4(\mathrm{E}_2 \mid \mathrm{C})}{\sum_C P_4(C \mid \mathrm{E}_1)\,P_4(\mathrm{E}_2 \mid C)} \\ &= \frac{J\,\alpha_2}{J\,\alpha_2 + (1-J)\,\beta_2} \\ J &:= \frac{c\,\alpha_1}{c\,\alpha_1 + \overline{c}\,\beta_1} \end{aligned}$$

Let $\Delta_2 := P_4(\mathrm{C}_1 \mid \mathrm{E}_1,\mathrm{E}_2) - P_5(\mathrm{C}_1^* \mid \mathrm{E}_2)$. Then

$$\Delta_2 = \frac{c\,\alpha_1\,\alpha_2\,\beta_2\left[1 - \frac{c\,\alpha_1 + \overline{c}\,\beta_1}{c\,\alpha_1 + \overline{c}\,\beta_1}\right]}{(c\,\alpha_1\,\alpha_2 + \overline{c}\,\beta_1\,\beta_2)(J\,\alpha_2 + (1-J)\,\beta_2)} = 0$$

■

Since $P_4(\mathrm{C}_2 \mid \mathrm{E}_1,\mathrm{E}_2) = 1 - P_4(\mathrm{C}_1 \mid \mathrm{E}_1,\mathrm{E}_2)$ and $P_5(\mathrm{C}_2^* \mid \mathrm{E}_2) = 1 - \mathrm{P}_5(\mathrm{C}_1^* \mid \mathrm{E}_2)$, then given Theorem 2 it also true that $P_4(\mathrm{C}_2 \mid \mathrm{E}_1,\mathrm{E}_2) = P_5(\mathrm{C}_2^* \mid \mathrm{E}_2)$. Similarly we get that $P_4(\mathrm{C}_1 \mid \mathrm{E}_1,\mathrm{E}_2) - P_6(\mathrm{C}_1^* \mid \mathrm{E}_1) = 0$ and $P_4(\mathrm{C}_2 \mid \mathrm{E}_1,\mathrm{E}_2) - P_6(\mathrm{C}_2^* \mid \mathrm{E}_1) = 0$ (proofs omitted).

Incremental understanding of conjunctive generic sentences

Michael Henry Tessler, Karen Gu, and Roger Levy
{tessler, karengu, rplevy}@mit.edu
Department of Brain and Cognitive Sciences, MIT
Cambridge, MA 02139 USA

Abstract

Generic statements convey generalizations about categories, but how generic predications combine is unclear. "Elephants live in Africa and Asia" does not mean that individual elephants live on both continents. In addition, such conjunctive generics pose interesting questions for theories of incremental processing because the meaning of the sentence can change part-way through: "Elephants live in Africa" would imply most or all do, but "Africa and Asia" implies some live in each. We extend a recently proposed computational model of generic language understanding with an incremental processing mechanism that can begin to interpret an utterance before a speaker has finished their sentence. This model makes novel predictions about partial interpretations of conjunctive generic sentences, which we test in two behavioral experiments. The results support a strong view of incrementality, wherein listeners continuously update their beliefs based on expectations about where a speaker will go next with their utterance.

Keywords: semantics; pragmatics; incremental processing; generics; psycholinguistics

Introduction

Much of what we come to learn about the world comes not from direct experience but from knowledge conveyed to us from others, often in the form of linguistic utterances. "Elephants eat 300 pounds of a food in a day" succinctly conveys information extending beyond any particular moment in time or space: It could apply to any elephant, on any day of the week. Utterances that communicate generalizations are called *generic* utterances (Carlson, 1977; Carlson & Pelletier, 1995), and they are the foremost case study of rich, abstract knowledge conveyed in simple utterances (Gelman, 2009).

Generics are rife with philosophical puzzles that make it difficult to develop a unified, formal theory of their meaning (for useful reviews: Carlson & Pelletier, 1995; Nickel, 2016). One largely understudied puzzle concerns how generic predications combine. Consider the null hypothesis that generics convey information about the percentage of the category with the property—the *prevalence*—in a way analogous to how majority quantifiers (e.g., *most*, *all*) work (e.g., "Most elephants eat 300 pounds of food in day"). How can such an account treat a generic involving a conjunctive predication like "Elephants live in Africa and Asia"? No elephant actually lives on both continents; instead, the sentence should be understood as *(generically) elephants live in Africa and (generically) elephants live in Asia*, but this is impossible if each individual generic sentence means that the majority holds the property (i.e., it is impossible for more than half of elephants to live in Africa and more than half of elephants to live in Asia; Nickel, 2008). The prevalence implied by a generic involving a conjunctive, mutually-exclusive predicate seems more lax than if only one of conjuncts were mentioned: If a speaker said "Elephants live in Africa", you might think they all do.

The puzzle of understanding conjunctive generic sentences deepens when one considers that linguistic input is processed incrementally (e.g., Altmann & Kamide, 1999): Listeners ubiquitously form expectations about the intended meaning of a sentence before the speaker finishes it (e.g., Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). For conjunctive generics about mutually exclusive properties, strongly incremental language understanding might produce non-monotonic belief updates: after the sentence prefix "Elephants live in Africa…", a comprehender might infer a higher prevalence than after hearing the sentence completion "…and Asia". If such non-monotonic updates occur, what types of linguistic input trigger them?

In this paper we show that a recently proposed model of generic language can accommodate these complex inferential patterns and we empirically test two predictions about generic interpretation that address these puzzles. The model of Tessler and Goodman (2019) treats generics as a kind of vague quantifier: interpretation of a generic depends on prior beliefs about properties. First, we show how when properties are likely to be mutually incompatible (as in *live in Africa and Asia*), listeners infer lower prevalences of each property following a conjunctive generic sentence than when the properties are compatible. Second, we show how the above model, when integrated with expectation-based probabilistic theories of syntactic processing (Hale, 2001; Levy, 2008), predicts that comprehenders update their beliefs about property prevalence not just when encountering a second, conjoined property, but immediately upon encountering evidence that a second, conjoined property is likely to be forthcoming. We test these predictions in two behavioral experiments that probe listeners' understanding of conjunctive generic sentences at different points mid-sentence, analogous to gating paradigms in psycholinguistics (Grosjean, 1980). Our empirical data confirm both predictions, suggesting that generic language interpretation interacts jointly with world knowledge and strongly incremental syntactic processing according to principles of probabilistic inference under uncertainty.

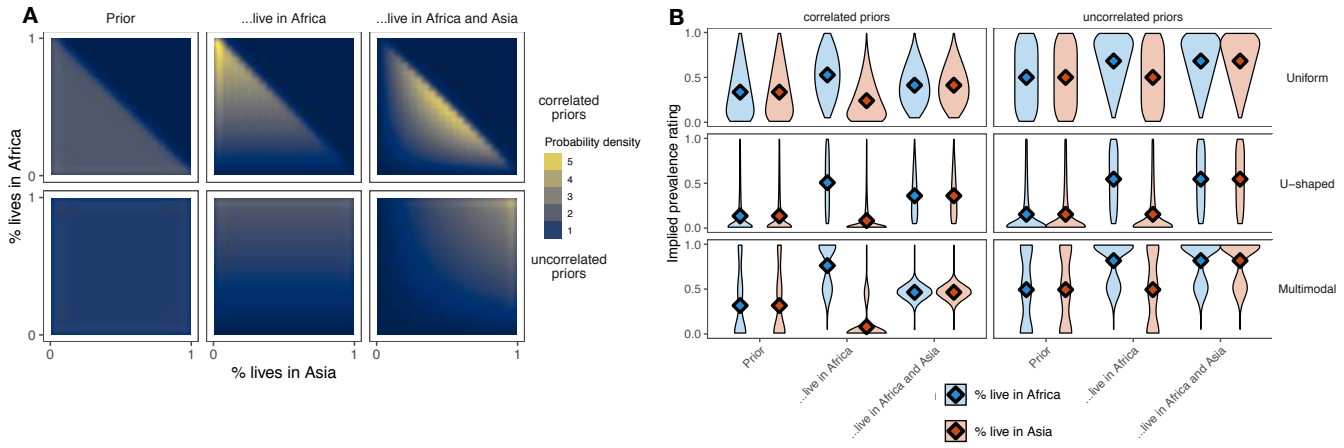

Figure 1: Model's sequential interpretation of "Elephants live in Africa... and Asia." A: Correlated priors reflected in the joint probability distribution over two features result in a mutual exclusivity inference. When the model hears only "... live in Africa", it believes that probably all live in Africa (middle facet); when it hears they live in Asia as well, the model non-monotonically updates its beliefs about how many live in Africa. B: The mutual exclusivity inference holds for priors of different shapes and never holds if the prior knowledge about the two features is uncorrelated. Points show means of distributions. U-shaped priors were Beta(0.1, 1); multimodal priors were an equal mixture of a Beta(1, 100) and a Beta(25, 1). Correlated priors were created by adding an additional factor that decreased the probability of a prevalence-level if the sum of the prevalence of the two features exceeded 100%.

Computational Model

We extend a model for interpreting generics to incorporate an incremental processing mechanism that allows a listener to understand partial utterances. The original model of Tessler and Goodman (2019) interprets a generic utterance predicating a property of a category ("Elephants eat 300 pounds of food in a day") as meaning that the prevalence (or probability) x of the property given the category—P(eats 300 lb. of food in a day| is an elephant)—is greater than an *a priori* uncertain threshold θ. The literal meaning of the generic—an uncertain threshold function, with uniform uncertainty over the threshold $P(\theta)$—combines with a listener's prior knowledge about the prevalence of the feature $P(x)$ within a relevant set of alternative categories (e.g., other animals) to compute a posterior distribution over prevalence x:

$$P(x \mid u) = \int_{\theta} P(x, \theta \mid u) d\theta \propto P(x) \cdot P(\theta) \cdot \delta_{[\![u]\!](x,\theta)} \quad (1)$$

where $\delta_{[\![u]\!](x,\theta)}$ is the Kronecker delta function assigning a value of 1 for utterances that are literally true (in the case of a generic: where $x > \theta$) and 0 for utterances that are false.

To interpret a generic with a conjunctive predicate such as "Elephants live in Africa and Asia", we assume the semantic representation contains a conjunction of two generic statements: $[Gen(\text{elephant})(\text{live\_in\_Africa})] \wedge [Gen(\text{elephant})(\text{live\_in\_Asia})]$, where the *Gen* operator acts according to the belief-updating rule of Eq. 1 (see Nickel (2008) for supporting arguments of this semantic parse). A listener starts with a joint prior over the prevalence of the two properties (we denote variables associated with *living in Africa* with subscript r and *Asia* with s): $P(\mathbf{x}) = P(x_r, x_s)$, which is incrementally updated with each successive generic. The model can then interpret multiple generics in succession, using the posterior distribution over prevalence $P(\mathbf{x} \mid u)$ (Eq. 1) as the prior for the next utterance.

$$P(\mathbf{x} \mid u_r, u_s) \propto \int_{\theta_s} \int_{\theta_r} P(\mathbf{x}, \theta \mid u_r) \cdot \delta_{[\![u_s]\!](x_s,\theta_s)} d\theta_r d\theta_s \quad (2)$$

where $P(\mathbf{x}, \theta \mid u_r)$ is the posterior that results from hearing "Elephants live in Africa" given by Eq. 1.

The predictions for a sequential understanding of "Elephants live in Africa and Asia" are shown in Fig. 1. Upon hearing the first part of the utterance, the model believes that almost all elephants live in Africa (simulations assuming a uniform prior shown in Fig. 1A). What happens next depends upon the correlational structure of the prevalence prior: If the listener has prior knowledge suggesting the properties (living in Africa, living in Asia) are mutually exclusive (Fig. 1A top), they interpret the next part of the utterance ("...and Asia") as indicating that some (perhaps half) of elephants live in Africa and other ones live in Asia. Without this correlation in the prior, the model ends up believing that most or all elephants live both in Africa and in Asia (Fig. 1A bottom). These inferences are robust to a variety of different prevalence prior distributions, so long as the prior has the necessary correlational structure (Fig. 1B shows predictions assuming a uniform, U-shape Beta, and mixture-of-Beta distributions).

When processing a conjunctive phrase, listeners may form expectations about the complete utterance even before the sentence is over. For example, when a speaker reaches the word *Africa* in "Elephants live in *Africa*", she has many syntactically distinct options available to her to complete the sen-

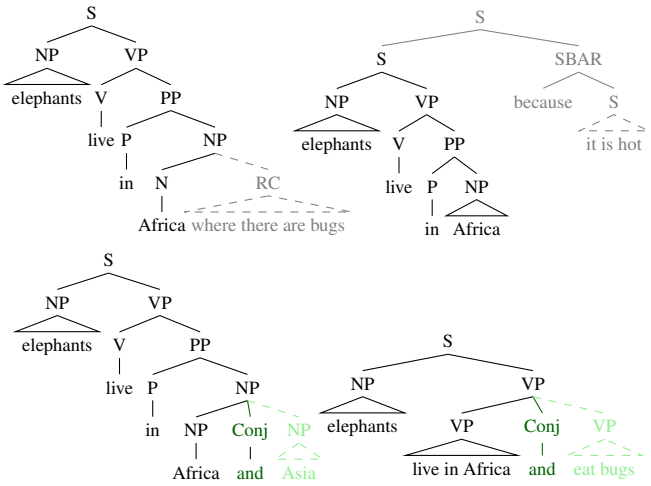

Figure 2: Incremental parse trees and syntactic expectations for upcoming conjunct properties in generic predication. The string prefix "Elephants live in Africa…" is compatible with a variety of continuations, including the four listed above. The next word, "and", rules out the continuations in the top row (depicted in gray) and sharpens expectations around a conjunct at potentially different structural levels (light green). Probabilistic renormalization implies that an upcoming conjunct mutually exclusive with the first conjunct becomes more likely when "and" is encountered, driving the strong incremental predictions depicted in Fig. 3.

tence (Fig. 2 shows four possibilities). One such possibility is that she continues with a NP-coordination that includes a mutually exclusive property (e.g., *and Asia*; bottom-left tree). When the listener encounters the word *and* in "Elephants live in Africa *and*", he knows he is entering into a coordination and the relative probability of a forthcoming mutually exclusive property increases. Such a continuation would yield a different inference about the prevalence of elephants in Africa than a continuation with a non-mutually exclusive property (e.g., with a verb phase such as "and eat bugs").[1] If listeners parse and interpret utterances incrementally at the level of individual words, then we would expect their inferences about the prevalence of elephants in Africa to represent a mixture of the inferences derived from different possible continuations, which can be represented by conditional probabilities of the full utterance u' given the sentence fragment heard f:

$$P(x \mid f) = \sum_{u'} P(x \mid u') P(u' \mid f) \tag{3}$$

If, however, listeners do not derive incremental interpretations at each moment, but instead wait for meaningful pieces of an utterance (e.g., content words like *Asia*) to compute interpretations, then we would not expect such an intermediate degree of interpretation: "Elephants live in Africa and…" should mean the same thing as "Elephants live in Africa…" (Fig. 3). We test this prediction in Expt. 2 using a gating paradigm in the spirit of Grosjean (1980).

[1] For illustrative purposes, we assume a correlation between NP vs. VP coordination and mutually exclusive vs. non-mutually exclusive predicates. Of course, it is possible to continue with a verb phrase about a mutually exclusive property such as "…live in Africa and live in Asia" as well as continue with a noun phrase about a non-mutually exclusive property (e.g., "…eat figs and nuts"). The crucial fact is that the probability of a forthcoming mutually-exclusive property increases when the comprehender encounters the word *and*.

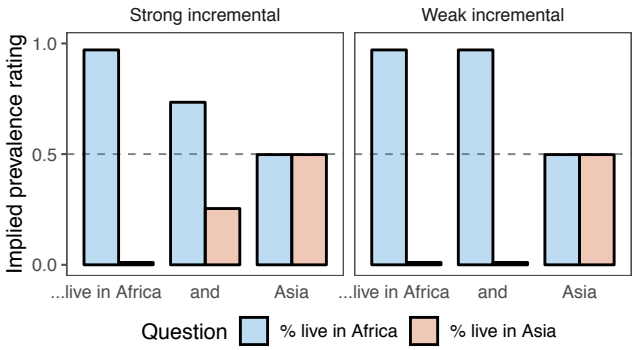

Figure 3: A model that incorporates syntactic expectations at the level of individual words (*strong incremental*) predicts intermediate mutual-exclusivity inferences part-way through the conjunction (at "and"), whereas a model that waits for content-words (*weak incremental*) does not show a difference in expected prevalence at the word "and."

Experiments

We design two experiments to test the mutual exclusivity (ME) and incremental predictions. Expt. 1 tests the ME prediction that "Elephants live in Africa and Asia" means roughly that half live in Africa and half live in Asia; this experiment also serves to validate the gating procedure we employ in the second experiment. Expt. 2 is a pre-registered study that uses the gating paradigm to test the fine-grained incremental predictions of the model. The experiments and a full list of materials can be viewed at `tinyurl.com/elephants-cogsci`.

Experiment 1: Mutual exclusivity inference

Participants We recruited 27 participants through Amazon's Mechanical Turk. Participants were restricted to those with verified U.S. IP addresses and at least a 95% work approval rating. The study took about 10 minutes and participants were compensated $1.50.

Materials Participants read a storybook with chapters about creatures on a faraway planet. Each chapter contained a short paragraph presented across 2–4 screens, with a button to "turn the page" (Fig. 4A). A chapter introduced one or a few novel categories (e.g., *wugs*) and semi-novel properties (e.g., *live on the continent of Caro*). Critical trial chapters ended with a generic sentence about conjunctive properties, which differed only in whether the second property was mutually exclusive with the first (*conjunct type*): "Glippets live on the continent of Caro and *on the continent of Este* (ME) /

See main text for full description of conditions.

enjoy the sunshine there (not ME: NME)."

The earlier content of the chapter supported the mutually exclusive interpretation of the properties when the properties were not *ipso facto* mutually exclusive. For example:

> Krens are a tribe of the aliens that live on the continent of Benli. Animals like stups, four-legged creatures with large antlers, are a resource for the Krens. Stups roam all over the windy highlands of Benli, far from the oceans. Krens are stup-herders and (*fishermen / incorporate stups into their religion*).

Conjunct type (ME vs. NME) was manipulated within participants and items. There were 14 filler chapters with content similar to the critical chapters but using explicit quantifiers (*most*, *all*, *none*) to describe the properties of categories.

Procedure Participants were told they would be reading a storybook with a question in each chapter. Questions were all of the same type, an *implied prevalence* question (Gelman, Star, & Flukes, 2002; Cimpian, Brandone, & Gelman, 2010): "What percentage of Ks do you think F?", where K represents a category and F a feature. Responses were recorded using a slider with endpoints labeled 0% and 100%, with the exact value selected appearing above the slider. Participants were familiarized with the response variable in a practice trial, where they were asked to report how many *dogs bark*, *birds are male*, *cats get cancer*, and *lions lay eggs*. These questions encouraged participants to use the full range of the response scale as well as served as a comprehension check.

In each critical chapter of the storybook, two questions appeared either at the end of the chapter (*Uninterrupted* conditions) or interrupting the chapter right before the final page (*Interrupted* conditions; Fig. 4). In the Interrupted conditions, the question came in the middle of a conjunctive generic sentence, but before the conjunction so the reader was unaware the sentence would continue with a conjunction. The questions asked about the mentioned property (e.g., *Africa*) and either a mutually exclusive property (*Asia*; *ME* conditions) or a nonmutually exclusive property (e.g., *eats bugs*; *NME* conditions); the chapter then concluded with a conjunction about an unmentioned, nonmutually exclusive property (Fig. 4B), so as to not give the impression that the participant was being tricked by being asked about a property that we would eventually reveal. In the critical trials, the second question was asked about the second property mentioned (ME vs. NME). Filler trials asked about two properties described in the chapter using quantifiers (i.e., *all*, *most*, or *none*). The order in which the two questions appeared on the screen was randomized on each trial.

Each participant read a total of 21 chapters, which included 8 ME conjunctions, 4 NME conjunctions, and 6 quantifier fillers; for each of these categories, equal numbers of interrupted and uninterrupted were used. The experiment began with a chapter with no questions and 2 filler trials; the remaining trials were presented in a random order such that no two critical trials were presented back-to-back. Subjectively, the task is very difficult as participants learn about many different animals with lots of new names; in practice, however, participants only need to recall information from the previously en-

countered sentence to answer the trial questions. Following the storybook, participants completed a memory check where they had to select all the facts they had learned from a list of 10 (5 real, 5 distractor); in addition, participants were asked to explain what the experiment was about in broad terms.

Results 11 participants were excluded for failing to respond accurately to all of the practice trials or failing to respond accurately to at least 7 of the 10 memory check prompts (same exclusion criteria for Expt. 2). We describe the results using the running example of "Elephants live in Africa and Asia", but the experimental stimuli used novel categories and relatively novel properties.

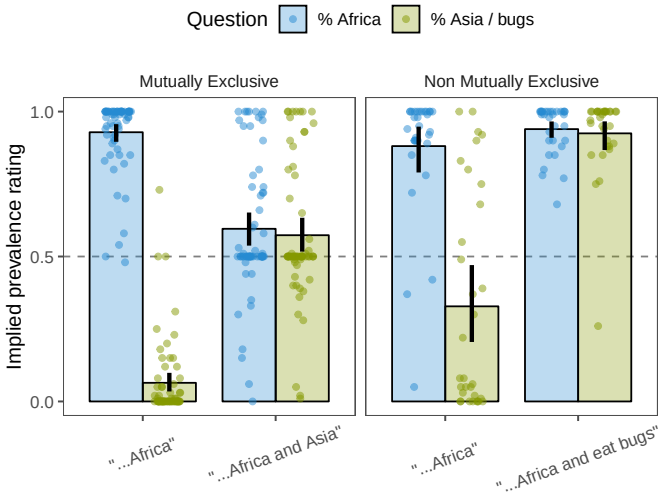

Figure 5: Experiment 1 results. Participants rate prevalence for mentioned property (% live in Africa) and either the mutually exclusive property (left facet) or non-mutually exclusive property (right facet), mid sentence ("Africa") or after the sentence finishes ("Africa and X"). Error-bars denote bootstrapped 95% confidence intervals.

The results are visually apparent in Fig. 5. Reading only "Elephants live in Africa..." led listeners to believe, on average, that all elephants lived in Africa and that none lived in Asia, whereas if the sentence finished "...and Asia", listeners inferred that roughly half live in Africa and half live in Asia. This inference is not categorical, however; there are a number of responses to ME conjunctive generics wherein participants infer that all or almost all have both properties (recall that many of our items are unfamiliar properties). A different pattern was observed for the NME properties, where hearing about the second property ("eat bugs") only increased participants' degree of belief in each property applying. Further, when answering about unmentioned properties, participants rated the prevalence of ME properties close to 0% whereas NME properties were rated as somewhat prevalent (green bars, "Africa"). The results replicate intuitions about how "Elephants live in Africa" should be interpreted in a context where the sentence is interrupted. The comparison with the non-mutually exclusive condition shows that the results cannot be attributed to the very act of being asked about two properties mentioned in a conjunctive generic sentence.

Experiment 2: Strong incrementality

In Expt. 1, we demonstrated that the mutually exclusive inference effects can be measured using a gating paradigm wherein participants are queried for their beliefs part-way through a sentence. Here, we exploit this paradigm to test the strong incremental processing predictions of the model, where syntactic expectations can modulate the interpretations of generic sentences in a fine-grained manner. Sample size, participant exclusion criteria, and analyses for this experiment were pre-registered on OSF `osf.io/pjt9c`.

Participants We recruited 108 participants through Amazon's Mechanical Turk. Participants were restricted to those with verified U.S. IP addresses and at least a 95% work approval rating. The study took about 10 minutes and participants were compensated $1.50.

Materials and procedure The materials and procedure followed those of Expt. 1 with the following exceptions. We modified the critical conjunctive generics to primarily involve the conjunction of two noun phrases (e.g., *ascribe to Caboo-ism and Daithism*) in order to strength the correlation between the NP-conjunction and mutual exclusivity.[2] The fillers were modified to introduce page breaks immediately before and immediately after conjunctions ("and") in order to raise participants' expectations that a sentence might be broken at a conjunction. We used additional examples of the Uninterrupted ME condition of Expt. 1 ("live in Africa and Asia.") as fillers to raise participants' expectations about ME continuations. Half of the filler trials had page breaks immediately before the "and" and half immediately after.

On critical trials, questions always interrupted the chapter right before the last page. On the question screen, the page number of the penultimate page remained on the screen to provide an additional cue that the chapter was not complete (Fig. 4A). There were three conditions corresponding to the point in the sentence at which the page break and prevalence questions occurred: "Elephants live in Africa__ and__ Asia__" (where __ denotes the page-break). In the two conditions where participants did not see the full conjunctive property before the question (INT A and A&), the sentence continued with a non-mutually exclusive property (e.g., *eat bugs*).

Finally, we changed the question about the second property (% live in Asia) to ask about "some other X", where X was the kind of property that was mentioned in the first conjunct (e.g., *live on some other continent*). This change was introduced to raise the plausibility that a second, ME property was possible while not naming one explicitly, which would be pragmatically odd given that the property is unmentioned in the INT A and A& conditions. Participants saw 18 chapters. The story started with a chapter with no questions, then participants saw 4 fillers: 2 quantifiers with interrupting questions

[2]Of the 13 items in this experiment, 9 of them were NP-coordinated (the others used coordination of prepositional phrases and adjectives). In both experiments, critical conjunctive generics always involved conjunctions of the same syntactic types (e.g., *ascribe to the Caboo religion and the Daith religion*).

and 2 uninterrupted ME fillers, in a random order. Finally, participants saw 2 of each kind of critical trial with 4 uninterrupted ME fillers and 3 quantifier fillers interleaved to avoid back-to-back critical trials.

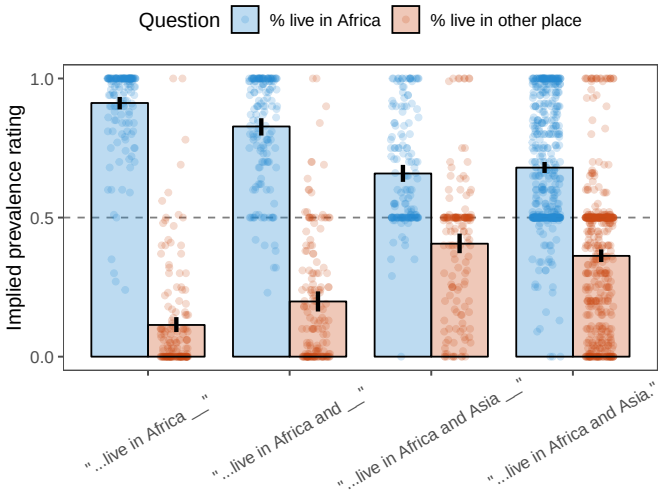

Figure 6: Experiment 2 results. Participants are interrupted at various stages of the sentence (after *Africa*, *and*, or *Asia*) to be asked about the prevalence of *living in Africa* and *living in some other place*, or asked at the end of the sentence (rightmost bars). When participants are interrupted before the second conjunct (*Asia*), the sentence continues with a non-mutually exclusive property. Error-bars denote bootstrapped 95% confidence intervals.

Results 28 participants were excluded for failing at least one of the two attention checks.[3] To test our main prediction, we constructed a Bayesian mixed-effects regression model predicting implied prevalence ratings for the first conjunct (e.g., % Africa) as a function of the point in the sentence in which participants were queried. We included by-item and by-participant random intercepts and slopes.[4] The regression model was created in Stan (http://mc-stan.org/) accessed with the brms package using default priors (Bürkner, 2017).

Replicating the findings of Expt. 1, when participants only read that "Elephants live in Africa", they tended to infer that almost all lived in Africa. When they read that "Africa and Asia", they tended to infer that the distribution was close to 50%-50%. Finally, as predicted by a strong version of incremental processing, participants began to anticipate a mutually-exclusive conjunct when only the word "and" was mentioned, as evidenced by their implied prevalence ratings being substantially less for the "..live in Africa and__" condition than the "live in Africa" condition (posterior mean estimate and 95% credible interval: $\beta = -0.08$ (-0.13, -0.04)). In addition, these ratings were substantially higher than when the full conjunctive predicate was present "..live in Africa and Asia" ($\beta = 0.17$ (0.12, 0.23); Fig. 6). Thus, we find that participants' implied prevalence ratings of how many elephants live in Africa monotonically decreased as a function of how many words of the conjunctive predicate they were allowed to see. These results suggest that listeners begin to draw pragmatic interpretations of generics before the end of the sentence and even in the absence of additional content words.

It is notable that in the "Africa and Asia" conditions, participants on average infer greater than 50% prevalence for *Africa* and lower than 50% for *Asia*, a departure from the results of Expt. 1. This deviation may be due to participants forgetting what they have read and/or not making the inference that the second conjunct stands in a subset relation to the category in the second question (e.g., that *Asia* is a kind of "some other continent"). Explicitly asking about the conjuncts alleviates memory demands by allowing participants to merely recognize, rather than recall, that they have seen this conjunct mentioned. Asking about *some other continent* (Expt. 2) requires participants' to recall the second conjunct and could lead to lower prevalence ratings in response to this question.

Discussion

Generic sentences exhibit extreme sensitivity to context that make it difficult to precisely define what a single generic conveys. "Elephants live in Africa and Asia" means neither that *most elephants live in (both) Africa and Asia* nor that *most elephants live in Africa, and most live in Asia*. Here, we empirically measured interpretations of generics about conjunctive predicates, building on the observation of Nickel (2008) of the range of troubling examples for quantificational views of generics. Notably, the uncertain threshold model of Tessler and Goodman (2019) accounts for such conjunctive generics seamlessly: An underspecified threshold can be updated as more information comes in and is sensitive to prior beliefs regarding compatibility of the conjunct properties.

We extended that model to include syntactic expectations and found evidence for the strongest form of incremental syntactic processing, wherein beliefs are continually updated based on expectations of how a sentence will continue. The fact that generic language understanding can be modulated simultaneously by correlations in background knowledge and by syntactic expectations calls for a tighter coupling between models of syntactic processing (Levy, 2008), pragmatic language understanding (Goodman & Frank, 2016), and intuitive theories (Tenenbaum, Kemp, Griffiths, & Goodman, 2011).

It remains an open question, however, how specific the effects observed in this paper are to generics rather than to quantification more generally. For example, it appears that, in some contexts, one can use *most* to convey similar mutually exclusive conjunctions: "Elephants are the largest land animal on Earth and are one of the gentlest creatures. Most live in Africa and Asia but are brought to other places for the entertainment of humans."[5] Further work is needed to determine the felicity and interpretation of such utterances.

Using Big Data to Understand Memory and Future Thinking

Robert Thorstad & Phillip Wolff
{rthorst, pwolff} @ emory.edu
Emory University Department of Psychology

Abstract

Imagining the future and remembering the past both involve mental time travel. This commonality could indicate shared mental processes, as held by the Constructive Episodic Simulation Hypothesis (Schacter & Addis, 2008), or else interactive processes that complement one another, a possibility we call the Complementarity Hypothesis. According to the Complementarity Hypothesis, future thoughts are constructed from schemas making them episodically poor, whereas past thoughts are constructed from schemas and direct retrieval of memory traces, making them relatively episodically rich. We tested these hypotheses using machine learning to data mine mental operations in language, much as a geologist can recover physical processes from the geological record. People's natural, unprompted talk on web blogs was automatically analyzed for past, present, and future references using a temporal orientation classifier. In Study 1, we found that perceptual details were mentioned more often in past than future talk, implying greater use of episodic processing in past than future thinking. In Study 2, a neural network using schemas generated from Latent Dirichlet Allocation better predicted the content of references to the future than the past, implying that constructive processes are more common in future than past thinking. In Study 3, we used the results from the two prior studies to construct an episodic-by-constructive process space. We adapted techniques from fMRI analysis to analyze this space for clusters of activity, as if the frequency of past and future thinking were BOLD responses in cortical space. We found that past and future thinking occupy highly separable regions of processing space, supporting the Complementarity Hypothesis.

Keywords: Prospection; Memory; Future Thinking; Big Data; Naturally Occurring Datasets

Introduction

Memory is not just used to remember the past. It also helps people predict and plan for the future (Schacter & Addis, 2007; Klein, Robertson, & Delton, 2010). At a minimum, then, the cognitive process used to think about the future must be able to connect with those used to remember the past. Such a connection would be facilitated by overlap in the processes used to think about the future and past. According to the Constructive Episodic Simulations Hypothesis (Schacter & Addis, 2008) the overlap in these processes is considerable. An alternative possibility is that the thought processes used to think about the past and the future are largely unique and non-overlapping, but connect with each other in manner that complements the other. We will refer to this later possibility as the Complementarity Hypothesis. In this research, we seek to test between these two competing proposals using information afforded by machine learning and big data analytics.

The idea that thinking about the future and the past might involve similar kinds of process has received significant empirical support. Viard et al (2011) found that past and future thinking engage several common brain regions including the hippocampus, precuneus, prefrontal cortex, and posterior cingulate cortex. Addis, Wong, & Schacter (2007) found that past and future thinking both engage the left hippocampus, a region known to be involved in episodic memory. Meta-analyses suggest that the overlap between past and future thinking is robust and involves a broad set of regions in the brain's default network (Benoit & Schacter, 2015; Spreng, Mar, & Kim, 2009).

The evidence for common processes is not, however, uniform. Irish, Addis, Hodges, and Piguet (2012) found that conceptual knowledge impairments in semantic dementia were more severe in future thinking than past thinking. Craver, Kwan, Seindam, and Rosenbaum (2014) found that people who lost the ability to remember the past due to hippocampal amnesia often retained some ability to think about the future. Such patients make normal future-oriented decisions in delay discounting and score normally on surveys of future orientation. Findings such as these suggest that past and future thinking may rely on different cognitive processes.

The conflicting findings from past research are associated with different kinds of methodology. Studies supporting shared process have been those using brain imaging, while those indicating differences have been based on neuropsychological research investigating the effects of brain damage (although see Klein, Loftus, & Kihlstrom, 2002 for neuropsychological evidence for similar processing). Both kinds of research have their limitations. One of the challenges in neuroimaging work is the problem of how to elicit thoughts about the past and the future without bias to the results. Typically, temporal thoughts are elicited by explicit instructions to do so. The problem is that these instructions may alter the cognitive processes involved. For example, to image the future, participants are often instructed to imagine specific events that are highly likely to occur (e.g., Addis, Wong, & Schacter, 2007). These instructions might bias people to use their memory of the past to imagine future events because it requests that they offer specific details, a process that may not necessarily be associated with future thinking. Neuropsychological research investigating brain damage is limited by the (fortunately) relatively small numbers of participants. Most importantly, the research using both kinds of methodology has focused on people's ability to remember or imagine scenes with significant perceptual detail, but not all thoughts about the future and past are necessarily high in episodic detail. Certain thoughts about the future and past might be driven by abstract conceptual knowledge, possibly by schemas. Some research has investigated the role of cultural life scripts on future thinking (Bernsten & Bohn, 2010), but life scripts are only a small

portion of people's abstract conceptual knowledge. In sum, prior research has been limited in its ability to study the potential impact of abstract knowledge and schemas on people's thoughts about the past and the future for lack of an inventory of the generic abstract knowledge structures that people are likely to possess.

The limitations of prior work can be addressed using big data methods. Big data methods involve mining large-scale naturally occurring behavior to provide insight into human cognition (Goldstone & Lupyan, 2016; Thorstad & Wolff, 2018a). In the case of mental time travel, people talk regularly about the past, such as what they did yesterday, and the future, such as what they plan to do tomorrow. This talk can be mined to understand the cognitive processes of memory and future thinking. These big data methods address some of the challenges of prior work. Big data methods avoid the explicit prompting in prior work by studying natural, unprompted talk about time. Big data methods also allow investigation of a much wider set of conceptual knowledge by learning the relevant concepts from the data.

Here, we examine people's temporal talk in a large web blog corpus. This corpus is ideal for studying mental time travel because people write without prompting about topics of their choosing. Once the sentences in the corpus are analyzed for their temporal orientation, we can investigate the cognitive processes associated with this talk to test between the Constructive Episodic Simulation and Complementarity hypotheses.

Study 1: What is the Content of Past and Future Thinking?

The view that past and future thinking share common cognitive processes makes a strong prediction about the content of people's temporal talk. Past and future thinking have been argued to rely on shared episodic processes (Schacter & Addis, 2008), and these episodic processes have characteristic types of representation that can be identified in text. Episodic thoughts are highly concrete and perceptual, with episodic future thinking typically described as a kind of pre-experiencing (Atance & O'Neil, 2001) or simulation (Schacter & Addis, 2008). Episodic thoughts also involve a spatial location (Tulving, 1993), as also reflected in work using spatial relations as a marker of episodic future thinking (Russell, Alexis, & Clayton, 2010). We measured these episodic representations in people's talk about the past, present, and future, based on psychometric dictionaries. If past and future thinking rely on common episodic processes as predicted by the Constructive Episodic Simulation Hypothesis, then we should observe similar amounts of episodic processing in past and future talk. By contrast, if past and future thinking rely on different processes as predicted by the Complementarity Hypothesis, then we should observe more episodic processing in talk about the past than the future. Such a pattern could occur if thoughts about the future are more constructed than thoughts about the past.

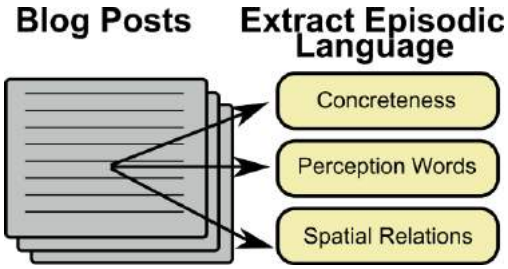

Fig. 1. Analyzing Episodic Language in Blog Posts. We extracted three episodic language indicators from a corpus of blog posts: concreteness, the amount of perceptual words, and the presence of spatial relation words.

Methods

All procedures were approved by the Emory University IRB.

Materials The analyses used the Blog Authorship Corpus (Schler, Koppel, Argamon, & Pennebaker, 2006). The corpus is demographically diverse, including 19,320 bloggers (50% female) from 40 different occupational categories and a wide range of ages (13-17y: N=8,240, 23-27y: N=8,086, 30-47y: N=2,994)**.**

Procedures Several preprocessing steps were taken to clean the corpus. Special characters, emoticons and URLs were removed. Misspellings were automatically corrected using a dictionary from Han, Cook, & Baldwin (2012). Extremely short posts with less than 10 words were dropped. Non-English sentences were removed using the Python library langdetect.

We extracted temporal talk from the corpus by automatically classifying the sentences using a temporal orientation classifier. As a first step, the sentences in the corpus were syntactically parsed using the Stanford Parser (Chen & Manning, 2014). These parses could then be used to determine temporal orientation using a set of 121 syntactic and lexical rules written in the regular expression-like language Tregex (Levy & Andrew, 2006). References to the past were flagged using rules like "VP>VG>have" and references to the future by rules like "MD>will" (Copley & Wolff, in prep.)

Before running the classifier on the corpus, the performance of the classifier was verified in a separate rating study where we recruited 30 human raters via Amazon Mechanical Turk. We obtained 3 ratings for each of 1,000 randomly drawn sentences from the blog corpus (100 ratings/participants), as to whether the sentences referred to the past, present, future, atemporal, or unintelligible. Participant quality was ensured using unmarked attention checks and by requiring participants to have completed 100 previous MTurk tasks with 95% approval rating. We found that the performance of the classifier, as indicated by the *F* statistic (Raschka, 2015), $F = 0.61$, where chance = 0.33, approached human-level accuracy, $F = 0.67$. We also compared the classifier to other classifiers based on the Linguistic Inquiry and Word Count psychometric dictionary (Pennebaker et al, 2015), a decision-tree model based on a variety of language features (Schwartz et al, 2015), and a

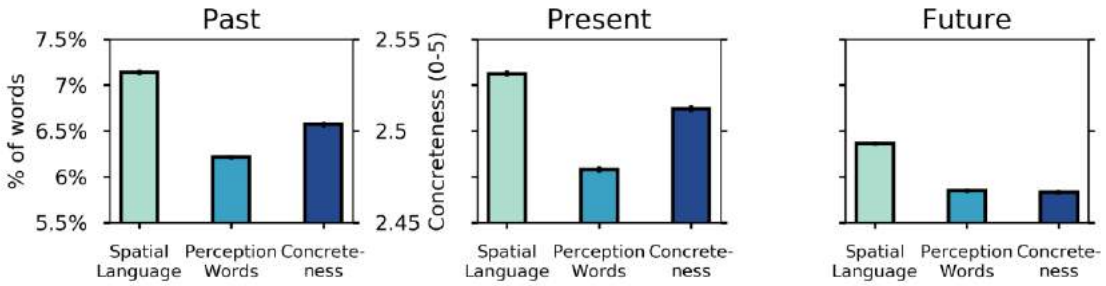

Fig. 2. Amount of episodic processing (+/- 95% CI) in sentences about past, present, and future.

regular-expression pattern-based temporal classifier known as SUTime (Chang & Manning, 2012). Our temporal orientation classifier outperformed these other temporal orientation classifiers, specifically SUTime, $F = 0.25$, decision trees, $F = 0.33$, and the Linguistic Inquiry and Word Count psychometric dictionary, $F = 0.56$.

Once applied to the blog corpus, the classifier was able to identify which sentences referred to the past (2,134,357 sentences, 39.5%), present (1,428,626 sentences, 26.5%), or future (1,834,206 sentences, 34.0%).

As shown in Fig. 1, we measured the episodic processing in each sentence in the blog corpus using three measures. We analyzed concrete language based on averaging the concreteness of the words in each sentence using concreteness ratings of 40,000 English lemmas from Byrsbaert et al (2014). We analyzed the perceptual and spatial language in each sentence by **c**alculating the proportion of words in the sentence matching predefined lists from the Linguistic Inquiry and Word Count psychometric dictionary (Pennebaker et al**.**, 2015).

Results and Discussion

We found that past thoughts involved more of all three types of episodic representations than future thoughts. In all three cases, past thoughts were more similar to present thoughts, which do not require mental time travel, than to future thoughts. As shown in Fig. 2, references to the past were rated as more spatial, $t_{(18,808)} = 48.34$, $p < 0.001$, perceptual, $t_{(18,808)} = 23.27$, $p < 0.001$, and concrete, $t_{(18,806)} = 46.65$, $p < 0.001$, than references to the future. As also shown in Fig. 2, references to the past are as perceptually rich as references to the present. Together, the results suggest that past thinking is more episodic than future thinking, a result that is fully consistent with the Complementarity Hypothesis.

Study 2: What Processes are used for Future Thinking?

Study 1 suggests that past thoughts are more episodic than future thoughts. These results raise the question of what processes are used to think about the future. An intuitive possibility is that because the past has happened but the future has not, future thoughts may be more constructed than past thoughts. This construction could be performed by relying on stored knowledge structures known as schemas. While the possibility that future thoughts rely more on schemas is intuitive, it is broadly agreed that memory also relies on schemas (Bransford & Johnson, 1972), and so one could also predict that past and future thoughts rely equally on schemas. In Study 2, we therefore asked whether future thoughts rely more on schemas than past thoughts.

There are two challenges to quantifying the influence of schemas on temporal thoughts. First, it is difficult to know in advance which schemas people use to mentally time travel. It seems likely that the most important schemas may be used in everyday talk. With a large enough sample of everyday talk, it should be possible, then, to extract these schemas. To do this, we analyzed 1 month of posts from the social media website Reddit (307 million words). We extracted the 500 most common schemas using a machine learning model known as a topic model (Blei, Ng, & Jordan, 2003). As shown in Fig. 3, a topic model works by inferring the latent topics that organize people's choices of which words to write in certain documents, or Reddit posts. These topics can thought of as probability distributions over words. While these topics do not share every feature of schemas (for example they are not hierarchical), they share some of the essential features, such as the fact that the important words represent slots that can be filled by words, which are conceptually similar, but not necessarily semantically related.

The second important challenge is that the mere presence of a schema does not necessarily imply a cognitive process. It is necessary to ask whether an author used a schema to guide their writing or merely invoked the schema incidentally. To make this leap from describing schemas to cognitive processes, we capitalized on a key cognitive function of schemas: schemas are thought to fill in missing information. For example, if a person goes to a restaurant, they can use their schemas to know that there will be a waiter even before they have seen a waiter. We created an analogue of this prediction in text by asking whether, if only a part of a sentence is provided, the rest of the sentence can be filled in based on knowledge of the schema. We did this by training a neural network to use the schemas evident in people's blog posts to predict the words they wrote next. We performed this prediction separately for sentences about the past, present, and future, thus allowing us to investigate whether schemas are more involved in filling in missing information for the past, present, or future.

If past and future thinking rely on common cognitive processes as predicted by the Constructive Episodic Simulation Hypothesis, then we would expect schemas to be

equally useful for predicting the content of people's past and future talk. By contrast, if past and future thinking rely on different cognitive processes as predicted by the Complementarity Hypothesis, then we would expect schemas to be more useful for predicting the content of people's past talk than future talk.

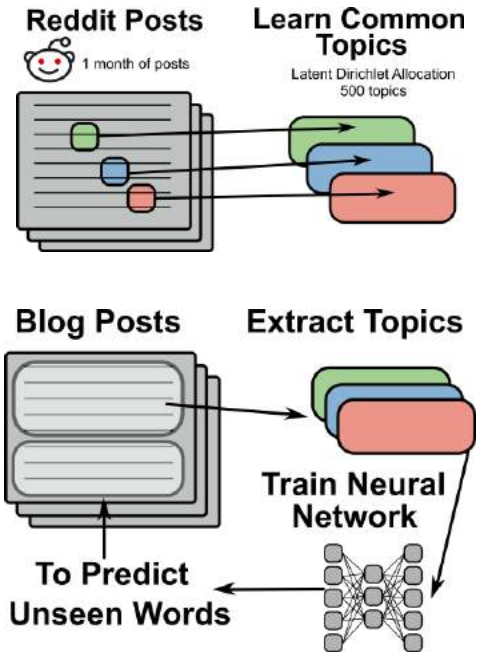

Fig. 3. Learning and Identifying Schemas in Temporal References. (Top) We identified the most prevalent schemas in a large social media corpus using Latent Dirichlet Allocation, which learns the 500 most common topics across many social media posts. (Bottom) For a particular blog post, we identified the schemas implicit in the post, and then trained a neural network to use those schemas to predict words in the unseen last sentence of the post. We conducted this prediction separately for sentences referring to the past, present, and future, allowing us to ask whether schemas were more useful for filling information for particular kinds of temporal references.

Methods

Schema Identification As shown in the top row of Fig. 3, we identified common schemas in a large corpus based on every post to the social media website Reddit in the month of January 2017 (307 million words). As shown in the top row of Fig. 3, we identified schemas in the posts by training a type of topic model known as Latent Dirichlet Allocation (Blei, Ng, & Jordan, 2003). The model was trained using the Python library *gensim* with the parameters α = 0.002, η = 0.002, *number of topics* = 500, using 100 training iterations.

Using Schemas to Fill in Information As shown in the bottom row of Fig. 3, for every post in the blog corpus, we used the LDA model to identify the schemas in the post based on every sentence except the last sentence in the post. Next, we created a dataset where the input was the schema of the post, and the output was a randomly selected word from the unseen last sentence in the post, restricting to the 5,000 most common words in the corpus. We then trained a neural network model to use the schema to predict the unseen word (out of 5,000 possible words). The model had a relatively simple architecture, with a single hidden layer with 500 units and a *relu* activation function, and was trained to minimize cross-entropy loss with *Adam* optimization, based on 25,000 training batches with a minibatch size of 100. The model was evaluated using unseen test data (10%). As described in the main text, we also trained a scrambled version of the model using the same procedure but randomly assigning words to Reddit posts.

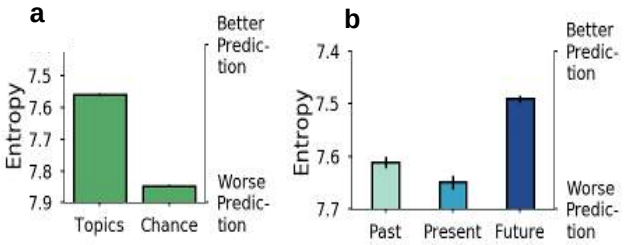

Fig. 4. Schema Usage. (A) The schemas learned by our model could predicted unseen words better than random schemas, replicating a key property of schemas. (B) These schemas were more useful for filling in unseen words for future references than past or present references.

Table 1. Schemas learned by the topic model.

Feelings	Reading	Studying	Food	Sounds	Health-care
Feeling	Read	Study	Food	Hear	Care
Feels	Reading	Subject	Eat	Sound	Health
Felt	Book	Passed	Eating	Sounds	Insuran-ce
Pain	Books	Studying	Healthy	Audio	Letter
Worse	Library	Studies	Diet	Hearing	Legal
Bad	Stuff	Exam	Dinner	Noise	Medical

Results and Discussion

We found that our model learned semantically coherent schemas from social media. We also found that future thoughts drew more on these schemas than did past thoughts, consistent with the Complementarity Hypothesis.

We first asked whether our topic model learned semantically coherent schemas. Several of the schemas are shown in Table 1. The schemas are highly coherent on visual inspection. For example, the model learned a schema about feelings including the words *feeling*, *feels*, *felt*, *pain*, *worse*, and *bad*. We quantified this semantic coherence by training a second model but ablating the semantic information by randomly assigning words to documents in the Reddit corpus. We asked human raters to judge which model generated more semantically coherent topics. Raters judged the topics from the real model as more semantically coherent than the

semantically ablated model, $t_{(22)} = 11.68$, $p < 0.001$, a difference that was observed in every individual rater (23/23 raters).

We next asked whether these schemas fill in missing information in a sentence. We trained a neural network to predict the words in people's talk in the blog corpus based on either the real schemas, or based on ablating schema knowledge using randomly generated schemas. As shown in Fig. 4A, we found that the model based on real schemas outperformed the model based on scrambled schemas, $t_{(220,174)} = 174.26$, $p < 0.001$, suggesting that these schemas do indeed fill in missing information.

Finally, we asked whether these schemas fill in more information for references to the past, present, or future. We found that past references drew on schemas, evidenced by increased prediction performance for past relative to present thoughts, $t_{(110,952)} = 4.60$, $p < 0.001$ (Fig. 4B). However, we found that future references drew more on schemas than did past references, $t_{(175,248)} = 18.53$, $p < 0.001$ (Fig. 4B). This increased prediction for future thoughts relative to past thoughts suggest that thoughts about the future rely more on schemas than thought about the past. This result is consistent with the predictions of the Complementarity Hypothesis.

Study 3: Are these Findings the Result of Different Processes?

Studies 1-2 suggest differences in the cognitive processes used for past and future thinking. However, these results are also open to an alternative interpretation, which we may call the Difference-in-Amount view. On this account, past and future thinking rely on the same basic cognitive processes, but to different extents.

Testing between the Difference-in-Amount and Complementarity Hypothesis requires an analysis for determining whether two operations reflect different underlying cognitive processes. Our key idea is that such a procedure exists in cognitive neuroscience, and can be adapted to big data. In fMRI studies, it is widely accepted that there are different cognitive processes if the two processes activate non-overlapping patterns of voxels in the brain. Indeed, the spatial overlap between past and future thinking in the brain has been taken as evidence for common processing. While this analysis is based on a brain space, a similar logic should hold for operations projected into what we will call a cognitive process space. As shown in Fig. 5, a process space can be created by projecting the candidate operations into a space composed by two or more cognitive processes. Evidence for a single process would be largely overlapping representations in process space (Fig. 5A), while evidence for multiple processes would be largely non-overlapping representations in process space (Fig. 5B). To evaluate the Difference-in-Amount and Complementarity Hypotheses, we pooled the data from Studies 1 and 2 to create a cognitive process space defined by constructive and episodic processing. We projected both past and future thinking into the process space, and quantified the amount of overlap between the processes. We asked whether this overlap was better explained by the Difference-in-Amount view or the Complementarity view.

Methods

Materials We combined the data from Studies 1-2. We created an aggregate measure of episodic processing by separately *z*-scoring the concreteness, spatial relation, and perceptual measures and then averaging the resulting *z*-scores for each sentence.

Process Space Creation We created a 10x10 cognitive process space using the episodic and constructive processing scores. For each measure we calculated 10 deciles. For example the bottom-left corner represents 0-10% episodic processing and 0-10% constructive processing. We then calculated the proportion of past and future thoughts falling in each region of process space. We stored the difference score (future - past) for each region and retained only scores larger than 0.25 in magnitude to avoid false positives.

Cluster Permutation Test We next tested how large a cluster would be obtained in the process space by chance. We did this by creating 10,000 permutations of the data by shuffling the past and future labels. In each permutation we repeated the cognitive process analysis and stored the size of the largest cluster, again retaining only scores large than 0.25 in magnitude. We used these cluster sizes to create a chance distribution (Fig. 5D, green distribution).

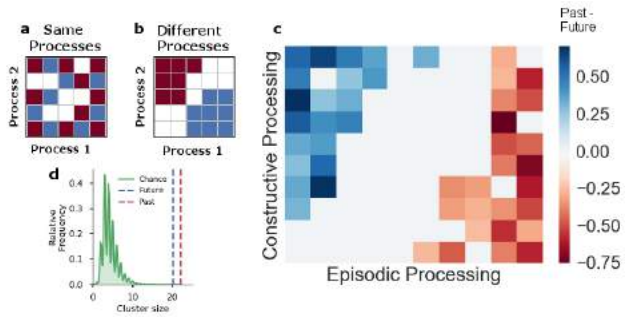

Fig. 5. Cognitive Process Space. (a-b) Hypothetical results in cognitive process space that would indicate reliance on the same or different processes. (c) Past thinking (blue) and future thinking (red) projected into cognitive process space. (d) Chance distribution of clusters in process space (green) compared to observed cluster sizes (vertical dotted lines).

Results and Discussion

We found that past and future thinking occupied largely non-overlapping clusters of the process space, supporting the predictions of the Complementarity hypothesis.

As shown in Fig. 5C, when past and future thinking were projected into cognitive process space, they occupied largely non-overlapping regions of the space. As shown in Fig. 5D, we quantified whether this pattern would be expected due to chance. We did this by creating 10,000 random permutations of the data, and recording the largest cluster size observed in each permutation (Fig. 5D, green distribution). We found that both the past thinking cluster (red dotted line) and the future thinking cluster (blue dotted line) were larger than those

observed in any of the 10,000 permutations, suggesting dissociable cognitive processes that would not be likely observed due to chance (e.g. $p < 0.0001$). This result suggests that past and future thinking rely on different cognitive processes, consistent with the Complementarity Hypothesis.

General Discussion

There is growing consensus that memory is not just for remembering the past, but also for imagining the future. Here, we considered a strong version of this idea that past and future thinking could rely on largely similar cognitive processes. In a series of three studies based on people's natural talk about time, we found support for the alternative hypothesis that past and future thinking rely on different cognitive processes. In Study 1, we found that thoughts about the past were more episodic than thoughts about the future, as revealed by the increased presence of concrete words, perceptual words, and spatial relation words. In Study 2, we found that thoughts about the past were less constructed than thoughts about the future, as revealed by the decreased ability of a machine learning model to use the topics of people's writing to predict the contents of future references compared to past references. Finally, in Study 3 we found that these findings were better explained by differences in cognitive processing than by a Difference-in-Amount view, a conclusion supported by projecting the data into cognitive process space.

While we believe that the schemas learned by our model are quite general, a limitation of the current analysis is that the schemas are only derived from a single social media corpus. The social media corpus spans a broad range of topics and covers millions of posts, but it may be limited in some ways; for example, social media users may be younger than or more likely to be male than the general population (Duggan & Brener, 2013). Future work should address whether similar schemas would be discovered in other kinds of corpora.

Beyond future thinking, our results have implications for the role of big data in psychology. It has previously been shown that big data can predict many psychological traits, including personality (Youyou, Kosinski, & Stillwell, 2015), mental illness (Thorstad & Wolff, 2018b), and decision-making (Thorstad & Wolff, 2018a). However, psychologists are often interested in going beyond prediction to make inferences about the underlying cognitive processes. It is not obvious that cognitive processes are recoverable from big data, since in written text the cognitive processes that generated the text have already occurred. Our findings suggest that big data can in fact recover cognitive processes, in two ways. First, big data can be used to look for characteristic representations of a cognitive process, such as the episodic language markers in Study 1. Second, big data can be used to train a model to mimic the cognitive process used to generate the text, as in the schema-based prediction model in Study 2. Both of these techniques suggest that big data may be useful not just for predicting human psychology, but also for understanding cognitive processes, a kind of data mining the mind.

Children's causal inferences about past vs. future events

Abstract

Causal and temporal reasoning are fundamentally linked, but few studies have directly examined how the ability to make causal inferences about the past vs. the future develops. We used a counterfactual reasoning task to explore 4- to 6-year-old children's understanding of the causal relationships among past, present, and future events. Like adults, even 4-year-olds judged that future, but not past, events could be altered by interventions in the present. This early sensitivity to the causal asymmetry between the past and future became more pronounced with age. We also found that children and adults selectively and appropriately use evidence about the present to make inferences about past events. Implications for theoretical accounts of the development of causal reasoning and abstract concepts of time are discussed.

Keywords: cognitive development; temporal cognition; causal inference; counterfactual reasoning

Introduction

You can change the future, but you can't change the past. This fundamental distinction between the past and future is central to an abstract, linear concept of time, and has profound effects on adults' everyday behavior. Although philosophers and physicists have argued about the ultimate reality of the past/future asymmetry, many of us find it difficult, if not impossible, to conceive of a world without it. Is the past/future distinction a "built in" feature of human cognition? If it isn't, when and how does it develop? While we know that children's reasoning about both temporal and causal relationships improves during the preschool years, few studies have directly explored the relationship between children's reasoning about causality and their knowledge of the ontological distinction between past and future (see McCormack & Hoerl, 2017). Here, we use a counterfactual[1] reasoning task to explore how children use information about present events to make causal inferences about the past and future.

Despite the central role of the past/future distinction in expliciting temporal reasoning, it remains unclear to what extent young children possess this understanding. While it is difficult to test this in preverbal infants, researchers have looked to children's earliest production of temporal language for clues. The past-tense verb marking *-ed* is one of the first grammatical inflections English-speaking children produce, usually at or before age 2 (Brown, 1973), which has been taken as evidence that understanding of the past/future status of events relative to the present develops early. However, there is debate in the language acquisition literature over how accurate and generalizable children's early uses of tense are, and particularly whether they may indicate perfective aspect, rather than event time (Anderson & Shirai, 1996). Deictic time words like "tomorrow" and "yesterday" are also early to appear in the child's lexicon, though children don't use them reliably for several years (e.g., Tillman et al, 2017). Nonetheless, while these studies suggest early onset and prolonged development of past-future reasoning, it remains possible that children's understanding the causal asymmetry of the past and the future develops prior to the ability to express these differences in language.

When do children understand how causality operates over time? Suggesting that even infants intuitively understand the relationship between temporal order and causality, 4-month-olds look longer when presented with impossible causal chains of events, including those with apparent breaks in temporal continuity (Cohen et al., 1998). Nevertheless, recognizing the temporal-causal structure of a simple event, like one ball striking another, does not imply that infants have a concept of the past or the future. Later in development, when asked which of two possible events caused another event to happen, 3-year-olds chose the prior rather than the subsequent one (Bullock and Gelman, 1979). Four-year-olds recognize that past, but not future, events determine present mental states and states of the world (Busby Grant & Suddendorf, 2010). However, 4-year-olds struggle to use information about the relative ordering of multiple past events to make inferences about the present, and fail to solve temporal reasoning tasks in which the order they receive information about events doesn't match the order in which those events occurred (e.g., McCormack & Hoerl, 2007), suggesting that young children lack flexible temporal perspective-taking.

[1]The precise definition of counterfactual reasoning, and thus the age at which children are first capable of it, is the subject of much debate (e.g., Beck, 2016; Weisberg & Gopnik, 2013). In the present paper, we take a broad view of counterfactual reasoning, which incompasses hypothetical questions about the past, present, and future, as well as conditionals.

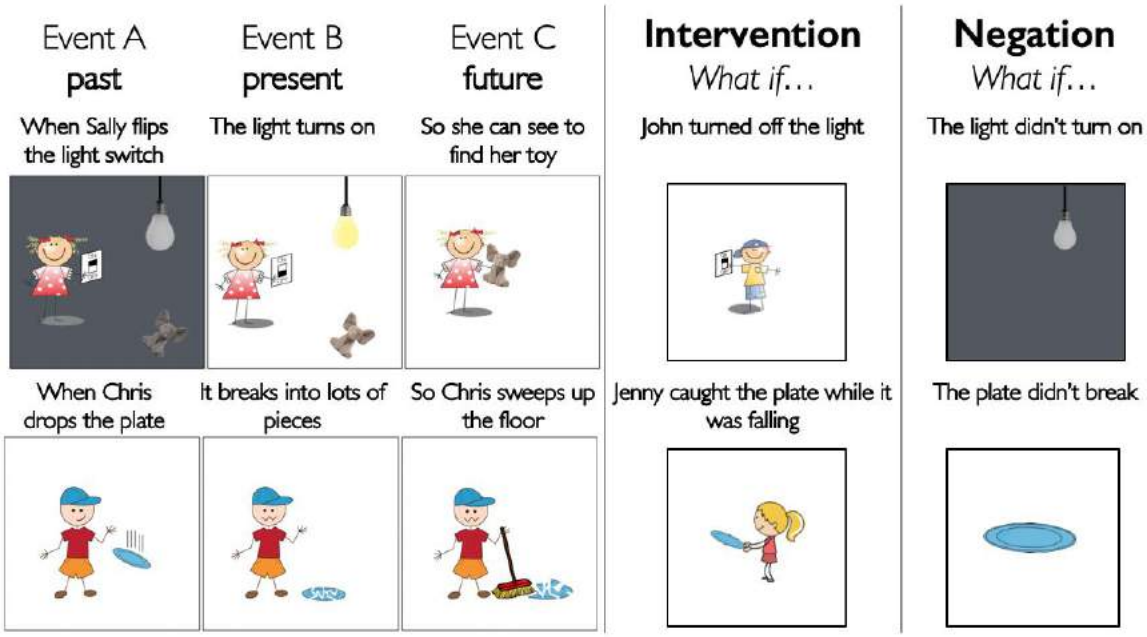

Figure 1: Example storyboards and intervention/negation cards. The experimenter (E) recited the story on the front of the card, then flipped it to reveal three empty boxes. At test, E placed either an intervention or negation card in the center square (B) before posing counterfactual questions about its effects on past (A) and future (C) events.

Critically, none of these prior studies directly test whether children understand that the future is alterable in the present, but the past is not. Instead, a separate literature has explored the development of children's causal reasoning skills (see Gopnik & Wellman, 2012 for a review), and, despite the related subject matter, this literature has developed largely independently from the work on the development of temporal cognition discussed above. Within the causal reasoning literature, some accounts suggest that causal relationships are defined in terms of their counterfactual dependency. That is, if event A causes event B, then an intervention on A will lead to a change in B (Pearl, 2000). Relevant to this, researchers have examined children's understanding of this link between causal and counterfactual reasoning. For example, in early work, Harris, German, and Mills (1996) conducted a series of studies in which 3- and 4-year-olds were presented with scenarios in which they were asked to reason about a short causal sequence (e.g., a character walks across the floor with muddy boots [A], making a mess [B]). When asked conditional questions about what would have happened had A not occurred (e.g., "What if Carol had taken her shoes off? Would the floor be dirty?"), children made accurate judgements about effects on B.

If children have a unidirectional view of causality, given a 3-step causal chain of events, A → B → C , they should judge that an intervention at B can alter future event C, as previous studies have found. Importantly, however, they should also judge that the intervention will *not* alter past event A (Sloman & Lagnado, 2005).

Consider the following scenario (Figure 1): *When Sally flips the lightswitch, then the light turns on, so she can see to find her toy.* If told that another character, John, turned off the light[2] (at B), adults may reasonably predict that Sally will no longer be able to see (at C). However, they should not infer that Sally never turned the light on in the first place (at A), because John's actions at time B can't change what happened in the past, at time A. Here we test whether 4- to 6-year-old children make the same inferences.

Retrospective reasoning

Despite understanding time itself to be linear, under some circumstances, adults use information about the present to reason "back in time" and make inferences about what already happened in the past. For example, if an expected event does not occur—and no other explanation for this is

[2] Note that under some definitions of counterfactual reasoning, our use of the simple past tense here, rather than pluperfect subjunctives such as "What if John *had turned off* the light?" or (in the negation condition) "What if the light *hadn't turned on*?", indicates that these statements are hypothetical rather than counterfactual *per se* (see Lucas & Kemp, 2015). We chose simpler language primarily to make the task more comprehensible to young children, but are currently exploring whether this tense modification impacts performance on our task.

given—an adult might reasonably infer that the event's usual cause must not have occurred. For example, when simply told that the light *didn't* turn on (at B; see footnote 2), an adult might indeed conclude that Sally never flipped the lightswitch (at A). Here, we presented children and adults with stories involving 3-step causal chains, and then asked them to consider scenarios in which the second step (B) was different. Importantly, we asked both about the effects of the "present" change on the future (C) and on the past (A).

Given prior work showing that adults generate different causal predictions following passive observation (e.g., observing that B did not occur) than they do following interventions (e.g. acting on B to prevent it from occurring; Sloman & Lagnado, 2005; Waldmann and Hagmeyer, 2005), we also varied this feature in the current study. In the *intervention* condition, an external agent (e.g., another character) caused the "present" change. We hypothesized that participants with a linear concept of time would judge that the future event would also change, but not the past event. In the *negation* condition, however, no explanation for the present change was given. Here we hypothesized, again, that participants with a linear concept of time would judge that the future would change. If participants also engage in retrospective causal reasoning, we hypothesized that, unlike in the intervention condition, they would also systematically judge that the past event (A) had changed (e.g., Sloman & Lagnado, 2005). In contrast, if participants do not reason retrospectively, we predicted that they would perform similarly in the two conditions.

Method

Participants

A total of 258 subjects participated, including 65 4-year-olds (M_{age} = 4.5 years, range = 4.0-5.0 years), 70 5-year-olds (M_{age} = 5.5 years, range = 5.0-6.0 years), 63 6-year-olds (M_{age} = 6.4 years, range = 6.0-7.0 years) and 60 adult controls (M_{age} = 21.6 years, range = 18.2-31.1 years). Participants were pseudo-randomly assigned to either the Intervention or Negation condition. An additional 43 children participated, but were not included in analyses due to being outside the target age range (n = 3), experimenter or technical error (n = 5), failure to complete the task (n = 4), developmental delay (n = 2), insufficient fluency in English (n = 1), incomplete age information (n = 2), or failing more than one control trial, as described below (n = 26).

Materials

Study materials included eight 3-panel storyboards illustrating sequences of events from left-to-right. Two examples are shown in Fig 1. Each panel was 2.8 in. × 2.8 in. Single images corresponding to event B in each story were also used in testing, which represented either identical pictures (control stories), interventions, or negations, depending on condition. Each individual image was square with a black outline, and on the reverse side of each storyboard were three empty black squares positioned like the filled images on the front of the card.

Procedure

Children were tested one-on-one, in a quiet room with the experimenter. The experimenter began the session by placing the first storyboard in front of the participant, saying "I'm going to tell you some stories. There are three things that happen in each story, see?" She then pointed to each image in the story while reciting the corresponding part of the narrative, in this case, "When [A] Julie opens the door, then [B] her dog runs outside, so [C] he smashes up all the flowers in the garden".

The experimenter then flipped over the storyboard, revealing the 3 empty boxes, and initiated a demonstration control trial. While placing a duplicate of the center image from the front of the card in the empty center square, she asked the child "tell me, *just like in that story*, if [the dog ran outside]...," and then pointed to the empty third [event C; future] box while completing the question with a forced choice: "will [he smash all the flowers in the garden] or not [smash the flowers in the garden]?" After receiving a verbal response from the participant, the experimenter repeated the procedure again, instead pointing to the first [event A; past] box and asking, "did [Julie open the door] or not [open the door]?"

Next, the experimenter flipped the card back over, repeated the original story, and explained that she would now be asking the participant to think about what would happen in the story if something had been *different*. In this demonstration critical trial, the experimenter placed a modified image B in the empty center square on the back of the card. This image showed either the **intervention, "**What if the dog were on a leash and couldn't get out?", or the **negation,** "What if the dog *didn't* run outside?", according to condition. The test concluded with the past and future test questions, as above. No feedback was given on either the control or critical trials using the demonstration story.

After this demonstration phase, the experimenter told the participant that she would tell some other stories, sometimes asking if things had been the same (control stories), and sometimes asking if things had been different (critical stories), and sometimes asking about the first part or the story, and sometimes about the last part. The remainder of the task included 7 new stories, 5 of which were used on critical trials (see examples in Fig. 1) and 2 were control stories. The ordering of the stories (other than the demonstration story), the past and future questions about each story, and the positive and negative response options in each question were counterbalanced across participants. The third and sixth stories were always control stories.

Procedures used in the intervention and negation conditions were identical, apart from the different counterfactual questions and corresponding images used during test.

Data from children who responded incorrectly more than one control trials, i.e., by denying that an event from the story they had just heard had occurred in that story, were excluded due to suspected incomprehension of the task. This exclusion criterion was particularly important because the predicted "adult-like" response pattern in the negation condition was one in which the participant judges that *none* of the events in either past or future critical trials had occurred. We therefore wanted to minimize the chances of potentially confusing a "no bias" in children who did not comprehend the task at all with adult-like conditional reasoning.

Coding

During testing, the experimenter recorded whether the participant affirmed or denied that each past or future event would occur. Yes responses were coded as 1, no responses as 0. These were later reverse-coded as described below. Participants who answered more than one of the four control questions incorrectly (i.e., by responding that the event did not occur; $n = 26$) were excluded from further analysis. Data from the demonstration story were not included in analysis. All analyses were conducted in R, using the *lme4* package for mixed-effects modeling.

Results

We began with two primary questions about our dataset: (1) Do participants differentiate past from future in the intervention condition? and (2) Do participants ever reason retrospectively (i.e., "back in time") when answering questions about the past in the negation condition?

Before addressing these, we asked whether children's performance differed between the two conditions. Because our DV was a binary choice (either an event would occur or not), we conducted a mixed-effects logistic regression. For ease of exposition, the data were reverse-coded, such that answers indicating that events would *not* occur in the counterfactual scenario were considered "changes" (1), while answers indicating that events would still occur were considered non-changes (0). We modeled the likelihood that a child[3] would say an event changed as a function of their age (continuous; between-subjects), condition (intervention vs. negation; between-subjects), and event time (past vs. future; within-subjects). We also included an interaction between event time and condition in this model, and random intercepts for subjects and stories. Results of this analysis revealed significant main effects of age ($\beta = 0.5$, $p = 0.004$) and event time ($\beta = -3.4$, $p < 0.001$) as well as a significant interaction between event time and condition ($\beta = 2.3$, $p < 0.001$). Given the evidence that children's behavior differed between conditions, we proceeded to analyze the data from the two conditions separately.

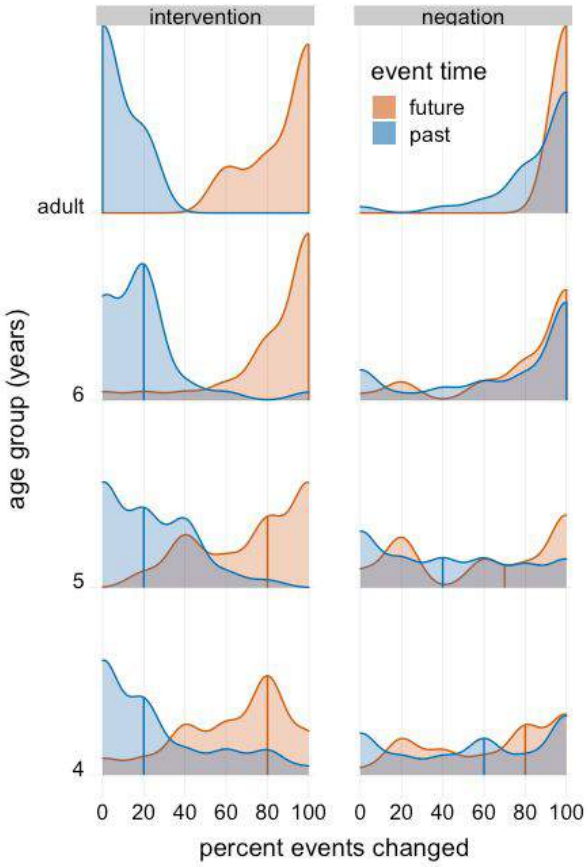

Figure 2: Distributions of responses to past (blue) and future (red) counterfactual questions, in the intervention (left) and negation (right) conditions. Height of shaded areas indicates the density of responses at each level of consistency, e.g., 80% = 4 of 5 events changed. Vertical lines = medians. Density calculation bandwidth = 8.

Intervention condition

Our goal in the intervention condition was to test whether participants differentiate the effects of present interventions on past vs. future events. In other words, do they know that you can change the future, but not the past? The distributions of responses to past- and future- questions, i.e., the percentage of target events that changed, for each age group are shown in the left column of Figure 2, with medians represented by vertical lines. As expected, and in line with prior work, adults strongly distinguished past from future: the median percentage of past events they said would change as a result of the intervention was 0%, 95% CI [0%-0%], while the median percentage of future events that would change was 100% [80%-100%].

[3] Adult controls were not included in this analysis.

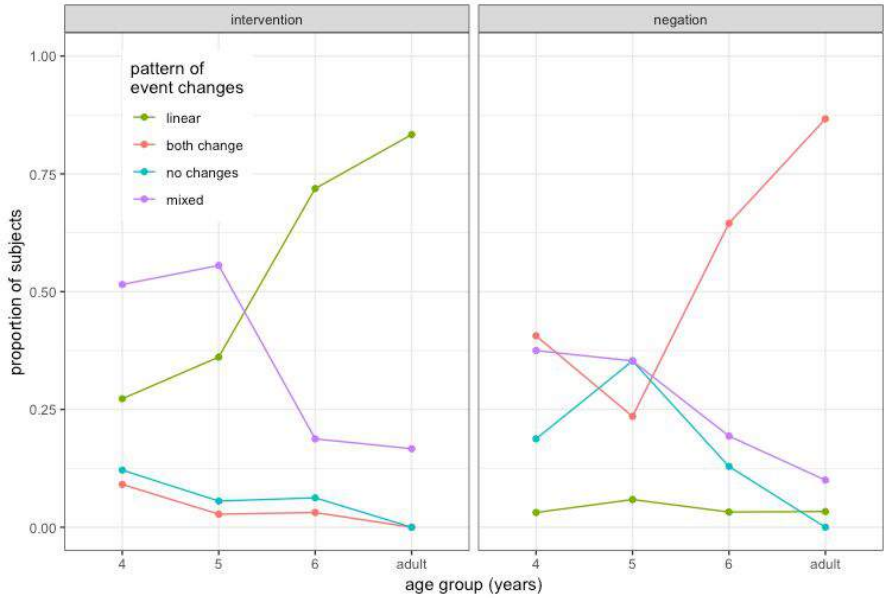

Figure 3: Proportion of subjects in each age group who demonstrated each of 4 response patterns across stories, in the intervention (top) and negation (bottom) conditions. "Linear" (green) = future events consistently judged to change, past events to stay the same. "Both change" (red) = both past and future events judged to change. No-changes (blue) = both past and future events were judged to stay the same. Mixed (purple) = inconsistent responses.

Considering the developmental data, a logistic regression of the children's likelihood of saying that an event changed revealed significant effects of age ($\beta = 0.7$, $p < 0.001$) and event time ($\beta = 2.5$, $p = 0.03$) as well as a significant interaction ($\beta = -1.1$, $p < 0.001$). As shown in Fig. 2, children were more likely to judge that interventions would change the future than the past, and this effect increased with age. Wilcoxon signed-rank tests confirmed that the past vs. future effect was significant even in 4-year-olds, who reported that 80% [60%-80%] of future events changed, but only 20% [0%-20%] of past events did ($W = 400$, $p < 0.001$).

Interestingly, the three groups of children did not differ in their likelihood of judging that past events changed (Wilcoxon rank-sum tests, 4's vs 6's, $W = 567$, $p = 0.6$), though even 6-year-olds were significantly more likely to do so than were adults ($W = 306$, $p = 0.006$). On future questions, 4- and 5-year-olds were significantly less likely to say that events changed than were 6-year-olds and adults (5's vs 6's, $W = 731$, $p = 0.04$), though neither of these pairs differed (4's vs 5's $W = 456$, $p = 0.09$; 6's vs adults $W = 489$, $p = 0.9$).

In addition to overall performance on past vs future questions, we were interested in the patterns of responses provided by individual subjects. For instance, did children who said the past wouldn't change also say the future *would* change, as a linear model of time would predict? For the purpose of this analysis, we operationalized a "linear" pattern as one in which the participant judged that at least 4 out of 5 future events would change after intervention, *and* that at least 4 of the 5 past events would not. As shown in Figure 3 (top panel, green line), we found that 83% [65%-94%] of adults conformed to this pattern, as did 72% [53%-86%] of 6-year-olds, 36% [21%-54%] of 5-year-olds, and 27% [13%-46%] of 4-year-olds. Subjects who didn't follow a linear pattern typically reported fewer than 4 changes to future questions, resulting in a mixed pattern. Patterns in which either both events or neither event changed were rare in all age groups.

Negation condition

In the negation condition we assessed whether participants would reason retrospectively, making the inference that an observed, unexplained change in the present was caused by a prior change in the past. As shown in Fig 2 (right column), we found strong retrospective reasoning in adults: when simply told that the present event "didn't" occur, they judged that the future effect would not occur on a median of 100%, 95% CI [100%-100%], of trials, and, in contrast to the intervention condition, that the past had changed on 100% [80%-100%] of trials, in line with prior adult work (e.g., Waldmann & Hagmeyer, 2005).

Next we considered the developmental data. A logistic regression model of the children's data in the negation condition, with the same effects structure as the one used in the intervention condition, revealed only a main effect of age ($\beta = 1.1$, $p = 0.04$). Older children were more likely than younger children to judge that events changed. However, unlike in the intervention condition, there was no significant effect of event time ($\beta = 0.35$, $p = 0.8$), and no interaction ($\beta = -0.29$, $p = 0.24$). In other words, we did not detect evidence that children were treating past and future events

differently in this condition. Examining the age effects further, we found that 5-year-olds were less likely to judge that past events had changed than 6-year-olds and adults (5's vs 6's, W = 302, p = 0.002), but no other age-group comparisons reached significance. On future questions, 4- and 5-year-olds could not be distinguished, but 6-year-olds were significantly more likely to say that future events changed than were 5-year-olds (W = 677, p = 0.04), and adults were more likely to do so than were 6-year-olds (W = 660, $p < 0.001$).

Importantly, retrospective reasoning about the implications of the present on the past, when combined with knowledge of how the present influences the future (i.e., future "prospective" reasoning), predicts not only that the past and future will *not* be differentiated, as we found above, but also that both will be judged to have changed. This pattern was less common across the 4- and 5-year-old groups, as can be seen in the flatter distributions (broader confidence intervals) in Fig 2. For example, the median percentage of past events that 4-year-olds judged to have changed was 60% [40%-80%], and for 5-year-olds was 40% [20%-60%]. In contrast, the median percentage for both 6-year-olds and adults was 100%. In our individual-subjects analysis, a consistent retrospective/prospective reasoning pattern was operationalized as one in which at least 4 or 5 past events and 4 of 5 future events changed. As shown in Fig 3, we found that 41% [24%-59%] of 4-year-olds, 24% [11%-41%] of 5-year-olds, 65% [45%-81%] of 6-year-olds, and 87% [69%-96%] of adults displayed this pattern, while linear response patterns were very rare in this condition. Interestingly, among children who did not show this pattern, particularly 5-year-olds (who were surprisingly less adult-like than 4-year-olds), a larger proportion said that *neither* event changed (Fig. 3, blue lines) than we observed in the intervention condition. We discuss this further below.

Discussion

In the current study, we explored the development of children's reasoning about causal relationships among events in the past, present, and future. We discovered that children as young as 4 already distinguish the past and future: they are more likely to judge that an intervention in the present will change a future event than a past one. To our knowledge, this is the strongest evidence to date that pre-school children appreciate the causal asymmetry between the past and future (see McCormack & Hoerl, 2017). Moreover, children treated counterfactual scenarios with an explicit causal agent differently from those in which the cause must be inferred. In the latter case, children did not distinguish past from future, and by age 6, 65% of children consistently demonstrated both prospective and retrospective causal reasoning.

To test their reasoning about past and future events, we told participants 3-step stories, and then asked them to consider counterfactual cases in which an outside agent disrupted the middle step. We found that even 4-year-olds very rarely judged that the past event would retroactively change. This finding extends previous literature showing that 4-year-olds understand that past (but not future) events can cause present ones (e.g., Busby & Suddendorf, 2010), and suggests that the understanding that time is irreversible is strong and early-developing. However, despite the high overall rate of denials that the past would change, we only found a consistently "linear" response pattern in about a quarter of 4-year-olds. This was because, compared to older children, younger children were less likely to judge that *future* events would change after intervention.

Finding more adult-like behavior from children on past than future trials is somewhat surprising in light of previous studies showing that 3-year-olds are capable of prospective ("forward") conditional reasoning (e.g., Harris et al., 1996). In fact, it has been proposed that future conditionals are easier than past counterfactuals for children, because they do not require them to hold both the real world, i.e., how things actually occurred, and the possible world, i.e., how things could have been otherwise, in mind simultaneously (e.g., Beck, 2016; Beck & Riggs, 2014; Raefsteder et al. 2010). Perhaps, however, children in our task were more variable in their predictions about the future than the past simply because the future is intrinsically more open-ended. In linear time, a given intervention may or may not be effective at generating a particular outcome, but will *never* change what has already occurred.

Although children consistently denied that the past would change in the intervention condition, their judgments about past events were not rigid. In the negation condition, children's responses to past questions were more mixed, and like adults, they were more likely to say that the past *had* changed than that it hadn't. Given the minimal changes to the task across conditions, our finding that children are already sensitive to the precise nature of the conditional statement, and to the increased ambiguity of negations relative to explicit interventions (with respect to the past) is striking. Given children's high performance in the intervention condition, and the lack of a bell curve centered around random responding in the negation condition, we do not believe these results can be attributed to confusion about the nature of the task. Instead, these findings may suggest that some children (but not others) are already able to reason backward in time.

One intriguing possibility is that children who perform like adults in the negation condition are deploying what the adult counterfactual reasoning literature has termed "*backtracking*" (i.e., engaging in a special type of counterfactual reasoning that involves inference about upstream causal variables; Gerstenberg, Bechlivanidis, & Lagnado, 2013; Rips, 2010; Rips & Edwards, 2013; Sloman & Lagnado, 2005). Although there has been substantial debate over what types of counterfactuals lead to backtracking inferences in adults (e.g., Han et al., 2014),

these investigations have not yet been extended to children. The tendency to engage in backtracking (or not) has important implications for interventionist accounts for causal reasoning. Specifically, because evaluating the effects of an intervention on a given variable requires "cutting off" that variable from its upstream causal antecedents, backtracking should not be possible (Pearl, 2000; see Lucas & Kemp, 2015). While our negation condition is similar to certain backtracking tasks previously used with adults (e.g., Han et al., 2014; Lucas & Kemp, 2015), given the methodological differences (e.g., using child-friendly events that operate over time; presenting interventions/negations in past vs. pluperfect tense), additional work will be required to explore this potential developmental link.

In sum, the current study brings together the literatures on the development of causal reasoning and temporal cognition, by leveraging a counterfactual reasoning task to explore children's understanding of the past and the future. We found that children are able to recognize the causal asymmetry between past and future prior to the age of 4, reflecting the early development of a linear view of time.

Interestingly, it has been hypothesized that counterfactual reasoning itself may hinge on the development of an abstract, event-independent concept of time (McCormack & Hoerl, 2017). To consider different possible worlds, one must separate the time-point at which an event occurred from the event itself. Linear time thus provides a framework in which events can be organized and even mentally "switched out," so that their causal consequences can be considered. By studying these phenomena in tandem, future studies may uncover new insights about how time and causality are mentally represented.

Explanation Versus Prediction: Statistical Differences in Detecting Fraudulent Events Do Not Necessarily Have Predictive Power

Abstract

A large body of research in the cognitive sciences relies on examining statistical differences. While the approach of examining differences can aid in explaining behavior, it does not necessarily mean that these differences have predictive power. Yet, understanding behavior both involves explaining and predicting behavior. As a point in case, the current study used a naturalistic email dataset to examine statistical differences and predictive power in fraudulent activities. Differences between 1st and 3rd person pronoun use in liars and people telling the truth are widely reported in the literature. The current study aimed to test for the effect of fraudulent events on pronoun use in emails using the Enron corpus and additionally applied a machine learning approach to estimate whether pronoun use predicts fraud. While the ratio between 1st and 3rd person pronoun use was related to fraud, this construct did not have predictive power. The current study highlights an important conclusion for the cognitive sciences: The importance of not only testing for differences, but of also applying predictive models. In this way it can be determined whether effects of a construct on an outcome can also predict the outcome.

Keywords: corpus linguistics; machine learning; deception; pronouns

Introduction

Many studies in the cognitive sciences rely on examining statistical differences. This approach provides us with important knowledge about differences in for example behavior between extroverts and introverts (Lu & Hsiao, 2010), clinical populations and non-clinical ones (Garnefski et al., 2002) and males and females (Bleidorn et al., 2016). While examining differences can aid in explaining behavior, it does not necessarily mean these differences have predictive power. Understanding behavior both involves explaining and predicting behavior (Rosenberg et al., 2018). A model focused on explanation could be appealing theoretically, but could be very limited in predicting actual human behavior (Yarkoni & Westfall, 2017).

One field of study in which differences have been widely examined is that of deception, in which comparisons are made between when people are lying and when they are telling the truth (DePaulo et al., 2003). Lying is cognitively more complex than telling the truth. To make a lie convincing we have to exert a lot of cognitive control, which might paradoxically be reflected in cues that betray our deception (Zuckerman et al., 1981), both verbally and non-verbally (DePaulo et al., 2003).

Several studies have examined these cues to deception using experimental manipulations, for example by asking participants to lie or to tell the truth, testing for a statistical difference between the manipulations. These studies demonstrated that there is a difference between liars and people that tell the truth: Liars provide fewer details and tell fewer compelling stories, as they are uncertain and less engaged (DePaulo et al., 2003). Liars apparently try to distance themselves from the content of the communication, with content increasing in abstractness (Louwerse et al., 2010). Abstractness in communication may be reflected in pronoun use (Hancock et al., 2008; Humpherys et al., 2011; Louwerse et al., 2010; Newman et al., 2003), with a decrease in self-references and an increase in other-references reflecting increasing abstractness. Even though experienced liars may be avoiding tainted words that reveal their intentions, pronoun use is outside of conscious control of speakers and writers and therefore a useful measure to determine whether statements are truthful or not (Pennebaker, 2011).

Newman et al. (2003) examined 1st person pronouns (self-references) and 3rd person pronouns (other-references) when participants were instructed to produce a story on abortion which matched their opinion or not. They demonstrated that participants who wrote a story they did not agree with used fewer 1st person singular and fewer 3rd person pronouns than participants that agreed with their story. Similarly, Hancock et al. (2008) asked participants to either write a truthful or untruthful story on several different topics. The participants that were untruthful used fewer 1st person pronouns and more 3rd person pronouns than truthful participants. A meta-analysis on 116 studies on lying and deceptive cues by DePaulo et al. (2003) also demonstrated that there is an effect of being truthful on pronoun use, with fewer self-references and more other-references showing up in liars. However,

Louwerse et al. (2010) found that fraudulent events were associated mostly with an increase in 1st person pronouns.

In sum, statistical differences between pronoun use in liars and people that are truthful have been established in the existing literature, although the direction of these effects varied across studies. Perhaps this is not entirely surprising, as the context and the ecological validity of these studies also differ. Most studies on pronoun use and deception induced lying with an experimental manipulation, by for instance asking participants to write about an opinion opposite to what they truly belief. These cases are considered to be deception (Newman et al., 2003), except that there is no consequence to participants' 'lying'. Such laboratory studies provide excellent insights in linguistic deceptive cues but lack ecological validity.

To use a case where the stakes of deception were higher than a manipulated laboratory setting, Louwerse et al. (2010), used an email dataset (Klimt & Yang, 2004), which contained 517,431 emails from about 150 Enron executives and employees from 1999 to 2001. The Enron Cooperation was one of the world's leading gas, electricity, and communication companies and is most famous for the elaborate and systematic way in which accounting fraud spread throughout the organization, which led to declaration of bankruptcy in 2001. The advantage of using this corpus is that, besides its ecological validity, it covers a relatively large time span and it has detailed information available on the company and its fraudulent activities (Diesner et al., 2005). The disadvantage of using a naturalistic corpus, however, is that it is very difficult to determine which emails actually contain deception and which ones do not. Louwerse et al. (2010) operationalized deception by identifying the periods during which fraudulent events took place, capitalizing on the sheer number of emails in these different time frames.

Although statistical differences show up between liars and non-liars in pronoun use and although this difference is theoretically making sense, it is not clear whether pronoun use allows for predicting deception, and if so, to what extent. The current study uses Louwerse et al. (2010) as an illustration. We used the Enron email dataset, but rather than only investigating whether there is an effect of fraudulent emails on linguistic variables as in Louwerse et al. (2010), we additionally applied a machine learning approach to estimate whether linguistic variables also predicted fraud. Moreover, rather than taking a large number of linguistic variables, we applied the principle of parsimony and only focused on pronoun use.

Table 1: Overview of events within the Enron Cooperation from 2000-2001. Marked events are considered fraudulent. Adapted from Louwerse et al. (2010) p. 964.

Event	Description of event	Date (month-year)
- Layoffs	Employees within Enron Corporation were laid off.	12-01
- CEO	Indicating involvement of the CEO within any coded event.	3-00, 08-00, 11-00, 01-01, 04-01, 08-01, 10-01, 11-01
- Fraudulent paperwork filled signed	Filing and/or signing of fraudulent paperwork (by the CEO or COO).	03-00, 08-00
- Fraudulent comments	Enron made fraudulent comments, to the employees and/or investors.	01-01, 09-01
- Discussion of ethics	A discussion of ethics occurred between Enron executives or between the CEO and employees.	07-00, 03-01, 05-01, 08-01, 09-01, 10-01
- Selling Enron shares	Selling of Enron stock by high-level executives occurs.	11-00, 05-01, 06-01, 07-01, 08-01, 09-01
- Rolling blackouts initiated	Intentional initiation of rolling blackouts in California.	01-01
- Meetings with national political figures	High-level Enron executives met with national political figures including the Secr. of the Treasury and the Secr. of Commerce.	02-01, 03-01, 04-01, 08-01, 10-01, 11-01
- Financial support of political candidate	High-level Enron executives (CEO & President) provided financial support for a newly elected national political figure.	01-01
- Profit announced	Profits were announced for the quarter.	04-01
- Loss announced	Losses were announced for the quarter.	10-01
- SEC inquiry developments	Beginning of the SEC inquiry and the point at which the SEC inquiry became a formal investigation.	10-01
- Shredding occurs	Shredding of Enron documents in Enron and/or Arthur Andersen accounting firm.	10-01
Shredding stopped	Shredding of Enron documents stopped in Enron and/or Arthur Andersen.	10-01, 11-01
- Fraud announced	Enron admitted to having overstated the company's profits.	11-01
- Bankruptcy filed	Bankruptcy was filed.	12-01

Methods

Selection and Classification of Data

Only emails sent by Enron employees were selected to filter the data from noise, such as advertisements, promotions, and other junk mail. Accordingly, we excluded duplicate emails and emails from other organizations (number of emails excluded in this step: 486,272). Next, we used the Interquartile Range rule for outlier removal: emails that had length above 1.5 times the Interquartile Range were excluded (number of emails excluded in this step: 2,157). This was necessary as some emails included the quoted replies from previous emails, thus providing redundancy. Finally, since our objective was to explore pronoun use, specifically the relationship between the use of different types of pronouns, we excluded emails that did not have at least one 1st person pronoun and one 3rd person pronoun (number of emails excluded in this step: 19,523). In summary, out of the 517,431 emails in the Enron dataset, 9,479 emails (1.83%) were included for further analyses.

Based on Louwerse et al. (2010), 16 types of events within the Enron Corporation from 2000-2001 were identified based on the timeline of the Enron case (Table 1). The event types 'fraudulent paperwork filed signed', 'fraudulent comments', 'rolling blackouts initiated' and 'shredding of documents' were identified as clearly fraudulent. Additionally, as Enron admitted to having overstated the company's profit, the events of 'profit announced' and 'loss announced' were also considered fraudulent. All events considered fraudulent are marked in gray in Table 1.

The dataset primarily consisted of emails from higher executives, increasing the probability that the content of the emails involved decision-making processes related to the fraudulent events. Emails sent during those activities that were sent in periods of fraudulent events were labeled as fraudulent. All other emails were labeled as non-fraudulent. Obviously, this is an overgeneralization, but a useful one given the illustrative purposes of the current study examining significant differences and predictive power.

A total of 28.1% (N = 2,664) of the 9,479 included emails was classified as being related to fraudulent events (compared to 71.9% [N = 6,815] being not related to fraudulent events). An overview of the distribution of normalized 1st and 3rd person pronouns in fraudulent and non-fraudulent emails is depicted in Figure 1.

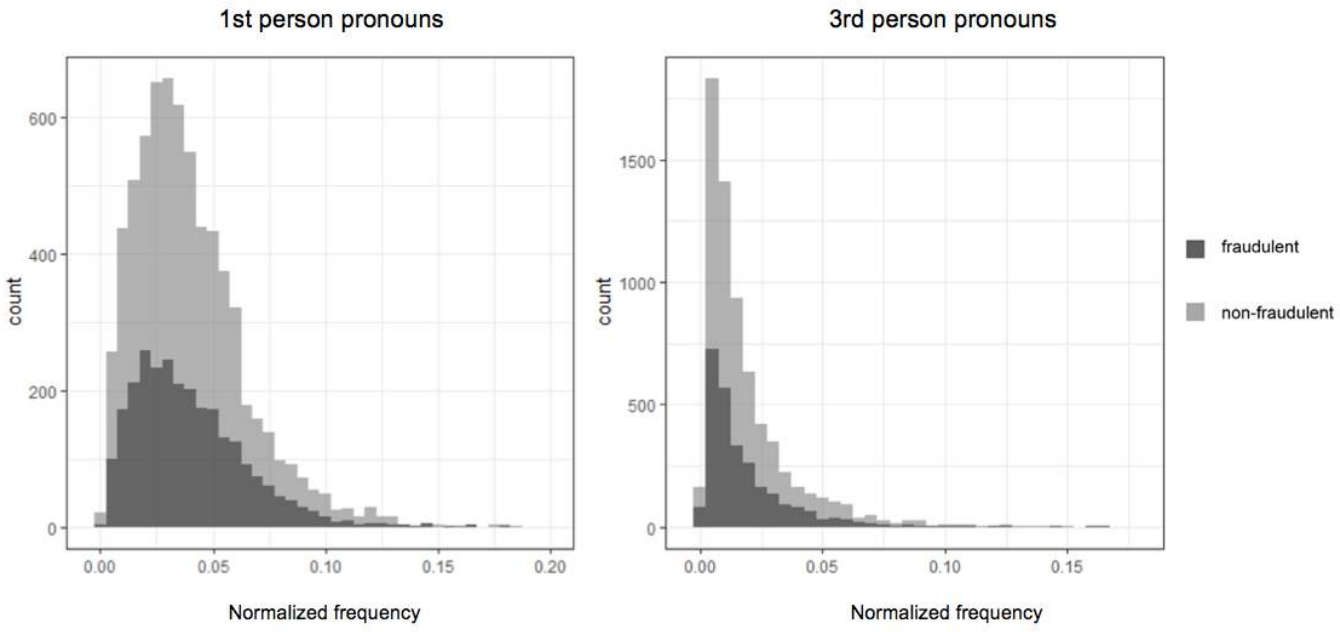

Figure 1: Distribution of normalized 1st and 3rd person pronouns in fraudulent (dark gray) and non-fraudulent (light gray) emails.

Feature Extraction

The number of occurrences of 1st person and 3rd person pronouns were computed for each of the 9,479 emails (see Table 2 for an overview of included pronouns). These occurrences were then normalized by the number of word tokens in each email.

Table 2: Included 1st and 3rd person pronouns.

Type of pronouns	Included pronouns
1st person	*I, me, my, mine, myself, we, us, our, ours, ourselves*
3rd person	*he, she, him, her, his, hers, himself, herself, they, them, their, theirs, themselves*

Data Analysis

Relationship Pronoun Use and Fraudulent Events The relationship between 1st person and 3rd person pronoun use frequency and fraudulent events was examined by computing two logistic regression models.

In Model 1, we used the (normalized) frequency of 1st person pronouns and the (normalized) frequency of 3rd person pronouns as independent variables, and the class label (fraudulent/non-fraudulent) as dependent variable. In Model 2, we computed whether the ratio between 1st person and 3rd person pronoun use had any relationship to the class label. Both models were fitted using a maximum likelihood estimator, using the Python package StatsModels.

Predicting Fraudulent Events Through Pronoun Use In order to predict whether an email was related to fraudulent events, we used two logistic regression classifiers. The classifiers were fitted using the same features as the logistic regression models; specifically, Classifier 1 was trained on the (normalized) frequency of 1st person pronouns and (normalized) frequency of 3rd person pronouns, while Classifier 2 was trained on the ratio between 1st person and 3rd person pronouns. In order to deal with imbalanced data in the training phase, class weight was set to "balanced". In this way, the classifier penalizes mistakes in each class with a weight inversely proportional to the frequency of that class, in order to avoid favoring only the overrepresented class. Both classifiers were evaluated on accuracy, precision, recall, and F1. We also plotted the ROC curve to facilitate the visualization of the relationship between precision and recall. The performance scores were calculated using 10 x stratified 10-fold cross validation, and we report the mean value of all 100 individual scores. For the implementation, we used the LogisticRegression class from the Python library Scikit-learn, with all default parameters (except for class_weight, set to "balanced" to deal with the imbalance over the classes).

Results and Discussion

Relationship Pronoun Use and Fraudulent Events Model 1, which uses normalized 1st and 3rd person pronouns as separate independent variables, did not show a significant relationship between pronoun use and fraudulent events, p = .108 (Table 3).

Table 3: Logistic regression results for Model 1 (normalized 1st and 3rd person pronoun frequency).

			p
Model likelihood			.108
Variable	β	S.E.	p
Intercept	-0.95	0.04	<.001
1st person pronouns	1.38	0.97	.155
3rd person pronouns	-2.61	1.34	.051

Table 4: Logistic regression results for Model 2 (ratio between 1st and 3rd person pronoun frequency).

			p
Model likelihood			.023
Variable	β	S.E.	p
Intercept	-0.99	0.03	<.001
1st/3rd person pronouns	0.01	0.01	.022

Model 2, which uses the ratio between 1st and 3rd person pronouns, did show a significant relationship between pronoun use and fraudulent events, p = .023 (Table 4). The results demonstrated that 1st and 3rd person pronoun use were not individually related to fraudulent events, but that the ratio between the two was. The average ratio for emails that were and were not related to fraudulent events was 3.93 and 3.74 respectively, demonstrating that during times of fraudulent events the use of 1st person pronouns relative to the use of 3rd person pronouns increased. This relationship conflicts with the notion that people try to distance themselves from the information they are conveying when they are being untruthful by increasing abstractness by reducing self-references and increasing other-references in their communication. Yet, these findings are in line with the study of Louwerse et al. (2010) which also did not find support for pronouns reflecting increased abstractness during fraud, but did find support for abstractness in verbs.

As it is important not only to examine the relationship between a construct and an outcome, but also to examine whether the construct has predictive power, we also report the results of the logistic regression classifiers, to predict whether or not an email is related to fraudulent events based on 1st and 3rd person pronoun use.

Table 5: Average results from the 10 x 10-fold cross validation for Classifier 1 (normalized 1st and 3rd person pronoun frequency).

	Accuracy	Precision	Recall	F1
Predicting fraud	48.24%	28.40%	55.39%	37.51%
Predicting non-fraud	48.24%	72.29%	45.44%	55.71%

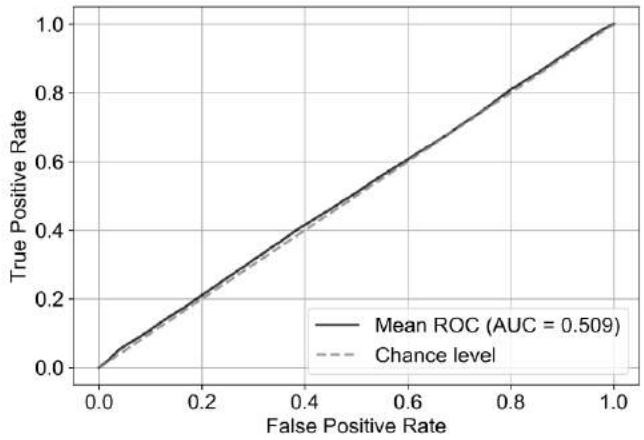

Figure 2: ROC curve for Classifier 1 (normalized 1st and 3rd person pronoun frequency).

Predicting Fraudulent Events Through Pronoun Use The evaluation scores from the 10 x 10-fold cross validation of Classifier 1 (trained on the normalized frequency of 1st person and 3rd person pronouns) are presented in Table 5 and the model's ROC curve is depicted in Figure 2.

As can be seen in Table 5 and in Figure 2, Classifier 1 did not perform above chance level (accuracy = 48.24%). F1 scores were also relatively low, reaching a maximum of 55.71% for predicting non-fraud. Precision scores were considerably higher for predicting non-fraud than for predicting fraud, indicating that the model favored the more common class. The evaluation scores and the ROC curve thus demonstrated the classifier based on the normalized individual frequencies has limited predictive power. This finding is in line with the absence of a significant relationship between these individual frequencies and fraudulent events.

The evaluation scores from the 10 x 10-fold cross validation for Classifier 2 (ratio between 1st and 3rd person pronoun use) are presented in Table 6 and the model's ROC curve is depicted in Figure 3. As can be seen in Table 6 and in Figure 3, the model using the ratio between 1st and 3rd person pronouns performed slightly above chance level (accuracy = 57.37%). F1 scores were again relatively low, reaching a maximum of 68.80%. As was the case for the classifier using the normalized individual frequencies, precision scores were a lot higher for the most common class. Considering all evaluation scores and the ROC curve, the model using the ratio between different pronouns also had limited predictive power.

Table 6: Average results from the 10 x 10-fold cross validation for Classifier 2 (ratio between 1st and 3rd person pronoun frequency).

	Accuracy	Precision	Recall	F1
Predicting fraud	57.37%	29.35%	36.79%	32.64%
Predicting non-fraud	57.37%	72.59%	65.41%	68.80%

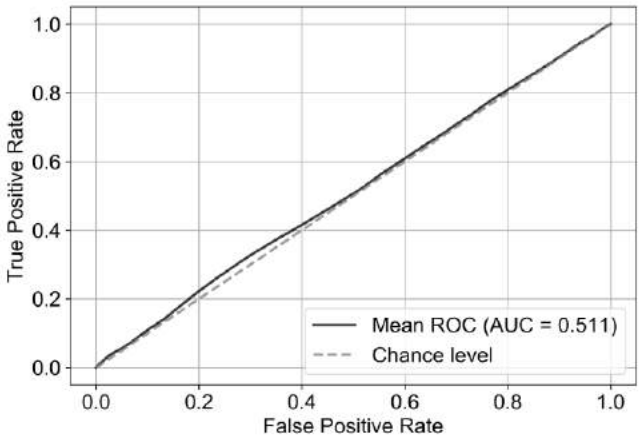

Figure 3: ROC curve for Classifier 2 (ratio between 1st and 3rd person pronoun frequency).

The mean ROC AUC of 0.511 indicates that this classifier is not able to classify deception any better than chance level. In conclusion, even though there was a significant relationship between pronoun use ratio and fraud, this construct had relatively little predictive power.

General Discussion

In the cognitive sciences many studies focus on examining statistical differences. This approach in which differences are examined provides us with valuable insights to explain behavior. Yet, it does not necessarily mean that these differences have predictive power. Understanding behavior both involves explaining and predicting behavior.

As a point in case, the current study examined the relationship between 1st and 3rd person pronoun use in emails sent by Enron employees and fraudulent activities. Additionally, we attempted to predict fraudulent events using 1st and 3rd person pronoun use in the emails.

Previous research demonstrated statistical differences between pronoun use in liars and people that are truthful, but the direction of the effects varied across studies. These studies generally examined the separate effects of 1st and 3rd person pronoun use. The current study demonstrated that the ratio between 1st and 3rd person pronouns was related to fraudulent events. This relationship indicated that the use of 1st person pronouns relative to 3rd person pronouns increased during times of fraudulent activities.

Differences in pronoun use between fraudulent and non-fraudulent communication do not necessarily imply that this construct has any predictive power. In our attempt to predict fraudulent events through pronoun use in emails, classification models scored relatively low on all evaluation measures. These models are therefore limited in their predictive power, not being able to classify deception any better than chance level.

The finding of the current study that differences in 1st and 3rd person pronoun use had no predictive power warrants reported differences in pronoun use between truthful and deceptive communication to not be interpreted as providing a meaningful tool for predicting fraud.

Possibly, classification models were limited in their predictive power in the current study due to the way in which the data were labeled. Whether an email was considered fraudulent or not was based on a general timeline, which might add extra noise to the data. One cannot be sure about the number of emails containing deception and the amount of emails containing no deception that was correctly labeled. However, this issue is inherent in using a naturalistic dataset. The fact remains that it is of utmost importance when one wants to gain a comprehensive insight to not only examine constructs in the laboratory, but also in settings that are of higher ecological validity.

Although effects of deception on 1st and 3rd person pronoun use in communication are widely reported and have been demonstrated in the current study, this construct seems to lack in predictive power. The current study highlights an important conclusion for the cognitive sciences: The importance of not only testing for differences, but of also applying predictive models in order to determine whether effects of a construct on an outcome are also meaningful in predicting the outcome.

Abstract

Using a novel adaptation of the visual world eye-tracking paradigm we investigated children's and adults' online processing of reference in a naturalistic language context. Participants listened to a 5-minute long storybook while wearing eye-tracking glasses. The gaze data were analyzed relative to the onset of referring expressions (i.e., full noun phrases (NPs) and pronouns) that were mentioned throughout the story. We found that following the mention of a referring expression there was an increase in the proportion of looks to the intended referent for both children and adults. However, this effect was only found early on in the story. As the story progressed, the likelihood that participants directed their eye gaze towards the intended referent decreased. We also found differences in the eye gaze patterns between NPs and pronouns, as well as between children and adults. Overall these findings demonstrate that the mapping between linguistic input and corresponding eye movements is heavily influenced by discourse context.

Keywords: visual world paradigm; eye-tracking; reference processing; discourse

Introduction

During spoken communication, we use different types of referring expressions in order to specify people, places and things. These include both full noun phrases (NPs) (e.g., 'Sarah', 'the bear') and pronouns (e.g., 'she', 'it'). In order for communication to be successful, speakers must choose appropriate referring expressions and listeners must rapidly map those referring expressions onto the intended referents. One method that has been used to investigate the online comprehension of reference is the visual world eye-tracking paradigm (VWP) (Cooper, 1974; Tanenhaus, Spivey-Knowlton, Eberhard, & Sedivy, 1995). In the VWP, an individual's eye movements are monitored as they receive spoken language input and view a visual scene. The eye gaze response relative to the spoken language input is taken to reflect underlying processes involved in online language comprehension.

In a seminal paper, Cooper (1974) found that when people were simultaneously presented with spoken language input and a visual scene, they naturally directed their eye gaze towards entities in the visual scene that are semantically related to the language being heard. For example, when participants heard phrases such as 'suddenly I noticed a hungry lion' they fixated on a lion present in the visual scene ~200 milliseconds (ms) after hearing 'lion'. Cooper proposed that the relationship between spoken language input and eye gaze fixations could be viewed as an active online process, and as such could be used to investigate online language processing. Tanenhaus and colleagues (1995) further investigated the influence of the visual scene on spoken language comprehension. They recorded participants' eye movements as participants followed spoken instructions and manipulated real objects visible in front of them. They found that participants fixated on target objects ~250 ms after hearing the word that uniquely identified the target. For example, when participants heard instructions such as 'touch the starred yellow square', they fixated on the target 250 ms after hearing 'starred' when there was only one starred object. However, if participants were given the same instruction and there were two starred objects, they did not fixate on the target until 250 ms after hearing 'yellow', highlighting the high temporal resolution between linguistic input and corresponding eye

movements. Both these studies were instrumental in the development of the VWP as a tool for investigating online language processing.

The mapping between linguistic input and corresponding eye movements has also been utilized to investigate language processing that relies on inference, as is the case in online pronoun resolution (e.g., Arnold, Eisenband, Brown-Schmidt, & Trueswell, 2000; Järvikivi, Van Gompel, Hyönä, & Bertram, 2005). Typically in these studies, participants view scenes with two (or more) referents while listening to passages that contain an ambiguous pronoun. Because pronouns do not have a fixed meaning, there is not a direct association between the linguistic input (i.e., 'he') and a corresponding referent in the visual scene. Thus, listeners must infer which referent the pronoun refers to and eye gaze is taken to reflect this process. For example, VWP studies have reported that following the mention of an ambiguous third person singular pronoun (i.e., 'he'), there is an increase in the proportion of looks to the grammatical subject of the preceding sentence/clause (e.g., Järvikivi, et al., 2005; Kaiser & Trueswell, 2008). This increase in the proportion of looks has been taken to suggest that participants interpreted the pronoun as co-referring with the preceding subject, providing further evidence for what is known as the subject bias (e.g., Crawley, Stevenson, & Kleinman, 1990; Frederiksen, 1981).

In addition to high temporal resolution, another advantage of the VWP is that it does not require participants to read or carry out demanding tasks, and therefore can be used to investigate online language processing in young children. This allows for direct comparisons between children and adults without the potential confounds introduced by response requirements. For example, VWP studies have reported that children as young as 2.5 to 4 years old appear to be sensitive to the subject bias (e.g., Hartshorne, Nappa, & Snedeker, 2015, for an overview; Järvikivi, Pyykkönen-Klauck, Schimke, & Hemforth, 2014; Pyykkönen, Matthews, & Järvikivi 2010; Song & Fisher 2005; 2007). However, the increase in the proportion of looks to the grammatical subject usually did not occur until relatively late (i.e., 1200 ms) after the pronoun onset, suggesting there is still a difference between children and adults.

Another advantage that has been attributed to the VWP is that it can be used to investigate language processing under relatively realistic conditions. This is primarily because the comprehension processes can proceed uninterrupted by response requirements. However, the majority of previous VWP studies have used carefully designed tasks that often encourage participants to carefully look at the visual scene. Furthermore, participants were usually presented with a series of isolated experimental items, where each item was no more than 2-3 sentences, and thus lacked any sort of rich context. This means that each item introduced a new situation or topic, for which participants had no context. In sum, previous applications of the VWP may not accurately reflect naturalistic language processing.

To date, only a single study has used the VWP to investigate reference processing in a continuous discourse. Engelen, Bouwmeester, de Brain and Zwaan (2014) had children listen to a 7-minute long story while viewing a display containing four black and white animal line drawings. They analyzed eye gaze data for both full NPs (e.g., 'rabbit') and pronouns (e.g., 'he') and found that following the onset of a referring expression there was an increase in proportion of looks to the target. However, they also found that overall target fixations (following an NP or pronoun) decreased as the story unfolded over time. However, given that participants viewed the same simple display for the entire 7-minutes, it is possible that the overall decrease was an artifact of fatigue or boredom. To date no study has used the VWP to investigate reference processing in a context where both the language input and visual scene reflect a natural language setting.

Present Study

The present study applied a novel adaptation of the visual world eye-tracking paradigm (VWP) in order to explore online reference processing in a naturalistic language setting. Children and adults listened to a 5-minute story containing multiple animal characters while wearing eye-tracking glasses (ETG). We opted to use ETG over a more traditional table-mounted eye tracker because we wanted to keep the language processing context as naturalistic as possible. The ETG are akin to normal reading glasses and allow for participants to move more freely throughout the duration of the experiment. We analyzed eye gaze patterns with respect to the onset of referring expressions (full NPs and pronouns) mentioned throughout the story. Given the novelty of the methodological application it was important to be able to compare the eye gaze patterns between the two types of referring expressions, as well as between children and adults. Our primary goal was to explore language mediated eye movements outside the context of a carefully designed VWP task. We were interested in what eye gaze patterns could tell us about the processing of continuous discourse in a naturalistic language setting.

Method

Participants

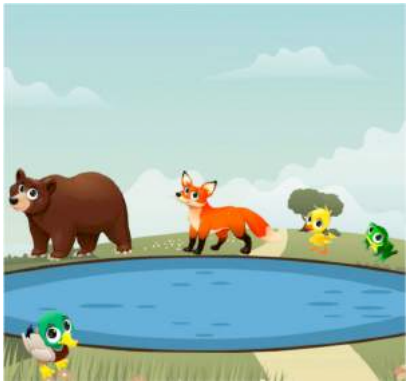
Thirty-five native English-speaking children recruited from preschools and daycares in Edmonton, Alberta, participated in the study. Written parental consent was obtained prior to participation and children received stickers and a t-shirt in exchange for their participation. Despite the fact that the ETG were supposed to be child-friendly, during the analysis it became evident that there

was large amount of gaze loss across participants. This was because the angle between the cameras on the ETG and children's pupils was too large, meaning that the ETG were too big to accurately keep track of eye gaze for some children. This resulted in 17 children being excluded from the analysis. An additional 3 children were excluded because they did not fit the age range (> 6 years old). This resulted in 15 children (7 female; mean age = 4.8 years; range 4.2-5.6) being included in the final analysis. All children had normal vision and hearing based on parental-report.

Sixteen native English speaking adults also participated in the study to serve as a control group. All adults were undergraduate students from the University of Alberta and received partial course credit for their participation. Written consent was obtained prior to participation. Four adults were excluded from the analysis due to technical issues with the ETG. This resulted in 12 adults (10 female; mean age = 20 years; range 18.2-22) being included in the final analysis. All adults had normal vision and hearing based on self-report.

Materials

A 22-page electronic storybook was constructed to be similar in style to an everyday storybook that would be read to children. The story was about a group of animal friends helping a duckling find his father. It contained multiple referring expressions in the linguistic discourse, with corresponding referents in the illustrations. The story began with a single character and after every 3-5 pages a new character was introduced so that it ended with 5 characters in total. All characters were referred to using the masculine pronoun 'he' to ensure ambiguity. The storybook illustrations were created using images from freepik.com. The audio was recorded by a female native speaker of English in a sound-attenuated booth. The illustrations and audio were then pieced together into a 5 minute and 26 second long .mp4 video, where the pages flipped as if it were a real book. An example illustration and associated dialogue can be seen Figure 1 below.



'But before anyone could start looking, Duckling spotted Daddy Duck across the pond! He flapped his wings with excitement. Daddy Duck looked up and saw Duckling. He sighed with relief and started swimming across the pond.'

Figure 1: Example illustration and associated dialogue

Critical Items

Thirty-six full NPs (i.e., character names) and 10 ambiguous pronouns (i.e., he) were selected as experimental items. These items were selected with the criteria that they did not overlap with other referring expressions, meaning that another referring expression could not occur within the ~1200 ms window following their onset. Furthermore, pronouns had to follow a clause where both the grammatical subject and object were animal characters. Because this was a natural story, there was variation in the input that both preceded and followed the critical pronouns. However, it should be noted that at pronoun onset (and for a period of time afterwards), all critical pronouns were ambiguous. Two examples can be seen below and the full set can be found in the supplementary materials[1].

1) Fox thanked Bear. He wanted to play a different game.
2) Bear told Fox to go and hide. He started counting to five.

Procedure

All children were tested individually at their preschool or daycare. The children sat approximately 50 cm in front of a Lenovo laptop and were first familiarized to the animal characters by being shown each animal individually and then being asked to name the animal. In the event that the child misnamed the animal they were corrected. The children were then told they would listen to a short story about the animals while wearing special ETG. The ETG were placed on the child's head and secured using an adjustable strap. The children completed a 3-point calibration and then listened to the electronic storybook. The eye gaze data were collected with SensoMotoric Instruments (SMI) ETG wireless 2 eye-tracking glasses, which included a built-in high-definition scene camera that recorded all audio and video. Registration was binocular with a sampling rate of 60 Hz (16.6ms/frame). After listening to the storybook children were asked a series of five comprehension questions in order to ensure that they had been paying attention. Children had to answer at least four questions correctly in order to be included in the analysis. All children met this criterion.

All adults were tested at The Centre for Comparative Psycholinguistics at the University of Alberta following a similar procedure.

Gaze coding

The gaze data were coded frame-by-frame using Noldus ObserverXT software (Noldus Information Technology, 2012). The areas of interest were each of the five animal characters. Eye gaze that fell outside of interest areas (IAs) was coded as 'elsewhere' or in the case of trackloss was coded as 'NA'. This resulted in a data frame in which each IA had a separate column and every row represented a single frame (~16.7 ms of time). For each frame the IA columns either had a value of 0 (gaze not within IA) or 1

[1]The supplementary materials can be found at: https://git.lwp.rug.nl/a.g.toth/VWP- discourse

(gaze within IA). The gaze data were then binned into 5-frame time bins each representing ~83 ms so that the values in the IA columns could have values between 0 and 5.We were interested in analyzing looks to the target referent (versus looks elsewhere), which in the case of pronouns was coded as the subject of the preceding clause. The time window we were interested in was 2 bins before the referring expression onset up until 14 bins after the referring expression onset (~1415 ms in total).

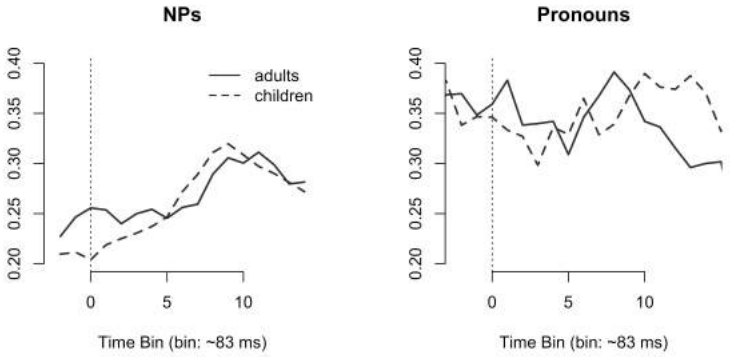


Figure 2: Average proportion of target looks across the time bin analysis window (~1415 ms)

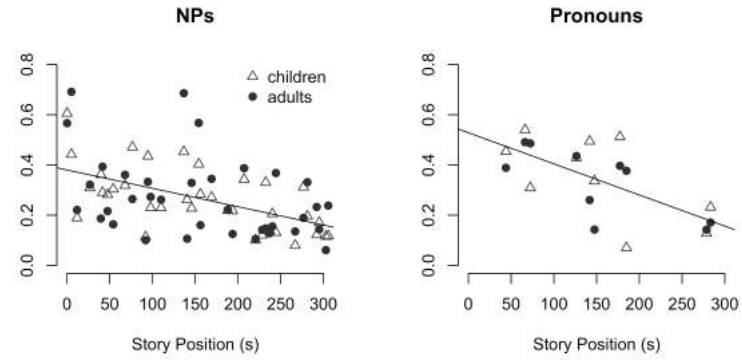

Figure 3: Average proportion of target looks across story duration

Results

Average proportion of looks

Figure 2 shows the average proportion of looks to the target referent across *Time Bin,* where the zero line indicates the referring expression onset and each time bin represents ~83 ms of time. The proportion of looks were averaged over age group (children versus adults separately) and items (NPs versus pronouns separately). For the NPs (left panel) you can see that the proportion of looks to the target increased following referring expression onset and more so for the children (dashed line) compared to adults (solid line). For the pronouns (right panel) the relationship is less clear. However, it should be noted that there were many fewer pronouns than NPs, which can also be seen in the relative smoothness of the lines. Figure 3 shows the average proportion of looks to the target across the duration of the story (*Story Position*), averaged over age group and time bin. For both NPs (left panel) and pronouns (right panel), as well as children (triangles) and adults (circles) there is a clear downward linear trend, meaning that the overall proportion of looks to the target decreased as the story progressed over time.

Analysis

The gaze data were analyzed in R (version 3.1.2; R Core Team 2014) using Generalized Additive Mixed Modeling (GAMM, Wood 2006, mgcv R-package). GAMM is a nonlinear regression method that allows for the modeling of both linear and nonlinear random effects. We opted to use GAMMs over more standardized linear modeling because GAMMs are specifically designed to model nonlinear data and like most time series data, eye-tracking data is almost always nonlinear (Porretta, Kyröläinen, van Rij, & Järvikivi, 2018). The nonlinear relationship between the dependent variable and the predictors is modeled as a smooth function, which is a weighted sum of a set of base functions that each have a different shape. Using logistic GAMMs, we analyzed the counts (looks to the target vs. looks elsewhere) for each time bin (see Porretta et al. for discussion of binomial GAMMs for eye tracking data).

To determine the best-fitting model we did not perform a model comparison procedure, as model comparisons are not very reliable for binomial data (Wood, 2017). Instead, we included binary predictors (which model the difference between conditions) so that we could use summary statistics provided by the mgcv package to determine the significance of the smooth terms. In addition, we used visualization methods to interpret and verify the contribution of the smooth terms (cf van Rij, Hollebrandse, & Hendriks, 2016; van Rij, Hendriks, van Rijn, Baayen, & Wood, in press).

GAMM model of target looks

In order to investigate the eye gaze patterns between the four experimental conditions (adult NPs, child NPs, adult pronouns and child pronouns), we created three binary predictors. *IsChild*, which models the difference between adults (reference level) and children, *IsPronoun*, which models the difference between noun phrases (reference level) and pronouns, and *IsChildPronoun*, which models the additive interaction effect between *IsChild* and *IsPronoun*. We then included the predictor *Time Bin,* in order to analyze looks to the target referent across the time bin analysis window (where time bin 0 was the referring expression onset). We also included the predictor *Story Pos* (i.e., how far into the story the referring expression occurred), in order to test whether looks to the target referent changed as the story progressed. All predictors were allowed to interact. The smooth functions (s()) model the nonlinear regression lines for *Time Bin* and *Story Pos* interacting with the four experimental conditions. The nonlinear tensor product interactions (ti()) model the nonlinear interaction surface between *Time Bin* and *Story Pos* and the four experimental conditions, allowing us to

investigate whether the gaze patterns relative to hearing the referring expression change over the course of the story. To account for individual variation between participants, we included nonlinear random by-Subject factor smooths for *Time Bin* and *Story Pos*, as well as a random intercept for Event (unique Subject-Item combination). To account for autocorrelation in the residuals, an AR1 model was included by specifying the rho parameter and starting point for each time series (cf. Baayen, van Rij, de Cat, & Wood, 2018; van Rij et al., in press). The full analysis can be found in the supplementary materials and the final model summary is presented in Table 1.

Table 1: Summary of the partial effects in GAMM fitted to count data (looks to target vs. looks elsewhere)

For the reference level (adult NPs) there was a significant nonlinear interaction between *Time Bin* and *Story Pos* (Chi.sq(14.429)=130.82; p<.001), meaning that target looks relative to hearing an NP changed as the story progressed over time. The interaction between *Time Bin* and *Story Pos* was also significant for each binary predictor: *IsChild* (Chi.sq(14.153)=126.29; p<.001), *IsPronoun* (Chi.sq(14.677)=182.72; p<.001) and *IsChildPronoun* (Chi.sq(14.448)=153.73; p<.001). Thus, we can conclude that all four experimental conditions have unique interaction surfaces. In order to interpret the interactions, we must use visualization. The contour plots in Figure 4 show how target looks relative to hearing an NP changed as the story progressed over time for both adults and children. The plots can be read like a topographic map with peaks and valleys, where pink indicates more looks to the target and green indicates more looks elsewhere. Both adults' and children's target looks increased after hearing an NP; however, this likelihood decreased in a nonlinear fashion as the story progressed over time. For example, approximately 30 seconds into the story (y-axis), it can be seen that the color changes from green to pink, moving from left to right (x-axis), indicating that target looks began increasing around time bin 3 (~250 ms after NP onset). However, 250 seconds into the story (y-axis), it can be seen that there is relatively solid green, moving from left to right (x-axis), indicating that there was almost no effect of Time Bin later on in the story. It can also be seen that the peak is steeper for children as compared to adults. The contour plots in Figure 5 show how target looks relative to hearing a pronoun changed as the story progressed over time for both adults and children. The white bands indicate the places throughout the story where there are no data, and thus should not be taken into consideration when interpreting the interaction surface. Similar to the NPs, both adults' and children's target looks increased after hearing a pronoun, but again the likelihood decreased in a nonlinear fashion as the story progressed over time. Reflected by the overall color becoming greener as you move from the bottom to the top of the plots (y-axis). It also appears that earlier on in the story (~30 seconds on the y-axis) the increase in target looks happens sooner for adults than it does for children; around time bins 3 (~250 ms) and 8 (~667 ms) respectively. However, because there were a lot less data for the pronouns we need to be careful to avoid over-interpretation.

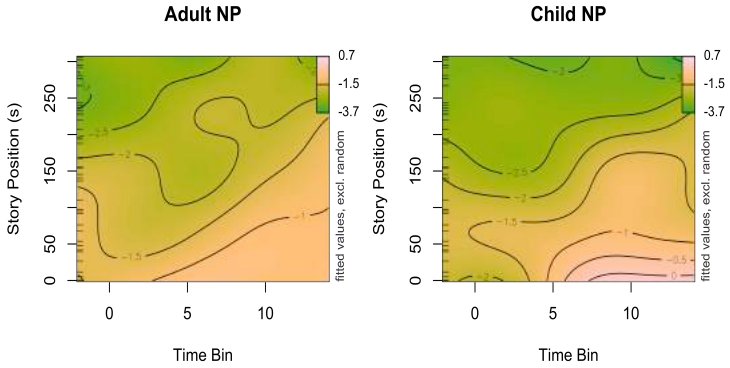

Figure 4: NP contour plots of the interaction between *Time Bin* and *Story Position* for adults and children. Pink indicates more target looks and dark green indicates fewer target looks.

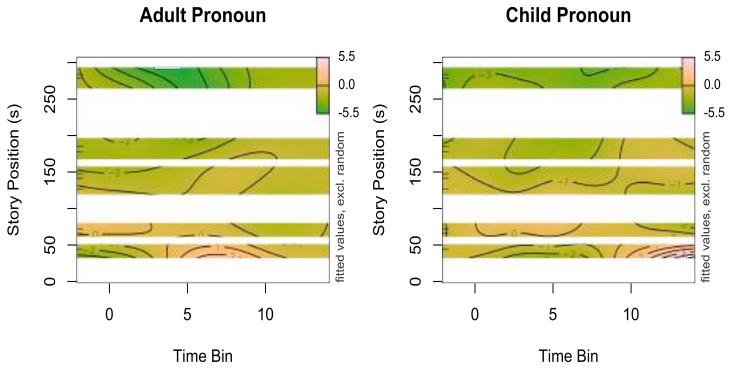

Figure 5: Pronoun contour plots of the interaction between *Time Bin* and *Story Position* for adults and children. Pink indicates more target looks and dark green indicates fewer target looks.

Discussion

The current study applied a novel adaptation of the visual world eye-tracking paradigm (VWP) in order to investigate the online comprehension of reference in a naturalistic language setting.

Overall, we found that eye gaze patterns relative to the onset of referring expressions (full NPs and pronouns) were largely influenced by when in the story the referring expressions occurred. When participants (both children and adults) heard a referring expression earlier on in the story, there was an increase in looks to the target referent. However, when participants heard a referring expression later on in the story there was no increase in looks to the target referent. This finding is in line with that of Engelen et al. (2014), who also found that overall target fixations following a referring expression decreased across a continuous discourse. They suggested that the visual scene may be particularly useful when first building a mental representation of the discourse, such that listeners search for appropriate referents in the visual scene, which results in eye movements being closely time-locked with the unfolding linguistic input. However, once a mental representation is well established, the visual scene does not provide any additional information and therefore eye movements are not closely time-locked. The argument for the visual scene not providing any additional information may be particularly relevant in the case of Engelen et al. (2014), given that the same visual scene was on display for their entire 7-minute discourse. As such, we originally proposed that their findings may be an artifact of fatigue or boredom. Interestingly, we found the same pattern despite using 22 different visual scenes throughout a 5-minute discourse. Based on the similarity of findings, we no longer believe that it is the type of visual scene (simple versus more complex) that causes the downward trend, but more likely a difference in the role that the visual scene plays throughout continuous discourse processing.

Although the visual context in the present study differed from that of Engelen and colleagues (2014), in both studies only a single mental representation of the linguistic discourse was required. This differs from more traditional VWP studies, in which items are presented in isolation and therefore participants must build a new mental representation for each item. In these studies, the eye gaze patterns associated with each item reflect the same type of processing that is, trying to understand who is doing what to whom (i.e., constructing a mental representation). But, because there is no additional linguistic context, the visual scene becomes particularly important for extracting information. This results in a close time-locking between linguistic input (i.e., the mention of a referring expression) and corresponding eye movements in the visual scene (i.e., looking at the referent almost immediately after it being mentioned). In our study, we also saw this for items that occurred earlier on in the discourse. So why did we not see it for items that occurred later on? Perhaps it is simply because later on in the discourse participants already know who the referents are and generally what is going on. In other words, participants already have an established mental representation of the discourse. Therefore, they do not rely on the visual scene for information to the same extent as they do at the beginning of the discourse (or in the more traditional VWP experiments that use thematically mutually unrelated 1-3 sentence stimuli). This results in eye movements not being closely time-locked with the linguistic input in the same way that they are at the beginning of the discourse and in more traditional VWP studies. It is not that eye gaze patterns later on in the discourse are arbitrary (or unmeaningful), but rather that they may reflect a type of processing for which the timing between the linguistic input and the corresponding eye movements and gaze location is not yet well understood. One possibility is that, as the discourse status of a referent changes due to repeated mentions and due to the continuous story context, participants engage in inspecting other aspects of the visual scene to refine their discourse representation, instead of looking at the referent each time it is mentioned.

In addition to looking at overall eye gaze patterns, we also compared the eye gaze patterns between full NPs and pronouns, as well as between children and adults. Following the mention of an NP, we found that earlier on in the story there was a greater increase in the proportion of looks to the target referent for children compared to adults. However, as the story unfolded children became less likely to fixate on the target compared to adults (i.e., there was a stronger effect of story position for children). Following the mention of a pronoun, we found that earlier on in the story children and adults showed a similar increase in the proportion of looks to the target referent, but this happened sooner for adults than children (~250 versus ~667 ms after pronoun onset, respectively). However, given that the dataset was relatively limited, these findings are preliminary and invite further research.

Given the novelty of the present study there were several challenges, the primary one being the technical issues with the eye-tracking glasses, which resulted in >50% of the children being excluded from the analysis. Furthermore, we ended up having a lot fewer referring expressions to analyze than we would have liked (especially in the case of pronouns). This was because our primary goal was to keep the story as natural-sounding as possible and including an excessive amount of referring expressions would have been counterproductive to this goal. Together, these two factors resulted in there being a relatively small dataset, which always runs the risk of lacking statistical power. Nonetheless, the findings from the current study build upon those reported by Engelen et al. (2014) and provide convincing evidence that the relationship between linguistic input and gaze behavior is heavily influenced by context. They further suggest that this relationship is affected by the discourse status of the referent, which changes over the course of a normal continuous story. Furthermore, the findings demonstrate the importance of investigating language processing under naturalistic conditions. Future research is needed to better understand the link between linguistic input and corresponding eye movements.

Acknowledgments

We would like to acknowledge the Social Sciences and Humanities Research Council of Canada (SSHRC), as well Words in the World (a SSHRC partnered research training initiative) for funding this research. We would also like to thank Kaleigh and Romy for all their help with the creation and recording of the experimental stimuli.

Abstract

Language processing depends on the integration of bottom-up information with top-down cues from several different sources—primarily our knowledge of the real world, of discourse contexts, and of how language works. Previous studies have shown that factors pertaining to both the sender and the receiver of the message affect the relative weighting of such information. Here, we suggest another factor that may change our processing strategies: perceptual noise. We hypothesize that listeners weight different sources of top-down information more in situations of perceptual noise than in noise-free situations. Using a sentence-picture matching experiment with four forced-choice alternatives, we show that degrading the speech input with noise compels the listeners to rely more on top-down information in processing. We discuss our results in light of previous findings in the literature, highlighting the need for a unified model of spoken language comprehension in different ecologically valid situations, including under noisy conditions.

Keywords: sentence processing; perceptual noise; pragmatic context; real-world semantics; rational inference.

Introduction

Language processing is based on the integration of bottom-up and top-down information (Marslen-Wilson, 1987; McClelland & Elman, 1986). As we process language, the incoming input is integrated with our existing knowledge—of the local discourse contexts, of the world, and of language—and creates a frame of reference for what comes next (Ferreira & Chantavarin, 2018). This integration happens rapidly (Christiansen & Chater, 2016) and entails that the available evidence must be promptly weighted against prior information, in an effort to determine the likelihood of different specific interpretations of the perceived input (e.g., Gibson, Bergen, & Piantadosi, 2013; Levy, 2008). Success in processing is therefore dependent on the availability of reliable (probabilistic) cues to correct sentence interpretation (Martin, 2016).

At least three sources of information seem to concurrently constrain this inferential process (Venhuizen, Crocker, & Brouwer, 2019). At a local level, the syntactic structure of the language input affects the interpretation of the content of a given linguistic input. An example hereof is that the meaning of syntactically complex sentences is more likely to be misconstrued than that of their less complex counterparts: for instance, listeners more often fail to identify semantic roles in passive sentences than in active sentences (Ferreira, 2003). It has also been shown that listeners tend to take the content of semantically implausible sentences at face value when their syntactic structure is relatively straightforward (e.g., prepositional datives: *The mother gave the daughter to the candle*), but prefer more semantically plausible interpretations when the syntactic structure of the sentences is more complex (e.g., the double-object dative *The mother gave the candle the daughter* is misread as *The mother gave the candle to the daughter*)—even if the semantic content of the two sentences is identical (Gibson et al., 2013).

Lexical-semantic information rooted in our 'real-world' knowledge also points toward specific interpretations of the linguistic input and can even overrule syntactic information (see e.g., MacDonald, Pearlmutter, & Seidenberg, 1994). Semantic properties of the constituents of a sentence, such as animacy, have been shown to affect the inferential process: for instance, listeners tend to interpret animate characters as agents in *who-did-what-to-whom* sentences, independently of syntax (e.g., Larsen & Johansson, 2008; Szewczyk & Schriefers, 2011). This animate-agency bias is consistent with the suggestion that our semantic knowledge may largely originate from sensorimotor representations (see e.g., *situation model* theories of sentence processing; e.g., Zwaan, 2016), which drives listeners toward interpretations of the input that fit with their knowledge of state of affairs in the real world (e.g., Fillenbaum, 1974).

Lastly, the broader discourse context in which a given linguistic input is embedded can affect (and even overrule) our interpretation of semantic and syntactic cues.

Referential/pragmatic contexts and lexical semantics seem to have an additive influence on processing, with (linguistic and extralinguistic) contextual information playing a central role in disambiguating syntactical ambiguities (e.g., the sentence *put the apple on the napkin in the box*, in which the listener can disambiguate whether *on the napkin* modifies *the apple* or *in the box* only by relying on the informativeness of, e.g., elements in the visual world; Snedeker & Trueswell, 2004; see also Spivey, Tanenhaus, Eberhard, & Sedivy, 2002). Pragmatic/contextual expectations can even override our semantic preference for animate agents, for instance through the introduction of a discourse context in which an inanimate object is presented as the agent: Nieuwland and Van Berkum (2006) showed that animacy violations (e.g., *The peanut was in love*), which normally elicit clear N400 effects in ERP experiments, do not do so when the sentences are presented in a context that justifies the violation (e.g., *A woman saw a dancing peanut who had a big smile on his face.* […] *The peanut was in love*). In these semantically implausible contexts, the more canonical sentences (e.g., *The peanut was salted*) suddenly become the violation to the pragmatic/contextual expectations.

All three information sources—pragmatic/contextual information, real-world semantics, and syntax—converge ideally to determine one unequivocal interpretation of the input (cf. Bates & MacWhinney, 1989). However, the relative weighting of each of these information sources in different processing situations seems to be affected by properties of the language input, as well as of the language users. For instance, Dąbrowska and Street (2006) showed that demographic factors such as years of formal education predicted the listeners' ability to interpret semantically implausible sentences when these were presented in passive constructions (e.g., *The soldier was protected by the boy*). Less educated listeners tended to disregard syntactic cues and focus more on semantic and pragmatic/contextual cues (e.g., interpreting the sentence as the more plausible *The soldier protected the boy*). Similar observations have been made in relation to language spoken by non-native speakers: for instance, Gibson et al. (2017) showed that English speakers were more likely to accept literal interpretations of semantically implausible sentences, if these were produced by native English speakers, than if the speakers talked with a foreign accent (thus giving foreigners the benefit of the doubt). Likewise, both children and adults have been shown to adjust their weighting of cues based on the apparent reliability of cues in the input, for instance by being more willing to accept implausible sentences from speakers who previously have produced more implausible utterances (Yurovsky, Case, & Frank, 2017; see also Gibson et al., 2013).

In this study, we suggest that factors pertaining to the communicative environment—e.g., the presence of perceptual noise—are also likely to affect the dynamic weighting of different information sources. The aim of the present study is therefore two-fold: First, we devise a novel experimental paradigm that allows us to individuate and access the relative weight given to different sources of information (pragmatic context, semantics, and syntax) in language processing. Second, we investigate how these weights are dynamically shifted relative to each other as a function of extra-linguistic conditions that can hinder speech communication—in this case, acoustic noise in the speech signal.

Language processing in the real world is prone to be affected by noise (Shannon, 1948): conversations in crowded places or phone calls with bad reception are but a few examples of how noise commonly affects language use in everyday situations (see Mattys, Davis, Bradlow, & Scott, 2012). In these situations, listeners have been shown to devote more cognitive effort to compensate for the reduced informativeness of the signal (Peelle, 2018). Here, we propose that, in order to compensate for less informative bottom-up input, listeners dynamically shift how they weight different information sources: in situations of noise, we are more likely to rely less on bottom-up information and implicitly adopt a more top-down-guided processing style. To test this hypothesis, we used a simple sentence-picture matching task to probe for comprehension. Participants listened to eight short stories; after each story, the participants were presented with four pictures in a four-alternative forced-choice (4AFC) test and instructed to select the picture that matched the central event of the story. In each 4AFC test, only one picture matched the actual language input; the three remaining pictures corresponded to different potential misinterpretations of the language input, and they were specifically designed to reveal processing biases driven by one or more of the three information sources under scrutiny. Half of the participants listened to the short stories in a baseline condition without noise; the other half was presented with the same stories under conditions of perceptual noise.

Method

Participants

167 native Norwegian-speaking (56% female; age: $M = 23.4$, $SD = 3.03$), right-handed undergraduate and graduate students from the University of Bergen (Bergen, Norway) participated in exchange for monetary compensation. Participants were pre-screened for previous or current neurological and/or psychiatric diagnoses, dyslexia, and hearing impairments. The participants were randomly assigned to two experimental conditions: Noise and No-noise ($N_{noise} = 89$, $N_{no\text{-}noise} = 78$).

Materials

Speech stimuli The language stimuli were eight aurally-presented short stories. All stories had an identical narrative structure consisting of four sentences, as in the following example (approximate translation from Norwegian):

S1: The boy walked into the pet store.
S2: His younger sister had been wanting a goldfish for a long time, and now it was time for her to get one.

S3: Everybody thought it was adorable that the boy bought a goldfish for his sister.
S4: As expected, his sister was very happy.

S1 and S2 provided the pragmatic context of the story; S3 was the target sentence and contained the central event of the story (underlined in the example), which was to be matched to the relevant image; and S4 served as a wrap-up sentence. All stories comprised three characters: an agent (e.g., the boy), an object (e.g., the goldfish), and a recipient (e.g., the sister). By switching roles between agent and object, we created different versions of each story, in which both the pragmatic context (S1+S2) and the central event of the story (S3) could be either plausible or implausible in relation to real-world semantics (e.g., S1: *the boy walked into the pet store* vs. *the goldfish walked into the pet store*; S3: *[…] the boy bought a goldfish for his sister* vs. *the goldfish bought a boy for its sister*). Additionally, we manipulated the markedness of the syntactic structure of the target sentence in S3, so that the main event was expressed either using a prepositional dative (unmarked, e.g., *the boy bought a goldfish for his sister*) or a double object construction (marked, e.g., *the boy bought his sister a goldfish*). Together, these 2×2×2 manipulations (pragmatic context semantics × central event semantics × syntactic markedness) resulted in eight possible versions of each story, as shown in Table 1. Participants were tested on all eight story structures. Each story structure-type was randomly assigned to a specific story-token for each participant, so that participants only heard one version of each of the eight stories (e.g., Participant 1 heard Story 1 version A, Story 2 version B, etc.; Participant 2 heard Story 1 version B, Story 2 version C, etc.). The eight stories were interspersed with eight stories from another experiment (with an identical procedure), which served as filler trials.

Table 1: The eight possible narrative structures of Story 1

	S1+S2: Plausible	S1+S2: Implausible	
S3: Unmarked syntax	Story 1a	Story 1b	S3: Plausible
	Story 1c	Story 1d	S3: Implausible
S3: Marked syntax	Story 1e	Story 1f	S3: Plausible
	Story 1g	Story 1h	S3: Implausible

The 64 sound files (8 stories × 8 story structures) were recorded in a soundproof booth by a male native speaker of Norwegian from the Stavanger area, using an Audio-Technica AT2020 Cardioid Condenser USB microphone and Audacity version 2.2.2 for Mac. For the participants in the Noise group, Brownian noise with a signal-to-noise ratio of –19 was added to the sound files using the MixSpeechNoise function from the *praat-semiauto-master* package (https://github.com/drammock/praat-semiauto) in Praat version 6.0.31 (Boersma, 2001).

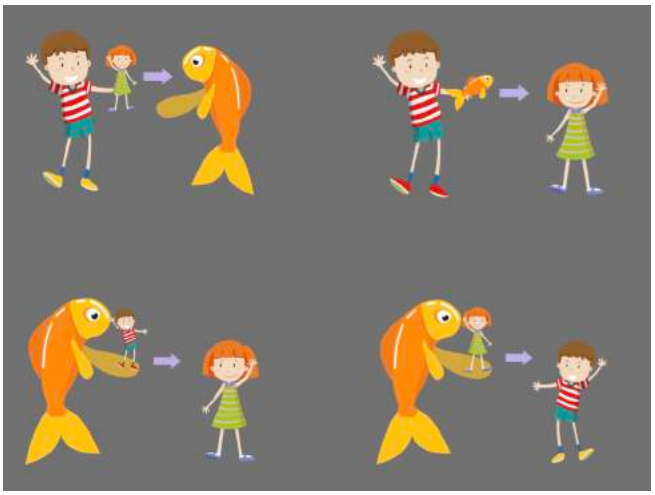

Fig. 1. The visual stimuli in the 4AFC test.

Visual stimuli For each story, four digital color images depicted the three story characters in four different agent-object-recipient relations to each other (Fig. 1). Each image featured an arrow intended to make the direction of the action (e.g., who gave what to whom) more explicit. For each version of each story, only one image corresponded to the central event described in the story and was therefore the correct choice. For instance, the correct match for the target sentence (S3) *the boy bought a goldfish for his sister* would be the top-right image in Fig. 1. The three remaining pictures were foils corresponding to possible misinterpretations of the narrative. These foils were designed to depict misinterpretations that were likely to be elicited by three different processing biases:

(i) *Pragmatic context bias*: an incorrect interpretation of the target sentence driven by the expectations set in the pragmatic context of the story (S1+S2). For instance, given the following pragmatic context: *The goldfish walked into the pet store. His younger sister had been wanting a boy for a long time, and now it was time for her to get one*, and the following target sentence: *The boy bought a goldfish for his sister*, a pragmatic-context bias would be indicated by the participant picking the bottom-left image in Fig. 1, instead of the correct picture match (the top-right image);
(ii) *Real-world semantics bias*: an incorrect interpretation of the narrative in which the target sentence is misinterpreted to match what is plausible in the real world. For instance, given the target sentence *The goldfish bought a boy for his sister*, choosing the top-right image in Fig. 1 (instead of the correct bottom-left image) would indicate a real-world semantic plausibility bias;
(iii) *Syntactic bias*: an incorrect interpretation of the narrative in which marked target-sentence syntax is misinterpreted as unmarked syntax (e.g., the double object construction is misread as prepositional object one), or vice versa. For instance, misinterpreting the target sentence *The boy*

bought the sister the goldfish as *The boy bought the sister for the goldfish* (through the accidental insertion of the preposition *for*) would result in the participant mistakenly clicking on the incorrect top-left image, instead of the correct top-right image.

Given the different narrative structure of each story, a one-to-one mapping between the three picture foils and the three processing biases under scrutiny was not achievable in every trial. However, we estimated that the chances of identifying the three biases in incorrect choices would be equally high when looking across all trials from each participant.

Procedure

Participants sat in front of a computer screen and wore headphones for the entire procedure. Responses in the 4AFC tests were given with a mouse click. Instructions were presented on screen in Norwegian Bokmål and were identical for all participants; however, the participants in the Noise group were advised orally about the presence of noise in the stimuli. The experiment was programmed in PsychoPy2 version 1.90.3 (Peirce & MacAskill, 2018) and began with a practice story (with plausible pragmatic context, plausible target-sentence semantics, and unmarked target-sentence syntax) intended to familiarize the participants with the procedure. After familiarization, the eight stories were presented in fully randomized order. Each story was introduced by a 3 s countdown on screen, after which the sound file was played and a drawing of the three characters of the story were shown on screen (order of presentation for the three characters was fully randomized across participants). After the end of the story, four pictures were presented at the four corners of the screen (as shown in Fig. 1), and the participants were instructed to click at the picture corresponding to what they thought to be the main event in the story. Mouse cursor position was reset at the center of the screen for each 4AFC test.

Data analysis

Accuracy and response time (RT) data were recorded by the experiment script. All possible types of incorrect responses were manually coded as being either due to a pragmatic context bias, a real-world semantics bias, a syntactic bias, or to a combination of two or more biases (for cases in which the incorrect choices were likely to be due to multiple biases). Data pre-processing and statistical analyses were run using R version 3.5.0 (R Core Team, 2018) in RStudio 1.2.1186. Linear mixed-effects models were run using the package lme4 version 1.1-19 (Bates, Maechler, Bolker, & Walker, 2015) and lmerTest 3.0-1 (Kuznetsova, Brockhoff, & Christensen, 2017). All accuracy (correct vs. incorrect) models were logistic mixed-effects models fit through maximum likelihood (Laplace Approximation) with a BOBYQA-optimizer. In addition to accuracy, we analyzed RTs for accurate answers using linear mixed-effects models with log-rescaled outcome variable. All models included random intercepts for subjects and items (random slopes were omitted for model convergence reasons). In the case of null results, we ran Bayes Factor analyses to get indication of whether there was evidence in favor of the null hypothesis, using the brms package (Bürkner, 2017) in R. All Bayesian models had weakly conservative priors for intercept (normal[μ=0, σ=1]), beta estimates (normal[μ=0, σ=1]), SDs of random effects (normal[μ=0, σ=.2]), as well as for correlation coefficients in interaction models (lkj[η=5]).

Results

Accuracy and RTs

To map the relative weight of pragmatic, semantic, and syntactic information sources in noisy and noise-free conditions, we looked at accuracy, response time (RT), and rate and types of errors. For both the No-noise group and the Noise group, overall accuracy on the 4AFC test was high. The average proportion of trials in which participants clicked on the correct picture was 0.78 (within-subject SD = 0.25) in the No-noise group, and 0.69 (within-subject SD = 0.21) in the Noise group. This difference was statistically significant (*Correct* ~ *Noise* + ε: β = –0.92, *SD* = 0.41, z = –2.25, p = .024), suggesting an overall detrimental effect of perceptual noise on comprehension. No statistically significant difference in RTs was found across conditions (*RTs* ~ *Noise* + ε: β = 0.38, *SE* = 0.69, t = 0.55, p = .58). We found no cumulative main effect of semantic plausibility and syntactic markedness on accuracy (*Correct* ~ *Plausibility/Markedness* + ε: β = –0.53, *SD* = 0.14, z = –0.38, p = .7) and RTs (*RT* ~ *Plausibility/Markedness* + ε: β = 0.01, *SE* = 0.32, t = 0.45, p = .65). A Bayes Factor analysis indicated substantial evidence for the null hypothesis (BF = 28.51, Post.Prob. = 0.97), suggesting that the concurrence of semantic implausibility and syntactic markedness did not consistently result in worse performance, compared to stories with plausible content and unmarked syntax. However, when looking at the three information sources individually, a significant main effect of syntactic markedness was found on accuracy (β = –1.5, *SD* = 0.36, z = –4.14, p < .001), revealing ca. 18% lower accuracy for target sentences with marked syntactic structures (i.e., double-object). We also found a statistically significant main effect of story-internal congruence on accuracy (*Correct* ~ *Congruence* + ε: β = –3.45, *SD* = 0.56, z = –6.11, p < .001) and RTs (*RTs* ~ *Congruence* + ε: β = 0.29, *SE* = 0.06, t = 4.74, p < .0001): accuracy was higher and RTs faster for stories in which the events described in S1+S2 and S3 were congruent with each other, and irrespective of whether the two cues were both plausible or implausible (*Correct* ~ *Congruence* × *Plausibility* + ε: β = 0.04, *SD* = 0.45, z = 0.09, p = .92) and RTs (*RTs* ~ *Congruence* × *Plausibility* + ε: β = 1.1, *SE* =

0.61, $t = 1.79$, $p = .076$).[1] Moreover, the effect of congruence was independent of the main effect of syntactic markedness observed above (accuracy, *Correct* ~ *Congruence* × *Syntax* + ε: $\beta = -0.04$, $SD = 1.62$, $z = -0.07$, $p = .94$; RTs, *RTs* ~ *Congruence* × *Syntax* + ε: $\beta = 0.15$, $SE = 0.82$, $t = -0.18$, $p = .85$). However, a Bayes Factor analysis did not provide substantial evidence for the null hypothesis in this case, suggesting that additional data is needed (BF = 1.11, Post.Prob. = 0.52).

Error analysis

In order to individuate how the three information sources were weighted during processing, and how they might be driving comprehension errors, we performed an error analysis. For this purpose, we looked at incorrect responses in situations of story-internal incongruence only, since pragmatic and semantic bias can only be fully distinguished in this case. Distribution of errors is presented in Fig. 2. Across conditions, pragmatics-biased errors accounted for 54% of all errors (No-noise = 22% (42 errors), Noise = 32% (97 errors)); semantics-biased errors accounted for 26% (No-noise = 8% (14 errors), Noise = 18% (55 errors)); and syntax-biased errors accounted for 20% (No-Noise = 8% (15 errors), Noise = 12% (36 errors)). Both semantic bias ($\beta = 0.94$, $SE = 0.04$, $t = 2.02$, $p = .043$) and pragmatic bias ($\beta = 0.46$, $SE = 0.04$, $t = 9.9$, $p < .001$) drove significantly more incorrect responses than syntactic bias; syntactic bias was in turn significantly different from zero ($\beta = 0.26$, $SE = 0.034$, $t = 7.79$, $p < .001$, model structure: *Response* ~ *Bias* + ε). We found no significant two-way interactions between the three sources of bias taken individually (i.e., pragmatics, semantics, and syntax) and noise, suggesting that the role of these information sources in eliciting incorrect responses was not affected selectively by the presence of noise. However, Fig. 3 indicates an evident increase in responses due to a semantic bias, when noise was added to the input, although this interaction was not significant: $\beta = 0.16$, $SE = 0.1$, $t = 1.6$, $p = .11$. A Bayes Factor analysis did not provide robust evidence for this null result (*Noise* × *Semantics* + ε: BF = 1.63, Post.Prob. = 0.62), suggesting that further investigation is needed.

Discussion

In this initial study, we investigated how three sources of information commonly acknowledged in the literature on linguistic processing (i.e., pragmatic/contextual expectations, real-world semantics, and syntactic structure) might contribute differently and dynamically to listeners' comprehension of spoken language input in noisy vs. no-noise conditions. Participants were presented with short stories, in which the three information sources under scrutiny either pointed unequivocally to the same interpretation of the narrative or toward conflicting interpretations. This allowed us to assess the relative weight listeners allocated to the different kinds of information in their interpretation of the linguistic input. Half of the participants listened to stories in the presence of Brownian noise. We hypothesized that listeners would change their processing strategy by generally weighting top-down information more in situations of perceptual noise than in noise-free situations. Moreover, we asked whether the relative weight given to the individual information sources would change when noise was added.

The results provided initial support for our hypothesis by showing that listeners relied more on top-down information in noisy contexts, compared to noise-free ones. In general, accuracy was lower for the Noise group, reflecting the fact that the presence of perceptual noise impedes processing. In both Noise and No-noise groups, listeners made incorrect responses that reflected processing biases driven by either the pragmatic, semantic, or syntactic information in the input—

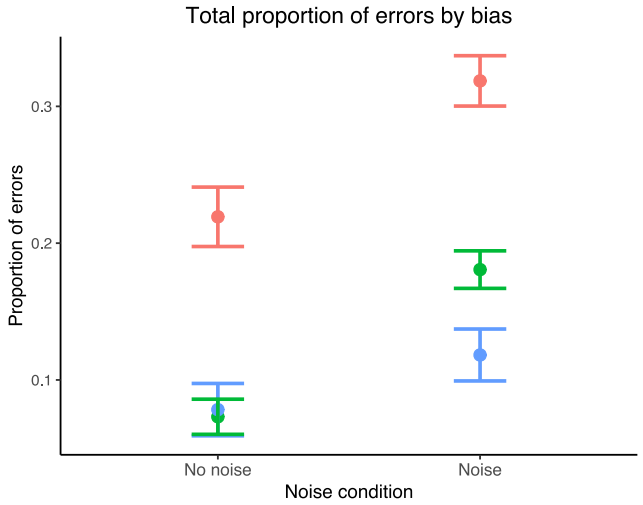

Fig. 2. Distribution of information source biases in incorrect responses (incongruent trials only)

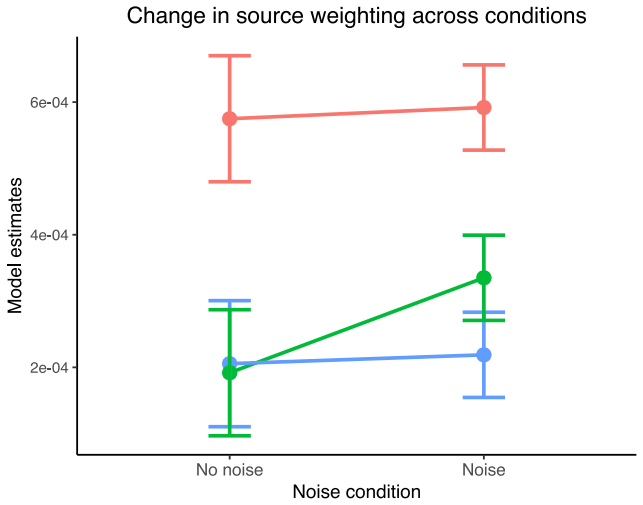

Fig. 3. Predicted values for the model *Response* ~ *Bias* × *Noise* + ε

[1] In the models, plausibility was coded as –1 (S1+S2 and S3 = implausible), 1 (S1+S2 = plausible, S3 = implausible), 2 (S1+S2 = implausible, S3 = plausible), and 3 (S1+S2 and S3 = plausible).

though this happened almost twice as often in the Noise group compared to the No-noise group. Moreover, we found indications that the relative weighting of the different information cues may change when noise is added, with real-world semantics gaining more weight. A number of computational models of language comprehension (e.g., Frank, Koppen, Noordman, & Vonk, 2003, 2008; Venhuizen et al., 2019) have shown that integrating knowledge about the world with lower-level representations of the linguistic input leads to more accurate inferences about the intended meaning of the input. It is possible that the presence of perceptual noise in the signal pressures the processing system and makes it harder for the listener to establish solid representations of the incoming input (e.g., of its syntactic structure and of its pragmatic/contextual information): this may push the listener to rely more on knowledge that is stable over time (i.e., semantic knowledge of the world; see e.g., Kintsch, Patel, & Ericsson, 1999). This mechanism would explain the increase in errors driven by a real-world semantics bias in conditions of noisy signal, but not of those driven by syntax and pragmatics (which are more dependent on establishing representations of the incoming input on the fly). However, this result is only tentative and will need further investigation with more statistical power. Note also that our experimental design only allowed to test comprehension offline (by allowing the participants to make a choice after the end of the story), therefore increasing memory pressure. A more online version of the paradigm (e.g., one that uses mouse tracking/eye tracking) may provide further insights into this issue.

Other interesting results emerged from the study. First, we found a significant main effect of congruence between the pragmatic context of the story and the semantics of the target sentence, with both noisy and non-noisy stimuli. This can be explained in terms of the previously observed mutual influence between story-internal coherence and semantics-based inferences in language comprehension (see e.g., Frank et al., 2003). Second, we found that whenever the pragmatic context of the story and the target-sentence semantics were incongruent (e.g., *the boy walked into the pet store* → *the goldfish bought a boy for its sister*), the pragmatic context "attracted" the listeners' incorrect interpretations to a significantly larger extent than real-world semantics. This evidence is in line with, for instance, previous ERP evidence from Nieuwland and Van Berkum (2006), who showed that listeners' natural tendency to assume animate characters (in our case, human-animate vs. nonhuman-animate) as being agents in stories can be overruled by counterfactual discourse contexts. Third, we found a significant main effect of syntax markedness in the target sentence (S3), in both noisy and noise-free situations, revealing that sentences with a double-object structure are consistently associated with lower accuracy, than sentences with prepositional dative structure. This finding adds to previous psycholinguistic literature documenting the effects of syntactic markedness on language processing (Dabrowska & Street, 2006), and nicely replicates the results from Gibson et al. (2013) and Gibson et al. (2017), in which prepositional dative sentences were shown to lead to literal (although semantically implausible) readings of the sentences more often compared to double-object sentences.

Existing models of language processing under conditions of acoustic challenge (e.g., in hearing-impaired populations) propose that listeners compensate for degraded input by increasing their cognitive effort in terms of memory, attention-based performance monitoring, and allocation of (extralinguistic) neurocognitive resources (e.g., Eckert, Teubner-Rhodes, & Vaden, 2016; Peelle, 2018). However, these compensatory top-down mechanisms have traditionally been thought to only become relevant as a "last resort", when all bottom-up information fails. Instead, our results may suggest that top-down information critically contributes to language processing by default—and more so when the signal itself becomes degraded and therefore less informative. Moreover, our findings hint at a hierarchical weighting of information sources that is flexibly changed in noisy processing situations—at least when the language input is internally incongruent (see e.g., Yurovsky et al., 2017). Reliance on top-down pragmatic context and real-world semantics is largely increased when the language input is degraded by perceptual noise: listeners may rely more heavily on top-down strategies to compensate for the reduced informativeness of the bottom-up cues. Priorities for future studies using the sentence-picture matching design presented here include focusing on languages other than Norwegian, as well as on cross-linguistic differences in the weighting of top-down information. Moreover, it may be important to move away from a binary noise vs. no-noise manipulation and toward a more continuous variation of the amount of noise added to the signal. This may not only lead to stronger patterns of results but also give rise to interesting non-linearities in the data.

Conclusions

Successful language processing depends on the seamless and rapid integration of bottom-up and top-down information. When the bottom-up signal is degraded by noise (as it happens in many everyday situations), listeners become more reliant on top-down information sources. This study presents a novel methodological framework within which to investigate the simultaneous contribution and dynamic weighting of three top-down information sources—pragmatic context, real-world semantics, and sentence syntax—to language processing in the presence of perceptual noise. Our results nicely dovetail with previous findings, while highlighting the need for a unified model of the relative weighting of bottom-up and top-down information in spoken language processing in noisy situations.

Abstract

Expert face recognition has been marked by holistic processing and left-side bias/right hemisphere involvement. Hence recognition for Chinese characters, sharing many visual perceptual properties with face perception, was thought to induce stronger holistic processing and left-side bias effect. However, Hsiao & Cottrell (2009) showed that expertise in Chinese character recognition involved reduced holistic processing, while Tso, Au & Hsiao (2014) suggested this effect may be modulated by writing experiences; in contrast, left-side bias was found to be a consistent expertise marker regardless of writing experiences. Here we examine holistic processing and left-side bias effect of Chinese character recognition between adolescents with and without dyslexia. Students with dyslexia were found to recognize Chinese characters with a stronger holistic processing effect than the typical controls. However, compared with the controls, dyslexics showed a more reduced left-side bias in processing mirror-symmetric Chinese characters. The theoretical and educational implications of these results were discussed.

Keywords: Reading, Dyslexia, Left-side bias, Holistic Processing, Perceptual Expertise

Introduction

Holistic Processing

Holistic processing is the tendency to process separable features of an object as a single whole unit. This concept was originally derived from Gestalt psychology, which postulates that the perception of an object as a whole that is a qualitative difference from the sum of its individual parts (Köhler, 1929; see also Wagemans, Elder, et al., 2012; Wagemans, Feldman, et al.,2012). Holistic processing has been a perceptual phenomenon commonly observed in face perception in which all facial parts are integrated and viewed as a whole (Piepers & Robbins, 2012). Holistic processing in face recognition can be demonstrated with the composite paradigm in which it induces the composite face illusion: the two identical top halves of a pair of faces are judged as different when the bottom halves of the two faces are from different faces (see Rossion, 2013). This illusion suggests a failure of selectively attending to facial parts as a result of people obligatorily attending to all facial features as a whole (i.e. holistic processing, see Figure 1; Richler, Wong, & Gauthier, 2011). The holistic processing assessed in the above paradigm demonstrates the second type of configural processing as suggested by Maurer, Le Grand, and Mondloch (2002), which is the inclination to perceive a stimulus as a Gestalt (Pomerantz & Portillo, 2011). Beyond face perception, some studies have posited that expertise-level recognition for subordinate-level objects requires holistic processing (Bukach et al., 2006; though some has suggested limited to face recognition, c.f. Mckone, Kanwisher, & Duchaine, 2007).

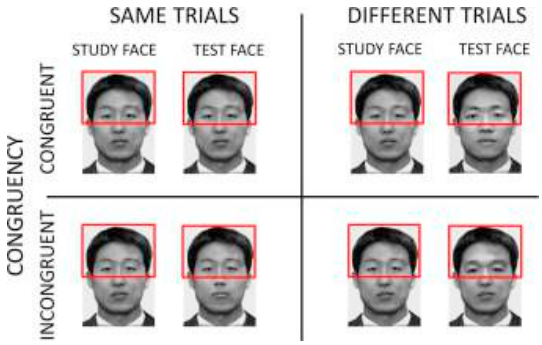

Figure 1. Complete composite paradigm to measure holistic processing for face stimuli. In each trial, participants are cued to attend to top or bottom half of each stimulus pair and judged whether the attended halves are the same or different (attended halves encircled in the figure). Holistic processing is demonstrated by the interference of the irrelevant halves (adapted from Hsiao & Galmar, 2016)

Holistic processing in Chinese character recognition

At first glance, Chinese characters may seem to be a separate class of visual stimuli to that of faces. For example, while the single features (such as eyes and mouth) of each individual face differ but appear in the same positions, the same radicals and strokes can appear in different positions in a character. While faces are always in a symmetrical top-bottom configuration, Chinese characters can appear in more than 10 types of configurations including top-bottom and left-right (Shu, 2003). However, Chinese characters also share many visual properties with faces: They have a homogenous, square configuration—with each character a grapheme mapping onto a morpheme (Shu, 2003). Moreover, strokes are the basic units which combine to form more than 200

basic Chinese character patterns (Hsiao & Shillcock, 2006), which in turn form the Chinese characters. Faces also have homogenous configurations, with facial features combining to form endless different individual faces. A person can differentiate and recognize different faces regardless of their facial expression, similar to a literate typically needing to recognize over 3000 characters regardless of fonts (Hsiao & Cottrell 2009; Wong & Gauthier, 2007). The process of individualizing different faces seems to be comparable with that of naming individual Chinese characters. Hence, theoretically Chinese characters should induce a similar perceptual expertise effect as faces (McCleery *et al*., 2008).

However, using the complete composite paradigm, Hsiao and Cottrell (2009) found that expert Chinese readers had a reduced holistic processing effect (i.e. more analytic) compared with novices. Tso, Au, and Hsiao (2014) showed that the reduced holistic effect of the expert readers in Hsiao and Cottrell's (2009) study may be explained by writing experiences. They showed that compared with novices, expert readers with limited writing performances (Limited-writers) showed increased holistic processing, while expert readers with typical writing abilities (Writers) showed a reduced holistic effect (Tso, Au, & Hsiao, 2014). These findings hint a modulating role of writing abilities on holistic processing: the typical Chinese-reading experts flexibly employ holistic or analytic processing to read and write Chinese characters. It seems that the use of holistic or part-based processing may depend on how readers allocate attention for task relevant information (Chung, Leung, Wong, & Hsiao, 2018).

Holistic processing in the population with special needs

There has been accounts of perceptual differences in processing visual stimuli in populations with a cognitive disability compared with typical controls. For example, reduced holistic processing in has been associated with face-recognition difficulties in patients with prosopagnosia (Avidan, Tanzer, & Behrmann, 2001). Reduced holistic processing also marks a cognitive deficit in people with autism, who were often tested to have poorer abilities in face and facial expression recognition than the general population (Tanaka, Wolf, & Schultz, 2010).

People with dyslexia in the Chinese language is also shown to be characterized by a visuospatial deficit (e.g. visual-orthography processing and visual-spatial attention skills; see Liu et al, 2017), while English dyslexia is generally associated with core deficits in phonological skills. Indeed, developmental dyslexia in an alphabetic script and in the Chinese writing system is characterized by different brain abnormalities (e.g. Siok et al., 2004; Siok et al., 2009): while dyslexia in alphabetic languages is characterized by neurological deficits related to phonological skills (e.g. left temporoparietal regions), dyslexia in Chinese is more associated with abnormalities in regions that are responsible for orthography or visuospatial processing (e.g. middle frontal regions). Chinese-word reading has indeed a strong basis in visual-orthographic processing demonstrated by writing and copying abilities (Tan et al., 2005). Children with reading difficulties are often observed to have a marked discrepancy between reading and writing abilities due to writing in Chinese being a more resource-intensive process than writing in alphabetic languages (Chung & Ho, 2010). As expert reading and writing in Chinese depends on one's ability to analyze local components within a Chinese character (Chung et al, 2018; Hsiao & Cottrell, 2009), people with dyslexia – who generally have backward reading and writing attainments – may fail to employ analytic processing as the components and radicals in a Chinese character may look inseparable to them (Ho, Ng, & Ng, 2003).

Left-side bias

Left-side bias is another visual-perceptual phenomenon commonly reported in face recognition (Burt & Perrett). This effect has also been demonstrated in Chinese character recognition and is suggested to be associated with right-hemisphere involvement (Hsiao & Cottrell, 2009). Left-side bias effect is usually demonstrated using chimeric faces, that is, people often judge faces that composed of two left halves to be more similar to the original face than faces composed of two right halves (Brady, Campbell, & Flaherty, 2005).

Though left-side bias or right-hemisphere lateralization have been thought to correlate with increase in holistic processing in visual object recognition (Gauthier & Tarr, 2002), left-side bias was found to be a consistent behavioral marker of Chinese character recognition regardless of writing experiences, whereas holistic processing could be affected by writing experiences (Tso, Au, & Hsiao, 2014). This effect is consistent with studies that showed right-hemisphere involvement in processing the Chinese orthography (Hsiao, Shillcock, & Lee, 2007; Yang & Cheng, 1999). However, compared with typically developing students, stronger left fusiform and weaker right hemisphere activities have been found in dyslexic children during Chinese character recognition (Siok et al, 2004; Xue et al., 2005). Hence students with dyslexia in this study may display reduced left-side bias compared with the controls.

The present study

This paper hence investigates the role of holistic processing in Chinese recognition by examining how Chinese readers in secondary school with and without a diagnosis of dyslexia process Chinese characters. Reduced holistic processing marks expert Chinese character recognition in Chinese readers with both typical reading and writing abilities. As developmental dyslexia in Chinese in characterized by difficulties in literacy, predominantly in writing performances, students with dyslexia are predicted to processing Chinese characters more holistically than their typical counterpart. Left-side bias of mirror-symmetric Chinese characters was also examined, and this effect was compared between students with and without dyslexia, in relations to holistic processing.

Materials and procedures

Chinese literacy

Dictation performance and Chinese word reading in both timed and untimed context were measured as a reference for their literacy performance. The stimuli were adopted from HKT-P(III). As the purpose of the study was not to yield diagnostic results, we used stimuli from HPT-P(III) for research purposes only to compare the literacy performance between students with and without dyslexia.

i) The untimed Chinese word reading task assessed students' Chinese word reading accuracy. Students read aloud from a set of 150 two-character Chinese words listed in ascending order of difficulty. A participant scored one point for pronouncing both characters of a word correctly.

ii) The Chinese one-minute word reading task assessed students' Chinese word reading fluency. Ninety simple two-character Chinese words were displayed in 9 rows containing 10 words each. Students read aloud as many words as they could in one minute, earning one point every time they read both characters of a word correctly, and the total number of points gave the score.

iii) The Chinese dictation task assessed children's Chinese word writing ability. Students wrote out 45 two-character Chinese words, read out by the examiner in ascending order of difficulty. A student scored one point for writing each character correctly.

Non-verbal Intelligence

To control for the effect of IQ on reading, nonverbal intelligence was assessed using the 9-item subset of Raven's standard progressing matrices (Raven, Court, & Raven, 1996; see Bilker et al., 2012, for its psychometric properties).

Holistic processing

One hundred and sixty pairs of medium to high frequency Chinese characters in Ming font were used as the character stimuli—half of the pairs in top-bottom configuration while the other half in left-right configuration (See Figure 2). 40 pairs were presented in each of the four conditions – same-congruent trials, different-congruent trials, same-incongruent trials and different-incongruent trials. In the congruent trials, the attended halves and the irrelevant halves always led to the same response (i.e. both the attended part and the irrelevant part were the same or different). In the incongruent trials, the attended halves and the irrelevant halves led to different responses – in same incongruent trials, the attended halves were the same while the irrelevant halves were different; whereas in different incongruent trials, the attended halves were different while the irrelevant halves were the same (Figure 3a).

Figure 2. Examples of Chinese characters with a left-right configuration (left) and a top-bottom configuration (right).

The participants' performance in each condition (congruent vs incongruent) is measured by discrimination sensitivity A' as:

$$A' = 0.5 + \left[sign(H-F)\frac{(H-F)^2 + |H-F|}{4\max(H,F) - 4HF} \right]$$

(H and F are the hit and false alarm rate respective) A' is used to measure sensitivity due to its bias-free nonparametric property (Stanislaw & Todorov, 1999). Hence the degree of HP is measured as the A' difference between the congruent trials and the incongruent trials—the larger the discrepancy, the larger the holistic effect. The discrepancy in response time between congruent and incongruent trials was also measured to demonstrate holistic processing. In addition, a misaligned condition was included to tease out the possibility of composite effects due to inhibition abilities, such that if the holistic-processing effect in students with dyslexia is indeed due to interference from the irrelevant halves, misalignment should reduce this effect. See Figure 3.

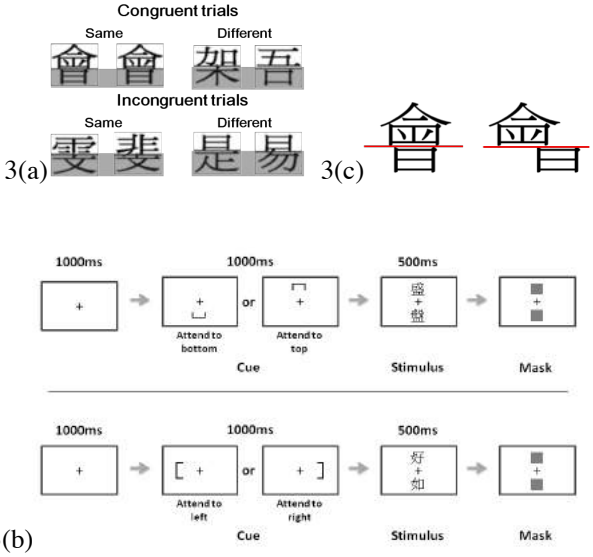

Figure 3. (a) Illustration of stimulus pairs in the complete composite paradigm (b) Trial sequences. (c) character in aligned (left) and misaligned conditions (right).

Left-side bias.

To test for left-side-bias effect, procedures from Tso, Au, & Hsiao (2014) were adopted. Eighty high-frequency mirror-symmetric Chinese characters were selected. Each character was presented once in Ming font. For each character, half of the trials displayed the originals were used on half of the trials, whereas in the other half of the trials displayed chimeric characters constructed from half of the original character and its mirror image, and this was counter-balanced across participants.

For each character stimuli, two left halves constructed the left chimeric character while two right halves formed the right chimeric character (Figure 4a). Each character spanned a visual angle of about 6.7° from a 55 cm viewing distance. After 500 ms of a central fixation cross in each trial, the

original character was displayed either on the left or right side of the screen randomly, at about 7.2° of visual angle away from the center. Each trial displayed the left and right chimeric characters such that one was above and one below an arrow at the screen center which pointed to the original character image. Each chimeric character image subdued about 3°of visual angle away from the center. All image stimuli were displayed on the screen until participants responded to judge which of the two chimeric characters looked more similar to the original one by pressing one of two buttons on the response box. Left-side bias was measured as the percentage of trials in which participants selected chimeric characters composed of two left halves (Figure 4b).

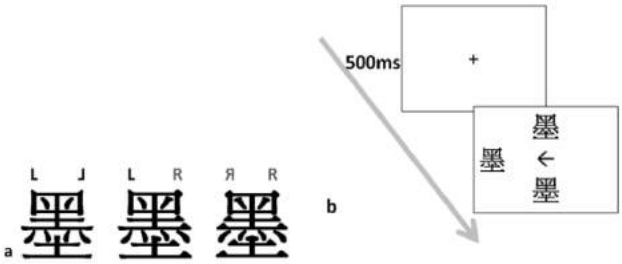

Figure 4. (a) Examples of the stimuli, and (b) the test sequence in the LSB experiment (note that the chimeric characters are still legal Chinese characters).

Results

Literacy abilities and non-verbal intelligence

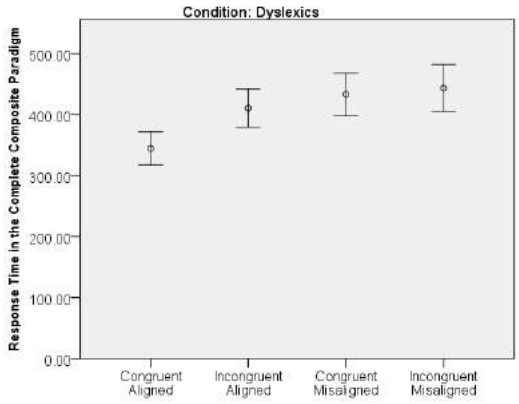
Separate one-way analyses of variance (ANOVAs) were carried out to examine the effect of group (Dyslexics vs Control) on each literacy test. We found that participants in the control condition had a marginally better performance than participants with dyslexia in Chinese word-reading $F(1, 39) = 3.076$, $p = .087$, but their performance in the one-minute word-reading task did not differ, $F(1, 39) = 1.551$, $p = .219$, suggesting that both groups having similar performance in word recognition and fluency in naming over-learned Chinese characters. However, participants in the control condition had significantly better performance in the Chinese word dictation task, $F(1, 39) = 7.229$, $p = .01$, suggesting the students with dyslexia had persistent difficulties in writing Chinese characters even when in high-school grades. The scores are summarized in Table 1.

Table 1. Summary of the scores of Chinese word-reading, Chinese one-minute word reading, Chinese dictation and non-verbal IQ (9-item Raven's) in high-school students with and without dyslexia.

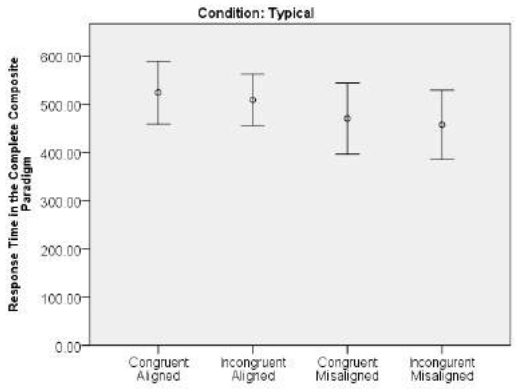
	Control *Mean (SE)*	Dyslexics *Mean (SE)*
Chinese Word-reading	102 (1.82)	99.96 (3.41)
One-minute word reading	93.43 (4.62)	85.91 (3.95)
Chinese dictation	59.73 (13.14)	47.52 (17.35)
Non-verbal IQ	3.91 (1.74)	3.96 (1.34)

Holistic processing

We next examined the ability to holistically process Chinese characters in participants with and without dyslexia. We first conducted a 2 (congruency: congruent vs. incongruent) × 2 (group: dyslexics vs. control) repeated measures ANOVA on A', which showed a main effect of congruency, $F(1, 38) = 27.35$, $p = .000006$, $\eta p2 = .419$, but no interaction between congruency and group, $F(1, 38) = 1.354$, $p = .252$, or main effect of group, $F(1, 38) = 1.342$, $p = .254$, was found. We then conducted a 2 (congruency: congruent vs. incongruent) × 2 (group: dyslexics vs. control) repeated measures ANOVA on response time. We found a significant interaction between congruency and group, $F(1, 38) = 5.854$, $p = .02$, $\eta p2 = .133$, and a main effect of group, $F(1, 38) = 5.306$, $p = .027$, $\eta p2 = .123$, but no main effect of congruency, $F(1, 38) = 2.254$, $p = .150$. Post-hoc ANOVA showed that students with dyslexia responded more slowly in incongruent than in congruent trials, $F(19) = 34.3$, $p < .000012$, $\eta p2 = .644$, whereas response times in congruent and incongruent trials were similar in typically developing students, $F(19) = 0.254$, $p = .620$. See Figure 5.



5a)



5b)

Figure 5. The composite effect in character perception was significant among dyslexics (a), but not the typically developing readers (b). Misalignments significantly reduced the effect in the dyslexics.

The results also showed that misalignment significantly reduced the congruency effect demonstrated by response time among students with dyslexia: a significant interaction between congruency and misalignment (aligned vs. misaligned), $F(1, 19) = 5.662$, $p = .029$, $\eta p2 = .239$; there was no misalignment effect among typically developing students.

Together, these results suggest that participants with dyslexia perceived Chinese characters more holistically than controls.

Left-side Bias

Finally, the results on left-side bias suggests that typical readers have a stronger left-side bias than students with dyslexia, $F(1,38) = 6.439$, $p = .015$, $\eta p2 = .145$. It seems that although the participants with dyslexia were more holistic than typical readers in Chinese character recognition, they revealed weaker left-side bias (Figure 6).

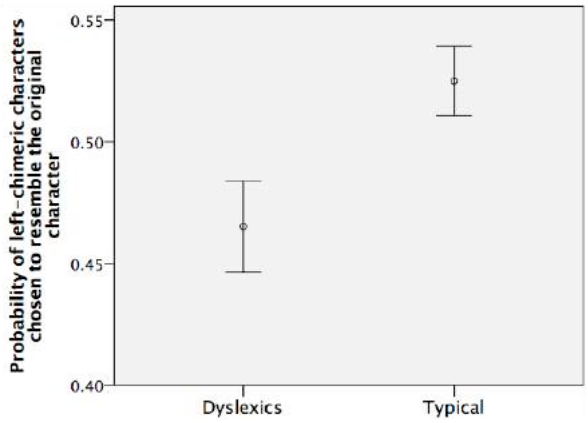


Figure 6. Preference for left chimeric characters in participants with and without dyslexia.

Discussions

This study investigated how high-school students with and without dyslexia differed in how they processed Chinese characters by examining two perceptual expertise phenomena: holistic processing and left-side bias. Our results show that high-school participants with dyslexia demonstrated a stronger holistic processing effect in Chinese character recognition compared with the typically developing controls. This study is consistent with Hsiao and Cottrell's (2009) study in which they showed that reduced HP is associated with expert Chinese character recognition compared with novices, though our study compared between typically developing expert readers and dyslexics in which the dyslexic participants were not completely novices but had relatively weaker Chinese literacy abilities. Our result is also comparable with Tso et al. (2014)'s study that suggested a modulating role of writing abilities on holistic processing: While the students with dyslexia in this study had marginally comparable reading performance to that of typical controls, they recalled and wrote fewer words. Unlike everyday face recognition in which one is not required to recall and draw faces, a typical Chinese reader is fluent in both Chinese character recognition and writing. Indeed, Zhou, et al. (2012) demonstrated reduced HP in artists with face-drawing experience compared with ordinary face-observers. Stronger holistic processing in students with dyslexia than in the typical controls, then, may indicate a perceptual difference between poor and proficient writers.

According to Maurer et al. (2002), holistic processing is a second-order configural processing in which both featural and spatial-distal information within an object are integrated and processed. Hence, the stronger holistic processing effect of the dyslexic students in the present study may also suggest that they recognized characters with an over-dependence on their visuo-spatial information of components, which may hinder developing literacy expertise, particularly in writing. It seems that students with dyslexia demonstrated persistent perceptual abnormalities even when they are in secondary school, which hinders them to selectively attend to individual character components. This in turn hindered Chinese character recognition as it is an ability facilitated by sensitivity to the specific positions of components radicals and structures within a character (Ho, Ng, & Ng, 2003). This speculation warrants future follow-up studies.

This study also echoed with Hsiao and Cottrell's (2009) and Tso, Au and Hsiao's (2014) findings demonstrating that left-side bias was a consistent expertise marker of Chinese character recognition: The dyslexic readers showed reduced left-side bias of Chinese characters than typically developing readers. Our result is also consistent with previous studies that suggested a stronger left-hemisphere but weaker right-hemisphere involvement for Chinese character recognition in readers with dyslexia (Siok et al, 2004; Xue et al., 2005). These effects suggest that dyslexics employ a strategy to process Chinese characters which may be both perceptually and neurologically different from typical readers. Similar to face perceptual processes which involves RH/LSB, our results are consistent with that in prosopagnosic patients who had a reduced left-side bias in facial perception—suggesting a reduced RH involvement in face recognition (Malaspina, Albonic, & Daini, 2016).

However, while HP was previously thought to associate with RH activation as demonstrated in face and subordinate visual-object recognition, the results of this study echoed Hsiao and Cottrell's (2009) study, demonstrating that increased LSB but reduced HP as expertise markers of Chinese character recognition. Holistic processing effect brought about by the composite-face illusion is due to obligatory attention directed to all facial parts, resulting in failure to selectively attending to parts (Hole, 1994; Richler, Tanaka, Brown, & Gauthier, 2008; Richler, Wong, & Gauthier, 2011). Therefore, one reason why Chinese character recognition is different from that of face perception may be because the spacing information between typical Chinese character components may be unimportant to typical Chinese readers (Hsiao & Cottrell, 2009), while spatial information is important in typical face recognition processes (i.e. small changes in spacing between features typically change the face identity; see Farah, et al., 1998). Hence, the relationship between holistic processing and right hemisphere lateralization may be modulated by whether spatial information is used during recognition of visual stimuli. To test above speculations, Hsiao and Galmar (2016) demonstrated through a computational simulation a positive relationship between holistic processing and RH

lateralization when a face recognition task relied purely on spatial information (i.e., all faces stimuli differ only spacing among the same features). On the other hand, when the task recognized faces based purely on features (i.e., all faces differed in features but the same spacing between them), holistic processing correlated negatively with RH lateralization (see also Chung et al., 2018). Therefore, whether the RH engages holistic processing in a recognition task may depend on the type of information used for its processing. Indeed, Chinese character recognition is facilitated by sensitivity to components radicals at specific positions within a character (Ho, Ng, & Ng, 2003), not the spatial distances between components. Hence left-side bias in Chinese character recognition is perhaps related to sensitivity to first-order relations in configural processing, i.e. the relative spatial locations of individual components within a character (Maurer et al., 2002).

To conclude, this study is the first to report the perceptual difference between typically developing and dyslexic students in high school by investigating holistic processing and left-side bias of Chinese character recognition. It has demonstrated preliminary evidence for the link between inability to reduce holistic processing and difficulties in Chinese literacy: dyslexic Chinese are less readily to engage in analytic processing to attend to character components. Finally, the reduced left-side bias of Chinese characters in the dyslexics may be related to deficits in forming first order relationship between components. This study suggested that high-school students with dyslexia in Chinese may still encounter difficulties in reading and writing due to persistent deficits in their literacy-related cognitive abilities, and they may require further supports in their learning to enhance attention to Chinese character components or radicals.

Do Bilingual Infants Possess Enhanced Cognitive Skills?

Abstract

Prior studies have reported that bilingualism enhances cognitive ability due to the regular conflict management of two language systems (Bialystok, 2015). Here, we explore whether infant bilingualism improves cognitive ability at 9.5 months. Twenty-four monolingual English and 23 bilingual French-English infants were first trained to predict a reward on the right based on a set of tone-shape rule structure (AAB pattern). Infants were later trained to predict a different reward on the left based on another set of new rule structure (ABB pattern). Correct anticipation of reward locations indicates successful learning. If bilingualism improves infants' cognitive skills, bilingual infants would be better at learning a new pattern-reward association. However, we did not find evidence that bilinguals looked at the correct location more than monolinguals or learned the new pattern-reward association faster. Thus, our results suggest bilingualism may not enhance cognitive ability at 9.5 months, as least using the current paradigm.

Keywords: infant bilingualism; cognitive ability; bilingual advantage

Introduction

Bilingual infants face key language learning challenges. For example, as their time listening to language input is divided between the two languages, they therefore hear less input from each language. In addition, bilingual infants often learn their languages in a more variable environment than monolinguals. It is not rare for bilingual infants to listen to parents mixing languages in one conversation (Byers-Heinlein, 2013) or to hear words form speakers with non-native accents (Bosch & Ramon-Casas, 2011). Yet, bilingual infants reach basic language milestones at similar age as monolinguals, such as sensitivity to native sounds (Ferjan Ramìrez et al., 2017) and basic word learning (for a review, see Fennell, Tsui, & Hudon, 2016). This raises the possibility that bilingual infants may have better cognitive control processes because they are remarkably efficient in managing two different language systems.

A number of studies have suggested that bilingual experiences may enhance individuals' executive functioning (see Bialystok, Craik, & Luk, 2012 for a review). Executive functioning is an umbrella term describing a set of cognitive abilities, including inhibition of dominant responses, shifting between tasks or mental sets, as well as updating and monitoring working memory (Miyake et al., 2000). As bilinguals activate both languages even they only speak in one language at a time (e.g., Thierry & Wu, 2007), they must selectively attend to the correct language while inhibiting the other competing language for effective communication in daily life. Earlier theories, such as Green (1998), have proposed that bilinguals' routine of inhibiting the irrelevant language during production can improve their inhibitory ability in non-verbal domains. For example, a number of studies have shown that bilinguals outperform monolinguals in a number of non-verbal conflict tasks, including the flanker task (Costa, Hernández, Sebastián-Gallés, 2008), the Simon task (Bialystok et al., 2004), and the Spatial-Stroop task (Bialystok, 2006).

Subsequent studies have extended research to other aspects of executive control components aside from inhibition. A major reason for this move was that researchers (e.g., Bialystok, 2006; Costa et al., 2008) not only found a bilingual advantage in the incongruent trials of the above conflict tasks, which require inhibitory control, but also in the congruent trials that do not require inhibition. Hence, researchers suggested bilinguals' cognitive advantage is not limited to inhibition ability, but is instead related to an enhancement in executive attention (Bialystok, 2017). Executive attention is the ability to control ones' attention, including ones' ability to maintain attention to the relevant part of the task and avoid directing attention to distractors. Bialystok (2017) has suggested that bilingual experience improves learners' attention systems as bilinguals regularly need to control their attention to accommodate two different language systems. For example, they need to differentiate between the two languages, switch attention between the two, and allocate their attention to the relevant language. Importantly, Bialystok (2015) has highlighted that bilingual experience not only enhances learners' executive function processing when they are selectively producing one of their languages, but also when they are selectively processing the two languages during comprehension. As such, infant bilinguals, who possess richer language comprehension than production, may also enjoy a cognitive advantage before the onset of a large productive vocabulary.

Indeed, some infant studies demonstrate that infant bilingualism may improve executive functioning. In a pioneering study, Kovacs and Mehler (2009a) examined whether Italian monolingual and Italian-other bilingual 7-month-olds differ in cognitive control. Infants were

conditioned to associations between a set of rules and visual rewards. These sets of rules could be conveyed auditorily or visually. For example, two rule structures were composed of three syllables, one with an AAB pattern (e.g. la-la-ga) and one with an ABA pattern (e.g. la-ga-la). In the experiment, infants were first trained to look at a toy (e.g., puppy A) at a particular visual location (e.g., right-side) after hearing one rule structure (e.g., AAB) and later were required to learn a new association (e.g., look at the puppy B on the left when hearing ABA). This task thus required infants to inhibit an earlier learned response and flexibly switch to a new reward response. Across three experiments that used either syllable or visual geometric shape rule patterns, the authors consistently found only bilingual infants successfully learned the new associations. In a similar study, Kovacs and Mehler (2009b) tested whether monolinguals and bilinguals of 12 months were able to simultaneously learn two different tri-syllabic structure rules: AAB and ABA. They again associated each rule to a visual toy at a particular position on the screen (e.g. AAB-object A-left side; ABA-object B-right side). At test, the researchers presented new tri-syllabic auditory stimuli that conveyed either an AAB or ABA structure. They then measured whether infants looked to the correct position after hearing the new auditory stimuli (e.g. AAB structure provokes looks to the left side). If infants looked at the correct corresponding position, it means they learned the corresponding structure rule. The researchers found that bilinguals were able to learn both rules, but monolinguals learned only one of the rule patterns (AAB but not ABA). To summarize, the two studies have suggested that bilingual infants may be better able to control interference and switch between two rule structures.

Over the past decade, however, only a few studies have attempted to replicate the studies in Kovacs and Mehler (2009a). For example, Ibánez-Lillo, Pons, Costa, & Sebastián-Gallés (2010) discovered that both monolingual and bilingual infants of 8 months could inhibit the previously learned cue-reward pairing and successfully learn a new cue-reward pairing, suggesting no early bilingual advantage in cognition. In contrast, Pourllyaei and Byers-Heinlein (2018) found that 7-month-old bilinguals, but not monolinguals, were able to inhibit a previously learned cues' position and anticipate a newly learned cues' position. They specifically presented infants with a visual-auditory cue (e.g., a colorful butterfly paired with a whistle sound) for the first 9 trials on one side of the screen (e.g., left) and then switched the position (e.g., right) of the visual-auditory cue for the next 9 trials. Further, Comishen, Bialystok and Adler (2019) also found that 6-month-old bilingual infants outperformed monolingual infants in a visual expectation cueing paradigm in which infants needed to change their anticipatory looks in response to the varying positions of the rewards. Together, the current evidence of bilingual infants' cognitive advantage is somewhat mixed and the literature is quite limited.

The current paper aims to address this research gap by attempting to replicate Kovacs and Mehler (2009a) in a different population of bilingual infants. Studying whether bilingual infants may have enhanced cognitive skills is a key research question, as it can inform researchers how a variety of language inputs in the early language environment (i.e., processing two language systems) may alter learners' cognitive and/or attention systems. However, we were not able to answer this question based on the current literature as there were only a few studies (n = 3, two of which are unpublished) that have tried to replicate Kovacs and Mehler (2009a) and the limited findings are somewhat mixed. Given that a number of studies have failed to replicate bilingual cognitive advantages in adult participants (e.g., Kousaie & Philips, 2012; Paap & Greenberg, 2013), it is possible that the infant bilingual cognitive advantage is similarly not robust. Replication is a central focus in the current scientific community, with recent specific concerns about replicability in psychological science (Open Science Collaboration, 2015). Infant research is particularly vulnerable to the replication crisis as recruiting and testing infants is difficult, and researchers therefore normally report findings and draw conclusions from small samples (Frank et al., 2017). As such, the current paper contributes to the literature by testing whether bilingual infants would outperform monolingual infants in an experimental paradigm modified from Kovacs and Mehler (2009a) Experiment 3. The current experiment used geometric shapes to convey the abstract rule patterns. This would be a key test of the bilingual cognitive advantage, as researchers have argued that bilinguals' enhanced attention system should transfer to non-verbal cognitive tasks that require attention control (Bialystok, 2017).

There were several methodological differences between our experiment and those reported in Kovacs and Mehler (2009a). First, we tested 9.5-month-old infants, who were slightly older than those reported in Kovacs and Mehler (2009a). As mentioned above, Kovacs and Mehler (2009a) tested infants with abstract rule patterns (i.e., AAB/ABB structures) and paired these structures with different visual rewards at different locations of the screen. Some researchers have raised concerns of testing infants with abstract rules patterns (i.e., extracting patterns from stimuli) as this may quite challenging to participants this young (Comishen et al., 2019). Given that 7-month-old infants can learn some abstract rule patterns (Marcus et al., 1999) and Ibánez-Lillo et al (2010) reported that both monolingual and bilingual infants at 8 months can switch their responses when the cue-reward pairings had changed, we decided to test 9.5-month-old infants, who are a bit older than 8-months, to ensure that the infants were sufficiently mature to handle the task demands. Furthermore, these slightly older infants would have even more bilingual experience, perhaps enhancing any effect of dual language exposure. Second, our abstract rule patterns were conveyed using both visual and auditory (non-linguistic) cues, as presenting

information bimodally should facilitate infant abstract rule learning (Frank et al., 2009). Lastly, we reduced the number of trials during pre-switch and post-switch phases from nine to six. Our decision was based on pilot data (not included in this paper) that revealed 9.5-month-old infants lost interest in the screen after six to seven trials presenting the same abstract rule patterns during the pre-switch phase. Moreover, Kovacs and Mehler (2009a) have shown that 7-month-old bilingual infants began switching their responses during post-switch phase from the fourth trial in Experiment 3. As we were testing older infants, we expected that older infants could switch their responses earlier in the post-switch phase. Thus, we set the number of trials in pre-switch and post-switch phases to six.

Methods

This experiment involved an anticipatory eye movement paradigm, modified from Experiment 3 in Kovács and Mehler (2009a). Infants were trained to predict the locations of visual rewards based on the structures of tone-shape sequences. The key manipulation was that the structure of the tone-shape sequence would change in the middle of the experiment. Successful learners must inhibit the previously learned tone-shape sequence and then learn the new one. Similar to others, we argue that this task measures infants' general cognitive skills, including working memory, attention and inhibitory control. First, infants need to use their working memory to process and track the information in the tone-shape sequences. Next, infants need to pay attention to the common structures across tone-shape sequences and the association between those structures and the locations of visual rewards. Lastly, as mentioned above, infants must rapidly inhibit the previously learned tone-shape sequence structure in order to learn new tone-shape sequence structure during the post-switch phase.

Participants

Twenty-four monolingual English infants and 23 French-English bilingual infants of 9.5 months were tested (Mean = 9.49 months; S.D. = 0.64 months), 22 female). All participants were living in a French-English city in an officially bilingual (French-English) country.

We used the Language Exposure Questionnaire (Bosch & Sebástian-Gallés, 1997) to measure infants' language exposure to English and French. Infants were categorized as monolinguals if they had 90% or greater exposure to English. Infants were categorized as bilinguals if they had a minimum of 20% exposure to one language and a maximum of 80% exposure to the other language (Mean English exposure = 54.96%, SD = 15.64%; Mean French exposure = 44.71%, SD = 15.77%). An additional four infants (2 monolinguals, 2 bilinguals) were tested but not included in the final analysis because of crying or fussiness.

Stimuli

Figure 1 illustrates sample stimuli and the procedure of the study. All stimuli were organized into 3 tone-shape sequences of two structures: AAB or ABB. For AAB sequences, the first two tones and geometric shapes in the sequence were identical and the final pairing differed (e.g., circle-tone C, circle-tone C, star-tone F). By contrast, for ABB sequence, the last two shape-tone pairings were identical and the first pairing differed (e.g., star-tone F, circle-tone C, circle-tone C).

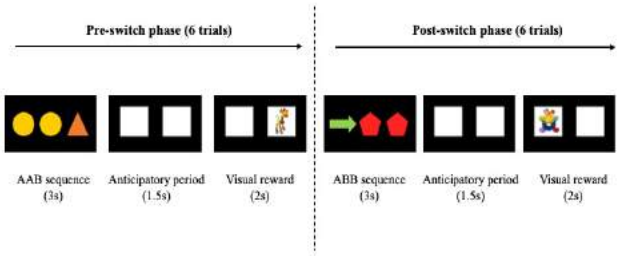

Figure 1. Sample visual stimuli and the procedure of the anticipatory eye movement paradigm.

The visual stimuli comprised six AAB shape sequences and six ABB sequences. Following the methodology in Kovács and Mehler (2009a), specific geometric shapes were used to generate the sequences. Three geometric shapes (arrow, circle, pentagon) were used for position A of the AAB and ABB sequences, whereas three other geometric shapes (moon, 5-pointed star, triangle) were used for position B. Each shape was presented in a different colour. For symmetrical geometric shapes (i.e., circle, pentagon, 5-pointed star and triangle), the size of each shape was 32cm X 32cm. For asymmetric geometric shapes (i.e., arrow and moon), the size of each shape was 34cm X 32cm. The shape sequences appeared on screen in the following manner. The first shape of the sequences was presented on the left side of the screen alone. Next, the second shape was added in the middle of the screen while the first remained onscreen. Finally, the third shape was added on the right side of the screen so that all three shapes appeared simultaneously on the screen for 3 sec. All shape sequences were displayed against a black background.

The audio stimuli were sequences of three musical tones. Two tone structures (i.e., AAB and ABB) were constructed to pair with the corresponding visual shape sequences. Three musical tones (A, D, E) could be paired with objects in position A, whereas three other musical tones (C, F, G) could be paired with objects in position B.

The tone-shape sequence would be followed by a visual presentation of two white squares and the visual reward (see procedure for more details). The two white squares were presented side by side on the screen (each was 52.5cm to 53.5cm in size) for 1.5 sec. For the visual reward, one of two puppets (i.e., a giraffe or hippopotamus toy) appeared inside one of the two white squares on the left or right side of the screen. The puppet loomed from 20cm X 30cm to

28cm X 49cm in size for 2 sec. The presentation of puppets was accompanied by a chime sound.

Apparatus and procedure

Infants were seated on a parent's lap during the experiment. The parent wore headphones playing music with vocals to mask the sounds. The parent was instructed not to turn his/her head to the left-hand side or right-hand side. Instead, parent could either look at the infant or look at the center of the screen in order to minimize their influence of infants' attention to a particular side of the screen. At the beginning of each trial, we presented infants with attention-getting stimuli (e.g., an image of a baby and audio of a baby giggle). Once infants oriented their attention to the screen, the experimenter pressed a key to present the orientation stimuli to the infants. For the first trial, infants saw a video where a rotating ball changed its position from the left side to the right side of the screen. The ball first appeared on the left side and remained onscreen for 3.3 sec. The ball then reappeared on the right side of the screen for another 3.3 sec. The trial served to accustom infants with the experiment procedure where they would be trained to look at the left and right side of the screen to predict different visual rewards based on the tone-shape sequences.

After this orientation trial, there were two phases in the experiment: pre-switch and post-switch (see Figure 1). Each phase consisted of 6 trials. In the pre-switch phase, infants were trained that one tone-shape sequence structure (either AAB or ABB) predicted a visual reward in a particular location (i.e., on the right or left of the screen). On each trial, infants were first presented with a tone-shape sequence (e.g., AAB) for 3 sec. The tone-shape sequence would then be replaced by two white squares on the screen for 1.5 sec. During this window of time, infants could make an anticipatory eye movement by directing their eye gaze to the square where the object would appear (anticipatory window period). Finally, a looming puppet (e.g., giraffe) would appear on one side of the screen (e.g., right side) for 2 sec. After presenting infants with 6 pre-switch trials, infants then entered a post-switch phase where a new structure of tone-shape sequences (e.g., ABB structure) predicted a different reward (e.g., hippopotamus) on a different location (e.g., left side). The procedure and length were identical to the pre-switch phase, aside from the differences above (i.e., sequence structure, visual reward type and location).

Coding

Following Kovács and Mehler (2009a), we coded infants' eye gaze during the anticipatory window period (1.5 sec) for the dependent variable (DV). We coded infants' eye gazes to the right and left positions. We only counted eye gazes to the appropriate reward location as correct responses. Eye gazes to the opposite side of the reward location were all counted as incorrect. Videos were coded frame by frame (30 frames per second). Two trained undergraduate coders coded all trials independently and the reliability between their coding was high (r = 0.90, p < 0.0001). To obtain the proportion of correct anticipatory looks, we divided the number of frames looking at the correct location by the sum of total frames that infants looked at the correct and incorrect positions during anticipatory window period. For example, on a test trial, an infant looked at the correct position for a total of 20 frames and looked at the incorrect position for a total of 10 frames. The proportion of correct anticipatory looks would be 0.67 for this infant on this particular trial.

Data analysis

The DV was infants' proportion of correct anticipatory looks in each trial. Further, we expected that infants would increase the proportion of correct anticipatory looks over time, thus we tested whether the relationship between the DV and the number of trials (i.e., DV-trial slope) was positive or not. We also tested whether infants' language background would influence the DV-trial slope. For example, bilingual infants may have faster rate of learning the association between tone-shape sequence and the corresponding visual rewards. This would be reflected by a steeper DV-trial slope in the bilingual infant group. To model the variations of the DV and the DV-trial slopes in the experiment, we employed hierarchical linear modeling in our analyses. Because we have different hypotheses about infants' performance in the pre-switch and the post-switch phases. We ran two separate hierarchical linear models, one examined infants' performance in the pre-switch phase (pre-switch model) and the other examined infants' performance in the post-switch phase (post-switch model). We predicted that infants' inhibitory control ability would only be reflected in their performance during the post-switch phase. As such, we expected that monolingual and bilingual infants would have similar proportion of correct anticipatory looks and DV-trial slopes during the pre-switch phase. By contrast, monolingual and bilingual infants would differ in terms of their proportion of correct anticipatory looks and DV-trial slopes during the post-switch phase. We used the lme4 package in R (Bates et al., 2015) to perform the hierarchical linear regression models. The regression models were fit by the restricted maximum likelihood approach and the p values in the models were estimated by Satterthwaite approximations in the lmerTest package (Kuznetsova, Brockhoff, & Christensen, 2016). The model was specified as follow: DV ~ trial*language background + (1+trial|Subject) in the lme4 package.

Results

See Figure 2 for infants' performance across trials during the pre-switch and post-switch phases. In the pre-switch model, infants' language background [β = 0.047, *S.E.* = 0.066 p = 0.47] was not a significant predictor. We also

found that the interaction between infants' language background and DV-trial slopes was not significant [β = 0.020, *S.E.* = 0.011, p = 0.997], suggesting that the learning rate between monolingual and bilingual infants were similar in the pre-switch phase. The average DV-trial slope was significantly higher than zero across all participants [β = 0.020, *S.E.* = 0.076, p = 0.012], suggesting that infants made more correct anticipatory looks over time. Finally, a one-tailed t test revealed that the average proportion of correct anticipatory looks in the pre-switch phase was significantly greater than the chance level [M = 0.59, t(276) = 4.909, p < 0.001].

In the post-switch model, we also did not find a significant effect of infants' language background [β = -0.015, *S.E.* = 0.063, p = 0.82]. The interaction between infants' language background and DV-trial slopes was not significant [β = -0.004, *S.E.* = 0.023, p = 0.878]. This again indicates that the learning rate between monolingual and bilingual infants were similar in the post-switch phase. The average DV-trial slope was significantly higher than zero across all participants [β = 0.031, *S.E.* = 0.012, p = 0.009], suggesting that infants also showed a trend of improving their proportion of correct anticipatory looks over time during the post-switch phase. Finally, a one-tailed t test revealed that the average proportion of correct anticipatory looks in the post-switch phase was not significantly greater than the chance level [M = 0.45, t(268) = -2.63, p > 0.99].

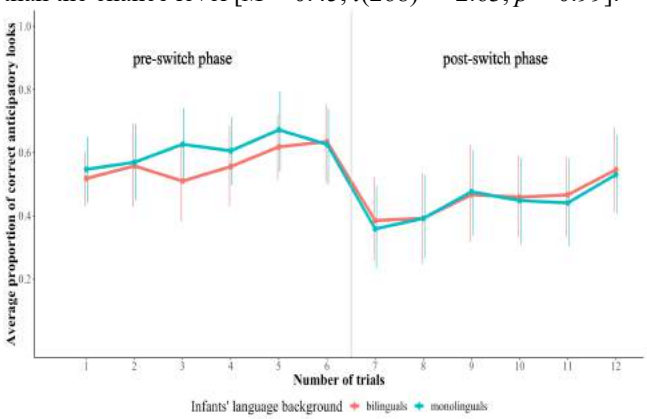

Figure 2. Infants' average proportion of correct anticipatory looks across trials during pre-switch and post-switch phases. Error bars indicate the 95% confidence intervals.

We did some follow up hierarchical linear regression models to further explore whether the degree of bilingual experience influences infants' performance. One aspect of bilingual experience is whether the bilingual infant has balanced exposure to the two languages. The degree of bilingualism was determined by the difference of percentage exposure between dominant language and non-dominant language. For example, an infant with 60% exposure to English and 40% exposure to French would get a score of 20, while an infant with 50% exposure to English and French would get a score of 0. Here, a smaller value in the degree of bilingualism reflected that the infant received a more balanced language exposure to French and English. The degree of bilingualism can be treated as a proxy for the variation of bilingual experience among our bilingual infants. In the following analyses, we only focused on bilingual infants and measured whether the degree of bilingualism contributes to the difference in infants' average proportion of correct anticipatory look during pre-switch and post-switch phases. We specified two separate models for the pre-switch and post-switch phases. Each model was specified as DV~ trial*infants' degree of bilingualism + (1+trial|Subject) in the lme4 package. Across two models, we did not find any significant main effects and interaction between trials and bilingual infants' degree of bilingualism (ps > 0.30). This suggested that bilingual experience (whether they hear more or less balanced exposure in daily environments) did not predict infants' performance in our cognitive task.

Finally, we also computed one-tailed t tests to examine whether infants' average proportion of correct anticipatory look in the last two trials during post-switch phase was significantly greater than chance level. The t test results were both non-significant in trial 11 [M = 0.45, t(40) = -0.95, p = 0.827] and in trial 12 [M = 0.54, t(44) = 0.79, p = 0.217], suggesting that infants' performance across the last two trials did not significantly differ from the chance level.

General Discussion

Our goal was to replicate Kovacs and Mehler (2009a) study and examine the potential positive effects of early bilingualism to infants' cognitive ability. We found that both monolingual and bilingual infants could extract the abstract rule patterns and associate the patterns to particular reward locations. Their performance generally improved as they made more correct anticipatory looks based on the abstract rule patterns over-time. However, we did not find evidence supporting that early bilingualism improves infants' inhibitory control, at least for the experiment tested here. In our study, we tested slightly older infants, who would have even more bilingual experience, and attempted to maximize the learning effects by presenting infants with bimodal visual-audio stimuli. Despite using these manipulations that may enhance any effect of bilingualism, we still found a null effect. Thus, our findings are consistent to recent studies (e.g., Kousaie & Philips, 2012; Paap & Greenberg, 2013) that bilingualism may not have a robust effect on learners' cognition.

Notwithstanding our efforts to maximize the learning effects in the current paradigm, it is important to note that infants' average proportion of correct anticipatory looks during the post-switch phase was not significantly above chance. This implies that infants generally found learning the associations between the tone-shape structure and the visual rewards in the post-switch phase more difficult than

those in the pre-switch phase. Although 7-month-olds were previously reported to succeed in learning using this paradigm (Kovacs & Mehler, 2009a), our results suggest that it may still be cognitively challenging for 9.5-month-olds to learn the new association within the six trials of the post-switch phase. Future work is perhaps needed to explore a range of age-appropriate and simplified cognitive tasks to fully address the question of a correlation between cognitive ability and bilingualism in infancy.

Another possibility is that our null findings may be related to the language contexts in the bilingual infants' home/community. Byers-Heinlein, Morin-Lessard and Lew-Williams (2017) have suggested that bilingual infants' enhanced cognitive ability may be driven by exposure to language mixing contexts in their environments. Language mixing is prevalent in early bilingual environments where one/both parent(s) switch between two languages when speaking to their infants. Byers-Heinlein et al., (2017) have discovered that bilingual French-English infants demonstrated a switching processing cost when hearing sentences that alternated between two languages. The switching costs suggest that bilingual infants need to monitor and control their two languages when listening to speech that mixes languages. Thus, bilingual infants' enhanced cognitive skills may be a result of listening to mixed speech on a daily basis. Although the local area is quite bilingual, perhaps the specific bilingual infants in our study were not living in a home language environment where parents often mix their languages, thus minimizing their need of monitoring and switching between two language systems regularly. In the current paper, we did not collect relevant data to examine this possibility. Future work should explore how the degree of language mixing in early bilingual environment affects infants' cognitive ability.

In conclusion, we did not find support for bilingual cognitive advantages at 9.5 months, suggesting that advantages may not be robustly seen across different bilingual populations or different ages. However, we made note of other possible accounts for the replication failure, including how the bilingual environments and task demands of the current experiment matter. It is our hope that future work can address the existing research gap to further understanding of the effects of early bilingualism on infants' cognitive ability.

Abstract

Humans have an intuitive understanding of physics. They can predict how a physical scene will unfold, and reason about how it came to be. Adults may rely on such a physical representation for visual reasoning and recognition, going beyond visual features and capturing objects in terms of their physical properties. Recently, the use of draped objects in recognition was used to examine adult object representations in the absence of many common visual features. In this paper we examine young children's reasoning about draped objects in order to examine the develop of physical object representation. In addition, we argue that a better understanding of the development of the concept of cloth as a physical entity is worthwhile in and of itself, as it may form a basic ontological category in intuitive physical reasoning akin to liquids and solids. We use two experiments to investigate young children's (ages 3–5) reasoning about cloth-covered objects, and find that they perform significantly above chance (though far from perfectly) indicating a representation of physical objects that can interact dynamically with the world. Children's success and failure pattern is similar across the two experiments, and we compare it to adult behavior. We find a small effect, which suggests the specific features that make reasoning about certain objects more difficult may carry into adulthood.

Keywords: intuitive physics, cloth, cognitive development, object recognition, analysis-by-synthesis

Introduction

Imagine draping an elephant. What shape do you see? Probably not an exact silhouette, but a rough outline with a coarse bottom (Figure 1). This mental image also likely changes as you imagine draping an elephant placed on its side, or turned upside down. This simple feat of the imagination is quite remarkable. Imagining an elephant on its own may involve reactivating a learned representation or a visual memory of an elephant, but imagining an elephant draped by a cloth means 'seeing' a new object (the reader with extensive experience of draped elephants is free to imagine some other animal here). How do we come to this new image? One possible account is that we run a mental simulation and examine the outcome under noisy dynamic laws. But such a simulation requires object representations that go beyond representing image patches. Under this account, objects are represented as three-dimensional bodies, and the mental simulation is able to imagine the transformation and variation of the object under different processes. By examining people's ability to reason about the outcome of draping or to perceive draped object, we examine people's ability to reason visually without most of the traditional visual features that are assumed to play a part in recognition (Yildrim et al., 2016).

Recently, Yildrim, Siegel, and Tenenbaum (Yildrim et al., 2016) have investigated adult reasoning about cloth-covered objects as part of a larger examination of people's object representation as physical entities with the properties necessary for physical interaction. These studies showed that adults can reliably reason about the identity of covered objects in a match-to-sample task, even when the distractor object is within the same category type as the target object. Adult responses were best captured by a model based on a physics and graphics engine, which formalize the proposal that adults base their recognition and reasoning in part on a physical model of objects and a causal dynamical model of their interactions with the world.

More broadly, the Mental Physics Engine proposal suggests that the representations underlying much commonsense physical and visual reasoning are similar to those of modern game engines, software that is useful for quickly rendering an approximate simulation of a physical environment (see e.g. Battaglia et al., 2013; Gerstenberg et al., 2012; Smith & Vul, 2013; Hamrick et al., 2016; Ullman et al., 2017). Such game engines have also been proposed as an essential part of machine intelligence for commonsense reasoning (see e.g. Wu et al., 2015; Lake et al., 2017; Chang et al., 2017). While such a physics engine proposal predicts adult recognition and perception better than neural-network models based on visual image features, it is possible that adults come to this sophisticated understanding of objects and physics over time. Much less is known about children's representation of objects as physical objects for recognition. Here, we propose to examine young children's reasoning about draped objects as a way of examining the development of understanding objects as physical bodies, and of the causal processes that determine the behavior of objects.

Beyond this, we suggest that examining the development of intuitions about cloth is of interest in and of itself. This is because *cloth* (in the sense of a mesh or sheet of connected point masses, which can capture entities such as blankets, towels, and clothes) may be a basic ontological category in intuitive physical reasoning, akin to *rigid body* or *fluid*. At a high level, game engines separate physical entities into several broad classes based on their expected behavior, and the computational resources necessary to simulate them. This

high-level division is limited to only a few classes, and one of the common classes in modern engines is *cloth*, required specialized modular simulation Gregory (2009), and suggesting this may form a basic mental category as well. So, while it may initially seem that there are a large number of intuitive physical categories that can be investigated, of which cloth forms only a small subset, the success of the game engine approach to mental reasoning motivates us to focus on the small number of broad categories that have proven useful for engineers.

While cloth exists as a separate category in modern game engines, it is not obvious that an understanding of cloth has its origin in childhood. On one hand, by their first year many children have extensive experience with clothes, blankets, towels, tissues, and so on. A general mental physics engine with the right computational primitives may use this experience to generate the cloth category. On the other hand, our core knowledge physical reasoning is shared with many other animals and is believed to have a long evolutionary past (Spelke & Kinzler, 2007). Cloth, unlike liquids and rigid bodies, is a relatively recent category, and early human ancestors would not have needed to reason about it on a daily basis. Thus the mental physics engine may lack the right primitives to quickly construct this category.

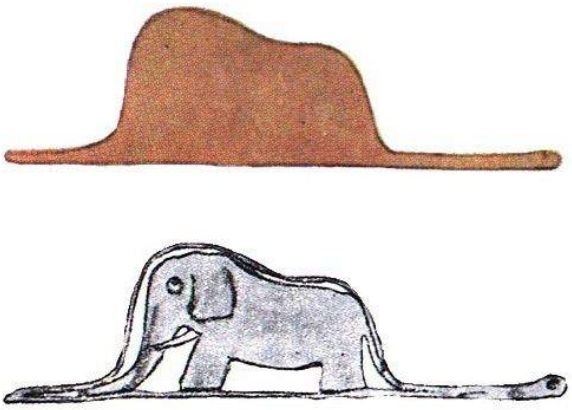

Figure 1: "My drawing was not a picture of a hat. It was a picture of a boa constrictor digesting an elephant. Then, I drew the inside of the boa constrictor, so that the grown-ups could see it clearly. They always need to have things explained." *The Little Prince*, by Antoine de Saint Exupéry.

In this paper, we probe young children's ability to reason about cloth using two basic tasks: reasoning from an uncovered object to a covered image (Experiment 1), and reasoning from a covered object to an uncovered image (Experiment 2). These tasks do not span the full space of the possible behavior of cloth, but they are meant to establish the existence (or lack) of basic competency. We consider an age range of 3–5 years, when children have for the most part not started a formal education, yet possess a sufficiently large vocabulary to understand the language used in the task. We find that children perform above chance in both tasks, and use an adult comparison to examine their patterns of success and failures. In the General Discussion, we consider the implication for generative vs. feature-based models, and the extension of cloth studies to infants.

Experiment 1: Uncovered → Covered

Participants

Sixteen individuals ($N = 16$, 5 female, median age 3.9 years, range 3.2-4.8) were recruited at the [City] Children's Museum. The size of the sample was pre-specified, based on a pilot study which indicated medium-to-large effect sizes can be expected.

Materials and methods

Participants were tested in a designated area in the [City] Children's Museum. Parents gave their informed consent, and advised not to encourage responses from their child.

Participants were presented with a touch-screen device (iPad), and told that they were going to play a game. Participants first played two warm-up rounds, in which they were shown a test-object on top of the screen (e.g. a bird), and asked to match it with one of two possible objects below (e.g. a bird and a horse). The warm-up round was meant to familiarize the participants with making a forced choice between two items based on a target item. By the second warm-up all participants correctly selected the matching object.

During test, participants saw 6 trials in succession, in random order (see Figure 2, top). Each trial contained a pair of objects, for example a mug and a bench. One object in the pair was randomly selected as the test object. The test object was shown at the top of the screen, uncovered. Below the test object were the pair of objects, covered in cloth. Participants were told to imagine that the test object had been covered by a blanket, and asked to indicate what the resulting image would be. Participant choices were automatically stored. Participants were given general encouragement, but no indication of whether their choice was correct.

All the stimuli pairs used in the experiments are shown in Figure 3. Uncovered and covered stimuli images were created in Blender (Blender, 2015). Covered objects were created by draping the uncovered objects using a physical cloth simulation. Objects were chosen from a collection of available objects previously used in experiments with adults (Yildrim et al., 2016). The size of the objects was scaled such that they took up approximately the same amount of visual space when covered.

Results and analysis

Participants' responses were summed across the object pairs, and are shown in Figure 4 (left). The summation resulted in a labeling score going from 0 (no objects correctly identified) to 6 (all objects correctly identified), with chance performance at 3. On average, participants correctly labeled 4.14 objects (95% CI 3.54–4.68, bootstrapped with 10,000 samples). The

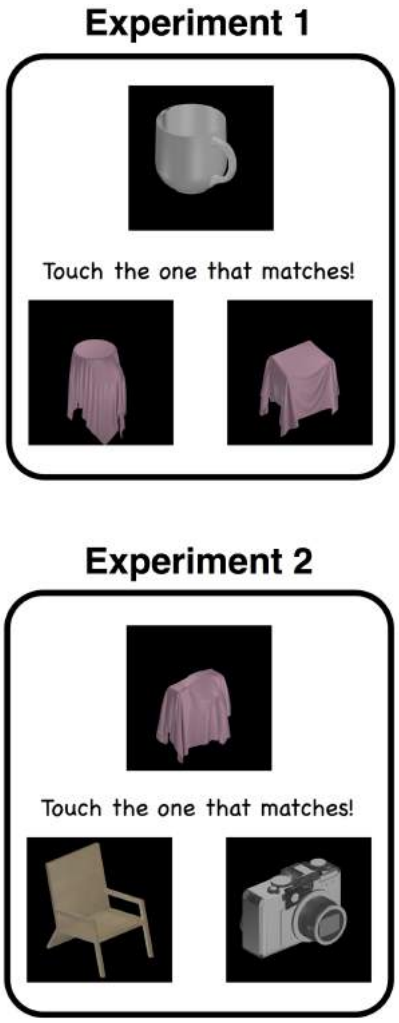

Figure 2: Schematic of example test trials in Experiments 1 and 2. At the top of a touchscreen is the target object (Uncovered in Experiment 1, covered in Experiment 2). Participants were asked to match the target object to one of the pair of objects at the bottom of the screen (Covered in Experiment 1, uncovered in Experiment 2).

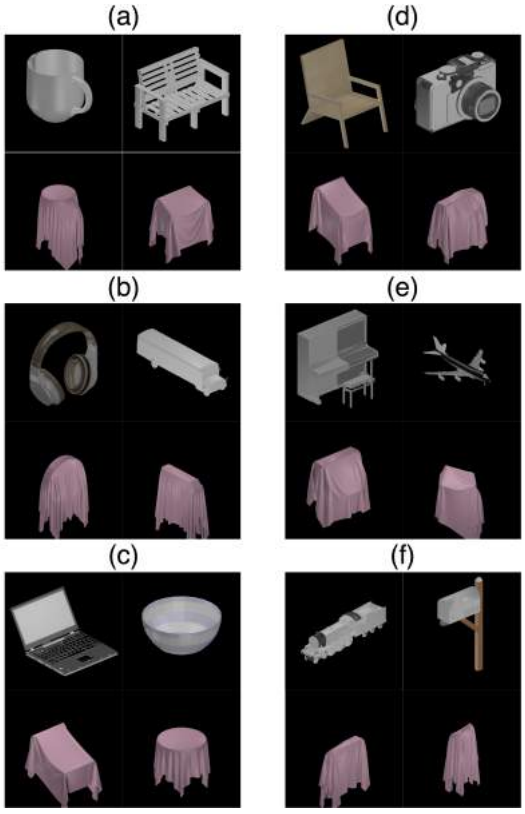

Figure 3: All stimuli pairs used in Experiments 1 and 2, uncovered and covered. In Experiment 1 participants saw one of the objects in the top row as the target, and matched it to the two items in the bottom row. In Experiment 2, participants saw one of the objects in the bottom row as the target, and matched it to one of the items in the top row.

confidence intervals are clearly above chance performance, and a standard two-sided T-test also indicates this result is statistically significant ($t(15) = 3.09, p < 0.01$).

We did not predict nor find a significant effect of age on participant performance. A logistic regression of labeling score on age was not significant, and neither was a median split comparison. Given the small sample size, however, we do not take this to strongly indicate the non-existence of an age effect, but simply the lack evidence for it.

Considering the stimuli by pair, we found that the identity of the objects in a given pair had an effect on participants' labeling. That is, some pairs were harder to discern than others. Specifically, using a standard two-sided binomial test at the $p < 0.05$ level, participants correctly distinguished mug/bench, headphones/bus, and laptop/bowl (Figure 3 a, b, c). Participants were unable to distinguish mailbox/train, piano/airplane, and chair/camera (Figure 3 d, e, f). The exact number of participants correctly labeling the objects by pair is shown in Figure 5.

Experiment 2: Covered → Uncovered

We took the results of Experiment 1 to indicate pre-school children have a general ability to match objects to their cloth-covered representations, though they may have been using one of several different strategies to do so. We next examine whether children were able to go in the inverse direction, inferring the identity of an object hidden under cloth.

Participants

Seventeen individuals ($N = 16$, 5 female, median age 4.0 years, range 3.0-5.0) were recruited at the [City] Children's Museum. The size of the sample was pre-specified at 16 to match Experiment 1.

Materials and methods

Participants were tested in a designated area in the [City] Children's Museum. Parents gave their informed consent, and

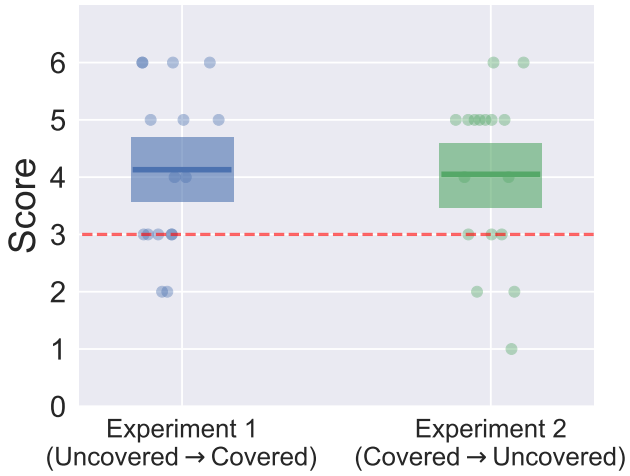

Figure 4: **Left**: Results of Experiment 1, seeing uncovered object and matching to cloth-covered image. **Right:** Results of Experiment 2, seeing cloth-covered image and matching to uncovered object. Score ranges from 0 (no trials correct) to 6 (all trials correct). Bold lines indicate mean score, and shaded colored area indicates 95% CI. Dashed red line indicates chance performance. Each dot indicates the response of one participant, jittered for visibility.

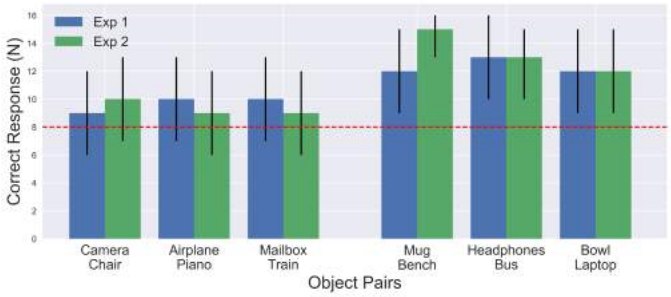

Figure 5: Results of Experiments 1 and 2 by object pair. The number of participants who correctly identified the target object is shown against specific object pairs. Black lines indicate 95% CI, dashed red line indicates chance performance. Children performed at chance or above chance levels for the same object pairs in both experiments.

advised not to encourage responses from their child.

Prior to the touch-screen part of the experiment, participants were shown 6 images of covered items in succession (printed on paper), and asked what they thought was under the cloth covering. That is, participants provided a free-form verbal response. The experimenter did not provide feedback on whether the response was correct or incorrect.

The touch-screen part of the experiment was similar to Experiment 1. Participants were shown an iPad, and told that they were going to play a game. As in Experiment 1, participants first engaged in two warm-up trials, and by the second trial all participants correctly labeled the matching object.

The test phase was also similar to Experiment 1: participants saw 6 trials in succession, in random order. Each trial contained a pair of objects, using the same pairs as in Experiment 1. However, in this experiment, the test object in a pair was covered by cloth, and the two objects below it were uncovered (see Figure 2). Participants were asked to indicate which of the two objects was under the cloth. Participant choices were automatically stored. As before, participants were given general encouragement, but were not told whether their choice was correct.

Results and analysis

The verbal response of participants to the first part of the task (freeform response when prompted to guess what is under a cloth) is summarized in Table 1. We did not predict that participants would correctly guess what was under a cloth, rather we used this task to examine the range of possible guesses. Note that many of the participants responded 'table' as this was a salient object mentioned by the experimenter.

Participants' responses to the forced-choice part of the task were summed across the object pairs, and are shown in Figure 4 (right). The summation resulted in a score going from 0 (no objects correctly identified) to 6 (all objects correctly identified), with chance performance at 3. On average, participants correctly labeled 4.26 objects (95% CI 3.66–4.74, bootstrapped with 10,000 samples). The confidence intervals are above chance performance, and a standard two-sided T-test also indicates this result is statistically significant ($t(15) = 3.87, p < 0.01$).

As in Experiment 1, a logistic regression of labeling score on age was not significant, and neither was a comparison which split participants by median age. We again stress that while we did not expect an age effect, we also do not believe these results necessarily indicate a 'true null' (the nonexistence of an age effect), merely a lack evidence for it.

The identity of the objects in a given pair again had an effect on participant labeling. Interestingly, the exact same pattern emerged when using a standard two-sided binomial test at the $p < 0.05$ level. That is, in Experiment 2 participants correctly distinguished mug/bench, headphones/bus, and laptop/bowl, but did not distinguish mailbox/train, piano/airplane, and chair/camera. Figure 5 shows the performance of participants by pair.

We considered two hypotheses regarding the observation of the same pattern of successes and failures in both experiments:

- H1: Children's performance on both tasks is unrelated
- H2: Children's cloth-related reasoning is affected by object properties due to underlying object features.

We captured hypothesis H1 by assuming children's response is the result of informed inference (a biased coin with weight $\theta = 0.8$) or a random guess ($\theta = 0.5$), and that there are 3 weighted coins and 3 random coins per each experiment, but they are unrelated across experiments. The value of the weighted coin reflects an average of participant performance across the two experiments. We captured hypoth-

Covered object	Verbal description
Chair	table (5), box (3), chair (2), monster (1)
Camera	table (3), box (1), present (1)
Bench	table (3), square box (2), tall present (1)
Mug	table (3), chair (2), box (1), mountain (1), couch (1), squiggle strips (1), circle (1)
Laptop	table (3), square table (1), box(1), dot (1), rectangle (1), square (1), bridge (1)
Bowl	table (3), round table (1), circle (1), chair (1)

Piano	house (3), box (2), ladder (1), table (1), chair or table (1)
Headphones	rainbow machine (1), dog (1), ball (1), mountain (1), band-aid (1), diamond (1), front of crib (1), chair (1), jelly-fish (1), table (1)
Bus	box (1), square (1), fountain (1)

Table 1: Verbal responses of participants in Experiment 2. Numbers in brackets indicate the number of participants giving the preceding response. Numbers do not add up to the total number of participants as not all participants replied in all trials.

esis H2 by assuming the same set-up as hypothesis H1, but with the additional assumption that the weighted coins are matched with the same object pairs in both experiments. Assuming an uninformed uniform prior over both hypotheses, we can assess K, the Bayes factor of the two hypotheses, by estimating the ratio of the likelihood of the data under each hypothesis: $K = \frac{P(H2|D)}{P(H1|D)}$. The data under consideration is passing 3 binomial tests for each experiment, for the same object pairs. Using a bootstrap analysis in which 16 simulated participants have their behavior sampled from the coins described for H1 and H2, using 10,000 samples, we find a Bayes factor of $K = 21$, indicating strong evidence in favor of H2. Put briefly, the 'suspicious coincidence' that children are able to distinguish the same 3 pairs in both experiments is indicative of underlying features of the objects interacting with cloth-based reasoning.

Experiment 3: Adult comparison

While pre-school children were able to overall correctly reason about cloth-covered objects, they also made characteristic mistakes, indicating an underlying difficulty in reasoning about how particular objects will interact with cloth. Such difficulties may be due to simple lower-level feature interaction (for example, covering the mailbox and train both result in elongated rectangular shapes), or due to the end-result of a coarse draping simulation resulting in similar images, or a different reason altogether. Whatever the source of the difficulty, we wanted to examine whether it carried into adulthood. In the next experiment we examined the targeted prediction that adults would overall do worse on the trials that children failed.

Participants

One-hundred and twenty (N=120) participants were recruited online via Amazon Mechanical Turk. Eleven participants were discarded after failing to answer a catch question, and the remaining participants (N=109) are considered in the analysis below ($Median_{age}$ = 33 years, age range 20–70, 48 self-identified as female). We anticipated the task would be easy for adults, and based the number of participants on the expectation of small effect sizes.

Materials and methods

Participants were shown 6 trials, similar to Experiment 1. For each trial, participants were shown a target object and asked to imagine it covered with cloth. On a following page, participants were asked to select which of two covered objects matched the target object. The object pairs were the same as those used in Experiment 1. The order of presentation, the right/left location of the covered objects, and the identity of the target object were all randomized. Participants were asked to respond as quickly as possible. At the end of the 6 trials participants were asked to describe their task was in the study, and irrelevant answers (e.g. 'opinion', 'work', '0') led to discarding their data prior to analysis. Participants were also asked to provide information regarding their age and gender.

Results and analysis

Participants responded within about a second of presentation, with a median response of 1.1 seconds (95% CI 1.04–1.16) per trial. Participants also found the task relatively simple, with an average success rate of 98% (95% CI 96%–99%) per trial.

We considered the average correct response rate for the objects children found easier ('Children pass') and harder ('Children fail'). The average correct response rate by adults for the 'Children pass' trials was 99% (95% CI 98%–100%), whereas the correct response rate for the 'Children fail' trails was 96% (95% CI 94%–98%). The bootstrapped distribution over these variables and the response rate per object pair is shown in Figure 6.

The average correct response rate of adults per trial appears higher for the pairs that children found easier in Experiments 1 and 2, but this effect is very small as adults are nearly at ceiling.

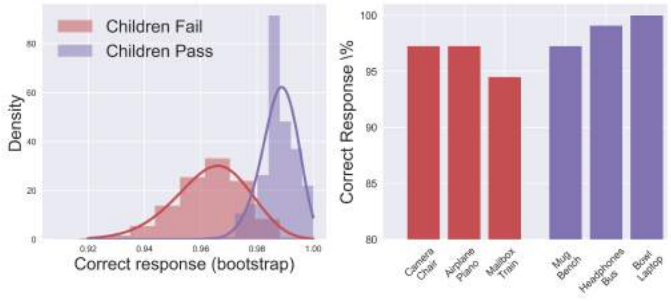

Figure 6: Results of Experiment 3. **Left**: bootstrap posterior distribution over the correct response rate aggregated by trial type ('Children pass' and 'Children fail'), 10,000 samples. **Right**: Correct response rate for each object pair, sorted by trial type.

General Discussion

People can reason intuitively about how things drape, wrap, envelop, sag, and droop. Recent experiments (Yildrim et al., 2016) have shown that adults perform well in a task that requires matching a covered and uncovered object, and that this ability can be captured by a physics and graphics engine which approximately simulates the draping of an object. Motivated by this work, as well as by the general category of 'cloth' in current game engines, we examined whether pre-schoolers can also reason about the interaction of cloth and rigid objects, and found their performance to be above chance in two such tasks. Children's pattern of failure and success was similar across the tasks, and a comparative task with adults found a small effect, suggesting that they too find the same object pairs hard or easy.

The current studies warrant tentative conclusions regarding object representation and the use of dynamic mental simulation in children. Previous studies with adults (Yildrim et al., 2016) rotated the objects, in a way that prevented simple feature-matching and meant in part to examine whether the adults were relying on a generative model reconstructions of the object. We did not use such a rotation in our studies, and we see them as a first step to examine whether children have *any* competence with cloth-based reasoning. It is possible that children's abilities rely on relatively simple feature matching, while adult reasoning is based more on reconstructing a mental representation of the 3D object shape It is also unclear which of several proposals for a generative model of 3D objects (whether for children or adults) is the right one (and see for example Soltani et al. 2017, for a comparison of several such methods for recovered objects from silhouettes). Further studies will need to use object rotations and a wider array of object pairs to examine this question.

The dynamics of cloth go beyond draping objects. For example, cloth sags when objects are placed on top of it, to a degree dependent on internal parameters related to its stiff and stretch. Can children reason about the likely sag of a piece of fabric, based on seeing its motion and knowing an object's felt weight? Are children sensitive to the weight of cloth, or will they reason about it as a weightless 2 dimensional manifold that only interacts geometrically with objects?

Even if both adults and young children rely on similar representations for reasoning about cloth, it is possible that these representations develop late compared to the basic expectations that infants have about rigid bodies (which innate or extremely early developing) and about liquids (which develop over the first year of life). Looking time experiments with infants could test this possibility by familiarizing infants to either cloth or a rigid body of similar proportions and texture, followed by an interaction in which the cloth and rigid body collide with or drape rigid objects.

To wrap up, while many issues remain hanging, this work begins to uncover the origin of cloth-based reasoning, which may form a separate ontological category within intuitive physical reasoning. It opens the door to future research probing the richness and origins of children's reasoning about a human invention that is ubiquitous in human cultures, and that occupies an interesting middle ground between rigid objects and amorphous stuff.

Complexity and learnability in the explanation of semantic universals of quantifiers

Abstract

Despite wide variation among natural languages, there are linguistic properties universal to all (or nearly all) languages. An important challenge is to explain why these linguistic universals hold. One explanation employs a learnability argument: semantic universals hold because expressions that satisfy them are easier to learn than those that do not. In an exploratory study we investigate the relation between learnability and complexity and whether the presence of semantic universals for quantifiers can also be explained by differences in *complexity*. We develop a novel application of (approximate) Kolmogorov complexity to measure fine-grained distinctions in complexity between different quantifiers. Our results indicate that the monotonicity universal can be explained by complexity while the conservativity universal cannot. For quantity we did not find a robust result. We also found that learnability and complexity pattern together in the monotonicity and conservativity cases that we consider, while that pattern is less robust in the quantity cases.

Keywords: semantic universals; generalized quantifiers; Kolmogorov complexity; learnability

Introduction

Even though there is huge variability between natural languages, they still share many common features. Such universal linguistic properties have been found at many levels of analysis: phonology (Hyman, 2008), syntax (Chomsky, 1965; Newmeyer, 2008), and semantics (Barwise & Cooper, 1981). Confronted with attested linguistic universals, the question naturally arises: why these properties? What explains the presence of the particular observed universals across languages?

In search of an explanation in terms of the interaction between linguistics and the specifics of human cognition, several theories have presented some form of learnability as an explanation of the presence of semantic universals (see, e.g., Barwise & Cooper, 1981; Keenan & Stavi, 1986; Szabolcsi, 2010). Recently, Steinert-Threlkeld and Szymanik (in press, henceforth ST&S) provided evidence for a version of this learnability hypothesis by using recurrent neural networks as a model for learning and applying this to several different semantic universals.

In this paper, we ask whether these semantic universals could also be explained by some measure of *complexity*, and whether this provides similar results as using a measure of learnability. It is a common expectation that there will be a connection between learnability and complexity and many theories of learning are built around such a connection (Tiede, 1999; Hsu, Chater, & Vitányi, 2013). At the same time, there are few examples that provide evidence for this expectation in concrete cognitive tasks. In particular, it remains open whether a connection between learnability and complexity exists for independently motivated measures of each of these factors in specific domains. In the present work, we study the meaning of generalized quantifiers and compare their complexity (in a sense to be made precise) with the learnability results of ST&S.

The complexity of generalized quantifiers has been intensively studied using methods from logic, automata theory, and computational complexity.[1] However, as we will explain in more detail in a later section, none of these theories have developed a notion of complexity that applies to all quantifiers and can capture the difference between those that are attested and non-attested in natural language. To overcome these limitations, in this paper we propose to evaluate the complexity of quantifiers from an information-theoretic perspective. This perspective has already proven fruitful as an explanatory device in linguistics (Gibson et al., 2019). More specifically, we suggest to adopt (approximate) Kolmogorov complexity (Li & Vitányi, 2008) as a measure for the complexity of quantifiers. Kolmogorov complexity roughly measures how much regularity exists in a string, which enables it to be described by a shorter program that generates it. It is not implausible that universals will have the function of creating "patterns" that enable such compression.

The paper is structured as follows. In the next section, we present generalized quantifier theory and the semantic universals that we will discuss. We also discuss a recent explanation of semantic universals in terms of learnability and previous approaches to measuring the complexity of quantifiers and their limitations with respect to the current study. Following that, we introduce Kolmogorov complexity and a tractable approximation to it, and we explain how we apply this measure to binary encodings of quantifiers. In the section after that, we apply this complexity measure to the same pairs of quantifiers as in the recent learnability study to see (i) whether—in addition to learnability—some of the attested semantic universals can be explained by differences in complexity and (ii) whether complexity and learnability pattern together. We conclude by discussing the results and outlining future work.

[1] See Szymanik (2016) for an overview.

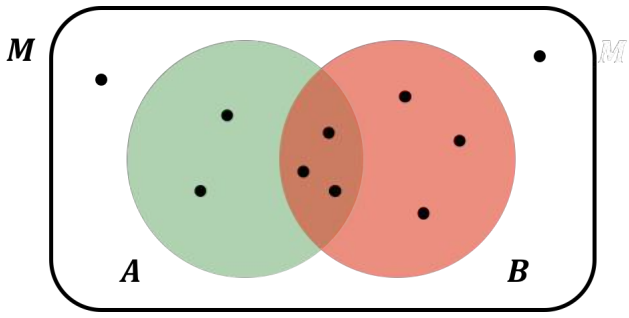

Figure 1: An example of a quantifier model $\mathcal{M} = \langle M, A, B \rangle$ with 10 objects, shown as a vendiagram. This model verifies quantifiers `some` and `most`, but does not varify `all`

.

Quantifiers and their universal properties

Quantifiers are the semantic objects that are expressed by determiners, such as `some`, `most`, or `all`. Determiners are expressions that can combine with common nouns and a verb phrase in simple sentences of the form *Det N VP*, like "some houses are blue". We assume a distinction of the determiners into the grammatically simple (e.g. `some`, `few`, `many`) and the grammatically complex (e.g. `at least 6 or at most 2`, `an even number of`).

We use the framework of generalized quantifiers to represent the meaning of quantifiers as sets of sets. In particular, determiners denote type $\langle 1,1 \rangle$ generalized quantifiers, which are sets of models of the form $\mathcal{M} = \langle M, A, B \rangle$, where M is the domain of the model, and A, B are two unary predicates (that is: $A, B \subseteq M$).[2] See Figure 1 for an illustration. This is an extensional representation of meaning, in which a quantifier is defined as the class of all models satisfying a given property (corresponding to the situations in which a simple sentence with that quantifier would be true). For a given model, $\mathcal{M}$, and quantifier Q we write $\mathsf{Q} \in \mathcal{M}$ if and only if: $\mathcal{M} \models \mathsf{Q}(A,B)$. For example, the meaning of the quantifiers `some`, `most`, and `every` can then be represented as follows:

$$[\![\texttt{some}]\!] = \{\langle M,A,B\rangle : |A \cap B| \neq \emptyset\},$$
$$[\![\texttt{most}]\!] = \{\langle M,A,B\rangle : |A \cap B| > |A \setminus B|\},$$
$$[\![\texttt{every}]\!] = \{\langle M,A,B\rangle : A \subseteq B\}.$$

The semantic universals that we consider build on specific properties of generalized quantifiers, namely *monotonicity*, *quantity*, and *conservativity*. Let Q be a generalized quantifier. Then we call Q *monotone* if it is either upward or downward monotone, which is defined as follows. Q is *upward monotone* := if $\langle M,A,B\rangle \in \mathsf{Q}$ and $B \subseteq B'$, then $\langle M,A,B'\rangle \in \mathsf{Q}$. Q is *downward monotone* := if $\langle M,A,B\rangle \in \mathsf{Q}$ and $B \supseteq B'$, then $\langle M,A,B'\rangle \in \mathsf{Q}$. Barwise and Cooper (1981) formulate and defend the following semantic universal:

MONOTONICITY UNIVERSAL: All simple determiners are monotone.

[2]For a textbook treatment of generalized quantifiers see Peters and Westerståhl (2006).

The property of *quantity* intuitively expresses that the meaning of a determiner only depends on the sizes; i.e., the quantity, of the relevant sets and not on the way those sets are presented or on the particular identity of the objects in those sets. Q is *quantitative* := if $\langle M,A,B\rangle \in \mathsf{Q}$, and $A \cap B$, $A \setminus B$, $B \setminus A$, and $M \setminus (A \cup B)$ have the same cardinality (size) as their primed-counterparts, then $\langle M',A',B'\rangle \in \mathsf{Q}$. Keenan and Stavi (1986) formulate and defend the following semantic universal[3] :

QUANTITY UNIVERSAL: All simple determiners are quantitative.

The property of *conservativity* intuitively expresses that a noun phrase of the form *Det N VP* is genuinely about the *N* and not about the *VP*. That is, to verify a quantifier in a quantifier model only the *A*'s that are *B*'s are relevant, not the *B*'s that are not *A*'s. Q is *conservative* := $\langle M,A,B\rangle \in \mathsf{Q}$ if and only if $\langle M,A,A\cap B\rangle \in \mathsf{Q}$. Barwise and Cooper (1981) formulate and defend the following semantic universal:

CONSERVATIVITY UNIVERSAL: All simple determiners are conservative.

Explaining semantic universals via learnability

The question naturally arises: can a unified explanation be given for these universals? ST&S develop the following *learnability hypothesis*: expressions satisfying semantic universals are easier to learn than those that do not.[4] To anthropomorphize: as languages are developing, they choose to attach lexical items to easy-to-learn meanings, and rely on complex grammatical constructions and compositional interpretation thereof to express hard-to-learn meanings.

The hypothesis immediately raises a challenge: to provide a model of learning on which it's true. ST&S train recurrent neural networks to learn minimal pairs of quantifiers, one satisfying the universal and one that does not.

Figure 2 shows an example learnability result from ST&S: an upward montone quantifier (in blue: `at least 4`) was robustly easier to learn for a neural network than a non-monotone quantifier (in red: `at least 6 or at most 2`). Similar patterns were observed for downward monotone and quantitative quantifiers, while conservative ones were found to be no easier to learn than non-conservative ones (but were argued to arise from a different source than learnability).

These computational results provide strong support for the learnability hypothesis. The approach has also worked well in explaining universals in disparate linguistic domains: color terms (Steinert-Threlkeld & Szymanik, 2019) and responsive predicates (Steinert-Threlkeld, in press).

Previous approaches to the complexity of quantifiers

In the literature on generalized quantifiers one can find several approaches to measuring complexity. Although these measures can capture some of the cognitive difficulty of quantifier

[3]See also Peters and Westerståhl (2006), van Benthem (1984), and ST&S.

[4]Hints of this hypothesis may be found in (van Benthem, 1987; Peters & Westerståhl, 2006; Magri, 2015).

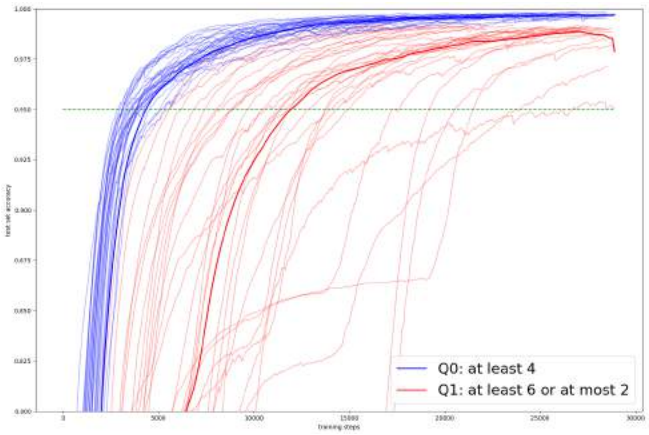

Figure 2: Learning curves on a neural network for the monotone *at least 4* (blue) versus *at least 6 or at most 2* (red). This was Figure 4 in ST&S.

processing,[5] we will see that they are not fine-grained enough to explain the presence of semantic universals.

The earliest approach uses logic, analyzing which quantifiers are definable in progressively more expressive logics. Many natural language quantifiers can be expressed in elementary (i.e. first-order) logic, e.g. `some` or `at least 4`. The seminal result here is that proportional quantifiers cannot be defined in elementary logic: one needs a stronger logical system, like second-order logic, to uniformly express the meaning of, e.g., `most`.[6] This definability criterion cannot, however, distinguish between the complexity of the quantifiers satisfying and not satisfying the universals we study. For example, `all` and `only` can be defined with elementary formulas of exactly the same form (and therefore the same complexity):

$$\texttt{All(A, B)} := \forall x(A(x) \implies B(x))$$
$$\texttt{Only(A, B)} := \forall x(B(x) \implies A(x))$$

Also, both monotone and non-monotone quantifiers can be defined by formulas of the same complexity.

Johan van Benthem (1984) has proposed to study minimal computational devices (automata) corresponding to generalized quantifiers. Under this approach, some quantifiers can be associated with canonical minimal finite automata. One can then use the size of such an automaton (i.e., the number of states) as a measure of quantifier complexity. For example, the automaton for `all` has two states while the automaton for `at least 3` has four states. Other quantifiers—for example, proportional quantifiers—must be associated with more complex computational devices, like push-down automata. This measure of complexity can explain some variance in the cognitive difficulty of quantified sentence verification against pictures (Szymanik & Zajenkowski, 2010). It is, however, not suitable for our purposes. One can easily construct a minimal quantifier pair that cannot be distinguished by this complexity measure. For instance, both `all` and `only` have minimal automata with two states. One can also easily construct a family of quantifiers with the same automaton complexity containing both quantifiers satisfying and not satisfying quantitity (`at least 4`, `first 3`) and monotone and non-monotone quantifiers (`at least 4`, `at least 3 or at most 2`). An extra problem for this approach is that for push-down automata corresponding to proportional quantifiers, there is no accepted complexity measure because they do not have a definition of a minimal automaton. So the measure does not apply to all quantifiers, including ones expressed in natural language.[7]

Another well-studied approach to identify the complexity of generalized quantifiers uses the toolbox of computational complexity theory (Szymanik, 2016). It measures quantifier complexity in terms of the asymptotic growth of the computational resources needed to recognize their meaning. The problem is that computational complexity distinctions are even more crude than the previously described alternatives. Even though computational complexity distinctions have been used to theoretically delimit the borders of natural language expressivity (Ristad, 1993; Kontinen & Szymanik, 2008), these borders include both quantifiers satisfying and not satisfying the semantic universals that we are interested in.

Kolmogorov complexity of quantifiers

To investigate whether the aforementioned semantic universals can be explained by differences in complexity, we need a measure of complexity that is suited for that task. As discussed in the previous subsection, setting up the right framework for this is a non-trivial challenge, as many well-know complexity measures are limited in their ability to distinguish between quantifiers with and without the universal properties under consideration.

Therefore, in this study, we use (approximate) Kolmogorov complexity—a finer-grained measure that has not yet been explored in this domain, and we investigate its potential to explain semantic universals. Because Kolmogorov complexity is more fine-grained than the previously discussed complexity measures, it has greater promise in capturing differences in complexity between the quantifiers that we consider. It makes intuitive sense that humans would be sensitive to Kolmogorov complexity, because it is a mathematical operationalization of the notion of compressibility and various aspects of cognition can plausibly be understood in terms of data compression: storing data compactly in a way that it can be (partially) recovered. Kolomogorov complexity has been shown useful in modelling a cognitive bias towards simplicity in a variety of cognitive domains (see Chater & Vitányi, 2003; Feldman, 2016).

Kolmogorov complexity (K) measures how much an individual sequence of symbols can be compressed. When a sequence contains regularities, these regularities can be exploited to produce a shorter description of that sequence. $K(x)$

[5] See Szymanik (2016) for an overview.

[6] See Peters and Westerståhl (2006) for an overview.

[7] This approach has also inspired learnability models (Gierasimczuk, 2005; Clark, 2010).

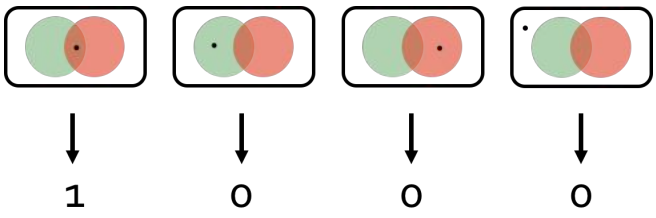

Figure 3: Encoding of some over models of size 1.

of a sequence x is defined as the length of the shortest program p that outputs x (see Li & Vitányi, 2008).[8]

The drawback is that K has been formally proven to be uncomputable. This means that there exists no algorithm that outputs $K(x)$, given x (Li & Vitányi, 2008). For this reason, we use a well-established and tractable approximation to K, that is based on the Lempel-Ziv algorithm for lossless data compression (Lempel & Ziv, 1976). The Lempel-Ziv algorithm parses a sequence x from left to right, and cuts up the sequence into subsequences. At each point it chooses the longest possible subsequence that is identical to an earlier part of the sequence, thereby identifying the number of unique subpatterns in x. The Lempel-Ziv complexity $LZ(x)$ is the number of these unique subpatterns of x. For approximate Kolmogorov complexity $\tilde{K}$, we use $C_{LZ}(x)$, which is defined as $\log_2(\mathsf{len}(x)) \cdot LZ(x)$.[9] Ziv and Lempel (1978) show that $C_{LZ}(x)$ approximates $K(x)$ in the limit; i.e, when $\mathsf{len}(x)$ approaches infinity.Vitányi (2013) shows that, in practice, lossless compression methods give adequate results also for finite sequences. Furthermore, C_{LZ} is considered particularly adequate as a measure for $\tilde{K}$ for shorter strings (Lesne, Blanc, & Pezard, 2009).[10]

To determine the approximate Kolmogorov complexity $\tilde{K}$ of a quantifier we need to represent it as a sequence of symbols. We encode a quantifier as a binary sequence, representing the quantifier as a distribution of truth values over all models (up to a certain size). First, we enumerate all possible models. Then, given such an enumeration, we represent a quantifier by placing a 1 in the sequence for every model that verifies the quantifier and placing a 0 for every model that does not verify the quantifier. See Figure 3 for an example. Given a sequence of models, this gives a unique binary representation for every possible quantifier. Then, for a given sequence of models up to a certain maximum model size, we can determine the complexity of a quantifier Q by computing $\tilde{K}(x_{\mathsf{Q}})$ over the binary representation x_{Q} of Q.

This framework allows us to compare the complexity of different quantifiers and investigate whether semantic universals might be explained by differences in complexity. In doing this, we are not interested in the absolute complexity values of the quantifiers but in the difference in complexity between a quantifier that satisfies a universal and its minimally differing counterpart that does not satisfy that universal. To make any such comparison across quantifiers, we need to fix an enumeration over quantifier models and use that as the base for our quantifier representations.

One way of doing that would be to take a random enumeration over quantifier models. Unfortunately, for our purpose, this is not a suitable method. For a random sequence, the complexity of a quantifier is mainly determined by the uniformity of that quantifier (defined by the ratio of 1's versus 0's in the quantifier representation).[11] When the uniformity of a quantifier is the main determiner for its complexity, differences between the complexity of two quantifiers might not reflect differences due to the presence or absence of a particular universal property.

For our purpose, choosing a structured sequence over models is more suitable than taking a random sequence. The intuition behind this can be understood as follows. If a quantifier that satisfies a universal has lower $\tilde{K}$ complexity than its minimally differing counterpart, then this will be because the universal property causes a regularity in the distribution of truth values across quantifier models. This difference in regularity between quantifiers could disappear when evaluating quantifiers over a random sequence of models, but it might be visible when evaluating those quantifiers over a structured and well-behaved sequence. For this reason, we evaluate our quantifiers over the lexicographic sequence of models, which is standardly used in the literature on generalized quantifiers. For robustness, we look at all 12 uniquely different possible lexicographical orderings, arising from the different ways of ordering the symbols for the four sets $A \cap B$, $A \setminus B$, $B \setminus A$, and $M \setminus (A \cup B)$.[12]

Results

With this framework in place we can now turn to our main question. To test whether approximate Kolmogorov complexity can explain the three proposed semantic universals, we

[8] Formally, K is defined given a particular universal Turing machine (UTM), but, by the Invariance Theorem, K given UTM V or given UTM W will not differ more than some constant c.

[9] In particular, we use the same version of C_{LZ} as used by Dingle, Camargo, and Louis (2018), which uses the average between $LZ(x)$ and $LZ(\mathsf{reverse}(x))$ to obtain an even more fine-grained complexity measure.

[10] There are also other popular lossless compression methods that can be used as approximations to K, such as gzip (based on LZ compression), and bzip2 (a block-sorting compressor). Graphs comparing the LZ and gzip2 complexity of the quantifiers that we considered can be found at https://tinyurl.com/quantifierLZ.

[11] This can be understood from the fact that among all different strings of a given uniformity there are only few strings of low complexity. This is because when a string x of length n has a low complexity, this means that x can be compressed to a shorter string x' of length $n' < n$, and there are only few strings of length n' compared to the amount of strings of length n. Therefore, when taking two quantifier representations with the same uniformity, over a random sequence of models, they are likely to both have complexity values that are close to the maximum complexity for that uniformity (which are thus similar).

[12] In fact, there are in total 24 different lexicographic enumerations over the quantifier models that we use, but only 12 of them are unique, and the other 12 are the reverse of one of those 12 unique sequences. As mentioned earlier, we use a measure that takes the average between the complexity over a sequence and the complexity of the reverse of that sequence. So this leaves 12 lexicographical sequences over which we can compute this measure.

look at minimally differing pairs of quantifiers in which one satisfies the universal and the other does not. To compare our complexity results with the learnability results of ST&S, we test the same pairs of quantifiers. Let $x_{i,\mathsf{Q}}$ be the binary representation of quantifier Q, based on a sequence of all models up to size i. For each quantifier Q, and for each model size i from 1 to 10, we computed $C_{LZ}(x_{i,\mathsf{Q}})$. We repeated this for all 12 lexicographical model sequences. For each pair we plotted the mean complexity against the maximum model size (with confidence intervals), and we compared the differences in complexity between the two quantifiers at each maximum model size and model sequence. The code that we used for generating these data and the data themselves can be found at https://tinyurl.com/quantifierLZ.

Monotonicity

To test the MONOTONICITY UNIVERSAL, we looked at two quantifier pairs, one with a downward- and one with an upward-monotone quantifier. First, we compared the downward-monotone quantifier `at most 3`, meaning $|A \cap B| \leq 3$, with the non-monotone quantifier `at least 6 or at most 2`, meaning $|A \cap B| \geq 6$ or $|A \cap B| \leq 2$. The mean complexity values over all 12 lexicographical model sequences and a 95% confidence interval are plotted in Figure 4. The descriptive statistics show that for all model sizes larger than 2, monotone `at least 4` has a lower complexity than non-monotone `at least 6 or at most 2` (for model size 1 and 2 the differences are 0). This holds for each of the 12 different model sequences. The 12 individual plots for this pair and all the other quantifier pairs can be found at https://tinyurl.com/quantifierLZ.

Second, we compared the upward-monotone quantifier `at least 4`, meaning $|A \cap B| \geq 4$, with the non-monotone quantifier `at least 6 or at most 2`, meaning $|A \cap B| \geq 6$ or $|A \cap B| \leq 2$. The mean complexity values over all 12 model sequences and a 95% confidence interval are plotted in Figure 4. Exactly like for the downward-monotone quantifiers, the descriptive statistics show that that for all model sizes larger than 2, monotone `at most 3` has a lower complexity than non-monotone `at least 6 or at most 2` (for model size 1 and 2 the differences are 0). Again, this holds for each of the 12 different model sequences.

These complexity results show the same patterns as the learnability results of ST&S. This supports the hypothesis that, in addition to learnability, the MONOTONICITY UNIVERSAL might be explained by differences in complexity, with monotone quantifiers being less complex than non-monotone quantifiers.

Quantity

To test the QUANTITY UNIVERSAL, we looked at two quantifier pairs with a quantitative and a non-quantitative quantifier. First, we compared the quantitative quantifier `at least 3`, with the non-quantitative quantifier `first 3`. The mean complexity values over all 12 model sequences and a 95% confidence interval are plotted in Figure 5. For model size 1, 2, and 3, the differences are 0, and for model sizes 4 to 10 the descriptive statistics show that `at least 3` is less complex in 59.5% of the cases, and more complex in 33.3% of the cases.

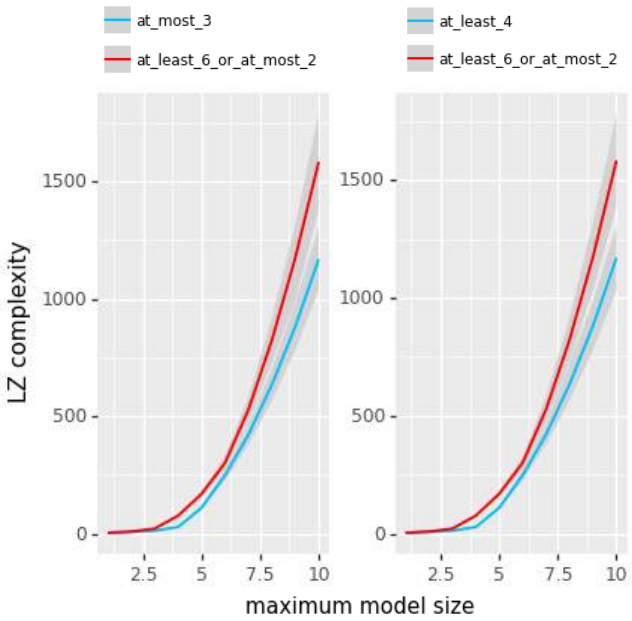

Figure 4: Complexity values for `at most 3` and `at least 6 or at most 2`, and for `at least 4` and `at least 6 or at most 2`. Mean values with 95% confidence interval over all 12 lexicographic model sequences

Second, we compared the quantitative quantifier `at least 3`, with the non-quantitative quantifier `last 3`. The main complexity values over all 12 model sequences and a 95% confidence interval are plotted in Figure 5. Again, for model size 1, 2, and 3, the differences are 0, while for model sizes 4 to 10 the descriptive statistics show that `at least 3` is less complex in 52.4% of the cases and more complex in 42.9% of the cases.

These complexity results do not show a robust pattern. However, they do show a tendency towards the quantitative quantifiers being less complex than the non-quantitative quantifiers. In the learnability results of ST&S, the quantitative quantifiers were significantly easier to learn than the non-quantitative ones. These findings neither confirm nor disconfirm the hypothesis that, in addition to learnability, the QUANTITY UNIVERSAL could be explained by differences in complexity.

Conservativity

To test the CONSERVATIVITY UNIVERSAL, we looked at two quantifier pairs with a conservative and a non-conservative quantifier. First, we compared the conservative quantifier `most`, meaning $|A \cap B| > |A \setminus B|$, with the non-conservative quantifier `M`, meaning $|A| > |B|$. The mean complexity values over all 12 model sequences and a 95% confidence interval are plotted in Figure 6. The descriptive statistics show that that for all model sizes and for all model sequences, conservative `most` has exactly the same complexity as non-conservative `M`.

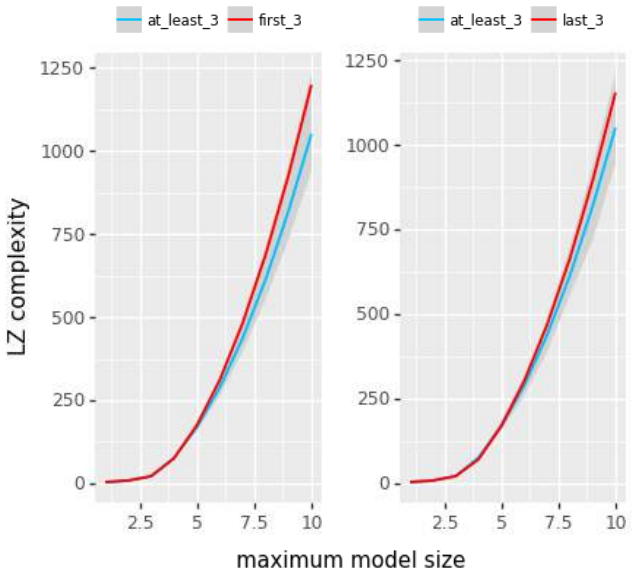

Figure 5: Complexity values for `at least 3` and `first 3`, and for `at least 3` and `last 3`.

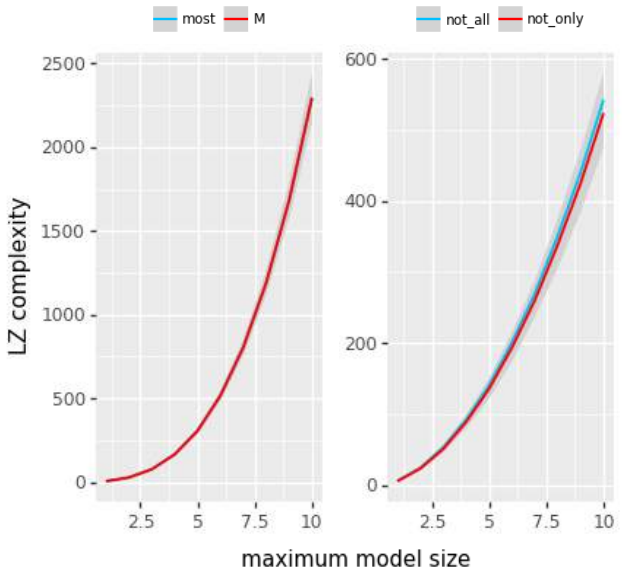

Figure 6: Complexity values for `most` and `M`, and for `not all` and `not only`.

Second, we compared the conservative quantifier `not all`, meaning $A \not\subseteq B$, with the non-conservative quantifier `not only`, meaning $B \not\subseteq A$. Again, the mean complexity values over all 12 model sequences and a 95% confidence interval are plotted in Figure 6. For model size 1 to 10 descriptive statistics show that `not all` is more complex in 55.9% of the cases and less complex in 40.8% of the cases.

These results do not support the hypothesis that the CONSERVATIVITY UNIVERSAL can be explained by differences in complexity. However, these complexity results do show the same patterns as the learnability results of ST&S, as in their results the conservative quantifiers were of similar learnability as the non-conservative ones. This, however, does not constitute a counterexample to the explanation of the universals via learnability. As explained by ST&S one should not expect the difference between conservative and non-conservative quantifiers under their framework. This universal should rather be explained in terms of the syntax-semantics interface.[13]

Discussion

Let us take stock. We have applied tools from algorithmic information theory—in particular, approximate Kolmogorov complexity—to measure the complexity of quantifiers expressed in natural language. We did this in order to see whether the complexity of a quantifier can explain the presence of semantic universals for quantifiers, and whether these complexity results show the same patterns as existing learnability results. We found that monotone quantifiers are robustly less complex than non-monotone quantifiers, and that conservative and non-conservative quantifiers have equal or similar complexity. For quantitative quantifiers we found a slight tendency towards being less complex, but this pattern was not robust. The results for monotonicity and conservativity agree with an existing explanation in terms of learnability due to ST&S, while the results on quantitativity hint in the same direction, but not robustly so.

The results of the exploratory study that we undertook are not decisive. Nevertheless, the results show substantial similarity between the complexity and learnability of quantifiers in the explanation of semantic universals. Our results for monotonicity show that approximate Kolmogorov complexity can indeed capture differences in complexity between quantifiers that could not be captured with the complexity measures from the previous approaches that we discussed. That neither complexity nor learnability distinguishes conservative from non-conservative quantifiers provides further evidence that conservativity has a different source than the other two universals, as suggested by ST&S.

Much work remains to be done. To corroborate our results, one would like to scale up beyond maximum model size of $n = 10$; how to make this computationally efficient is not a simple task. One would also like to expand the experiments beyond the minimal pair methodology employed here. In order to compare with existing results, it would be good to measure the complexity of many quantifiers and see which semantic properties best explain the complexities. The methods here could also be applied to semantic universals in other domains, to test the connection between complexity and learnability in a more general setting. Finally, one can also look at other measures of complexity: for instance, minimal derivation length in a Lanuage of Thought for generating expressions for quantifier meanings (Piantadosi, Tenenbaum, & Goodman, 2012; Goodman, Tenenbaum, & Gerstenberg, 2015).

[13] See Romoli (2015). Hunter and Lidz (2013) observe a difference in children learning conservative vs. non-conservative quantifiers. This result, if replicated, could be due to a bias acquired by the children in earlier exposure to only conservative determiners.

Preschoolers' Evaluations of Ignorant Agents are Situation-Specific

Abstract

Preschool children's preference for knowledgeable agents over ignorant and inaccurate agents (Sabbagh & Baldwin, 2001; Koenig & Harris, 2005; Rakoczy et al., 2015), is generally interpreted as epistemic vigilance. However, Kushnir and Koenig (2017) recently found that without a contrasting accurate agent, preschoolers will learn new information from an agent who professed ignorance, but not from one who was inaccurate. Employing a two-speaker design contrasting an agent who professed ignorance about familiar object labels with a speaker whose knowledge state was not revealed, we found that preschoolers (N = 41; 3.50-4.89 years, M = 4.08 years) avoided requesting and endorsing novel information from the ignorant agent in the same domain as her previous ignorance (i.e., labels). In different domains, however, (i.e. novel function learning, resource sharing, etc.) they were at chance in choosing the ignorant agent. This suggests that preschoolers' view of ignorance is situational, rather than uniformly negative.

Keywords: learning; testimony; social cognition; credibility; cognitive development; epistemic trust; accuracy; epistemic vigilance

Background

Numerous studies show an overwhelming preference in early childhood for a competent, confident, accurate, or knowledgeable agent over an agent who was inaccurate, ignorant, or uncertain (Birch, Vauthier, & Bloom, 2008; Brosseau-Liard & Birch, 2010, Brosseau-Liard, Cassels, & Birch, 2014; Fusaro, Corriveau, & Harris, 2011; Harris & Corriveau, 2011; Koenig & Harris, 2005; Koenig & Woodward, 2010; Pasquini et al., 2007; Rakoczy et al., 2015; Sabbagh & Shafman, 2009; Scofield et al., 2013; Tenney et al., 2011; Tummeltshammer et al., 2014; *For review, see* Harris et al., 2018). There may be many reasons for this preference--including assessments based on vigilance or trust—but in any case, there seems to be a general negative assessment of all uninformative agents by preschool age.

Recent findings suggest that children do not treat all uninformative agents as equally untrustworthy. Kushnir & Koenig (2017) measured preschoolers' evaluations of either an agent who professed ignorance about familiar object labels or one who was inaccurate. In one condition, 3- and 4-year-old children viewed an agent who professed ignorance about the names of familiar objects. In another, children viewed an agent who was inaccurate in naming the same objects. Kushnir & Koenig found that children were willing to learn new things from the previously ignorant agent, but not from the inaccurate one. This study suggests that children's evaluations of uninformative agents are not uniformly negative or vigilant. Specifically, that they don't see ignorance about some things as a sign to mistrust or avoid learning other things.

We can infer from Kushnir and Koenig (2017) that children respond more negatively to inaccurate agents than ignorant agents, but it remains unclear what these results imply about their evaluations of professed ignorance. It could be that by the presence of a preferred accurate agent overrode information from an ignorant agent in previous studies (e.g., Koenig & Harris, 2005), and that this single-speaker design revealed children's true ignorance evaluations. However, it could be that children were simply agnostic toward the previously ignorant agents, and were willing to learn from them when no alternatives were available.

What is the nature of children's stance on professed ignorance? We suggest that there are at least three possible answers. One is that children view ignorance as situation-specific. Broadly, this means children could discount past ignorance when learning new things (as in the above example) or they might treat an agent's claims of ignorance as specific to one domain of expertise and not another (e.g. Lutz & Keil, 2002; Kushnir, Vredenburgh & Schneider, 2013). The second possibility is that children look favorably on ignorant agents when they make new claims because they will admit what they don't know (i.e. they are "well calibrated" or even "virtuous" e.g. Kominsky, Langthorne, & Keil, 2016; Tenney et al., 2011). This suggests that children could show a preference for those who admit ignorance regardless of domain or situation because. A third possibility is that children only prefer previously ignorant agents when no other agents are available to provide information. This suggests that if any other reasonable (i.e. not inaccurate) source of information was present, children would avoid learning from an ignorant agent. Of course, these need not necessarily be mutually exclusive and could represent contributing factors in a nuanced assessment. We investigate the roles of these three possible interpretations in the current study.

We used a modified version the two-speaker design from Koenig & Harris (2005) which contrasts an ignorant with an accurate speaker to examine these three possibilities. The modification was to contrast an agent who admitted to not knowing the names of familiar objects with a neutral agent whose knowledge state has not been disclosed. To explore the specificity of children's ignorance evaluations, we measured children's willingness to learn from the ignorant agent about novel objects in two domains: labels and functions. To explore the depth of children's evaluations, we measured children's choices of the ignorant agent for requesting information and for endorsing new claims within both domains.

If children's evaluations of ignorance are situation-specific, we expect children to differ in their willingness to learn new information about object labels versus functions from a source who was ignorant about labels. If they instead view ignorance as a virtue or signal of calibration, we expect children to show willingness to learn from the ignorant agent in all cases. Finally, if children show overall vigilance, we expect them to avoid learning new information from the ignorant agent in all cases.

In addition to the learning tasks, we included three different measures of children's ignorant speaker evaluations in non-learning situations. To capture whether they had a preference or general positive regard for the ignorant agent, we measured how often children shared more stickers with her than with the neutral agent across three resource-sharing trials (*see* Chernyak & Sobel, 2015; Kanngiesser & Warneken, 2013; Moore, 2009). Toward testing for general dislike or mistrust, we controlled for agent knowledge state by measuring children's endorsements of claims about the location of a hidden object that both agents could see. Further, to determine whether evaluations permeated children's explicit understanding of agent knowledge, we asked children which of the two agents knows more. Together, these measures can provide evidence about the extent of overall positive or negative evaluations of the ignorant agent.

Method

Participants

We tested 41 preschool age children (16 girls) between 3.50 and 4.89 years old (M = 4.08 yrs., SD = 0.42 yrs.) from a large midwestern city. In addition, one child was excluded for experimenter error, and one child was excluded for ending the study early. Participants were predominately from white, upper-middle class families.

History Phase

Children were shown an image of the two agents and were told they were going to watch some videos of these two friends and then play a game. They then watched alternating videos of the ignorant (*I*) agent (3) and neutral (*N*) agent (3). For each video, the agent sat at a table with a confederate, who initiated a brief exchange with the agent. In order to control for features outside of demonstrated knowledge state, both agents responded to the confederate in a conventional way (e.g., returning a greeting or responding to a question) and were on screen for approximately equal periods of time. Agent who spoke first (*I* vs. *N*; speaker order was constant across all trials within subjects) and actor who was the ignorant agent (*blue shirt* vs. *red shirt*), were counterbalanced between subjects.

Ignorant Agent Videos The confederate handed a familiar object (ball, cup, shoe) to the ignorant agent, asking "Look what I have! Can you tell me what that is called?" (see Kushnir & Koenig, 2017). Each time, agent *I* held the item with both hands, shook her head, and responded "I don't know what that is called". All professions of ignorance concerned labels for familiar objects.

Neutral Agent Videos The confederate and the neutral agent both sat at the table using their cell phones with none of the familiar objects from the Ignorant condition present. The confederate briefly looked up and initiated a common, familiar interaction with agent *N*. ("Hi," "Good morning," and "How are you?") before looking back at her phone. The neutral agent then looked up briefly and responded with an appropriate but non-informative answer ("Hi," "Good morning," and "Fine").

Test Phase

The test phase consisted of 9 trials. The first 6 were two blocks of 3 trials: one novel label and one novel function trial (counterbalanced) followed by a resource sharing trial. The last three trials were (in this order): locations trial, final resource sharing trial, and knowledge attribution. Of the four novel objects, two were always used for label trials and two were always used for function trials. Each trial type is described below:

Novel Label Requests For each novel label trial, the experimenter (*E*) first displayed an image of the novel object on the screen and prompted the child by saying "Look at that thing! I've never seen one of those before! I wonder what it's called. I bet one of our friends can tell us!" *E* then showed the paused opening scene of the novel object video, in which the confederate is standing between the two agents and holding the object, and asked the child, "Who do you want to ask what that is called?" If the child did not reply, *E* prompted once more with "Which friend do you want to ask?" The child's first choice was recorded, and *E* responded with "Ok. Let's see!" regardless of the response.

Novel Label Endorsements *E* then played a video in which the confederate said "Look what I have!" and turned to each agent (order counterbalanced between subjects) and asked "Can you tell me what this is called?" Each agent gave a different label (e.g., danu or koba, counterbalanced). After each video, the child was shown a still image of the two agents with the item between them. *E* pointed to each agent in the order in which they spoke, saying, "So she said it's a danu, and she said it's a koba. What do you think it's called?"

Children's first response was recorded. If the child said "I don't know," *E* followed up with "do you think they could both be right or both be wrong?" Otherwise, no feedback was given.

Novel Function Requests The procedure for novel function requests was identical to that of the novel label requests, except that *E* said "I wonder what it's used for!" and "Who do you want to ask what it's used for?" instead of "I wonder what it's called…Who do you want to ask what it's called?" The objects used for function trials each had features that made both functional claims feasible.

Novel Function Endorsements Endorsement measures for novel functions were also the same as the label endorsement trials, except the confederate asked the agents what the object was for, and they named and demonstrated different functions (e.g., in *Figure 1,* for looking or for stacking).

Resource Sharing At each sharing trial, the experimenter placed two cups, each with a picture of one of the two agents taped to it, in front of the child. The child was then given five identical stickers and was told that for each sticker, they could share with whichever friend they want by putting the sticker in that agent's cup.

Location Endorsement Children watched a video in which the agents had two boxes (equal in size, varying in color) between them. In the video, the confederate showed a small toy, held up a barrier blocking the boxes from the child's view, and then made a motion of placing the toy somewhere behind the barrier while both agents followed the motion with their gaze to indicate they were watching. The confederate then asked where the toy was, and each agent made a different claim about which box it was in (counterbalanced). Children were then asked to endorse one of the locations.

Knowledge Attribution After all the test videos, children were shown the still image of the two agents one more time and were asked, "Who do you think knows more?" First response was recorded, and children were asked "why do you think she knows more?" as a follow-up.

Figure 1: Examples of novel function *(left*) and novel label (*right)* stimuli.

Coding

We coded four categories of responses to our request and endorsement questions. The majority of responses (77.32%) were selections of a single agent (ignorant agent or the neutral agent). The second most frequent response (15.12%) was expressing uncertainty about the choice (e.g. "I don't know"). A small percentage of children (2.44%) picked both agents. On endorse trials, a small percentage of children (5.12%) made up their own label or function (see below).

Requests For each request question (2 label, 2 function), children were given 1 point for each time they asked the ignorant agent (singly or by responding "both") and 0 points for each time they did not (by picking the neutral agent or saying "I don't know").

Endorsements For each endorsement (2 label, 2 function, 1 location) Similar to coding for requests, we gave children 1 point for each time they endorsed the ignorant agent and 0 points for each time they did not. In cases where children used an alternative name or function, we coded their response as a 0. In cases where children responded with uncertainty, we followed up with "Do you think they could both be right or both be wrong?" and assigned 1 point if they selected "both right" and 0 points if they selected "both wrong". (See *Table 2* for responses before follow up question).

Resource Sharing For each of the three sticker sharing trials, we coded two measures. Children were given a score of 1 for each time they gave more stickers to the ignorant agent and a score of 0 each time they gave fewer stickers to the ignorant agent, and we added these scores across the three trials for a possible score of 0-3. We also recorded the number of stickers (0-5) shared with the ignorant agent on each trial and calculated each child's average number of stickers shared with Agent I across all three trials.

Knowledge Attribution Children were given a score of 1 if they indicated that the ignorant agent knew more and 0 if they did not.

Results

McNemar's tests indicated that there were no significant differences in the proportion of Ignorant agent choices in Trial 1 and Trial 2 for label requests (p = 1.00), label endorsements (p = 0.344), function requests (p = 0.146), or function endorsements (p = 0.238). Therefore, we summed across both trials of each of the four questions types, creating four variables with possible scores of 0-2. Pearson's correlations indicated that age in months was not significantly related to ignorant agent choice in any question type or domain (see *Table 1)*, so we did not include age as a covariate in further analyses.

Table 1: Mean choices of ignorant agent and age correlations by task.

Task	*M*	SD	*r* with Age
Novel Labels			
Requests	0.63	0.799	0.23
Endorsements	0.634	0.799	-0.14
Novel Functions			
Requests	0.927	0.848	-0.14
Endorsements	1.024	0.758	0.24

Note. For all tasks, $N = 41$. Range (0-2). For all correlations, $p > .05$

Main Effect of Domain and Question Type

A 2 x 2 repeated-measure ANOVA of domain (label vs. function) by question type (request vs. endorse) revealed a main effect of the domain of the novel information on children's choices of the ignorant agent. Specifically, children were significantly less willing to choose to learn from the ignorant agent in the label domain than in the function domain; F(1) = 7.895, p <.01, 95% CI[-.587, -.096] (see *Table 1* for *M* and *SD*). There was no main effect of question type (F = 0.196) and no domain by question type interaction (F = 0.170).

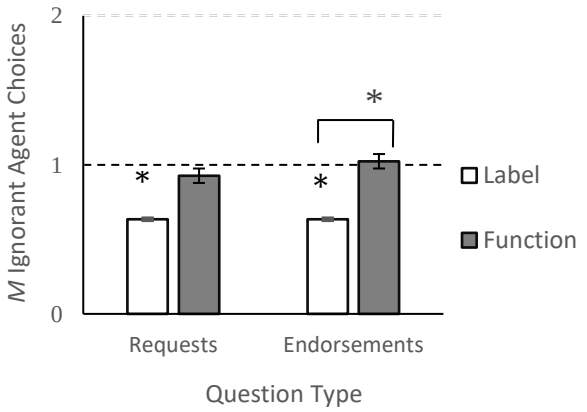

Figure 2: Mean selections of the ignorant agent across domains & question types. Dashed line refers to chance responding.

Domain & Question Type Differences

To further explain this domain effect, we tested choice of ignorant agent against chance for each task and the difference in ignorant agent choices between domains for each question type (e.g. label requests vs. function requests). See *Figure 2* for a visualization of these results.

Children's selections of the ignorant agent were significantly below chance for both requests and endorsement questions in the label domain; $t(40) = -2.933$, $p < .01$, 95% CI [-0.62, -0.11]. In the function domain, children were at chance for choices of the ignorant agent for both function requests (t(40) = -.552, p = .58, 95% CI [-0.34, 0.19]) and function endorsements; t(40) = .206, p = .84, 95% CI [-0.21, 0.26].

Follow up paired-samples t-tests revealed that the domain effect was stronger for endorsements than requests: there was no significant difference between domains on children's requests alone ($t(40) = -1.524$; $p = .153$), but children were significantly less likely to endorse the ignorant agent for novel labels than for novel functions ($t(40) = -2.72$, p = .01, 95% CI[-0.68, -0.10].

To further examine which alternative responses children made when they did not endorse the ignorant agent, we looked descriptively at the counts and percentages of all response categories for each task (see *Figure 3)*. While the percentage of Ignorant Agent choices were noticeably higher in the novel function domain than in the novel label domain, the percentage of choices of the Neutral agent remained similar across all tasks except the novel label requests. The distribution of responses shows that when children were not endorsing the Ignorant agent's label, they were expressing uncertainty or making up their own alternative label as often as they were endorsing the neutral agent's label.

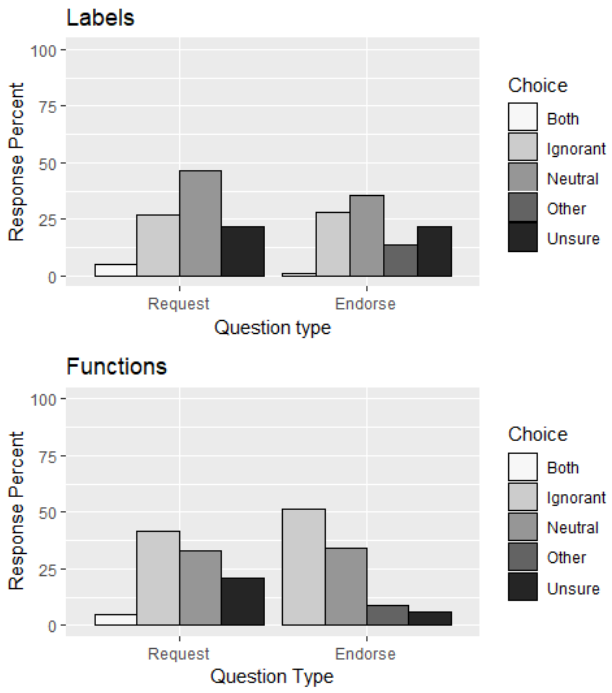

Figure 3: Percentage of raw response types by domain & question type.

Location, Knowledge Attribution, & Sharing

Binomial tests revealed that children were at chance for endorsement of the ignorant agent's hidden object location claim (54% ignorant agent endorsement, p = 0.76) and for attribution of knowledge to the ignorant agent (56%, p = 0.53).

Table 2: Pearson correlations for Ignorant Agent choices in tasks without novel object

	Attribute Knowledge	Share Freq.	Share Avg.	Label Total	Function Total
Endorse Location	.262	.378*	.162	.127	-.236
Attribute Knowledge	1	.564**	.364*	.117	.165
Share Freq.	-	1	.755**	.145	.211
Share Avg.	-	-	1	-.006	.106

Note. "Share Freq." is frequency of sharing more with agent *I* (0-3). "Share Avg" is the avg. amount shared with agent *I* (0-5). "Label total" and "Function Total" are the sum of *agent I* choices across all novel label trials and all novel function trials, respectively*; *p < .05, **p < .01*

Children were also at chance (M = 1.49, SD = .952) for the number of times (0- 3) they shared more stickers with the ignorant agent; t (40) = -.082, p = .935, 95% CI[-0.31, 0.39], and for the average number of stickers (0-5) they shared with the ignorant agent across trials (M = 2.54, SD = 0.774); t (40) = 0.303, p = .764, 95% CI[-0.21, 0.28].

We conducted 2-tailed Pearson correlations to explore the relation of these measures to all the other outcome variables. Agent choices on location endorsement, knowledge attribution, and resource sharing were not related to agent choices on any of the novel label or function questions.

However, ignorant agent choices were strongly correlated between several of these three non-novel object tasks (*Table 2).* Notably, the number of trials in which children shared more stickers with the ignorant agent than with the neutral agent and the average number of stickers they shared with the ignorant agent were positively related to their attribution of more knowledge to the ignorant agent.

Discussion

When preschool children monitor agents' informativeness as evidence about their reliability, they often show an overwhelming social and learning preference for an agent who demonstrates knowledge, certainty, and accuracy over one who is lacking in any of these criteria. By contrasting an ignorant agent with a neutral agent, we tested three possible stances from which children could be considering professed ignorance. We found that children's responses to a previously ignorant agent are more nuanced than a uniform negative or positive judgment.

If children view professed ignorance as specific to the situation or domain in which they have seen evidence of her ignorance—in this case, object labels, we would expect them to respond to her further claims about object labels differently than her claims in another domain. In support of this explanation, we found that children avoided both requesting and endorsing novel labels from the ignorant agent but did not demonstrate this vigilance against her when learning novel object functions. This result suggests that there is a situational constraint of preschooler's pessimism about ignorant agents.

If children look favorably on agents who profess ignorance, perhaps seeing it as evidence of virtue, we would expect them to show a preference for the ignorant agent in their overall learning, perhaps in their resource sharing, and possibly even in their explicit judgments of agent knowledge. Our novel label and novel function data suggest that they avoided learning labels from, or were agnostic toward learning functions from the ignorant agent rather than preferring her over the neutral agent. On sticker sharing trials, which are often used to measure judgment of virtue or general liking of an agent (Chernyak & Sobel, 2015; Kanngiesser & Warneken, 2013; Moore, 2009), our results show no relation between children's learning from and willingness to share with an agent. Therefore, we did not find that children had a general positive regard toward the ignorant agent based on the sharing data, and having positive regard for the ignorant agent did not predict learning from her. However, children who explicitly stated that the ignorant agent knows more also shared more with her. Together, these results suggest that preschoolers do not think of professed ignorance as virtuous, but they may think of knowledge as a virtue.

If children avoid learning from ignorant agents unless no reasonable alternative is available, we would expect preschoolers not to request or endorse new information from the ignorant agent on any novel label or function trials. If children's avoidance of the ignorant agent expanded beyond epistemic vigilance and into mistrust, we would also expect children to share fewer resources with the ignorant agent and reject her claim about the location of a hidden object. Because children were at chance in responding to the ignorant agent across all trials outside of the label domain, we did not find evidence that children are generally pessimistic toward people profess ignorance.

Overall, we propose an explanation that combines elements of two of our three possibilities. Children's stance on professed ignorance is situation-specific—they show epistemic vigilance against new information from an agent only in situations similar to those in which she was ignorant before (e.g., the label domain). However, the extent of their vigilance is influenced by whether there is another reasonable option from whom to learn. When children saw only an familiar-label-ignorant agent in Kushnir & Koenig (2017), they were above chance in endorsing her later novel label and function claims, but when we presented a neutral agent as a contrast, children's domain-specific vigilance emerged, and their willingness to learn from the ignorant in a new domain was reduced to chance. This situational specificity is not apparent in studies contrasting an ignorant and accurate agent (e.g., Koenig & Harris, 2005), which suggests that preschool children are agnostic in their evaluations of ignorant agents outside of the specific situation in which they professed ignorance, treating them similarly to an agent whose knowledge state is unknown. Future studies should include professed ignorance in other, non-linguistic domains in order

to determine whether these situation-specific evaluations are actually specific to ignorance about labels.

The situational nuances in preschoolers' evaluations of agents who profess ignorance aligns with the extant literature on the development of children's understanding of knowledge and expertise. Our findings highlight preschoolers' stance on professed ignorance as part of a greater developmental trajectory for epistemic trust and social learning (as in Kushnir & Koenig, 2017). By 4 years old, children have begun to distinguish ignorant agents from both accurate and inaccurate agents, distinguish agents by their demonstrated domains of expertise (e.g., labels or causal functions), and use these distinctions to inform learning from those agents (Kushnir et al., 2013, see also Brosseau-Liard & Birch, 2011 and Sobel & Corriveau, 2010). This corresponds with our finding that children also evaluate an agent's ignorance—which could be considered the opposite of expertise—based on the domain in which it is demonstrated. However, in alignment with other studies showing that children do not successfully use an agent's calibration of certainty as a sign of epistemic virtue until the end of middle childhood (Tenney et al., 2011; Kominsky et al., 2016; Brosseau-Liard et al., 2014), we found that preschoolers did not show a significant preference of or deference to the ignorant agent on any trials.

Because we only considered one, specific kind of ignorance—familiar object labels—it would be useful to test children's responses to an ignorant versus neutral agent when the ignorance is professed in different domains, such as familiar object functions and causal knowledge (e.g., Bridgers et al., 2016) or with information that is unfamiliar to the child. Further, we are limited in our knowledge of how children evaluate the neutral agent and what exactly makes an agent "neutral" as a source of information, so future studies should explore different presentations of an agents whose knowledge states are not revealed.

In order to draw more detailed, concrete conclusions about children's understanding of knowledge and the development of their epistemic trust, future work should continue to unpack the different ways children respond after evidence of ignorance. We focused on children's willingness to choose the ignorant agent in different situations, but the variety of responses from children who did not choose her suggest that professing ignorance may be influencing children's behavior outside of signaling someone's reliability as a source of information. Because our study showed the ignorant agent later assigning names to unfamiliar objects, the combination of these factors could have given children license to find an answer on their own. In that case, the number of responses where children made up their own answer rather than endorsing either agent could be related to children's increased exploration in the absence of pedagogical cues (Bonawitz et al., 2011). Future studies should consider individual differences in children's responses and in other sensitive developmental areas for preschool-aged children, such as social cognition (e.g., Sabbagh & Baldwin, 2003).

Both thematic role and next-mention biases affect pronoun use in Dutch

Oude Kijk in 't Jatstraat 26, 9712 EK Groningen, the Netherlands

Abstract

An important question is whether speakers consider listeners' expectations when choosing whether to use a pronoun. It has been suggested that certain thematic roles are more expected to be mentioned again, and are therefore more likely to be pronominalized. In the present study, we aim to disentangle predictability effects on pronoun use from thematic-role effects. To this end, we conducted two web-based continuation experiments in Dutch, in which the next-mention biases associated with Source-Goal and Agent-Patient verbs were manipulated to create a shift in the bias. Experiment 1 confirmed that the manipulations changed the biases. Experiment 2 showed that while thematic role mainly influenced demonstrative and full pronoun use for non-subjects, next-mention biases played a role in the choice between reduced and full pronouns and between pronouns and full NPs, irrespective of thematic role or grammatical function. Thus, thematic role and predictability seem to affect pronoun use in different ways.

Keywords: Dutch; next-mention biases; predictability; pronouns; referring expressions; thematic role

Introduction

Listeners' expectations about whom or what the speaker will mention next influence their interpretation of pronouns. For example, in the sentence *Anna hurt Meryl so she...* the pronoun *she* most likely refers to Meryl (e.g. *so she got mad at her*), while in *Anna recognized Meryl so she...* the pronoun is more likely to refer to Anna (e.g. *so she walked up to her to greet her*). An important question is whether speakers take such expectations into account when choosing to use a pronoun or not. A logical hypothesis would be that speakers use a pronoun when its interpretation is in line with the semantic bias, i.e. when it refers to the person that the listener expects to be mentioned next. If the speaker instead wants to continue with the person that is not expected to be mentioned next, she will signal this by repeating the name.

This is exactly what certain accounts of reference production predict (e.g. Arnold, 2001, 2008; Givón, 1983): Speakers use pronouns for referents that they believe the listener is already expecting to be mentioned, and they use more elaborate referring expressions when the referent is thought to be not very predictable. However, several researchers have found that the choice for a pronoun is not influenced by how predictable the referent is (Fukumura & Van Gompel, 2010; Rohde & Kehler, 2014; Stevenson, Crawley, & Kleinman, 1994). Recently, it has been suggested that whether predictability plays a role in pronoun use may depend on the verb in the preceding clause (Rosa & Arnold, 2017). For example, whereas Fukumura and Van Gompel (2010) did not find a predictability effect on pronoun use in implicit causality contexts with Stimulus-Experiencer verbs, Arnold (2001) and Rosa and Arnold (2017) found in transfer-of-possession verbs that Goal referents were more often pronominalized than Source referents, with the assumption that Goal referents are more predictable than Source referents. However, they did not test the effect of predictability directly (cf. Pickering & Majid, 2007; Kehler & Rohde, 2013). While it may be true that Goals are more likely to be pronominalized because they are more predictable, it may also be the case that this thematic role is more salient for other reasons, for instance because it is often an obligatory argument of the verb (cf. Fukumura & Van Gompel, 2010).

The first aim of this study is therefore to disentangle predictability effects on pronoun use from thematic-role effects. The second aim is to explore whether predictability and thematic role also play a role in the choice of referring expression in Dutch. So far, almost all psycholinguistic studies on this topic have been done on English (but see Bott, Solstad, & Pryslopska, 2018 for a study on German). Dutch is an interesting language to investigate, because it offers more referential options than English. First, Dutch, like German, has a set of demonstrative pronouns that can refer anaphorically to humans as well as inanimates. Second, most personal pronouns in Dutch have two variants: a full form (e.g. *zij* 'she$_{full}$') and a reduced form (e.g. *ze* 'she$_{reduced}$'; see e.g. Kaiser, 2011).[1] It is an open question how the different factors that are argued to play a role in referring expression selection affect speakers' choices between these multiple possible referential forms.

We conducted two web-based written continuation experiments in which participants were presented with a context sentence for which they needed to type a suitable continuation, starting with the connective *vervolgens* 'subsequently'. To be able to generalize across different thematic roles, the context sentences contained either a Source-Goal verb, such as *geven* 'give', or an Agent-Patient verb, such as *bellen* 'call'. All verbs had a default next-mention bias to the second NP (NP2) when combined with either a forward temporal or a consequence coherence relation, as established by previous research (Commandeur, 2010; Koornneef & Sanders, 2012)[2]. That is, when the continuation of a sentence fragment expresses a consecutive event or a consequence of the event expressed by the verb, people tend to interpret a subject pronoun in the continuation as referring to the NP2.

[1] The masculine 3rd person reduced pronoun *ie* 'he' is different from the feminine reduced pronoun in that it mostly occurs in spoken language. It also behaves differently syntactically in that it cannot appear sentence-initially.

[2] We could not find data on next-mention biases for Dutch Source-Goal verbs, so we took these from translations of the English verbs in Rosa and Arnold (2017). Also, some Agent-Patient verbs were translations from English verbs used in Cheng (2016).

We then manipulated these next-mention biases, such that they would shift to the first NP (NP1), which is normally less likely to be mentioned next. We did this in two ways: For some sentences we varied the social status of the referents. When combining social roles with a high or low status with verbs such as 'criticize' or 'mock', the person with low status is expected to be more likely to feature in the continuation of the event (cf. Garvey, Caramazza, & Yates, 1974). Table 1A presents examples for this manipulation, with the expected effect on the next-mention bias. For other sentences we included either a neutral adverb such as *meteen* 'right away', an adverb expressing unintentionality such as *per ongeluk* 'by accident', or the adverb *eerst* 'first'. In combination with the connective *vervolgens* 'subsequently', the latter is expected to create a strong expectation for a subject continuation, because it induces a parallel coherence relation (cf. Kehler, Kertz, Rohde, & Elman, 2008). For the unintentionality adverbs, we expected a tendency to shift the next-mention bias more to the Source/Agent character (cf. Cheng, 2016). Table 1B presents sample sentences for the adverb manipulation.

In Experiment 1, participants were free to continue the context sentences in any way they wanted, as long as they started with the connective *vervolgens* 'subsequently'. The goal of this experiment was to test whether the manipulations indeed affected the next-mention bias. That is, we predicted that participants would be more likely to continue with the NP1 when it refers to a low-status character, or is accompanied by one of the critical adverbs (see Table 1). In Experiment 2, either NP1 or NP2 was underlined, and participants had to refer to this NP as the subject of their continuation. The goal of this experiment was to test whether participants' choice of referring expression would depend on whether they had to refer to a referent that was consistent or inconsistent with the next-mention bias. Here, we predicted that participants choose a more reduced type of referring expression for referents that are more likely to be mentioned next, and a more elaborate expression for less-expected referents. If the thematic-role effect found in previous research is a predictability effect, thematic role should not play a role in referring expression choice. Alternatively, if thematic role has a separate effect, it should affect referring expression choice irrespective of next-mention bias.

Experiment 1

Methods

Participants. Seventy-four Dutch-speaking participants were recruited via social media and email. We discarded the data from participants who did not complete the experiment, leaving 48 participants. Of these, 33 were women, 13 were men, and 2 did not make a choice. Mean age was 27.7 years (range 18-60). Participants were not paid.

Materials. We created 30 Dutch context sentences containing verbs identified as having an NP2 next-mention bias. Of these, 15 were Source-Goal verbs, and 15 were Agent-Patient verbs. For all items, the bias was manipulated either by varying the social status of the characters in the sentence

Table 1. Sample sentences for the social-status (**A**) and adverb (**B**) manipulations, by verb type. The rightmost column shows the expected next-mention bias for each condition. *Unintent.* = Unintentionality adverb.

A. Social-status manipulation			**Expected bias**
Source-Goal	*High-Low*	*De moeder gaf een uitbrander aan haar dochter. Vervolgens ...* 'The mother gave a scolding to her daughter. Next ...'	NP2 (default)
	Low-High	*De dochter gaf een uitbrander aan haar moeder. Vervolgens ...* 'The daughter gave a scolding to her mother. Next ...'	NP1
Agent-Patient	*High-Low*	*De bazin bekritiseerde de assistente. Vervolgens ...* 'The $\text{boss}_{\text{female}}$ criticized the $\text{assistant}_{\text{female}}$. Next …'	NP2 (default)
	Low-High	*De assistente bekritiseerde de bazin. Vervolgens ...* 'The $\text{assistant}_{\text{female}}$ criticized the $\text{boss}_{\text{female}}$. Next …'	NP1
B. Adverb manipulation			
Source-Goal	*Neutral*	*De gravin gaf op het feest de halsketting aan de meid. Vervolgens ...* 'The countess gave the necklace to the maid at the party. Next ...'	NP2 (default)
	Unintent.	*De gravin gaf per ongeluk de halsketting aan de meid. Vervolgens ...* 'The countess gave the necklace to the maid by accident. Next ...'	NP1~NP2
	First	*De gravin gaf eerst de halsketting aan de meid. Vervolgens ...* 'The countess first gave the necklace to the maid. Next ...'	NP1
Agent-Patient	*Neutral*	*De boerin belde meteen de vroedvrouw. Vervolgens ...* 'The farmer's wife called the midwife right away. Next …'	NP2 (default)
	Unintent.	*De boerin belde per ongeluk de vroedvrouw. Vervolgens ...* 'The farmer's wife called the midwife by accident. Next …'	NP1~NP2
	First	*De boerin belde eerst de vroedvrouw. Vervolgens ...* 'The farmer's wife first called the midwife. Next …'	NP1

(e.g. *bazin–assistente* 'boss$_{female}$'–'assistant$_{female}$'; 12 items: 9 Agent-Patient and 3 Source-Goal verbs) or by varying the adverb in the sentence (18 items: 6 Agent-Patient and 12 Source-Goal verbs). The adverb was either neutral (e.g. *meteen* 'right away'), an unintentionality adverb (e.g. *per ongeluk* 'by accident'), or the adverb *eerst* 'first'. To discourage participants to only use pronouns, character pairs were always same-gender (although sometimes they were gender-ambiguous, such as 'officer'–'soldier'), and they did not include proper names. To control for grammatical function, we also created Goal-Source and passive Patient-Agent variants of each item (e.g. *De dochter kreeg een uitbrander van haar moeder* 'The daughter got a scolding from her mother'; *De vroedvrouw werd eerst door de boerin gebeld* 'The midwife was first called by the farmer's wife'). The first word of the participant's continuation was given, and was always the connective *vervolgens* 'subsequently'.

In addition, we created 36 filler items using a variety of syntactic structures, and including proper names, animals and NP conjunctions. The connective was also varied. The items were presented in a pseudo-random order, interspersed with the filler items, such that no two experimental items followed each other directly.

Procedure. The experiment was distributed via the online survey software Qualtrics. Upon clicking on the link, participants received an instruction screen, saying that they would see a series of sentences, for which they had to type a continuation (starting with a pre-given connective) in the text-entry bar, using their first intuition. There was no time limit. After about every 10th trial, a cute animal picture appeared on the screen, and participants were allowed to take a short break. The experiment took about 30 minutes to complete.

Design and analysis. Varying thematic role order (Goal/Patient=NP2, Goal/Patient=NP1) and either social status of the Goal/Patient (low, high) or adverb (neutral, unintentional, first) as within-items factors resulted in a 2x2 or 2x3 design, depending on the manipulation. Given this design, the items were distributed over 6 lists, such that each item occurred only once on a list. Since social status had only two levels, lists 5 and 6 repeated conditions from lists 1 and 2 for this variable. Verb type (Source-Goal, Agent-Patient) was varied between items.

We analyzed the proportion of Goal/Patient references out of all references, in separate analyses for the social-status and the adverb manipulation. The binary predictors were centered. The predictor adverb was contrast coded with neutral adverb as the reference level. Logit mixed-effects analyses including all main effects and second-order interactions with either social status or adverb were run. We aimed for a maximal random-effects structure, but removed random slopes step-by-step in case of non-convergence (see Bates, Kliegl, Vasishth, & Baayen, 2015). We furthermore tested for the inclusion of random slopes and the fixed effects of the control variables verb type and thematic role order using Likelihood Ratio tests.

Results

We excluded trials in which participants did not refer to NP1 or NP2 as the subject of their continuation (298 cases), used a plural expression (47 cases), selected the wrong gender (15 cases), did not produce a completion (9 cases) or did not use verb second word order (4 cases), as well as trials in which three annotators could not reach agreement on the referent (68 cases). This resulted in the removal of 30.6% of the data, leaving 999 cases for analysis.

We found clear effects of both the social-status and the adverb manipulation on the choice of referent. In the social-status analysis, there were significant main effects of social status (β = -1.49, SE = 0.26, p < .001) and thematic role order (β = 0.89, SE = 0.24, p < .001): When the Goal/Patient had a higher social status than the Source/Agent, participants were less likely to continue with the Goal/Patient, and in the canonical (Source-Goal, Agent-Patient) orders even showed a Source/Agent-bias (see Figure 1). In the non-canonical (Goal-Source, Patient-Agent) orders, there was an overall stronger Goal/Patient-bias, suggesting an additional subject-bias. The main effect of verb type was not significant (p = .10), and there were no interactions (ps > .1).

For the adverb manipulation, there was a significant difference between the adverb 'first' and neutral adverbs (β = -1.73, SE = 0.47, p < .001), a significant main effect of the-

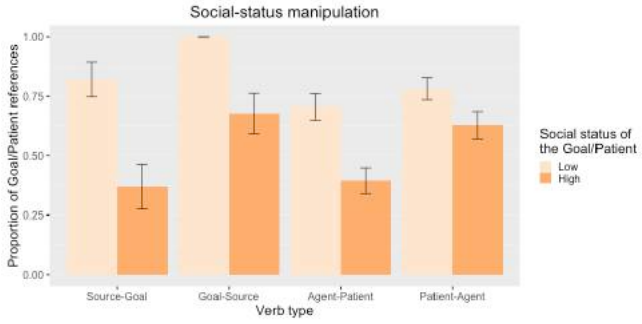

Figure 1: The proportion of Goal/Patient references after Source-Goal and Agent-Patient verbs, including their reversed orders, by the social status of the Goal/Patient.

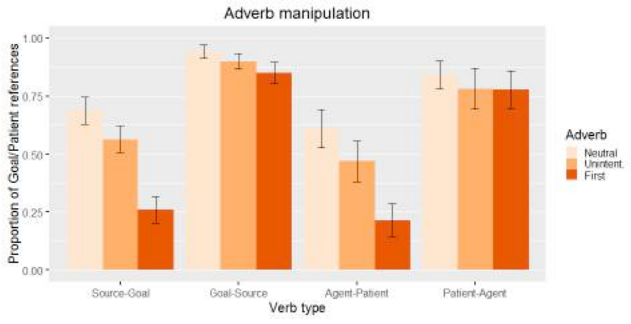

Figure 2: The proportion of Goal/Patient references after Source-Goal and Agent-Patient verbs, including their reversed orders, by type of adverb.

matic role order (β = 2.26, *SE* = 0.25, $p < .001$), and an interaction between the two predictors (β = 1.55, *SE* = 0.67, $p < .05$): In the canonical (Source-Goal, Agent-Patient) orders, participants were less likely to continue with the Goal/Patient when the context sentence contained the adverb 'first', and even showed a Source/Agent-bias (see Figure 2). In the non-canonical (Goal-Source, Patient-Agent) orders, there was again an overall stronger Goal/Patient-bias, and a weaker effect of adverb.[3] The difference between unintentionality and neutral adverbs was not significant (p = .55), and neither was the main effect of verb type (p = .13).

Discussion

The results of Experiment 1 confirm that the next-mention bias of Source-Goal and Agent-Patient verbs can be influenced by manipulating the social status of the referents and by adding certain adverbs. For the canonical thematic role orders, the original Goal/Patient bias even shifted to a Source/Agent bias. In the non-canonical orders, the effect was smaller, probably due to an added bias to refer to the first-mentioned NP (e.g. Gernsbacher & Hargreaves, 1988).

In Experiment 2, we subsequently tested whether manipulating the next-mention bias also affects the choice of referring expression, predicting more pronouns for referents that are consistent with the bias.[4] We used the same method as in Experiment 1, except that one referent in the context sentence was underlined, and participants were asked to start their continuation with this referent.

Experiment 2

Methods

Participants. Ninety-eight Dutch-speaking participants were recruited via social media and email. None had participated in Experiment 1. We removed 44 participants who did not complete the experiment, and 2 participants who were not native Dutch speakers, leaving 52 participants. Of these, 40 were women and 12 were men. Mean age was 37.0 years (range 16-75). Participants were not paid.

Materials. In order to shorten the experiment duration, we selected 16 items from Experiment 1 that showed the largest effect of the next-mention-bias manipulations: 8 from the social-status manipulation (5 Agent-Patient and 3 Source-Goal verbs) and 8 from the adverb manipulation (2 Agent-Patient and 6 Source-Goal verbs). Because the unintentionality adverb condition was not significantly different from the neutral adverb condition, we dropped the former.

We manipulated which referent had to be referred to in the continuations (either NP1 or NP2) by underlining this referent in the context sentences. The referent had either a Source/Agent or a Goal/Patient role. Furthermore, in the social status manipulation the referent had either low or high social status. In the adverb manipulation, it was either combined with a neutral adverb or with *eerst* 'first'. The items were distributed over 6 lists, and interspersed with 24 fillers, in the same way as in Experiment 1.

Procedure. The procedure was identical to Experiment 1, except for the fact that participants were now instructed to start their continuation with the referent that was underlined. The experiment took about 20 minutes to complete.

Design and analysis. We performed separate analyses testing the effect of our next-mention-bias manipulations on three dependent variables: the proportion of pronouns *including* demonstratives out of all references, the proportion of pronouns *excluding* demonstratives out of all references, and the proportion of reduced pronouns out of all pronouns. In all analyses, we included the next-mention-bias manipulation (high/low social status; neutral adverb/first), as well as the referent's grammatical function (Subject (NP1), Non-Subject (NP2)) and thematic role (Source/Agent, Goal/Patient) as predictors, resulting in a 2x2x2 within-items design. Since the effect of verb type was not significant in Experiment 1, we collapsed over Source and Agent, and over Goal and Patient. All predictors were centered. Logit mixed-effects analyses including all main effects and second-order interactions with the bias manipulation were run in the same way as in Experiment 1.

Next, we also tested whether Goal referents were more likely to be pronominalized than Source referents. For this, we ran separate logit mixed-effects analysis on the two verb types (Source-Goal, Agent-Patient), with the referent's thematic role (Goal, Source; Agent, Patient) and grammatical function (Subject (NP1), Non-Subject (NP2)) as predictors, and the proportion of pronouns (including demonstratives) as the dependent variable.

Results

We excluded 61 cases where participants did not refer to the correct referent, 18 cases in which reference was unclear, and 1 case of self-correction, leading to the removal of 9.6% of the data and leaving 752 cases for analysis.

In the social-status analysis, we found a significant main effect of social status on the proportion of reduced pronouns out of all pronouns (β = -1.40, *SE* = 0.65, $p < .05$), with more reduced pronouns when the referent had lower social status (see Figure 3)[5], as well as a main effect of gramma-

[3] Contrary to expectation, in the non-canonical orders the preference to refer to the subject was weaker after 'first' than after a neutral adverb, suggesting a bias towards the Source/Agent rather than the subject. We henceforth consider Source/Agent referents in a sentence with 'first' as consistent with the manipulated bias.

[4] We designed a new experiment to test this question rather than coding the results of Experiment 1 for choice of referring expression because the biases in that experiment would yield a very unbalanced design, i.e. there would be many more references to expected than to unexpected referents.

[5] The data included only one occurrence of the masculine 3rd person reduced pronoun *ie* 'he'. The effect reported here is therefore entirely driven by the feminine reduced pronoun *ze* 'she'.

tical function (β = -2.05, *SE* = 0.80, p < .05), with more reduced pronouns for subjects than for non-subjects. No significant effect of social status was found on the proportion of pronouns out of all references, both including (p = .25) and excluding (p = .26) demonstrative pronouns.

In the adverb analysis, we found a significant interaction between adverb and thematic role on the proportion of pronouns (including demonstratives) out of all references (β = -1.73, *SE* = 0.80, p < .05), with more pronouns for Source/Agent and fewer pronouns for Goal/Patient referents in sentences with 'first' than with a neutral adverb (see Figure 4). This interaction effect was stronger when excluding demonstratives (β = -2.29, *SE* = 0.83, p < .01), suggesting that it is primarily driven by the use of personal rather than demonstrative pronouns. In both analyses, the main effect of grammatical function was also significant (β = -3.47, *SE* = 0.57, p < .001 and β = -5.11, *SE* = 0.78, p < .001, respectively), with more pronouns for subjects than for non-subjects. Although Figure 4 suggests an interaction between adverb and thematic role on the proportion of reduced pronouns out of all pronouns, this was not significant (p = .18).

Finally, Figure 5 shows that, irrespective of next-mention bias, pronouns were more frequent for Goal than for Source non-subjects, although the interaction did not reach significance (p = .06). In addition, the difference seems to be largely due to an increase in demonstrative and full pronouns.[6] For Agent-Patient verbs, pronouns seem to be more frequent for Agent than for Patient non-subjects, but the interaction was not significant (p = .95).

Discussion

The results of Experiment 2 showed effects of the next-mention-bias manipulations on pronoun use: more reduced pronouns for low-status than for high-status referents, and more personal pronouns for Source/Agent referents (as well as fewer pronouns for Goal/Patient referents) in contexts including the adverb *eerst* 'first'.

In addition, thematic role seemed to have an effect on the choice of referring expression beyond these next-mention-bias manipulations. Consistent with Rosa and Arnold (2017), Goal non-subjects were more likely to be pronominalized than Source non-subjects, although not reliably. Moreover, this difference seemed to be due to a larger number of full and demonstrative pronouns for Goal referents. Since full pronouns in Dutch are canonically used for contrastive referents, and demonstrative pronouns for less salient (non-topical) referents (e.g. Kaiser, 2011), this might suggest that Goals are not as salient as subject referents, but salient enough to not be referred to with a full definite NP.

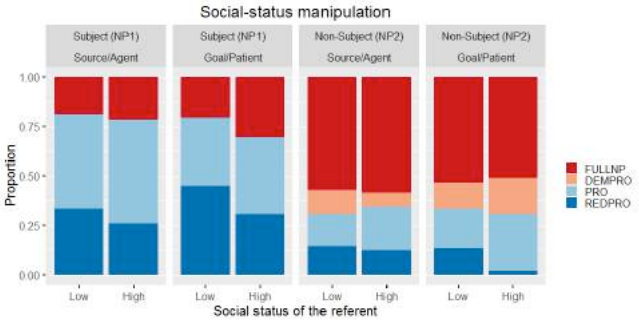

Figure 3. Choice of referring expression in the social status manipulation of Experiment 2, by the referent's social status, grammatical function, and thematic role.

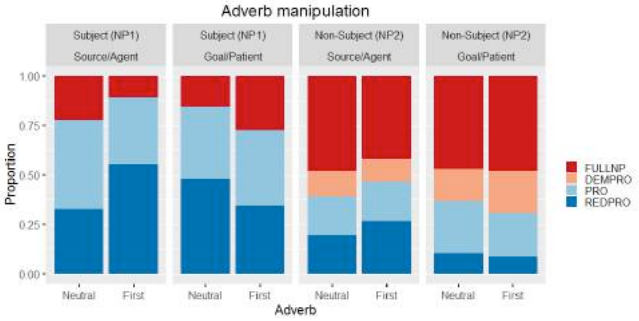

Figure 4. Choice of referring expression in the adverb manipulation of Experiment 2, by adverb and the referent's grammatical function and thematic role.

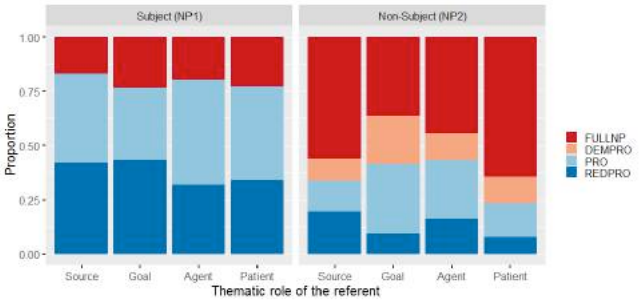

Figure 5. Choice of referring expression in Experiment 2, by the referent's thematic role and grammatical function.

Thus, assuming that next-mention bias is an accurate measure of predictability, the results of Experiment 2 suggest that thematic role and predictability affect referential choices in different ways: Goals stand out among the thematic roles because they attract more demonstrative and full pronoun references, while predictable referents are more likely to be referred to with reduced forms (reduced vs. full pronouns or personal pronouns vs. full NPs).

[6] Post-hoc analyses supported this: When excluding demonstratives, the trend for an interaction between thematic role and grammatical function disappeared (p = .69); An analysis on the proportion of reduced pronouns out of all pronouns showed a significant interaction between thematic role and grammatical function (β = -2.05, *SE* = 0.91, p < .05). Paired comparisons showed a significant increase in reduced pronouns for Goal vs. Source non-subjects (p < .01), but not for subjects (p = .20).

General discussion

In this paper, we investigated whether expectations about what will be mentioned next influence the choice of referring expression. The first aim was to disentangle predictability effects on pronoun use from effects of thematic role. We did this by manipulating the next-mention bias in sentences with Source-Goal and Agent-Patient verbs. For some sentences, we varied the social status of the characters, hypothesizing that the lower-status character would be more likely to be mentioned next. For other sentences, we varied the type of adverb, hypothesizing a stronger Source/Agent bias with unintentionality adverbs and a stronger subject bias with the adverb *eerst* 'first'. The second aim was to explore predictability effects on reference production in Dutch, which has a rich spectrum of anaphoric expressions.

The results of Experiment 1 confirmed that the manipulations affected next-mention biases, especially in sentences in which the Goal or Patient was the second NP, where the bias shifted from the NP2 to the NP1. Sentences including 'first' showed increased references to the Source/Agent rather than to the subject, suggesting that the induced parallel coherence relation was semantic rather than syntactic. The effect of the unintentionality adverb was not as strong (cf. Cheng, 2016), and we therefore removed this condition from Experiment 2.

Experiment 2 showed that the shifts in next-mention bias also affected the choice of referring expression: When the referent had a relatively low social status, participants were more likely to mention it in their continuations (Experiment 1), and they also produced more reduced pronouns as compared to full pronouns, irrespective of grammatical function or thematic role (Experiment 2). This finding is consistent with information-theoretic accounts of language production, which propose that more predictable linguistic material is reduced (e.g. Levy & Jaeger, 2007). It is also in line with a contrastive interpretation of full pronouns (Kaiser, 2011), in which use of the full form pragmatically implicates that it refers to something else than the predictable referent.

When the context sentence anticipated a parallel coherence relation (in the form of 'first…next…'), participants were more likely to mention the Source/Agent referent in their continuations (Experiment 1), and they were also more likely to use a personal pronoun compared to a full NP to refer to these referents. Conversely, they were less likely to pronominalize the Goal/Patient character (Experiment 2). This suggests that next-mention biases may also affect the choice between a pronoun and a full NP in Dutch. Whether there is a fundamental difference between referential biases stemming from the social-status and the adverb manipulations is unclear. The current experiment may simply have lacked the power to detect all the effects.

Irrespective of next-mention bias, thematic role also seemed to have an effect on the choice of referring expression: Goals tended to be more likely to be pronominalized than Sources, at least for non-subjects, in line with Rosa and Arnold (2017). However, this preference was largely driven by the use of demonstrative and full pronouns as opposed to reduced forms. Demonstrative pronouns in Dutch are considered to be used mainly for non-topical referents (e.g. Kaiser, 2011). Indeed, in our study these forms exclusively occurred with non-subjects (see Figures 3-5). The choice of a full over a reduced pronoun is often driven by some form of contrast (Kaiser, 2011). The use of these 'stronger' pronominal forms to refer to Goal non-subjects might suggest that such referents are intermediately salient: They are more salient than other non-subjects, warranting the use of pronouns over full NPs, but not as salient as the average subject to allow for the use of a reduced pronoun.

Taken together, the results of this study have implications for current theories of reference. One line of research argues that what drives referential choices is how likely the referent is to be mentioned next (e.g. Arnold, 2008; Tily & Piantadosi, 2009). If a referent is highly predictable, a pronoun will be used; if it is unexpected, the speaker will signal this by using a full NP. The main evidence for this claim comes from the finding that Goal referents are more likely to be pronominalized than Source referents (Arnold, 2001; Rosa & Arnold, 2017). However, other researchers have argued that what makes a referent predictable is not necessarily its thematic role, but the specific event structure and coherence relation that links two references (Kehler & Rohde, 2013; Pickering & Majid, 2007). The present results point to the possibility that both thematic role and predictability based on event structure affect the choice of referring expression, but in different ways. Although it may still be the case that Goal referents are more likely to be mentioned next, the increase in pronoun use for Goals may also have a different origin. It has been noted, for example, that Goal non-subjects are often an obligatory argument of the verb (indirect object), whereas Source non-subjects are mostly optional (Fukumura & Van Gompel, 2010). This may make Goals more salient. Our results are therefore consistent with a form-specific multiple-constraints approach to reference, in which different referential forms are sensitive to different aspects of the referent (Kaiser & Trueswell, 2008).

A second line of research argues that there is an asymmetry between production and interpretation of referring expressions (e.g. Fukumura & Van Gompel, 2010; Rohde & Kehler, 2014): While reference resolution may be influenced by next-mention biases, reference production is driven only by grammatical or information structural factors. The present results suggest that next-mention biases may in fact influence reference production, at least in Dutch. So far, most studies on this topic have been on English, and investigating referential choices in a language with a richer set of referring expression types, such as Dutch, may reveal patterns that otherwise remain hidden.

Finally, effects of predictability may become more manifest in more engaging communicative settings that involve an actual addressee (cf. Rosa & Arnold, 2017). Since the effects we are seeking are probably small and tend to be overridden by stronger factors, the logical next step is to replicate the current findings in a larger-scale study in a more naturalistic, but still controlled, context.

Acknowledgments

This research was supported by the Netherlands Organisation for Scientific Research (NWO), under Grant 275-89-0360. Many thanks to Daniëlle Fluks, Anouck Braggaar, and Boudewijn Blank for their help with the creation of the materials and the design, conduction and analysis of Experiment 1.

Abstract

This paper investigates which cognitive abilities predict the interpretation of complex sentences by older adults. Participants performed a picture-selection task after hearing complex and simpler sentences, as well as a broad test battery of cognitive tests. The results show that different cognitive factors serve as predictors for the interpretation of complex sentences compared to simpler sentences. For complex sentences, verbal intelligence, cognitive flexibility, and working memory capacity are strong predictors. Our study thus shows that older adults' interpretation of sentences of varying complexity is influenced by different cognitive abilities, and stresses the need to take such individual differences into account when studying language processing.

Keywords: language processing; cognitive factors, complex sentences; syntactic structure; age; individual variation

Introduction

It is well-known in cognitive-linguistic research that syntactically complex sentences can be difficult to process (a.o. Bahlmann, Rodriguez-Fornells, Rotte, & Münte, 2007 (object-first sentences); Tun, Benichov, & Wingfield, 2010 (object relative clauses), Bader & Meng, 1999 (embedded clauses)). Especially older adults show difficulties with the processing and interpretation of complex sentences (e.g., Emery, 1985). These difficulties could partially be caused by cognitive abilities, as language processing has long been suggested to be influenced by (working) memory capacity (e.g., King & Just, 1991). In reading research, it has been found that working memory capacity and reading experience (but not vocabulary) can mediate older adults' reading times on temporarily ambiguous sentences (Payne et al., 2014). Contrary, in sentence processing in adverse listening conditions, vocabulary was found to influence older adults' performance, as was cognitive flexibility (also described as mental flexibility; McAuliffe, Gibson, Kerr, Anderson, & LaShell, 2013; Rosemann et al., 2017).

So, several cognitive factors have been suggested to influence older adults' language processing performance. Nevertheless, no consensus has been reached about which cognitive factors exactly influence complex sentence processing in older adults, and little is known about influence of cognitive abilities on the processing and interpretation of complex in comparison to simpler sentences. We therefore ran a broad test battery to examine **which cognitive abilities predict the interpretation of complex sentences by older adults**.

Object-first sentences are a common example of complex sentences. In German, canonical word order in a main clause is subject-verb-object (Zwart, 1997). However, the language allows for structurally more complex object-before-subject sentences, for example:

(1) *Den*$_{ACC}$ *Jungen* *wäscht der*$_{NOM}$ *Vater*
The$_{ACC}$ boy washes the$_{NOM}$ Father
'The father washes the boy'

In (1), case on the determiners indicates which noun phrase is the object (den Jungen) and which is the subject (der Vater). Although unambiguous, such object-first sentences have been found to elicit longer reading times (Hemforth, 1993) and more interpretation errors (Carroll, Uslar, Brand, & Ruigendijk, 2016) compared to subject-first sentences in German. Alternatively, an adjunct can be added at the beginning of the sentence to create a structure in which all information about the protagonists follows the verb, such as in (2).

Table 1: Examples of the four experimental conditions. Note that although the conditions use different word orders, their meaning remains the same.

Subject-object order	Adjunct position	Condition	Example sentence
subject-before-object	3	SVAO	Der Igel berührt am Montag den Hasen
object-before-subject	3	OVAS	Den Hasen berührt am Montag der Igel
subject-before-object	1	AVSO	Am Montag berührt der Igel den Hasen
object-before-subject	1	AVOS	Am Montag berührt den Hasen der Igel
			On Monday the$_{NOM}$ hedgehog touches the$_{ACC}$ hare

(2) *Am Montag wäscht den$_{ACC}$ Jungen der$_{NOM}$ Vater*
On Monday washes the$_{ACC}$ boy the$_{NOM}$ Father
'On Monday the father washes the boy'

In this paper, we describe an auditory sentence-processing paradigm followed by a picture-selection task. Two types of syntactic manipulations are used, namely subject-object order and adjunct position. We measured performance of our older participants on several cognitive factors that have been argued to be related to sentence comprehension: age, years of education, working memory capacity, subjective memory complaints, vocabulary, cognitive flexibility, and a composite measure of cognitive performance, which is widely used as screening for cognitive impairment.

Overall, we expect structurally more complex object-before-subject sentences to be more difficult to interpret than subject-before-object sentences (in line with Carroll et al., 2016). We additionally expect adjunct-first sentences to be more difficult to interpret than adjunct-third sentences, as adjunct-first sentences also violate canonical word order (i.e. verb-subject-object rather than subject-verb-object). Moreover, we expect considerable variation in both the interpretation of complex sentences (cf. Vos, Gunter, Schriefers, & Friederici, 2001) and the performance on the cognitive tasks. We expect the performance on several cognitive factors to influence the interpretation of complex sentences, such as age (Rosemann et al., 2017), working memory (Payne et al., 2014; Vos et al., 2001), and vocabulary and cognitive flexibility (McAuliffe et al., 2013; Rosemann et al., 2017). It will then be investigated which of these cognitive tasks best accounts for the interpretation of complex sentences by older adults.

Methods

Participants

20 older adults (age 51-70, mean age 60; 15 females) participated in the study. All participants had age-normal hearing as tested before the experiment and normal or corrected-to-normal vision. The participants were all monolingual native speakers of German and reported no language impairments and no psychiatric or neurological issues. The ethics committee of the University of Oldenburg approved of the study (reference number Drs. 28/2017) and written informed consent was obtained from all participants.

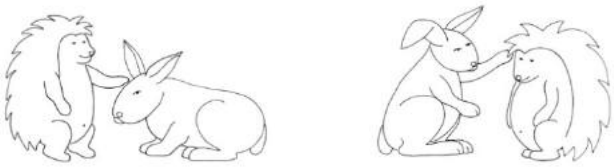

Figure 1: Example pictures corresponding to the sentences in Table 1.

Main Linguistic Task

The linguistic task used auditorily presented German sentences based on the OLACS corpus (Uslar et al., 2013), each followed by two pictures for a picture-selection task. Each sentence consisted of a Subject (S), a transitive Verb (V), an Adjunct (A), and an Object (O). Four different sentence conditions were used (see Table 1): SVAO sentences with canonical word order, OVAS sentences in which the object is placed sentence-initially, adjunct-initial AVSO sentences, in which the verb is placed before its arguments, and adjunct-initial AVOS sentences, in which the subject-object order is additionally manipulated. The task was performed in an fMRI scanner, which inherently creates noise. Therefore, a pre-task was used to control for the loudness of presentation of the stimuli[1].

After each sentence, two pictures (modified from Wendt, Brand, & Kollmeier, 2014) were displayed. These presented both characters mentioned in the sentence performing the mentioned action (the adjunct was not displayed in the pictures, see example pictures corresponding to the sentences in Table 1 in Figure 1). Participants could indicate the picture that best fit the sentence with a response box: the left button for the left picture and the right button for the right picture. The location of the target picture on the screen (left or right) was counterbalanced across trials.

[1] The loudness was adjusted for each participant individually to 80% intelligibility with the Oldenburg Matrix Sentence Test (OLSA; Wagener, Kühnel, & Kollmeier, 1999). The average adjusted loudness of stimuli presentation was 71.5dB (SD = 6.8).

The experiment used 24 sentences per condition, so 96 trials in total. The trials were distributed over two sessions. Two lists with pseudo-randomized presentation orders were created.

Cognitive Tasks

In addition, several cognitive tests were applied: A standard backwards *Digit Span* task (Tewes, 1991) as a measure of simple working memory capacity, the Comprehensive *Trail Making* test (Reynolds, 2002) as a measure of cognitive flexibility, a German *Vocabulary* test called 'Wortschatztest' (Schmidt & Metzler, 1992) as an index of verbal intelligence, the Montreal Cognitive Assessment (*MoCA*; Nasreddine et al., 2005)[2] as a concise screening tool for mild cognitive impairment, and a German version of the self-reported age-related *Memory Assessment* Clinics Questionnaire (Crook, Feher, & Larrabee, 1992) as an index of subjective memory complaints. Finally, participants' *Age* and years of formal *Education* (from primary school up to high school/university/PhD) were assessed through a questionnaire. Of the Trail Making task, following Rosemann et al. (2017), only trail 1 (connecting numbers in order: 1-2-3...) and trail 5 (connecting numbers and letters alternatingly in order: 1-A-2-B-3-C...) were used and participants' score was calculated as the difference in completion time between trail 5 and trail 1.

Procedure

Participants were tested individually at the University of Oldenburg. First, participants were asked to fill out a questionnaire asking for age and years of education, as well as the self-reported Memory Assessment questionnaire. Second, pure-tone audiogram measurements were taken in a soundproof booth. Then, the Trail Making, MoCA, and Digit Span tasks were conducted. After two practice rounds of 6 sentences with the same conditions as in the main experiment, the main linguistic experiment started. The pre-task controlling for the loudness of the stimuli and the main linguistic experiment took place in an MRI scanner; the fMRI results will be published in a separate paper. Participants used headphones during all tasks in the MRI scanner. After the first session of the main experiment, participants came out of the scanner and performed the Vocabulary task, before going back into the scanner for the second session of the experiment and some structural scans. The total testing time was about 3 hours.

Analyses and Results

One participant's Trail Making task was not performed in line with the experiment protocol and therefore excluded from the analysis (the participant took off their glasses halfway through the task). All other participants completed all the tasks.

[2] Approval for the use of this test was obtained from the MoCA Clinic & Institute.

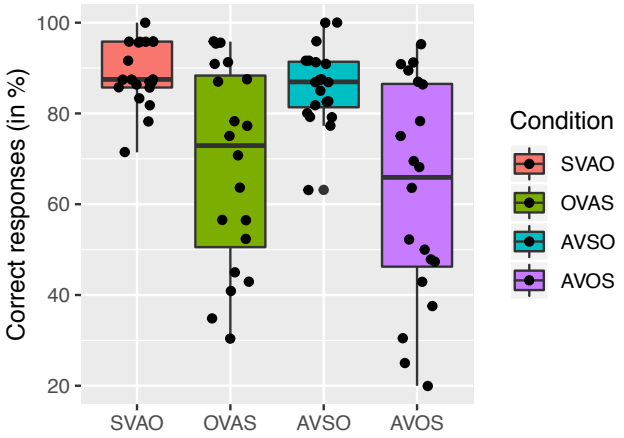

Figure 2: Percentages of correct responses and distribution of these responses on the linguistic task per condition. Each dot indicates the mean score of a participant on a condition. Overall means per condition are SVAO: 89%, OVAS: 69%, AVSO: 86%, and AVOS: 63%.

Main Linguistic Task

We first analyzed the correct responses per condition on the picture-selection task (Figure 2) with generalized linear mixed-effects models (lme4, Bates, Maechler, Bolker, & Walker, 2014). Based on the experimental design, the fixed effects of subject-object order and adjunct position as well as their interaction were included in the model. Based on model comparisons, random intercepts for subjects and items, as well as random slopes for subject-object order per subject and for subject-object order and adjunct position per item were included as random factors in the model. Subject-before-object and adjunct-third were used as the baseline.

The model results (Table 2) show lower performance on object-before-subject sentences (OVAS and AVOS) than on subject-before-object sentences (SVAO and AVSO). This confirms our expectation that object-before-subject sentences are more complex and more difficult to interpret than subject-before-object sentences. No significant effect of adjunct position or interaction between subject-object order and adjunct position was found.

Table 2: Statistical comparison of response accuracies in the linguistic task (corrected for multiple comparisons).

Factor	***ß***	***z*-score**	***p*-value**
Subject-object order	-1.38	-4.32	< 0.001
Adjunct position	-0.30	-2.09	0.07
Subject-object order* Adjunct position	-0.04	-0.16	0.87

As can be seen in Figure 2, on both of the more complex object-before-subject conditions, OVAS and AVOS, participants show very large individual variation; on the subject-before-object conditions participants show less variation. We will now look at whether this individual variation can be explained by the participants' cognitive abilities.

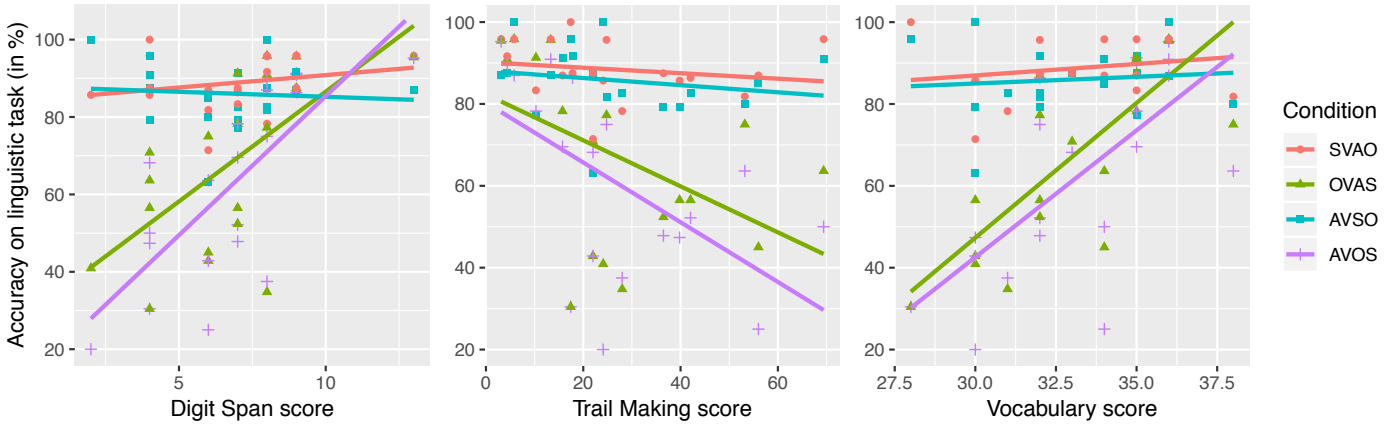

Figure 3: The relation between the performance on the linguistic task and on the Digit Span task (left), indicating working memory capacity, on the Trail Making task (middle), indicating cognitive flexibility, and on the Vocabulary task (right), indicating verbal intelligence.

Cognitive Tasks

We will perform two sets of analyses investigating the relation between the tested cognitive factors and performance on the linguistic task. First, we will examine the influence of each single cognitive factor by running generalized linear mixed-effect models with each factor separately. This analysis will show which cognitive factors influence the processing of simple and complex sentences. Additionally, we will examine the influence of the cognitive factors in combination with each other on the linguistic task by means of an inference tree. This will show which combination of cognitive factors has the strongest predictive power when it comes to interpreting sentences of different complexities and which are thus most useful to take into account when investigating (complex) sentence processing.

Linear mixed-effects models (lme4, Bates, Maechler, Bolker, & Walker, 2014) were developed for each cognitive task separately. The same model was used as for the analysis of the linguistic task, including the fixed effects of subject-object order and adjunct position as well as their interaction, but this time adding the cognitive tasks as co-variates. All significant effects are reported in the text, but only the most interesting effects will be elaborated upon. The results show, after correcting for multiple comparisons, no effects of *MoCA*, *Age*, and *Education* on the responses on the linguistic task (all p's > 0.05). A main effect of *Memory Assessment* was found (β = 0.08; z = 2.89; p < 0.01), indicating that people with more memory complaints actually performed better on the linguistic task.

For *Digit Span*, a significant main effect (β = 0.22; z = 3.38; p < 0.001) as well as an interaction with subject-object order (β = 0.38; z = 4.08; p < 0.001) were found. In Figure 3 (left panel), the relation between participants' scores on the Digit Span task and on the linguistic task per condition is plotted. The figure shows that participants with higher scores on the Digit Span task (indicating better working memory capacity) perform much better on the object-before-subject conditions than participants with lower scores. Conversely, no clear effect of working memory capacity is observed in the subject-before-object order, suggesting that processing the object-before-subject sentences requires additional working memory capacity compared to subject-before-object word order.

For *Trail Making*, also an interaction with subject-object order (β = -0.04; z = -2.86; p < 0.001) was found. Figure 3 (middle panel) shows the relation between participants' scores on the Trail Making task and on the linguistic task per condition. A higher trail making score reflects worse performance on the Trail Making test. Hence, subjects with worse scores on the Trail Making task perform worse on the linguistic task with object-before-subject sentences.

Finally, for *Vocabulary,* a significant main effect (β = 0.21; z = 3.59; p < 0.001) as well as an interaction with subject-object order (β = 0.33; z = 4.04; p < 0.001) were found. In Figure 3 (right panel) the relation between participants' scores on the Vocabulary task and on the linguistic task per condition is shown, making it clear that participants with higher verbal intelligence performed better on the object-before-subject conditions than participants with lower verbal intelligence.

All three interactions occur with object-before-subject sentences, indicating that interpretation of complex object-before-subject but not simpler subject-before-object sentences is influenced by these factors. Thus, it appears that processing more complex sentences draws on additional cognitive resources, whereas processing the simpler subject-before-object sentences requires less resources, presumably because they do not require additional analysis.

Best Predictors

One could argue that performance on Digit Span, Trail Making, and Vocabulary could be intercorrelated, and therefore these tasks may all explain the same effects in the data. Therefore, we will now investigate which cognitive factors *in combination* form the best predictors for the interpretation of sentences with different complexities and thus which are most useful to take into account in future investigations. Because investigating all factors within one mixed-effects model creates difficulties due to the large amount of variables, we favor conditional

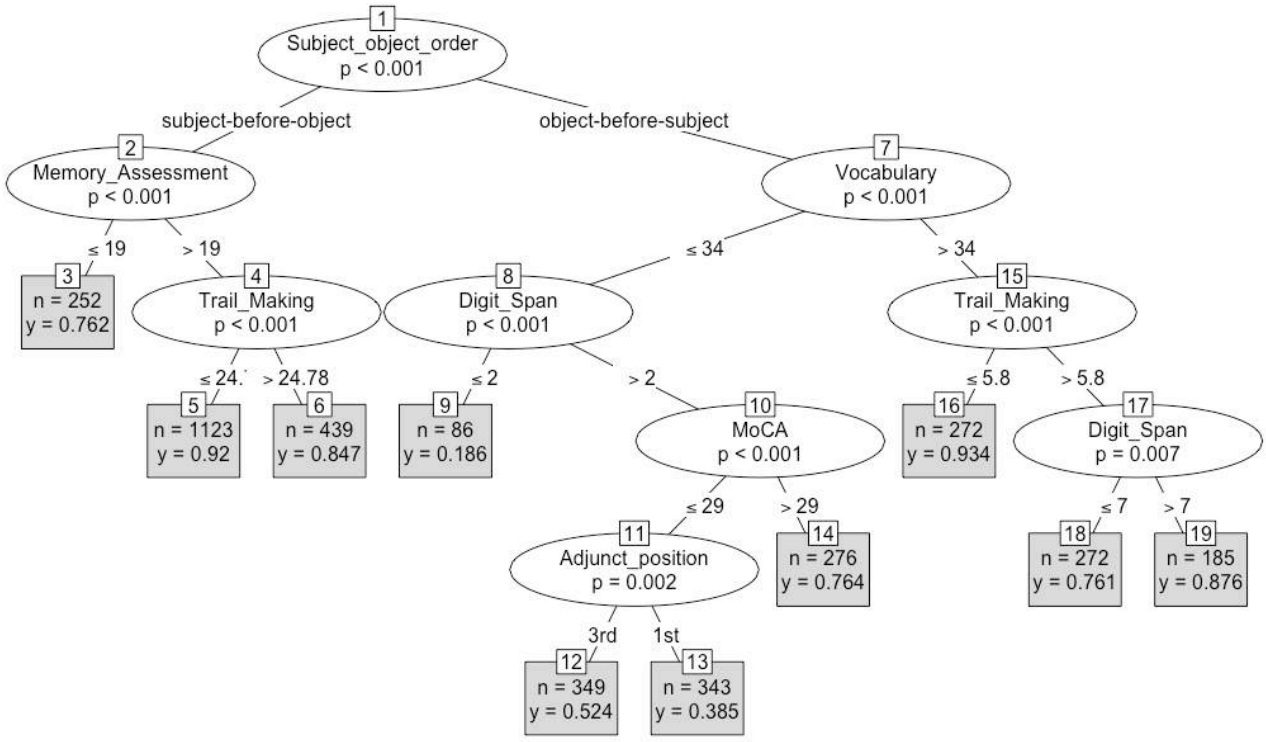

Figure 4: A conditional inference tree showing which of the tested predictors (*Subject-object order, Adjunct position, Digit Span, Trail Making, Vocabulary, MoCA, Memory Assessment, Age,* and *Education*) are the best predictors of response accuracy. The gray boxes indicate the number of trials (n) and proportion of correct responses (y) per branch.

inference trees (ctree from the party package, Hothorn, Hornik, & Zeileis, 2006), which are a type of decision tree. These provide non-parametric tree-based regression models and can handle large numbers of variables.

This method uses a significance test procedure in order to select the variables (cognitive factors) that best predict the response accuracy on the linguistic task. Notably, our two linguistic conditions, subject-object order and adjunct position, are entered as possible predictor variables as well. Using this method, we can investigate which variables most strongly predict the accuracy on our picture-selection task; stronger predictors are higher up in the tree. Variables that are not significant predictors do not occur in the tree at all. Besides showing which variables are predictors of response accuracy, the tree also shows how well individual performance can be predicted given these variables. The results of the analysis are shown in Figure 4 (including *p*-values per variable). Each branch of the tree represents the trials in certain conditions for participants with certain cognitive scores.

The results show that subject-object order is the strongest predictor for the performance on the picture-selection task, as it is highest up in the tree. For subject-before-object sentences, subjective *Memory Assessment* is the strongest predictor, followed by *Trail Making* score lower in the tree. In the gray boxes, the number of trials (n) and the mean proportion of correct responses (y), are displayed for each branch. For example, the 252 trials in the leftmost branch, in the simpler subject-before-object conditions responded to by people with a Memory Assessment score equal to or smaller than 19, were answered correctly 76.2% of the time.

For more complex object-before-subject sentences, *Vocabulary* is the strongest predictor of performance on the linguistic task, followed by *Digit Span* and *MoCA* for participants with a lower Vocabulary score, and *Trail Making* and *Digit Span* for participants with a higher Vocabulary score. Notably, MoCA is a significant predictor only for people with a lower Vocabulary score and a higher digit span score; this explains why there was no main effect of MoCA in the linear mixed-effects models. Interestingly, for participants with a lower Vocabulary score, a higher Digit Span score and a lower MoCA score, adjunct position is a significant predictor of performance on the linguistic task, whereas for other participants no influence of adjunct position is found.

Importantly, Vocabulary, Digit Span, Trail Making (and MoCA) all appear in the decision tree, indicating that they explain different parts of the data, i.e. they are complementary, and therefore that taking all these tests into account is useful when examining complex sentence interpretation.

Discussion

In this paper, we aimed to identify cognitive abilities that can predict the interpretation of complex sentences by older adults. We will focus on the most clear and convincing results here. As predicted, complex object-before-subject sentences were more difficult for older adults to interpret than subject-before-object sentences. Contrary to our predictions, adjunct-first sentences were only more difficult to interpret than adjunct-third sentences for part of the participants. Regarding cognitive abilities, we found that working memory capacity (*Digit*

Span), cognitive flexibility (*Trail Making*), and verbal intelligence (*Vocabulary*) are not only correlated with complex sentence processing as single factors, but also when they are combined. The analysis of all factors combined showed an additional effect of general cognitive performance (*MoCA*) for participants with lower verbal intelligence. Interestingly, age and years of education did not influence participants' performance (compare Stine-Morrow, Ryan, & Leonard, 2000).

The strong predictive power of verbal intelligence is striking. This does not reflect familiarity with the words in the linguistic task, since all conditions, simple and complex, used the same words. Rather, it could indicate that people with a broader and deeper vocabulary are able to access and process words more easily, thereby freeing up capacity for higher-level processing (in line with evidence from speech recognition, McAuliffe et al., 2013, but contra Ramscar, Hendrix, Shaoul, Milin, & Baayen, 2014). Moreover, verbal intelligence could be related to general intelligence or language (e.g., reading) experience (cf. Payne et al., 2014), which may increase familiarity with and aid the processing of complex structures.

Overall, our linguistic picture-selection task was quite challenging, which is reflected in the large amount of individual variation. Some participants showed around chance performance on object-before-subject sentences, suggesting that (1) their working memory capacity was insufficient to keep and manipulate all information in memory (cf. Just & Carpenter, 1992), (2) their verbal intelligence was insufficient to access their lexicon efficiently (cf. McAuliffe et al., 2013), (3) their cognitive flexibility was insufficient to process sentences with non-typical word order, and/or (4) their general cognitive performance was insufficient to process complex sentences. Conversely, simpler subject-before-object sentences do not seem to require high working memory capacity or verbal intelligence. This dissociation is in line with the idea that processing syntactically simpler constructions loads general cognitive resources less than processing syntactically more complex constructions.

One could argue that all cognitive factors that were found to affect complex sentence processing actually all belong to one latent factor. Ramscar et al. (2014), for example, suggest that a larger and more experienced lexicon has more complex representations, which require more demanding searches to be accessed, causing delays and decreased performance on linguistic and other psychometric tests. Our analyses show, however, that the different cognitive factors have a *complementary* effect; they explain different parts of the data, suggesting that the tasks tap into different underlying mechanisms.

Conclusion

Our study identified several cognitive factors that can serve as predictors of the interpretation of complex sentences by older adults, which differ from the factors that predict the interpretation of simpler sentences. The investigation thus highlights the complementary influence of different cognitive abilities on language processing, and emphasizes the need to consider not only working memory capacity, but also factors such as verbal intelligence and cognitive flexibility when investigating complex sentence processing.

Social dilemmas conceptually suggest distinguishing direct individual and group-level effects (also involving indirect effects on others). Furthermore, the success of organizations appears to rely on identifying not only individual excellence but positive impact on others as well. In 'Two-Level Personnel Evaluation Tasks' (T-PETs) participants as human resource managers evaluate employees when individual and group contributions are dissociated. Von Sydow, Braus, & Hahn (2018) have suggested a potential 'Tragedy of Personnel Evaluation': A group-serving employee with the smallest individual contribution but by far the greatest positive effect on the group's overall earnings was often rated the most negatively. Here we investigate, in two experiments with conflicting information, whether emphasizing the group can avert the 'tragic' outcome. Our results suggest that the tragedy is not as complete as suggested, and that contextual information can mitigate the tragedy. Nonetheless, the results also corroborate the stability of underestimating the impact of team players.

Keywords: Co-variation Detection; Inner-Individual Dilemma; Co-operation; Multi-Level Approach Simpsons Paradox

Individual versus Group Utility

Co-operation between individuals – over and above direct *individual* benefit – is essential for the common good of organisations, companies, and society on the whole. Successful co-operation often involves setting personal interests aside and devoting oneself, at least partly, to the success of an organization or team. Thus when evaluating behaviour one must distinguish direct individual utility from group utility.

In evolutionary biology, multi-level selection-approaches stress the differences between behaviour benefiting either the individual or the group; and these models allow for the rise of altruism (Sober & Wilson, 1999; Nowak & Sigmund, 2005; Wilson & Wilson, 2007).

Likewise, social-dilemma situations can be interpreted as conflicts of individual and group interests; and it has been argued that purely self-interested, economically 'rational' behaviour may inevitably lead to the depletion of public and natural resources. This has become associated with the label 'Tragedy of the Commons' (Hardin, 1968). Research in game-theory, behavioural economics and psychology (e.g., on ultimatum games, dictator games and public-good games) has revealed strategies for solving social-dilemma situations, and that many people do *not* act in a purely self-interested manner, but rather demonstrate at least some preference for distributing goods justly or behaving in a group-serving manner (Engel, 2011; Hendrich et al., 2005, Fehr & Gächter, 2002, Gollwitzer, Rothmund, Pfeiffer, & Ensenbach, 2009; Melis, Hare, & Tomasello, 2016).

In Organisational and Social Psychology, the importance of the team-level has been increasingly acknowledged, emphasizing that teams may be greater than the sum of their parts (Haslam, Steffens, Peters, Boyce, Mallett, & Fransen, 2017; Mathieu, Maynard, Rapp, & Gilson, 2008; Memmert, Plessner, Hüttermann, Froese, Peterhänsel, & Unkelbach, 2015). Likewise, the role of pro-social or altruistic role or extra-role behaviours in teams has been identified as central to the success of companies and organizations (Brief & Motowidlo, 1986; Li, Kirkman, & Porter, 2014; Nielsen, Hrivnak, & Shaw, 2009; Organ, 1997; Podsakoff, Whiting, Podsakoff, & Mishra, 2010).

A crucial question, however, is the extent to which people recognize those who clearly serve the overall good at the team level. This question should be particularly pressing for human-resource managers who must evaluate or select employees and must often only base their judgment on abstract performance data (sales numbers, etc.).

Tragedy of Personnel Evaluation

For human-resource management, it seems crucial to address the potential dissociation of employees' individual and collective impact on team performance. While underlining this, recent research has also provided some first evidence that such behaviour is sometimes rewarded – particularly when managers have direct acquaintance with the processes and persons involved (Organ, 1997; Scotter, Cross, & Motowidlo, 2000; cf. Grant & Patil, 2012, 562). However, personnel managers must increasingly evaluate without first-hand experience, often based on abstract performance numbers (Brandl, 2002).

We have begun to study evaluation situations from an experimental perspective as well, using well specified Two-level Personnel-Evaluation Tasks (T-PETs; von Sydow & Braus, 2016, 2017; von Sydow, Braus, & Hahn, 2017, 2018). In these T-PETs, participants obtained information about employees' earnings on individual as well as overall group levels. The T-PET used involves strongly conflicting information at both levels. The group-serving person *A* is characterized by lowest individual earnings yet has a consistent, strongly positive impact on the overall team earnings by substantially increasing the earnings of the other employees. This group-serving person is here called 'altruist'. Although (behavioural) altruism in biology and economics seem to be associated with this kind of indi-

vidual and group impact, it should be noted that such patterns do not imply *motivational* altruism (only 'prosocial' behaviour). For simplicity, however, we call the group-serving person, team-player or positive interactor simply 'altruist' (*A*).

In previous work on T-PETs, participants evaluated the 'altruist' who was best for the team and company as worst, and they tended to ostracize the altruist in selection tasks. These results led to the suggestion of a potential 'tragedy of personnel selection': Personnel managers may neglect or underestimate group impact with substantial damage to personnel and ultimately companies and organisations (von Sydow & Braus, 2016; von Sydow et al., 2018). This occurred despite the strong correlations between group membership and team performance (von Sydow et al., 2018). Further studies showed that, although negative group-interaction or 'egoist' detection (egoism here again defined behaviourally only) differed slightly from 'altruist' detection, they both demonstrated a broadly similar tragedy of ignorance regarding overall group-level effects (von Sydow & Braus, 2017). Another study already has investigated the role of group size in T-PETs. Holding the effects of *A* on *single* other individualy constant, the small group demonstrated no considerable advantage (von Sydow, Braus, & Hahn, 2017).

The current personnel-evaluation experiments again involve similar scenarios with conflicting information at the individual and group levels (T-PETs). However, they investigate whether a shift in the known importance or salience of the group level, by either varying cover-stories (Exp. 1) or selective information presented (Exp. 2), yields improvement. Experiment 2 additionally examines ratings distinguishing explicitly direct impact, impact on others, and overall impact on a team.

Figure 1: Example of shown earnings at the individual and group levels on a particular day.

Experiment 1: Story-Induced Focus

We used a straightforward manipulation, providing participants with texts stressing either the role of the individual or the team as central for personnel management. The experiment had four conditions, with stories focusing on different levels (C1 individual; C2 global; C3 individual & global; C4 control, no focus and no additional text). Additionally, the order of the dependent variables in all four learning phases was counterbalanced (evaluation → selection vs. selection → evaluation).

Method

Participants The experiment was conducted via MTURK with participants from the US. 121 participants passed the two selection-criteria (time spent on the first page, and the correct choice of a rephrasing of the instructions) and finished the experiment. The participants obtained a compensation of $1.50. 49% were male; the mean age was 36; 55% had a Bachelor's or Master's degree and 30% a high school degree as their highest level of education.

Procedure and material The computer experiment resembled previous T-PETs (von Sydow et al., 2018) and was implemented using SociSurvey.

Participants first obtained general instructions that their role as personnel manager was to evaluate the employees of a particular shop. Daily they would obtain information about individual and total earnings of the team working that day. Overall there were five staff members working in the shop, in day-shifts of four people.

On the next slide, participants read that the retired founder of the company had delivered a talk, mentioning the essential role of the personnel management to a company's success. As space precludes exhaustive citation here, we present only the first and fourth of five paragraphs of C1 and C2:

C1: "What is a company? A company is composed of **individual employees working on their tasks**, and it rises and falls with their performance. Thus a company needs to incentivize the performance of **each individual employee**. […] This alone will do justice to those individuals **who do a good job over those who do a bad job**. In particular, you need to detect those **employees** who **individually perform best and worst."**

C2: **"**What is a company? A company is **more than just the sum of its employees**; it is a **whole**, a finely attuned **organism.** It is made up of **teams** in which employees need to **interact** in a positive way. Thus, a company needs to incentivize **team performance**. […]. This alone will do justice to those **teams with positive interaction** and to **good over bad team players**. In particular, you need to detect the **members of the group** who **support and those who exploit the group"** (bold print added).

C3 analogously emphasized the importance of monitoring both individual AND group effects of employees.

In the main part, participants sequentially obtained for each day transparent overview information about the individual earnings of each of the four employees (presented by a picture) working on the shift that day, as well as information on overall earnings (see Figure 1). The structure of the earnings is shown in Table 1 (we added some noise to each value; a normal distribution with SD = 600 €). On the level of individual earnings there were relatively small mean differences (400 €) between the four non-interacting normal workers N_x and the altruist *A*: *N1 > N2 > N3 > N4 > A*.

Apart from the lowest individual earnings of the 'altruist', his/her presence had by far the most positive impact on the group earnings – when *A* is present, the earnings of all co-workers increase by 1000 €, leading to an overall average increase of 2500 € (normally exceeding the salient mark of 10,000 €).

Table 1: Mean earnings of normal workers (*Nx*) and altruist; and mean overall earnings.

	With Altruist	Without Altruist
N1	3,600 €	2,600 €
N2	3,200 €	2,200 €
N3	2,800 €	1,800 €
N4	2,400 €	1,400 €
Altruist	1,500 €	-
Total	10,500 €	8,000 €

The presence of this worker correlated with $r = .99$ with the overall outcome – a correlation easily detectible by machine-learning algorithms.

Overall, 80 panels (Table 1) were sequentially shown and participants could view the overview panels for each day as long as required, with a minimum of four seconds. The role of the altruist (team player) was randomly assigned to one of the five persons of which four are working in a particular shift. He or she appeared randomly 50% of the days (shifts) in the overview panels (Table 1); the four normal workers appeared randomly. We further counterbalanced the presentation-order of the four employees working in each shift.

In four test phases, after the 20, 40, 60 and 80 rounds, the 'personnel managers' evaluated all employees in an evaluation task and a selection task. The order of these tasks was counterbalanced. In the evaluation task, participants rated the contribution of all employees to the overall earnings of the company, on a scale of one to ten. In the personnel selection task they had to answer which four of the five workers they chose to work another day "to optimise the overall profit for the company". At the end of the fourth test phase, we added a total utility task: "Which person is of the greatest/lowest total utility for your business?" and assessed participants' preference for narrow self-interest and pro-social behaviour, using the social-value orientation scale (Murphy, Ackermann, & Handgraaf, 2011). Finally, they provided comments and demographic data.

Results

Figure 2 shows the average evaluation ratings by person in the four test rounds for the four conditions. First, Figure 2 reveals that the average ratings, in all conditions, mainly reflects the average *individual* earnings of the employee, with the ratings of the altruist, *A*, always being lower than all (or at least most) normal workers, *N*. A repeated-measures ANOVA with factors Person (*N1* to *N4*, A) and Phase (R1 to R4) as within-subject factors, and the condition Story (C1 to C4) as between-subject factors, revealed a significant main effect of Person only, $F(2,257) = 216,20$, $p < .001$, $\eta^2 = .65$, but no significant main effects of Condition or Phase.

Second, the ratings reveal that the order of the mean ratings of the normal workers is always (even in Phase 1) in line with the actual (small) differences observed, resulting overall in order (*N1 > N2 > N3 > N4 > A*), with significant post-hoc tests for all four comparisons (each $p < .001$).

Figure 3 shows the percentage of group-based answers in the selection task (selections of *A*), the rating task (all $N \geq A$) through time, and the final comments (coding some insight into the difference between individual and group performance). Selection, comments, and in the beginning rating as well, seem to reveal a similar pattern: a slight advantage for the conditions with global stories (C2 and C3). Comparing these two conditions with those without global stories (C1 and C4), this predicted effect in Phase 4 reaches significance for selection: $\chi^2(\text{df}=1, N=121) = 4.30$, $p < .05$. For ratings there seems only an effect for the global condition, not the individual and global condition. This difference between selection and rating perhaps becomes understandable if one bears in mind that correct rating here involved a stricter test criterion than selection (not only judging *A* higher than *one* other worker, but *all* other workers).

Discussion Experiment 1

First, the results of Experiment 1 overall corroborate the postulated stability of the Tragedy of Personnel Evaluation with no strong impact of the story. The average ratings of the altruist, who actually very consistently causes strong improvements in group performance, are lowest; and at least 50% of the participants seem not to detect the effects of the presence of the 'altruist'. However, the results also suggest

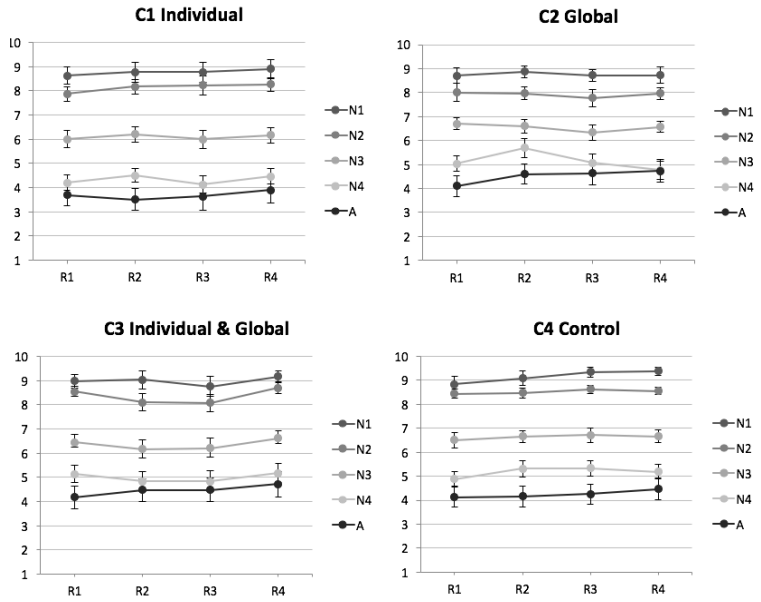

Figure 2: Mean ratings of the employees over test rounds in the four story conditions.

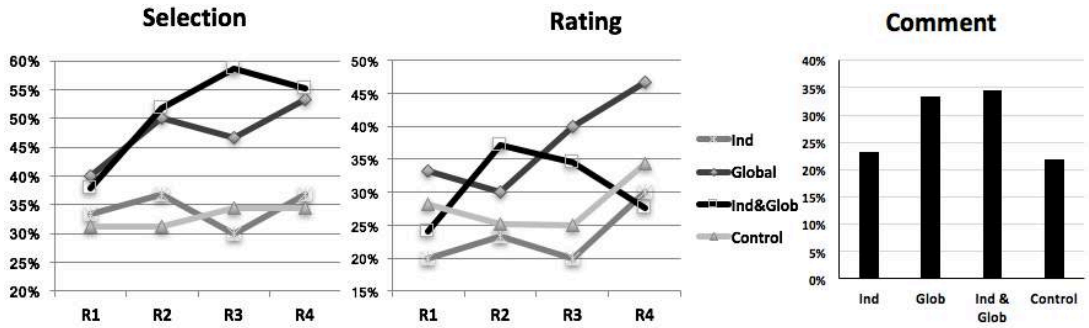

Figure 3: Percentage of group-based selections, evaluations (rating *A* > all *N*), and comments by conditions in Experiment 1.

some small effects of the story, and that thinking about the group level can reduce the Tragedy of Personnel Evaluation at least with regard to some participants.

Experiment 2 – Selective Information Presentation

Experiment 2 varies what information (group versus individual versus both) is presented and at what time. It also increases the number of test phases, to explore the temporal dynamics in more detail and what people could learn even after ten trials. Finally, it tests the ability of participants to detect group-level (and individual-level) effects, also using ratings explicitly differentiating between individual effects, effects on others and overall team effects.

With regard to selective information presentation, there is a condition focusing participants on group-level information alone (*G*) in order to investigate whether and how quickly the 'altruist' could be detected (now using eight test phases). Presenting only individual-level information (*I*), provides the other extreme base-line condition. Always presenting both – individual and a team's overall earnings (*B*) – replicates Experiment 1 but can now be compared to both benchmark conditions. Moreover, we added several further 'mixed conditions, where the three information formats (*G*, *I*, *B*) changed over time (e.g., GIGIGIGI).

The increased number of test phases may allow participants more easily to realize the tension between individual-level success and overall group-level effects. The contrast to both extreme base-line conditions (only *I* or only *G*), should serve as controls for the level of performance in the intermediate conditions, that 'only *B*' or the mixed conditions. In a number of mixed conditions the shown information is varied over time (e.g., GIGIGIGI). We explore whether they may be adventitious in contrasting the global and individual level.

Method

Participants (recruited by Prolific Academic) came from English-speaking countries (i.e. the UK 52%, the US 32%, Ireland, Australia etc.). 172 participants passed all selection criteria and finished the experiment (cf. Exp. 1). Each participant obtained a compensation of £1.80. The mean age was 32 (59% male, 41% female). Regarding education, all participants had at least high school degree or *A* levels.

Procedure and material The materials and procedure apart from some differences strongly resembled the T-PET of Experiment 1. We used a similar, neutral introduction, but without stories. In the main part, participants again obtained, sequentially for each day, overview information (Figure 1) based on the same average earnings as before (Table 1). Thus, on the *individual* level, the rank-order of earnings for the normal (non-interacting) (N_i) workers and the altruist (*A*) worker was *N1 > N2 > N3 > N4 > A*, with small differences (400 €). The altruist impact on the other workers in a shift was larger, increasing each of their average earnings by 1000 € and the average earnings of the team by 2500 €, resulting in a reversed rank order: *A > N1 > N2 > N3 > N4*.

Participants in the role of personnel managers were again shown information on four employees' earning (out of five employees overall) for 80 shifts (days). We again counterbalanced presentation-order of persons shown (see Exp. 1). Participants could study the overview panels as long as required, but with a minimum of four seconds.

Table 2: Information in phases (P_x) and conditions (C_x).

	P1	P2	P3	P4	P5	P6	P7	P8
C1	*G*	*G*	*G*	*G*	*G*	*G*	*G*	*G*
C2	*B*	*B*	*B*	*B*	*B*	*B*	*B*	*B*
C3	*G*	*G*	*G*	*G*	*B*	*B*	*B*	*B*
C4	*G*	*B*	*G*	*B*	*G*	*B*	*G*	*B*
C5	*G*	*G*	*B*	*B*	*G*	*G*	*B*	*B*
C6	*G*	*I*	*G*	*I*	*G*	*I*	*G*	*I*
C7	*I*	*I*	*I*	*I*	*I*	*I*	*I*	*I*

Note: *B* = both individual & group; *G* = group only; *I* = individual only; C_x = condition; R_x = round

In contrast to Experiment 1, Experiment 2 uses eight (instead of four) test rounds and eight preceding learning phases, each composed of ten days. Moreover, we varied the information formats. In a learning phase 10 information panels (10 days, one for each shift) are shown, with information either only on the individual earnings (*I*; see Figure 1 without last row), on the group earnings (*G*; Figure 1 without middle row) or, finally, on both individual and group earnings (*B*; cf. Figure 1). Table 2 presents the information formats in different conditions and phases.

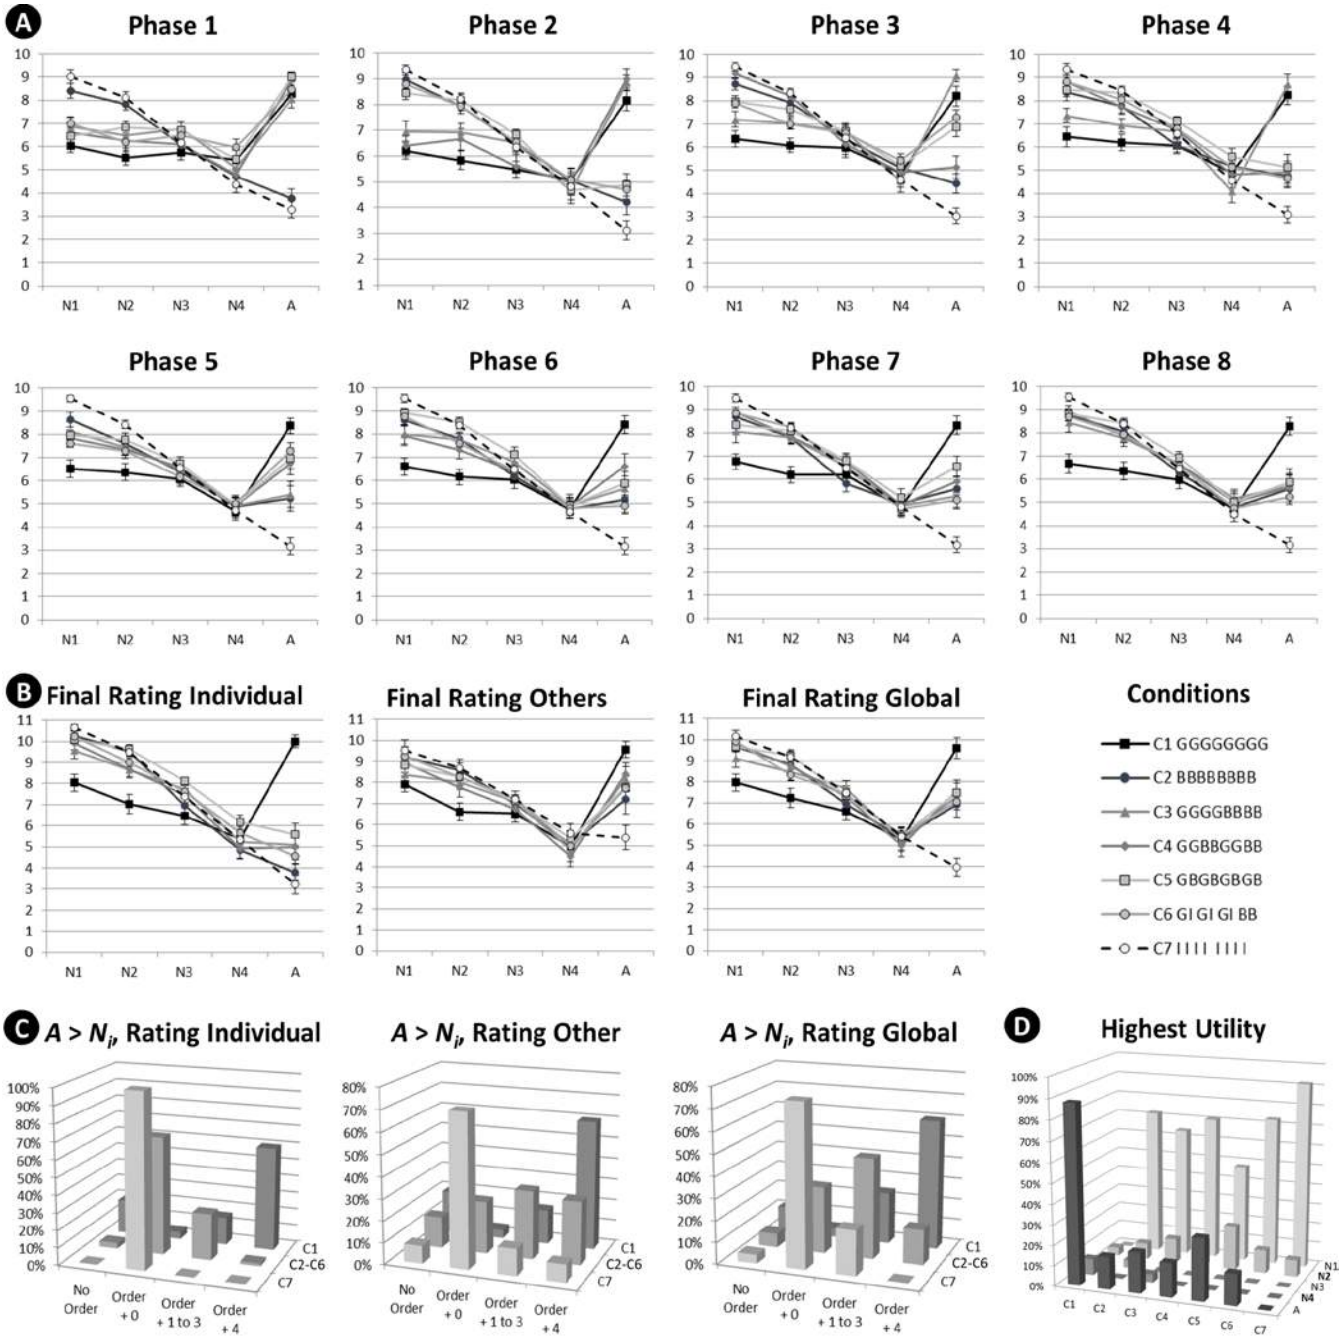

Figure 4: *Panel A* shows participants' mean ratings for the 'altruist' worker (*A*) and the four non-interacting normal workers (*N*) for the seven conditions and eight learning phases. *Panel B* presents the mean of the final ratings, differentiating between workers' individual earnings, effect on others and resulting overall effect (global). For these ratings, *Panel C* shows the percentage of participants who had no sense of individual differences between normal workers ('No Order'; N1+N2 > N3+N4). For those who detected this basic individual order ('Order'), we show the percentage, rating the altruist higher then none of the *N*s ('+ 0'), then one to three Ns ('+1 to 3'), and then all four *N*s ('+ 4'). *Panel D* shows the percentage of participants attributing the overall highest utility for the company to the 'altrust' or a particular normal worker.

In each test round, we administered rating scales and then a personnel selection task. At the end, participants should again provide ratings for all five workers but now explicitly using three rating scales differentiating between individual impact, impact on others and overall contribution. Finally, participants had to choose the employee with greatest or lowest utility and comment on their own behavior.

Results

Figure 4 presents the main results of Experiment 2. *Panel A* shows the participants' mean ratings of the five workers'

contributions in the eight phases. These results show that (a) even after ten presentations (Phase 1) participants' mean judgments suggest a high altruist-detection tendency (at the expense of less clear individual differences between the normal workers); (b) between the phases there was a strong variation of the mean ratings of the mixed middle conditions, suggesting that at least in the beginning participants had difficulties in integrating the results and were strongly influenced by the recent phase; and (c) at the end (Phase 8), however, all middle conditions (C2 to C6) show a middle result between the benchmarks (C1 and C7), and there is no large difference between the middle conditions. Despite still underestimating the altruist, participants clearly do not focus only on individual-level information.

Panel B shows the results of the final ratings differentiating between workers' individual earnings, their impact on others, and the overall impact. (a) Participants in the middle conditions (C2 to C6) clearly differentiate between these ratings. (In the two extreme conditions this was unlikely, but there is even a small effect in C7.) In the middle conditions the individual ratings show $A < N_s$, but the 'other-ratings' show that *A* is, on average, rated higher than N_4, and similarly high as N_3 and N_2. The global rating may be a mixture that seems even more strongly to resemble the 'other-ratings' (but note the incommensurability of the other-rating that used a bipolar scale). In any case, the global rating in the middle conditions clearly does not reach the C1 benchmark, suggesting a remaining tragedy. (b) Comparing the final ratings with the ones in Phase 8 suggests that participants do interpret the latter largely as global ratings (with a small individual influence). (c) Given that the impact-on-others rating would correctly be answered following $A>N_1=N_2=N_3=N_4$, there is not only a correct $A>Ns$, but also an incorrect impact of the individual order $N_1>N_2>N_3>N_4$. This suggests the heuristic '(s)he who is good individually also helps others'.

Panel C investigates the individual differences of the final ratings. (a) Only few participants demonstrate no sense of individual differences ('No Order'; not $N1+N2 > N3+N4$). Though the individual condition C7 does have advantages here, also all other conditions fare reasonably well.

(b) Looking at the others who detected the basic order between the *N*s, the individual and the group condition (C7 and C1) show highly similar results for the three ratings, suggesting a transfer in both directions. In contrast, the middle conditions (C2 to C6) differentiate between the conditions: In the individual ratings, most participants here detect correctly that $A < N$s (Order + 0); and in the 'others-ratings' they rate *A* higher than one, two, three (Order + 1 to 3) or even all four *N*s (Order + 4). The 'others-ratings' and global-ratings make clear that the results of the middle conditions lie between both extreme conditions. Thus it is clearly wrong to claim that all participants completely ignore the group effect; but it is also apparent that only a few rate the altruist as high as would be appropriate based on A's overall (direct and indirect) impact on overall earnings. *Panel D*, finally, shows who the participants judge to be of highest overall utility for the company. (a) C1 shows that, with a focus on group-information, all participants learned the foremost utility of *A*, whereas none learned it in the individual C7. (b) Despite the cited positive effects in the middle conditions, the dependent variable shows that the altruist is still underrated. Nonetheless, a considerable minority also in 'C2 to C6', and more than in C7 ($p < .001$), rates altruist as high as would be appropriate based on A's (direct and indirect) impact on overall earnings ($A >$ *all N*s).

General Discussion

Experiment 1 documents the stability of the Tragedy of Personnel Evaluation. The altruist's or team-player's outstandingly positive *overall* effects on a team were ignored or inadequately acknowledged by most participants; providing a context emphasizing the group had no large effect. However, Experiment 1 suggests that the postulated tragedy could – at least for some participants – be mitigated by contextual cues enhancing focus on the group-level.

Experiment 2 varied the information presented (individual information, group information, or both), used several test-phases, and at the end used rating-scales differentiating between individual earnings, effect on others, and overall impact on group earnings. The results show that participants in principle can learn the overall advantage of *A* as early as in Phase 1 (even after 10 'days') if forced to focus on the global information alone (C1). Second, toggling what information is presented over time did not provide the strong boost we hoped for. Third, and this seems important, the base-line conditions reveal that the tragedy is not at all a total one (at least here after 8 test phases). That is, participants' judgements in all middle conditions (including the only *B* condition) did differ also from an individual-focus condition. Nonetheless, the average ratings, the percentage of correct ratings, and the highest utility judgments show that most participants still substantially underestimate the overall impact of the 'altruist' team player.

Overall, the results are two-fold. They show that the postulated tragedy is neither completely immune to improvement (Exp. 1) nor as radical (Exp. 2) as perhaps originally suggested. However, despite using strong group-level effects, the results obviously do not allow for acquittal but rather corroborate a remaining (but reduced) tragedy. Even though this provides some first evidence for a means to mitigate the tragic, it also continues to underline the danger of potentially similar tragedies in the real world.

Future avenues of research should explore theoretical implications, mediating mechanisms, applications, and boundary conditions of these findings also in real-life settings. Although we here used highly educated participants and strict selection criteria, it would for instance be important to explore the stability of our findings with real personnel managers as well, with or without a number-based task (cf. von Sydow et al., 2018).

Moreover, this research may well be connected to several lines of more theoretically inspired research. For instance, our social-cognition two-level personnel evaluation tasks

may be understood more generally as studies of Simpson's paradox (Waldmann & Hagmayer, 2001; Fiedler et al., 2003; cf. von Sydow, Hagmayer, & Meder, 2016).

Second, we have suggested *some* rational basis for the apparently irrational reluctance to check for large correlations with a high overall outcome (the sum effect of many causal effects). We have suggested that this may be due to a concern with local causal relations rather than ephemeral overall outcomes (von Sydow et al., 2018; cf. Lagnado, Waldmann, Hagmayer, & Sloman, 2006; Sloman & Hagmayer, 2006; Hagmayer & Meder, 2013). Thus other interaction patterns may be more easily detected. For instance, it is known that people are well able to see some logical or causal interaction-patterns if focusing on two or three variables only (e.g., von Sydow, 2016).

In any case, the phenomenon seems of high importance, and the current research warns us that people, at least in the setting of number-based evaluations and perhaps beyond, may well tend to ignore or underestimate the strong overall group effects of team players in contrast to their individual effects.

Acquiring Agglutinating and Fusional Languages Can Be Similarly Difficult: Evidence from an Adaptive Tracking Study

Abstract

Research on the acquisition of morphology commonly predicts that agglutinating systems should be easier to learn than fusional systems. This is argued to be due to compositional transparency: the mapping between morphemes and meanings is one-to-one in agglutinating systems, but not in fusional systems. This is supported by findings in first and second language learning (Goldschneider & DeKeyser 2001, Slobin 1973), typology (Dressler 2003, Haspelmath & Michaelis 2017), and language evolution (Brighton 2002). We present findings from a series of artificial language learning experiments which complicate this picture. First, we show that when only two features (e.g., NOUN CLASS and NUMBER) are morphologically encoded, the learnability of fusional and agglutinating systems does not differ significantly. This finding holds when learners are given an additional cue to morpheme segmentation–which in principle should make the agglutinating system easier. However, the error patterns of the two groups provide some evidence that learners might have a bias for transparent structures. Our results suggest that the advantages of agglutinating over fusional systems may be overstated, particularly when a small number of features are encoded. Since agglutinating systems likely bear additional costs (e.g., segmentation, longer word length, and the online cost of mapping between morphemes and meanings), such systems do not guarantee learning ease under all circumstances.

Keywords: language acquisition; morphology; agglutinating; fusional; artificial language learning; transparency

Introduction

Classification of languages into morphological types is a commonly used parameter in language typology. Morphological type structures vary within and between languages, and they change over time. One key distinction is between fusional and agglutinating types. The distinction between these two is based on the ratio of morphemes to meaning, where a morpheme is defined as "the smallest meaning-bearing unit of language" (Kortmann, 2005). In fusional languages, morphemes typically express more than one meaning. For example, the German verb *spielst* ('you play') has the suffix –s*t*, which together expresses present tense, second person, and singular number. In comparison, morphemes in agglutinating languages typically only carry a single meaning. For example, the Turkish verb *konuşuyorsunuz* ('you speak') has three suffixes, *-yor*, *-sun*, and *-uz* individually expressing the same pieces of information (present tense, second person, plural number).

While both morphological types are well attested among the languages of the world, it has been proposed that fusional and agglutinating systems may differ in terms of learnability. In particular, it has been claimed that the more meanings a single morpheme carries, the less transparent it is, and therefore the more difficult it is to learn (e.g., Goldschneider & DeKeyser, 2001; Don, 2017; Haspelmath & Michaelis, 2017). For the purpose of this study, we use transparency to mean one-to-one correspondence between a form and its meaning (Don, 2017). Because agglutinating morphology is by definition more transparent, agglutinating systems should be easier to acquire, while fusional systems where a single morpheme encodes multiple meanings should be more difficult.

Support for this idea comes from research on both first and second language acquisition. In first language acquisition, a number of classic studies on morpheme order of acquisition in children have implicated transparency as part of the explanation for why certain English morphemes are acquired earlier than others (Brown, 1973; de Villiers & de Villiers, 1973; Dulay & Bert, 1974). For example, *–s* as in *plays* (which expresses 3rd person, singular, and present tense) is learned later than *–ing* (progressive). These studies build on more general claims relating transparency to ease of acquisition in children (e.g., Slobin, 1973)

More recent work has extended these findings to a number of other languages. For example, Sultana, Stokes, Klee, and Fletcher (2016) argue that the level of transparency of morphological forms predicts the order of acquisition in Bengali. Hengeveld and Leufkens (2018) point out that Turkish children generally master the agglutinating morphology of their language by the age of 3, whereas Dutch children have not yet acquired the fusional verbal system of their language at that age. This is in line with Dressler (2003), who reports earlier acquisition of morphology by children in Turkish than in English.

Second language acquisition research has echoed the role of transparency in morphological learning. In a meta-analysis

of 14 studies on L2 acquisition of English, Goldschneider and DeKeyser (2001) show that transparency correlates with earlier acquisition. For example, L2 learners, like children, acquire the English morpheme *–s* relatively late.

Finally, there is a clear relationship between agglutinating systems and the more general feature of compositionality. In compositional systems, complex signals are formed by combining meaning-bearing parts, with the meaning of the whole being a function of the meaning of the parts; this can be contrasted with holistic systems in which such re-combinable subparts do not exist, the relationship being between whole meanings and unanalyzable signals. A large body of research on the evolution of compositionality in language connects it to learnability (Brighton, 2002; Kirby, Cornish & Smith, 2008; Kirby, Tamariz, Cornish & Smith 2015, a.o.): compositional systems are simpler in that they have a shorter encoding length and are more compressible, making them simpler in a cognitively-relevant sense and therefore easier to learn; compositional systems also permit generalization to unseen meanings and signals. These same characteristics hold for agglutinating systems, suggesting that they too should be easier to learn.

To summarize, various lines of evidence suggest that agglutinating languages should be easier to learn than fusional languages. The inherent transparency and regularity of agglutinating forms, the higher frequency of a given morpheme in the system, and the possibility to generalize all point to a learnability advantage of these systems. However, in many cases, it is difficult to disentangle transparency from other features of the system. Most obviously, agglutinating systems often use *more* morphology overall, which could in principle also serve to obscure this advantage. However, Dressler (2003) argues that the systematic use of morphology in agglutinating languages relative to fusional ones may in fact serve to clue learners into its importance, triggering earlier learning. In this paper, we report a series of artificial language learning experiments which allows us to test the above claims by directly comparing agglutinating to fusional systems, while controlling for systematicity of morpheme use, and number of morphemes across conditions.

Experiment 1

We tested whether learners are faster at acquiring agglutinating systems compared to fusional systems by exposing participants to nouns encoding two binary features, one for NUMBER (singular/plural) and one for CLASS (animate/inanimate). Crucially, we held the number of morphemes to be learned constant across both conditions.

Methods

Participants. 80 participants were recruited on Amazon Mechanical Turk, all self-reported as English native speakers. They were paid $4 for their time. Participants were randomly assigned to one of the conditions described below (38 in the fusional and 42 in the agglutinating condition).

Materials. The language consisted of 96 nouns, referring to objects, and four suffixes, encoding NOUN CLASS (animate and inanimate) and NUMBER (singular and plural). Animate entities were always animals and inanimate entities were everyday objects such as household items and pieces of clothing. All stems were monosyllabic and adhered to English phonotactics. Morphemes used for both languages were identical: *-mu*, *-ka*, *-pi*, *-lo*. In the fusional condition, each of the four morphemes expressed one value for both features: animate+singular, animate+plural, inanimate+singular, inanimate+plural. For example, in Figure 1, *spur* is the noun stem, and *-ka* indicates animate+singular. In the agglutinating condition, the four morphemes each expressed a single value of NUMBER *or* CLASS. For example, in Figure 2, *foog* is the stem, *–ka* indicates inanimate, and *–mu* indicates plural. Note that the stem was directly followed by the CLASS morpheme, which was followed by the NUMBER morpheme. Mappings between morphemes and meanings were randomized across participants. Note that because we use the same set of morphemes in both languages, the words are longer in the agglutinating condition (by one syllable). This is a general characteristic of agglutinating languages, where words tend to be longer than in fusional languages.

Procedure. Participants were instructed that they would be learning part of a new language. On each trial (Figures 1, 2), participants saw an image and were given a choice of four words that could describe it. The four choices always represented the same stem with four possible grammatical combinations of affixes. Participants were instructed to click on the word that they thought correctly described the picture. Immediate feedback was given in every trial: the correct answer was highlighted with color, and the audio of the correct word was played aloud. The study consisted of 96 trials each of which displayed a unique picture. Therefore, no image or stem was ever repeated (and participants were not required to learn the mappings between images and stems). Each combination of grammatical meanings occurred as the correct choice 24 times in total. At the end, participants completed a short questionnaire.

Results. The design of our experiment aimed to compare performance across conditions over time. Since participants were necessarily guessing at the beginning, we expect performance in both conditions to be similar early on, but to potentially diverge over trials as they learned. Figure 3 shows mean accuracy across conditions by trial. As expected, participants generally improved over trials. However, performance appears to improve at a similar rate across conditions. Mean accuracy across all trials for the agglutinating condition was 0.65 (SD=0.24), for the fusional condition 0.60 (SD=0.24). To test whether the rate of improvement differed between conditions we fit a logistic mixed-effects regression model, predicting correct answer by

condition, trial (coded 0-95), and their interaction.[1] Condition was dummy-coded, with agglutinating as the reference level. The by-item intercept was removed because the model failed to converge. The model revealed a significant effect of trial number (b=0.04, SE=0.01, p<0.001), indicating that participants improved their accuracy over the course of the experiment, but no effect of condition (b=0.14, SE=0.18, p=0.42) and most importantly, no condition by trial number interaction (b=-0.01, SE=0.01, p=0.20). The latter would have indicated a difference in the rate of learning in one or the other condition, indicating a learnability advantage.

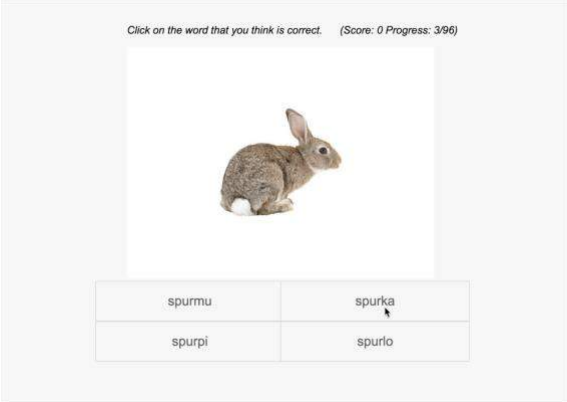

Figure 1: Example trial in Experiment 1, fusional condition. This trial shows an animate, singular object.

Figure 2: Example trial in Experiment 1, agglutinating condition. This trial shows an inanimate, plural object.

We conducted an exploratory analysis of participants' errors to investigate whether the highly similar overall performance masked a difference in error type between the two conditions. As described above, each of the four choices given in every trial constituted a different combination of grammatical meanings. Incorrect responses could either reflect the participant selecting a marker which was appropriate to the CLASS of the noun (e.g. selecting a morpheme marking animacy for an animate referent) but the wrong NUMBER (e.g. selecting a plural morpheme for a singular noun), selecting the wrong CLASS but the correct NUMBER, or selecting a morpheme which was incorrect for both CLASS and NUMBER. The rates for these three classes of error (correct CLASS only, correct NUMBER only, neither correct) are shown in Figure 4. The proportion of errors reflecting correct CLASS appears to be greater in the fusional condition. This impression is confirmed by a logistic mixed-effects regression model testing whether the proportion of CLASS correct only responses was significantly different between conditions. We ran the model predicting correct CLASS in the subset of the data with incorrect answers, including fixed effects of condition, trial number and their interaction. The by-item intercept was removed due to convergence errors. The model revealed a significant effect of trial (b=0.02, SE=0.01, p=0.003) no significant effect of condition (b=-0.02, SE=0.23, p=0.92), and a significant interaction between condition and trial (b=0.02, SE=0.01, p=0.04).

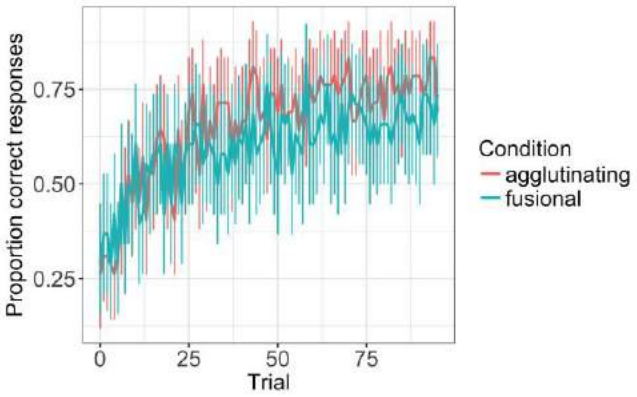

Figure 3: Mean accuracy by trial by condition in Experiment 1.

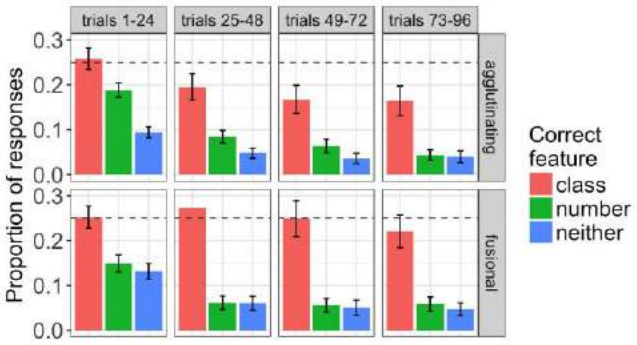

Figure 4: Classification of incorrect choices by correct feature (CLASS correct NUMBER wrong, NUMBER correct CLASS wrong, or neither correct) by trial block by condition

[1] All models were run using the package lme4 in R (Bates 2010). Unless otherwise noted, models included random by-participant and by-item (picture) intercepts, and by-participants slopes for the effect of trial.

in Experiment 1. Trial number is binned for readability. Note that the y-axis range does not display the full range.

This suggests that participants in the fusional condition and agglutinating condition diverged over time in their tendency to choose an answer in which only the CLASS morpheme was correct–while such errors decline in the agglutinating condition, they remain at a fairly constant level in the fusional condition. One possibility is that this reflects a bias for transparency: participants in the fusional condition may have been searching for a single feature with four values, rather than two binary features. While NUMBER is unambiguously binary (one vs. two), the stimuli could in principle encode more fine-grained distinctions of CLASS. In the post-test questionnaire, some participants indeed reported such a strategy, for instance, distinguishing land vs. sea animals and household items vs. clothing. They subsequently tried to map each of these four CLASS values onto one morpheme, ignoring NUMBER altogether. However, this analysis was performed post-hoc since the given distribution of answer types was unexpected. We therefore replicated the experiment.

Experiment 2

Methods

Participants. 100 participants were recruited on Amazon Mechanical Turk, all self-reported as English native speakers. They were paid $4 for their time. Participants were randomly assigned to one of the two conditions (48 in the fusional and 52 in the agglutinating condition).

Materials. Stimuli were identical to those of the previous experiment.

Procedure. The procedure was identical to Experiment 1.

Results. Figure 5 shows mean accuracy by trial across conditions. As in Experiment 1, participants generally improved from the start to the end as expected, and overall performance appears to be similar across conditions (agglutinating M=0.64, SD=0.26; fusional M=0.68, SD=0.25). We ran a model predicting correct answer by condition, trial (coded 0-95), and their interaction. Condition was dummy-coded, with agglutinating as the reference level. The model revealed a significant effect of trial number (b=0.04, SE=0.01, p<0.001), indicating that participants improved their accuracy over the course of the experiment, but no effect of condition (b=-0.10, SE=0.17, p=0.57) and no condition by trial number interaction (b=0.01, SE=0.01, p=0.25). Again, the latter would have indicated a more rapid improvement in one or the other condition, and thus a learnability advantage.

We repeated our analysis of error types across conditions (Figure 6). In this case, the model revealed a significant effect of trial (b=0.02, SE=0.01, p<0.001), no significant effect of condition (b=-0.02, SE=0.20, p=0.93), and no significant interaction between condition and trial (b=-0.004, SE=0.01, p=0.63). This suggests that the apparent difference in CLASS-based errors across conditions seen in Experiment 1 may have been spurious.

The strong expectation from previous research was that, all things equal, an agglutinating system should be easier to learn than a fusional system. This advantage was not borne out in Experiments 1 and 2. However, we are exploring the early stages of learning these systems, and thus one possibility is that participants in the agglutinating condition were not segmenting the morphemes–i.e., they may have been treating the string of two morphemes as a single morpheme, encoding both NUMBER and CLASS. If so, then we would not expect any difference between conditions. Indeed, the post-test questionnaire reveals that at least some participants failed to segment the stems and morphemes. In Experiment 3 we test whether an advantage for the agglutinating system is revealed if we provide a visual cue to aid segmentation.

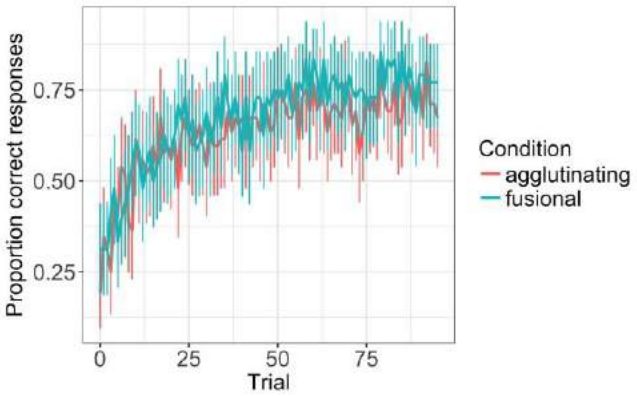

Figure 5: Mean accuracy by trial by condition in Experiment 2.

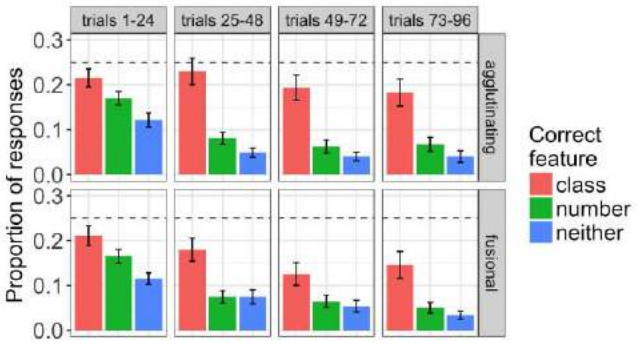

Figure 6: Classification of incorrect choices by correct feature (CLASS correct NUMBER wrong, NUMBER correct CLASS wrong, or neither correct) by trial block by condition in Experiment 2. Trial number is binned for readability. Note that the y-axis range does not display the full range.

Experiment 3

Methods

Participants. 100 participants were recruited on Amazon Mechanical Turk, all self-reported as English native

speakers. They were paid $4 for their time. Participants were randomly assigned to one of the conditions (51 in the fusional and 49 in the agglutinating condition).

Materials. The language was identical to Experiments 1 and 2, however, a visual cue to the segmentation of words and morphemes was provided. In each trial, morphemes were highlighted with color (Figure 7). In the agglutinating condition, the CLASS morpheme was highlighted in one color and the NUMBER morpheme in another. Participants were randomly assigned to see either CLASS in orange and NUMBER in blue, or vice versa. In the fusional condition, all four morphemes were randomly assigned a single color so that a participant would either see all morphemes across all 96 trials in orange or all morphemes in blue.

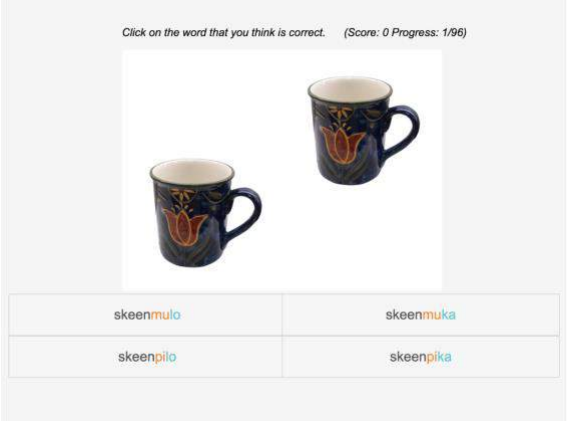

Figure 7: Example trial in Experiment 3, agglutinating condition. This trial shows an inanimate, plural object.

Procedure. The procedure was identical to Experiments 1 and 2.

Results. Figure 8 shows mean accuracy in correct answers across conditions. As in Experiments 1 and 2, participants generally improved from the start to the end as expected, and overall performance appears to be similar across conditions (agglutinating M=0.59, SD=0.25; fusional M=0.59, SD=0.23). We ran a model predicting correct answer by condition, trial (coded 0-95), and their interaction. Condition was dummy-coded, with agglutinating as the reference level. The model revealed a significant effect of trial number (b=0.03, SE=0.005, p<0.001), indicating that participants improved their accuracy over the course of the experiment, but no effect of condition (b=0.23, SE=0.18, p=0.21) and no condition by trial number interaction (b=-0.003, SE=0.01, p=0.64). The latter interaction would have indicated a more rapid improvement in one or the other condition indicating a learnability advantage for one type.

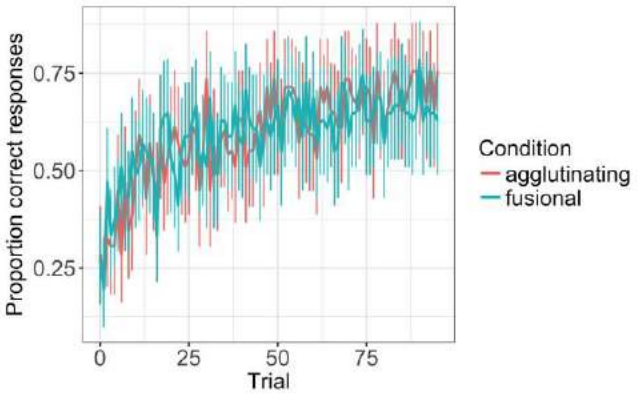

Figure 8: Mean accuracy by trial by condition in Experiment 3.

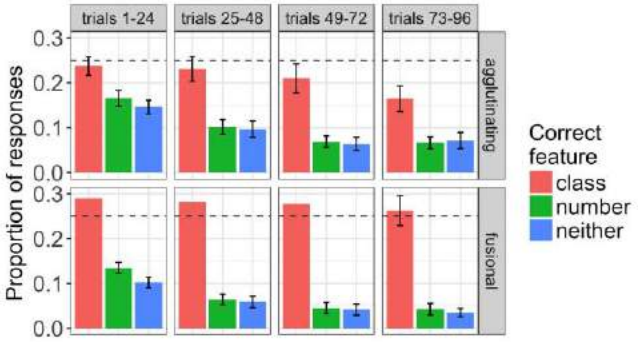

Figure 9: Classification of incorrect choices by correct feature (CLASS correct NUMBER wrong, NUMBER correct CLASS wrong, or neither correct) by trial block by condition in Experiment 3. Trial number is binned for readability. Note that the y-axis range does not display the full range.

We repeated our analysis of error types across conditions (Figure 9). In this case, the model revealed a significant effect of trial (b=0.01, SE=0.004, p=0.03), no significant effect of condition (b=0.29, SE=0.20, p=0.14), and a significant interaction between condition and trial (b=0.02, SE=0.01, p=0.01). Thus, as in Experiment 1, but not 2, participants in the fusional condition were significantly more likely to choose an answer in which only CLASS was correct.

Discussion

It has been claimed that agglutinating systems should be easier to learn because of their inherent transparency: there is a one-to-one mapping between morphemes and meanings in these systems. Here, we directly contrasted a fusional with an agglutinating system, holding the number of morphemes to be learnt constant. We found no clear learnability advantage for agglutinating systems across three experiments. In two of our three experiments, we found a difference in the error patterns between conditions: participants in the fusional condition were more likely to make errors involving NUMBER than CLASS. This error pattern could reflect a bias for

transparency. Participants may have been inferring a single four-way distinction, which was possible for CLASS but not NUMBER. However, this effect was not strong enough to result in an overall advantage for the agglutinating system, and it failed to replicate in one experiment. Our results are surprising, given the general and wide-ranging claims in the literature concerning relative ease of learning of agglutinating systems. It may be that an apparent advantage for agglutinating systems reported in the literature is due to confounding differences between the systems in question. However, below we discuss alternative explanations for our failure to uncover the advantage here.

One possibility is that the paradigms we are testing are too small to result in a discernable difference in learnability. It has been noted that compositionality (and therefore transparency) is increasingly beneficial the larger the paradigm is. This was explored computationally by Brighton (2002), who shows that a compositional system for expressing a few features is hardly more learnable than a holistic system covering the same semantic space; the learnability advantage of compositional systems is maximized when each meaning is composed of many binary features. However, the paradigms we used were intentionally small, consisting of just two features, allowing us to test for a learning advantage arising purely from transparency in the absence of benefits associated with increased generalizability. It is therefore possible that the advantages of agglutinating systems derive purely from the fact that they facilitate more rapid generalization, in which case we would not expect to see that advantage in our paradigm.

Another possibility is that agglutinating systems bear additional costs which have not been much discussed in the literature. One such cost is clearly segmentation. Learners can only profit from compositionality if they are able to segment a word into morphemes, but this process might be costly. To eliminate this issue, we used color highlighting in Experiment 3. However, the null effect of condition on overall accuracy was replicated, suggesting that segmentation alone will not suffice to explain why learners did not have an easier time acquiring the agglutinating system.

Compositional structure typically means more material to process for each word: for example, as is typical cross-linguistically, words were longer in our agglutinating condition than in our fusional condition. It is therefore possible that word length (perhaps combined with segmentation cost) has a detrimental effect on the learnability of the agglutinating system.

Finally, seeing a word and its referent (here, an image) in an agglutinating system does not illustrate the meaning of each individual morpheme. Learners of compositional systems need a set of examples to compare and pin down which morpheme expresses which meaning; learning an agglutinating system therefore potentially poses a cross-situational learning problem (similar to that explored by e.g. Yu & Smith, 2007, where multiple words are simultaneously mapped to multiple referents and the precise word-to-referent mapping can only be disambiguated across trials) that is less pronounced for fusional systems. It is possible that this cost, which is often overlooked, together with the length of words and the small size of the paradigm, did not provide a condition under which an agglutinating system becomes easier to learn than a fusional system.

Conclusion

In this paper, we investigated the frequently-made claim that agglutinating systems are easier to learn than fusional systems due to their inherent transparency. Results from three artificial learning experiments did not show the predicted effect. This held even when a visual cue to segmentation was added to help participants discover morpheme boundaries in the agglutinating condition. While some weak evidence for a possible bias for transparent structures was found in participants' error patterns, this did not lead to an overall difference in learning. We argue that this may be due to the small size of the paradigms, which narrow the extent of the benefit for transparency. Some natural language paradigms are of course larger, and these might provide conditions under which the costs of agglutinating systems outweigh those of fusional systems. Setting aside paradigm size, we also argue that agglutinating systems may present additional costs in processing which have not yet been fully explored.

Abstract

The purpose of these studies was to investigate the role of distributed cognition in defusing the impact of evaluative pressure caused by performance-approach goals on mental arithmetic performance. Performance-approach goals can generate worrying thoughts that can deplete working memory resources. However, some of these working memory limitations can be compensated by off-loading the internal cognitive process to the external environment. We tested this prediction in two experiments. Participants carried out modular arithmetic tasks in a performance-approach goal or mastery-approach goal condition crossed with interactivity or no interactivity. Performance-approach goal manipulation hampered cognitive performance (accuracies), (Experiment 1). However, these negative effects were defused with the help of interactivity (Experiment 2). Interestingly, the mastery-focused individuals had a performance drop in the interactive condition (Experiment 1 and Experiment 2). Finally, experiment 2 reported higher maths anxiety levels for the performance-focused individuals. Reasons for the findings and future implications will be discussed.

Keywords: achievement goals; working memory, mental arithmetic; distributed cognition; interactivity

Introduction

Achievement goals are said to reflect the aim of an individual's achievement pursuits. They are frameworks that can help to understand how individuals react to various achievement situations (Poortvliet & Darnon, 2010). There is a wealth of research on achievement goals and their effects on academic performance. But much less is known about the cognitive processes of these goals and particularly the effects on the working memory and whether distributed cognition could be used to reduce the negative effects of performance goals on academic performance.

Achievement goals

Individuals pursuing performance-approach goals are good at knowing the material that is essential for the task in hand (Elliott, Shell, Henry, & Maier, 2005). They listen to the cues about the future assignments and adjust learning based on these cues. Students perform better when they focus on topics that the teacher deems important and that are tested (Broekkamp, Hout-Wolters, & Van Hout-Wolters, 2007). Performance-focused students concentrate on memorizing rather than elaboration and knowledge construction (Entwistle, 1988). This can lead to surface learning and rote learning (Harackiewicz & Linnenbrink, 2005). Mastery-focused students are freer to pursue their own agenda guided by their own personal interests and curiosity of the current topic. Hence, mastery-approach goals predict the use of adaptive cognitive strategies that lead to deeper processing. This kind of approach might benefit the students in the long run as it promotes deeper learning but might not help in gaining the highest grades as it is based on personal interests rather than the areas that might be tested. When people pursue performance-approach goals, their focus is on the outcome of the task and therefore the individuals might not be fully engaged with the process. On the contrary, mastery-focused individuals focus on the process rather than the activity of outperforming others. Mastery-focused individuals focus on learning and their personal improvement, and therefore have a focus on the task that allows them to explore both intrinsic and utility value (Hulleman, Durik, Schweigert, & Harackiewicz, 2008).

The Effects of Performance-approach Goals on Working Memory

The pressure of outperforming others can generate concerns that deplete available working memory resources. (Crouzevialle & Butera, 2013). When high working memory load tasks were utilized, there was a performance drop in the high evaluative pressure condition (Beilock, Holt, Kulp, & Carr, 2004). Additionally, Avery and Smillie (2013) examined the influence of achievement goal pursuits on working memory capacity when varying levels of executive load were used. Under the high executive load, there was poorer working memory processing during the performance-approach goal than when mastery-approach goal or no-goal control were used (Avery & Smillie, 2013).

Distributed Cognition

Some of the possible working memory limitations can be compensated by off-loading the cognitive process to the

external environment (e.g., by using pen and paper), (Neth & Payne, 2011). According to Kirsh (2010), cognitive processes go to wherever it is easier to perform them. It might be easier to understand a particular sentence by drawing a picture of it rather than just thinking internally. Therefore, with the help of drawing the overall cognitive cost of sense making can be reduced (Kirsh, 2010). Kirsh (1995) conducted a simple coin counting experiment where he observed that complementary strategies could enhance performance (Kirsh, 1995). Neth and Payne (2011) asked participants to add coins on a computer screen in move versus look conditions. Accuracy increased with interactivity but not the speed. Both accuracy and speed were increased with the help of using hands (in the pointing condition) when counting arrays of items (simple arithmetic task), (Carlson, Avraamides, Cary, & Strasberg, 2007). Interactivity enhanced performance, and in particular, accuracy and efficiency for longer sums involving 11 single-digit numbers (Vallée-Tourangeau, 2013). Additionally, interactivity allows the agent to extend their working memory resources when there is a need for it. Dyslexic children (aged between 9 – 11 years) benefited the most form rearranging the letter tiles (interactive condition) in a word production task. By reshaping the physical presentation of the letters, their less efficient working memory capabilities could be compensated. The control group (typically developing children) did not benefit from externalizing the process. In fact, their performance was poorer (with easy set of letters) when they manipulated the letter tiles to produce words (Webb & Vallée-Tourangeau, 2009).

Maths anxiety

Maths anxiety is a multidimensional construct, and a full list of the causes is still undetermined. Maths anxiety can be defined as a feeling of apprehension and tension in a mathematical setting which can also affect overall mathematics performance. The highly maths-anxious individuals avoid mathematics as a topic and choose fewer elective mathematics courses in secondary school and university (Ashcraft, 2002). The maths-anxious individual is pre-occupied with the maths fears and the overall capacity of working memory gets affected. This pre-occupation functions as a secondary task that is heavily working memory resource demanding (Ashcraft & Krause, 2007). Maths anxiety causes a transitory disruption of working memory. The lower working memory capacity of high maths-anxious individuals is partially responsible for the maths performance decrements. This reduced working memory capacity is on-line effect that disrupts information processing in maths tasks (Ashcraft & Kirk, 2001). Finally, maths anxiety is higher among women than men (Ashcraft & Faust, 1994; Luttenberger, Wimmer, & Paechter, 2018). To increase the chances of selecting maths-anxious individuals, we included women only in the sample.

Experiment 1

The aim of the current study was to understand how mastery-approach goal and performance-approach goal engage working memory resources and whether interactivity could be used to reduce any of the negative effects of performance-approach goals on maths performance. If the working memory is loaded due to outcome related worry then there is additional taxation on the working memory (Crouzevialle & Butera, 2013). And together with the horizontally presented maths problems (modular arithmetic tasks) there can be maths performance decrements when in the performance-approach goal condition (Beilock, 2008). We reasoned that, if worries of outperforming others lead to poor maths performance, then giving students the opportunity to externalize the internal cognitive process would enhance this performance.

Method

Participants

Forty-one female undergraduate psychology students (M = 21.88 SD = 3.90) participated in this study for exchange of credits. After consenting to participate in the study, subjects were randomly assigned to one of the experimental conditions (performance-approach goal or mastery-approach goal crossed with interactivity or no interactivity). The participants were tested individually (15 minutes) in a psychology lab.

Material and Measures

Arithmetic task There were two blocks of 24 modular arithmetic tasks that relied heavily on working memory resources, adapted from Beilock and Carr (2005). The purpose of the tasks is to judge the validity of maths problems like $61 \equiv 18 \pmod 4$. The middle number is subtracted from the first number (i.e. 61-18) and then the difference is divided by 4. If the answer is a whole number the maths problem is true (Beilock & Carr, 2005). Modular arithmetic tasks as laboratory tasks are advantageous as most students have not seen them before and therefore previous task experience is controlled.

High-demand problems (e.g. $42 \equiv 27 \pmod 3$) requiring a double-digit subtraction operation were used as they required borrowing, resulting in using more working memory resources. Half of the maths problems required a true response by the participant. The order of the questions was randomized and each question was asked only once. The original questions used by Beilock and Carr (2005) were a mixture of high demand problems (two-digit numbers requiring borrowing) and low-load questions (single-digit numbers, without borrowing). The current study used the high-demand problems only because of limited benefits of using interactivity with low-demand tasks.

The modular arithmetic tasks were presented in a horizontal format as opposed to a vertical format (also called column subtraction). The horizontal presentation of the maths problems is more reliant on phonological resources (the verbal resources) because individuals maintain the required problem steps in their memory verbally (DeStefano & LeFevre, 2004). The possible worries of performing better than others places much heavier demands on working memory (phonological loop, in particular).

Experimental manipulations Participants were informed after completing the baseline block of modular arithmetic tasks (24) that they required to complete a second block (24) of modular arithmetic tasks, and this time their performance would be recorded. The participants in the performance-approach goal condition read the following instructions before starting the task that were aimed at activating performance-approach goals (Darnon, Harackiewicz, Butera, Mugny, & Quiamzade, 2007):

"During the recorded part of the task, the experimenters will assess your performance. It is important for you to be proficient, to perform well and obtain a high score, in order to demonstrate your competence. You should know that a lot of students will do this task. You are asked to keep in mind that you should try to distinguish yourself positively, that is, to perform better than majority of students. In other words, what we ask you here is to show your competencies, your abilities."

The participants in the mastery-approach goal condition read instructions that were designed to activate mastery-approach goals. There is no social comparison being made and the instructions are aimed to create task interest, use for everyday life, and there is no mention about scores or task performance (Crouzevialle, Smeding, & Butera, 2015).

"In previous research, we have observed that practice of the arithmetic task you are solving right now benefits to cognitive functioning and leads to a progressive improvement of mental processes. Hence, this task solving can proved to be beneficial on the long-term. It is however necessary that you focus your attention on calculation mastery, so as to quickly and accurately solve each problem, in order to experience these benefits. Try to master this task as much as you can; keep in mind its practice can be beneficial to you."

Interactivity The participants in the interactive condition were allowed to use pen and paper. The participants in the non-interactive condition were not allowed to use any external artefacts to complete the task.

Procedure

After consenting to participate in the study, the participants were randomly assigned to one of the experimental conditions. There was a short training session before starting the first block. The first block of questions (24) functioned as a base-line. The participants were told that it was a training block, and that their performance was not recorded to avoid any achievement goal activation. The second block of questions was done under the experimental conditions. The participants were told that their performance was recorded this time.

Results

Accuracy

Before the actual statistical analysis was conducted, it was concluded that there were no group differences between the participants in the mastery-approach goal condition and performance-approach goal condition on the baseline modular arithmetic performance (block 1), $F(1, 37) = .08$, $p = .78$, $\eta_p^2 = .002$, confirming that the groups did not differ in their ability to complete the modular arithmetic tasks. Our main performance measure was accuracy of the high working memory load tasks. Accuracy difference score was calculated by subtracting the modular arithmetic performance of block 1 from block 2. Furthermore, a difference score in latencies was used as a covariate in order to avoid any speed-accuracy trade-off of the participants. A 2 (instruction: performance-approach goal or mastery-approach goal) x 2 (level of interactivity: interactivity or control) between-groups analysis of covariance (ANCOVA) was conducted. The covariate, difference score in latencies, was significantly related to the modular arithmetic accuracy, $F(1, 36) = 5.76$, $p = .02$, $\eta_p^2 = .14$. There was a significant two-way interaction of interactivity (interactivity or control) and instruction (performance-approach goal or mastery-approach goal), $F(1, 36) = 4.39$, $p = .043$, $\eta_p^2 = .11$. As expected, performance-focused participants had lower maths performance in the non-interactive condition ($M = -7.43$, $SE = 2.50$) than the mastery-approach goal individuals ($M = 5.44$, $SE = 2.38$), (Figure 1). The post hoc tests confirmed this finding, $F(1, 18) = 11.1$, $p = .004$, $\eta_p^2 = .38$. However, mastery-focused individuals had a performance drop in the interactive condition ($M = -2.37$, $SE = 2.50$) compared with their performance in the non-interactive condition ($M = 5.44$, $SE = 2.38$), (Figure 1). Post hoc tests confirmed this finding, $F(1, 18) = 4.90$, $p = .04$, $\eta_p^2 = .21$. Additionally, there was a main effect of instruction (mastery-approach goal or performance-approach goal), $F(1, 36) = 9.72$, $p = .004$, $\eta_p^2 = .21$. The modular arithmetic performance of the mastery-approach goal participants was enhanced from block 1 to block 2 ($M = 1.53$, $SE = 1.72$). As predicted, there was reduced modular arithmetic performance of the performance-approach goal participants ($M = -6.16$, $SE = 1.76$). Finally, interactivity did not improve modular arithmetic performance, $F(1, 36) = 1.13$, $p = .30$, $\eta_p^2 = .03$.

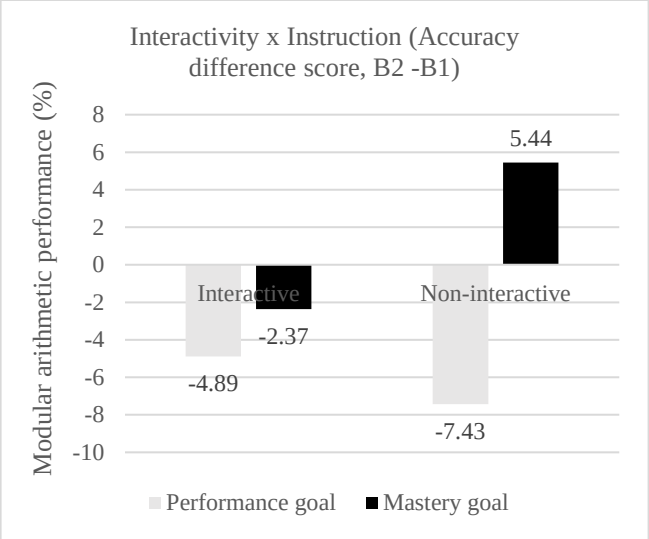

Figure 1: Mean difference in modular arithmetic performance (%) as a function of experimental condition (Experiment 1).

Discussion

We found that when the performance-approach goal was made salient, there was a drop in the mental arithmetic performance compared with the mastery-approach goal participants. Additionally, an interesting finding was made in relation to mastery-focused individuals, their modular arithmetic performance was reduced when the participants were allowed to interact with external resources (with the use of pen and paper).

Experiment 2

It was clear from Experiment 1 that the mental arithmetic performance of the performance-focused participants was depleted compared to the mastery-goal individuals. We therefore argued that it would be the performance-focused individuals that would show higher levels of maths anxiety due to the worrying thoughts of outperforming others, in a mathematical domain. Experiment 2 therefore measures maths anxiety of the participants both before the experiment (trait maths anxiety) and after (state maths anxiety). If maths anxiety is elevated when performance-approach goal is made salient then there should be more benefits of externalizing the internal cognitive process to the outside world (interactivity) for the performance-focused individual.

Method

Participants

Seventy-eight female undergraduate psychology students (*M* = 19.12, *SD* = 1.60) participated in this study for exchange of credits. This study only included females due to their higher levels of maths anxiety. After consenting to participate in the study, the participants were randomly assigned to one of the experimental conditions. The participants were tested individually in a psychology lab (40 minutes).

Material and Measures

Mathematics anxiety (trait) Maths anxiety was measured with the 23-item Mathematics Anxiety Scale (MAS-UK) by Hunt, Clark-Carter, and Sheffield (2011). The test comprises statements that relate to everyday situations that have a mathematics component (e.g., adding up a pile of change). The participants are expected to respond by confirming the level of anxiety that they feel on a 5-point Likert-type scale.
Basic arithmetic skills Basic arithmetic skill (BAS) was measured with the help of 45 simple expressions in a 60-second period (e.g. 10-5).
Computation span (Working memory) Working memory capacity was measured with the help of a computation-based span test. The participants were asked to read a simple arithmetic expression (e.g. 5 + **2** = ?, 9 – **6** = ?) and announce their answer aloud to the researcher (7, 3). Additionally, the participants were asked to remember the second number of each equation to be recalled later (**2**, **6**). The sequences of the simple arithmetic tasks varied from 1 to 7 tasks. The computation span task requires both on-line processing for the problem solution which is simultaneous with storage and maintenance of information in working memory for serial recall. People with maths anxiety have smaller working memory spans. This smaller span can lead to increased reaction times and errors when mental mathematics is completed at the same time as a memory load task (Ashcraft & Kirk, 2001)**.**
Arithmetic task The mental arithmetic task consisted of modular arithmetic tasks (two blocks of 24 questions) that relied heavily on working memory resources, adapted from Beilock and Carr (2005). The arithmetic task was identical to Experiment 1.
Mathematics anxiety (state) Maths anxiety was measured with the 23-item Mathematics Anxiety Scale (MAS-UK) by Hunt, Clark-Carter, and Sheffield (2011). This test was the same as the trait measurement used earlier during the experiment but this time referring to present time (now).
Experimental manipulations Participants were informed that after completing the baseline block of modular arithmetic tasks (24) that they required to complete a second block (24) of modular arithmetic tasks, and this time their performance would be recorded. The actual priming instructions were identical with the experiment 1.
Interactivity As before the participants in the interactive condition were allowed to use pen and paper to come to the solution. The participants in the non-interactive condition were not allowed to use any external artefacts.

Procedure

After consenting to participate in the current study, the participants started with the trait maths anxiety questionnaire. This was then followed by the timed basic arithmetic skills

test. Before commencing with the modular arithmetic tasks in primed conditions, computation span (working memory capacity) was assessed. There was a short training session (2 questions) before starting the first block of the modular arithmetic problems (24). Only high-demand problems requiring a double-digit subtraction operation (e.g. 42 ≡ 27 (mod 3)) were used as they required more of the working memory resources compared to low-demand problems (single-digit operation, and no carrying required) (Ashcraft & Kirk, 2001). After the baseline the participants were primed to either performance-approach goal condition or mastery-approach goal condition. If in the interactive condition, the use of pen and paper was allowed. After completing the second block of arithmetic tasks in primed conditions, the participants were asked to complete the state maths anxiety questionnaire.

Results

Accuracy

There were no group differences between the participants in the two achievement goal groups on the baseline modular arithmetic performance (block 1), $F(1, 74) = 1.77$, $p = .19$, $\eta_p^2 = .02$, confirming that the groups did not differ in their ability to complete the modular arithmetic tasks. Additionally, there were no group differences in working memory capacity, $F(1, 74) = 1.17$, $p = .28$, $\eta_p^2 = .02$, confirming the fact that the two achievement goal groups did not differ in their level of working memory capacity as a baseline measure. To test the hypotheses, accuracy difference in percentage score (block 2 - block 1) of the modular arithmetic tasks was examined. A 2 (level of interactivity: interactivity or control) x 2 (instruction: performance-approach goal or mastery-approach goal) between-groups analysis of covariance (ANCOVA) was conducted. There was a significant two-way interaction of interactivity (interactivity or control) and instruction (mastery-approach goal or performance-approach goal) after controlling for a difference score in latencies, $F(1, 73) = 10.04$, $p = .002$, $\eta_p^2 = .12$. The performance-focused participants benefited from the use of interactivity ($M = 3.70$, $SE = 1.80$) unlike the mastery-focused individuals whose performance was depleted with interactivity ($M = -3.30$, $SE = 1.90$), (Figure 2). The post-hoc test confirmed this finding, $F(1, 36) = 10.67$, $p = .002$, $\eta_p^2 = .23$. The accuracy of the mastery-approach goal participants was reduced in the interactive condition ($M = -3.30$, $SE = 1.90$) compared with the non-interactive condition ($M = 5.40$, $SE = 1.80$) (Figure 2). This finding was confirmed with a post-hoc test, $F(1, 36) = 6.82$, $p = .01$, $\eta_p^2 = .16$. The two main effects (interactivity or instruction) did not reach statistical significance. There was no significant difference in accuracy between the participants in the interactive condition and the participants in the non-interactive condition, $F(1, 73) = 2.35$, $p = .13$, $\eta_p^2 = .03$. Additionally, the main effect of instruction (mastery-approach goal or performance-approach goal) did not reach statistical significance ($F < 1$).

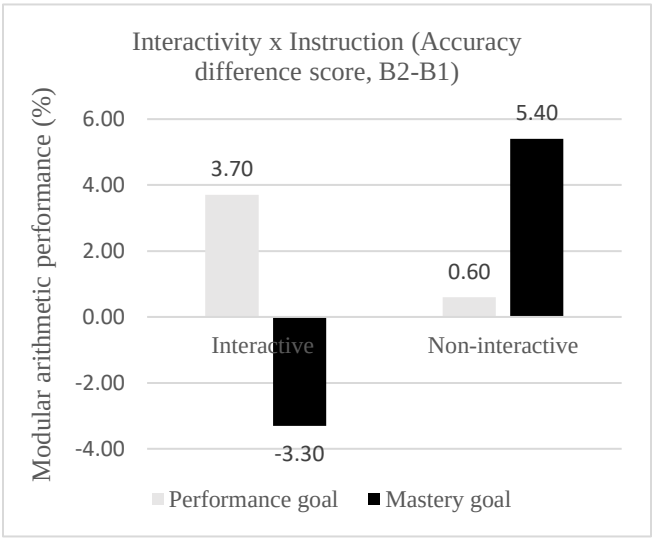

Figure 2: Mean difference in modular arithmetic performance (%) as a function of experimental condition (Experiment 2).

Maths anxiety (state)

A two-way between groups analysis of covariance (ANCOVA) was conducted to compare the effects of interactivity on two levels of instructions that were given to the participants (mastery-approach goals or performance-approach goals) when completing the modular arithmetic tasks. Participants' scores on maths anxiety (trait) were used as the covariate in this analysis. After adjusting for pre-existing maths anxiety levels (trait maths anxiety), there was a significant main effect of instruction (mastery-approach goal or performance-approach goal) on state maths anxiety, $F(1, 73) = 6.07$, $p = .02$, $\eta_p^2 = .08$. The performance-focused individuals showed higher levels of maths anxiety after completing the experiment in primed conditions ($M = 56.0$, $SE = 1.98$) than the mastery goal participants ($M = 49.1$, $SE = 1.98$) confirming the hypothesis set in the beginning. The main effect of interactivity did not reach statistical significance, $F < 1$, as did not the two-way interaction of instruction and interactivity either.

General discussion

The purpose of this study was to see whether the adverse effects of performance-approach goals on mental arithmetic performance could be alleviated with the use of distributed cognition. This investigation reported a performance drop in mental arithmetic performance for the performance-focused individuals in the non-interactive condition compared with the mastery-approach goal individuals (Experiment 1). However, interactivity mitigated the negative effects of performance-approach goal instructions on maths performance (Experiment 2). Additionally, we found that performance-focused participants felt higher levels of state maths anxiety, after completing the maths tasks (Experiment

2). Clearly, the priming instructions of performance-approach goals had strong carry-on effects on maths anxiety as they were still felt after completing the mental arithmetic tasks. However, it was evident that there were no carry-on effects of interactivity at the end of the experiment. An interesting finding was made as there was reduced maths performance for the mastery-focused individual in the interactive condition (Experiment 1 and Experiment 2). It was clear that distributed cognition hindered maths performance for the mastery-focused individual who was less maths anxious after the experiment but allowed the more maths-anxious individual (the participants in the performance-approach goal) to improve mental arithmetic performance. Similar findings have been made by Webb and Vallée-Tourangeau (2009) who concluded that when the agent had the required cognitive resources to complete the word production task, interactivity hampered the performance. If working memory resources are not compromised from increased maths anxiety levels (like in the mastery-approach goal environment), then there are little benefits of externalising the internal cognitive process to the outside world.

Conclusion

To allow for a successful distributed cognition outcome it is of importance to understand how individuals are affected by the different achievement goals. Clearly, the effective manipulation of the physical problem space is relative to the level of the task difficulty (e.g., modular arithmetic tasks) as well as the cognitive abilities (working memory resources in particular) of the individual. Finally, it is important to consider the implications of these studies on a practical level. Future mathematics education should take into consideration the findings of these two experiments in a way to make the learning experience more interactive for the more maths-anxious individuals (performance-focused individuals). The maths-anxious individual should be given the opportunity to reshape the presentation of the mathematical problems to extend their cognitive systems. By doing this, the working memory capacity can be augmented and as a consequence, the maths performance enhanced.

Active information seeking using the Approximate Number System

Jinjing (Jenny) Wang (jinjing.jenny.wang@gmail.com)

Elizabeth Bonawitz (lbaraff@gmail.com)

Department of Psychology, Rutgers University, Newark, NJ 07102

Abstract

Human adults share the ability to approximate large quantities without counting with newborn infants and non-human species. This ability is supported by the Approximate Number System (ANS) - a primitive and domain-specific cognitive system that supports noisy numerical decisions. How does the ANS support active exploratory decisions? Using a numerical comparison task, we found that the amount of active information seeking does not simply increase as the decision becomes more difficult. Instead, there seems to be an inverted U-shaped relationship between trial difficulty and how much one chooses to seek information. Additionally, this effect is not modulated by participants' performance, suggesting that participants' exploratory decisions based on ANS representations are driven by the utility of information seeking actions.

Keywords: Information Seeking; Active Learning; Approximate Number System; Decision Making

Introduction

How the mind processes sensory data and interprets the physical world is the hallmark question in cognitive science. However, the data we receive from the physical world is not readily interpretable. Rather than passively absorb all the information that is available, humans and animals actively explore and selectively attend to aspects of the world (Gottlieb, Oudeyer, Lopes, & Baranes, 2013). This kind of active exploration and selective attention is essential to effective learning and proper cognitive functioning. What determines when we want to explore and to what we choose to attend?

It has been widely demonstrated that observers, humans and animals alike, are drawn to novel and surprising events, which is often explained by a motivation to decrease errors in prediction (Loewenstein, 1994; Schultz & Dickinson, 2000). According to Loewenstein, an observer's desire to learn about a specific topic is driven by a discrepancy between the observer's existing knowledge and what they would like to know. Consistent with this account, infants as young as 10 months old can form expectations about object behavior, and explore more when these expectations are violated (Stahl & Feigenson, 2015). Relatedly, school-age and preschool children prefer to play with toys whose functionality are ambiguous or unexpected (Bonawitz, van Schijndel, Friel, & Schulz, 2012; Schulz & Bonawitz, 2007). This kind of prediction errors cannot only be mathematically defined, but has also been decoded from neuronal activities (Bromberg-Martin & Hikosaka, 2011).

In addition to novelty and surprise, humans and animals are also drawn to more complex stimuli or more difficult situations (Berlyne, 1966). For example, when confined in a minimally-stimulated space, adults prefer to produce light patterns that are the most diverse and unpredictable (Jones, Wilkinson, Braden, 1961). In another experiment, when probed about their curiosity about facts related to different animal species, adult participants were more curious about facts that they knew less about (Berlyne, 1954). These phenomena, that exploration is driven by novelty, surprise, and complexity, are consistent with the information processing account that defines information gain by uncertainty (Berlyne, 1960).

However, this tendency to be drawn to situations with maximum uncertainty (and to reduce it through learning actions) seems counterproductive in many cases. In particular, when the gap between one's current epistemic state and the information provided by the environment is too big, actions of learning and exploration can yield little benefit. For example, no matter how much effort a reader puts into staring at some foreign words without knowing the language or having access to a dictionary, the reader would still have no clue what the words mean.

Instead of linearly increasing exploratory actions as uncertainty increases, numerous studies have demonstrated a trade-off between the cost and benefit of information seeking actions (Coenen, Nelson, & Gureckis, 2018). When reading and rating contentful questions, such as "what instrument was invented to sound like human singing," adult participants' rated level of curiosity was the highest for questions that they had intermediate levels of confidence, and their level of curiosity was the lowest for questions in which they either had extremely low confidence or extremely high confidence (Kang et al., 2009). In a different exploratory situation, where each task option was initially hidden from participants, participants' exploratory decisions also followed a similar U-shaped pattern - they explored the most when the task was moderately difficulty, and explored less when the task was either too easy or too hard (Baranes, Oudeyer, & Gottlieb, 2014).

Consistent with these results, the field of developmental robotics suggests that exploration is based on dynamic changes in the rate of learning (Gottlieb, Oudeyer, Lopes, & Baranes, 2013; Oudeyer, Kaplan, & Hafner, 2007). Robots with this rate-based learning system can efficiently learn

skills in high dimensions without being distracted by activities that are either well learnt or unlearnable (Baranes & Oudeyer, 2013; Pape et al., 2012). Exploration increases as the rate of information increases. In cases when there is very low certainty (or high uncertainty), any particular action may produce new information, but if the problem space is complex enough, then additional information may not produce significant shifts in belief weights -- thus highly complex environments may not produce information that supports learning rates. Instead, learning rate may be highest in the Goldilock's spot (Kidd, Piantadosi, & Aslin, 2012), in which any particular action produces information to support a steeper learning rate. This predicts that, rather than a direct linear relationship, exploration should be lowest at both extremely low and extremely high levels of uncertainty, and exploration should be the highest at an intermediate levels, where information has the highest rate of return.

Results from infants' preference for object complexity are consistent with this account. Seven- and 8-month-old infants' probability of looking at an event was the lowest when looking at either highly predictable or highly surprising content (Kidd, Piantadosi, & Aslin, 2012; 2014; Piantadosi, Kidd, & Aslin, 2014; see also Pelz & Kidd, *in prep*). These results suggest that infants are able to direct their attention to maintain an intermediate rate of information absorption. It is possible that this kind of attentional mechanism is in place to prevent infants, who arguably have the most to learn and the least resources, from wasting cognitive resources on either overly predictable or overly unpredictable information.

One open question is whether adults reveal such trade-offs in active exploratory decision making situations. It is possible that this kind of balance between cognitive resource and exploration is unique to childhood. Another open question is whether such trade-offs are unique to novel learning environments or tasks that require higher-level conceptual reasoning, such as deciding what questions to ask or which route to take in a novel environment. When performing familiar activities using acquired skills, one may not need to adjust exploration based on uncertainty. Alternatively, the expected information gain from exploratory actions may explain information seeking behavior beyond these contexts.

To address these questions, the current study uses adults' exploratory decisions using a primitive cognitive system as a case study to test the relationship between problem difficulty and adults' exploratory decisions. Upon seeing 20 dots and 10 dots, without counting, we can immediately tell which array has more dots. This ability to automatically and effortlessly discriminate large numerosities is supported by the Approximate Number System (ANS; Dehaene, 1997), which produces noisy and ratio-dependent representations in human adults (Halberda, Ly, Wilmer, Naiman, & Germine, 2012), newborn infants (Izard, Sann, Spelke, & Streri, 2009), as well as non-human species (Cantlon, Platt, & Brannon, 2009; Dehaene, Dehaene-Lambertz, & Cohen, 1998). With ANS representations, discriminating 20 dots from 10 is just as easy as discriminating 40 from 20 (a ratio of 2), but both are easier than discriminating 15 from 10 (a ratio of 1.5). The discriminability of numerosities is determined by the numerical ratio, instead of set size, non-numerical dimensions (such as size of individual dots). In other words, the Approximate Number System strictly obeys Weber's Law (Dehaene, 2003). This well-established law allows us clean control over the difficulty and uncertainty of the trials - the less discriminable the trials (the closer the ratio), the more uncertainty. Additionally, infants and adults are able to maintain multiple numerical representations at once (Feigenson, 2008; Zosh, Halberda, & Feigenson, 2011).

This intuitive and automatic cognitive system provides a case study for testing the scope of the expected information gain account - whether adults' decision making using the intuitive and automatic numerical representations also demonstrate a cost and benefit trade-off of information seeking actions. It has been recently suggested that adults and children are sensitive to their internal confidence in numerical decisions (Baer, Gill, & Odic, 2018; Halberda & Odic, 2015), and numerical precision can be influenced by the order of trial difficulty (Odic, Hock, & Halberda, 2014; Wang, Libertus, & Feigenson, 2018; Wang, Odic, Halberda, & Feigenson, 2016). It is possible that this sensitivity to internal confidence or uncertainty drives adults' exploratory decisions in a way that balances the cost and benefit of information seeking actions. On the other hand, neuroimaging studies revealed that the encoding of ANS signals are extremely rapid - as fast as 180ms in the bilateral occipital-parietal sites (Hyde & Spelke, 2009; Park, DeWind, Wordoff, & Brannon, 2015). It is possible that this automatic encoding of numerical information leaves little room for improvement from exploratory actions, and hence adults may show no cost-benefit tradeoff in their exploratory decisions in a numerical task.

To test this, we designed a nonverbal numerical comparison task with four alternative forced choices. This design ensures that the numerical representations can be maintained in adults' working memory (i.e., about four items; Epelboim & Suppes, 2001; Luck & Vogel, 1997). On the other hand, a four-alternative-forced-choice paradigm lowers the chance level to 25%, which increases the performance gap between random guessing and effortful performance by 25% compared to two-alternative-forced choice tasks (which has a 50% chance level), potentially providing more utility for information seeking actions.

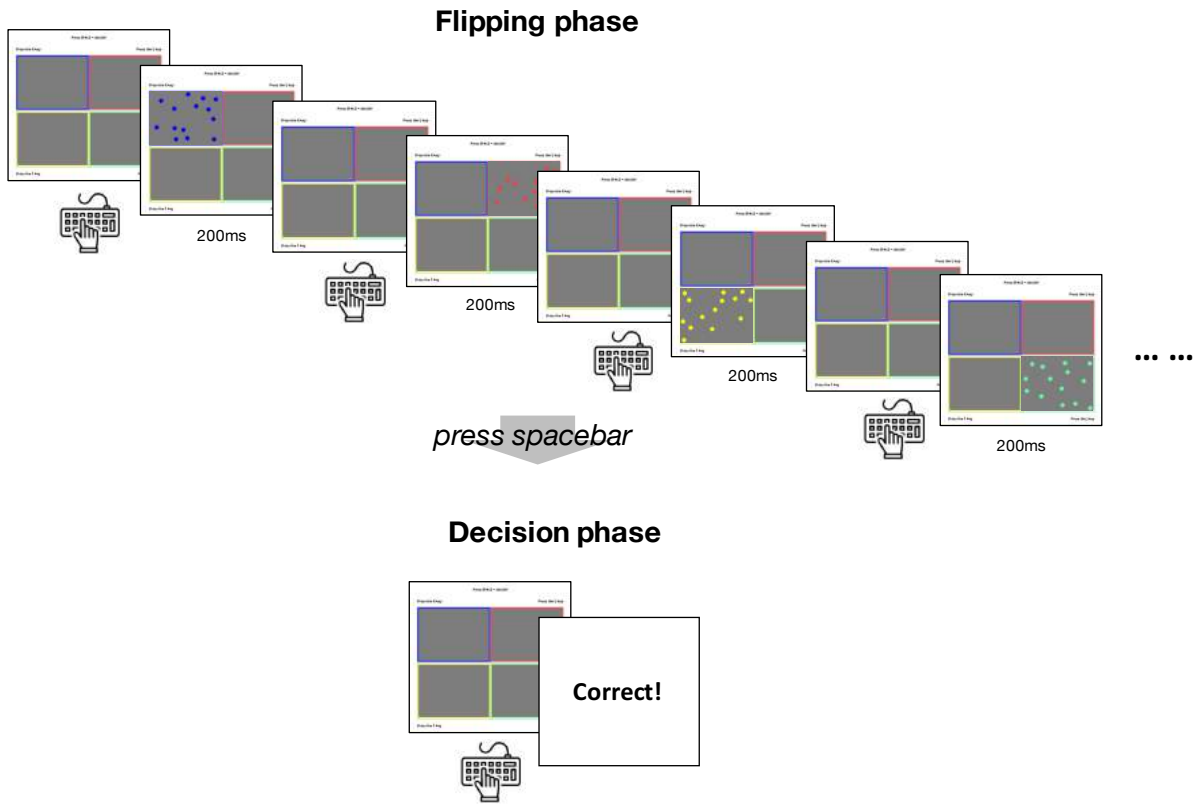

Figure 1: Schematic of the experimental procedure.

To further reduce random guessing, we also offered participants a small reward bonus depending on their performance. Participants can choose to see any one of four large arrays of dots, each for only 200ms which is too brief a window to count the dots. The key difference from traditional numerical comparison tasks is that participants are given the option to re-explore each array as many times as they would like before deciding the largest array. Participants then decide when they are ready to choose the array with the largest numerosity. Numerical comparison tasks allow us to systematically quantify and vary uncertainty and the difficulty of the task by changing the ratio between the numerosities.

If exploration is driven by the utility of information seeking actions, we would expect to see an inverted U-shaped relation between trial difficulty and the amount of exploratory actions. Alternatively, if exploration is driven by performance or error rate, then we should expect participants to explore most in trials in which the difficulty of the trials is the highest. Such an account would reveal information seeking to be linearly related to trial difficulty. Finally, if adults are not sensitive to the uncertainty of the trials, then exploration should not vary with the complexity of the trials.

Method

Participants Forty-two adults were recruited online through Amazon Mechanical Turk.

Stimuli Stimuli consisted of series of arrays containing collections of blue, red, yellow, and cyan dots on a grey background. During all the trials, three of the four arrays always contained the same number of dots (in different layout and configuration), and the fourth array differed from the remaining three with variable ratios. Difficulty was manipulated by changing the ratio between the largest number and the remaining number. Ratios varied between 1 (i.e., all four arrays were the same; the correct answer was pre-determined and randomly generated) and 2 (i.e., the larger number was twofold the smaller number), with at least 6 trials of each ratio. There were a total of 128 trials a participant could possibly complete.

Procedure After reading the instructions, each participant received an untimed practice session with eight practice trials. Participants then completed a timed test session where they had five minutes to complete as many trials correctly as possible. Participants were compensated based on how many trials they answered correctly during the test trials. Each trial started with four empty boxes outlined with distinct colors and paired with a reminding message about which key to press to "flip" the box and reveal the dots.

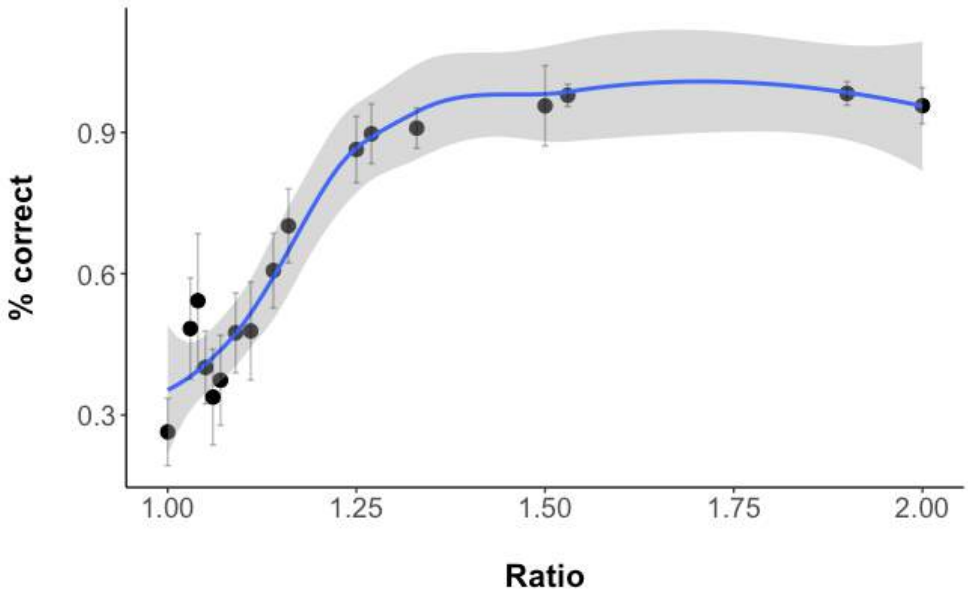

Figure 2: Average accuracy as a function of ratio (larger/ smaller). Error bars represent confidence interval of the mean.

After each keypress, dots appear for 200ms in the chosen box. For example, pressing the "R" key showed blue dots in the blue box, and pressing "U" showed red dots in the red box (Figure 1). During the flipping phase, the participant could press the spacebar to indicate that they were ready to move onto the decision phase at any point. Once the participant had moved to the decision phase, they were prompted to press a key to indicate which box contained the most dots. Feedback was provided after each trial. Participants on average completed 37.67 test trials (SD = 21.80).

Results

We first examined participants' accuracy in the decision phase. On average, participants performed correctly 62% of the time, well above chance (25%; binomial exact test $p < .001$).

We then averaged each participants' performance for each ratio to analyze the effect of ratio on accuracy. If participants used the ANS to solve the task, their performance should show the ratio-dependent signature of the ANS. Alternatively, it is possible that participants were able to count or maintain more precise representation of the numerical arrays after seeing them multiple times. As shown in Figure 2, participants' accuracy increases significantly as the ratio becomes easier. A log-linear regression model predicting accuracy using ratio explains over 72% of the variance, *beta* = .86, t = 6.54, $p < .001$, suggesting that participants primarily relied on ANS representations in the current numerical comparison task, even when they could receive additional information about the numerical stimuli. Consistent with previous research on adults' ANS precision, participants' accuracy on the task plateaued at about 1.5 ratio (Halberda & Feigenson, 2008).

The central question of the current study is how the difficulty of numerical decisions impacts people's information seeking. To test this, we examined the relationship between ratio and the number of boxes participants flipped before the decision phase.

.

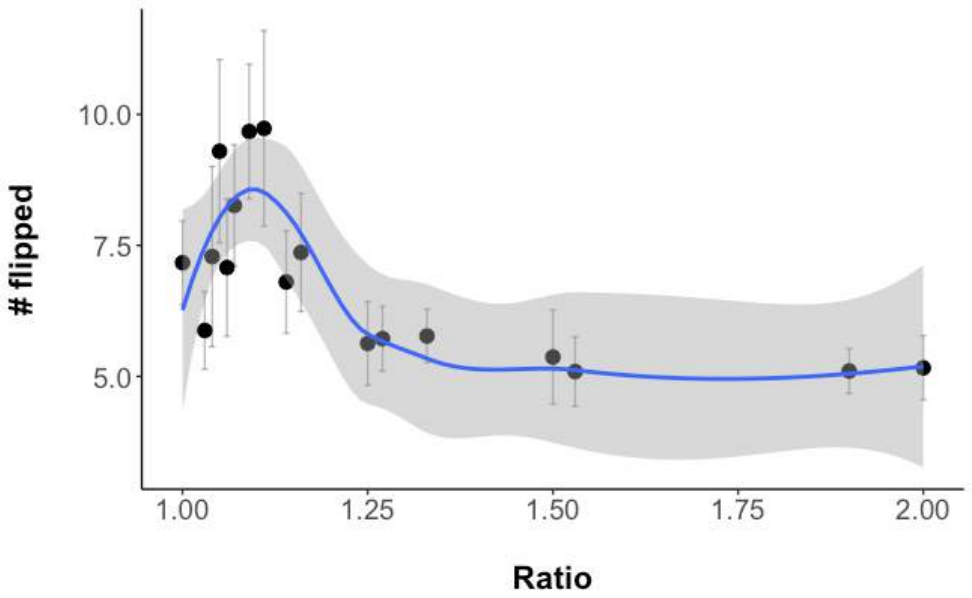

Figure 3: Average number of boxes flipped before decision as a function of ratio (larger/ smaller). Error bars represent confidence interval of the mean.

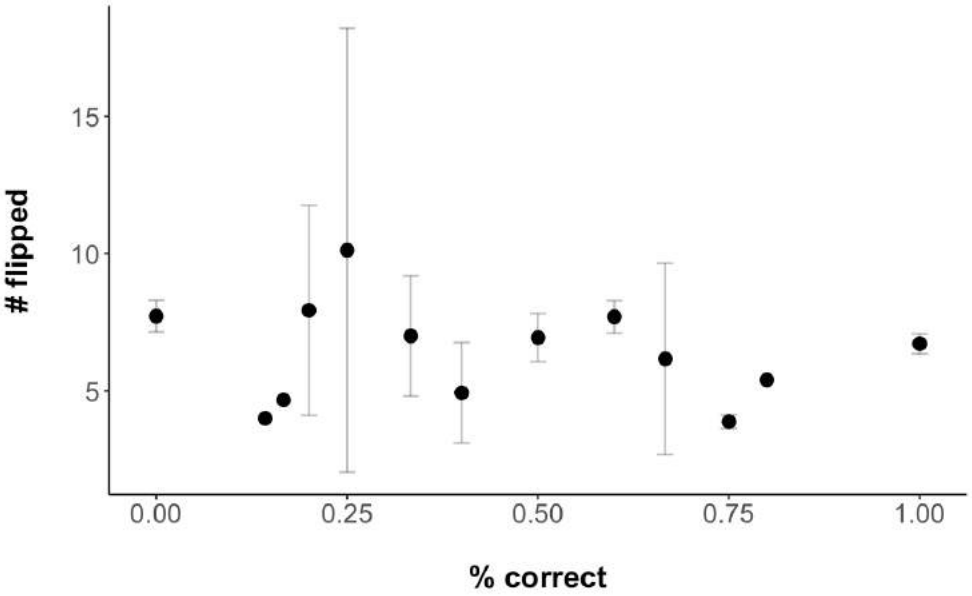

Figure 4: Average number of boxes flipped before decision as a function of accuracy. Error bars represent confidence interval of the mean.

As shown in Figure 3, overall, participants sought more additional information when the trials were more difficult. However, instead of a simple linear increase in number of flips as the ratio decreases, there is an inverted U-shaped relationship between ratio and flips when the ratio was between 1 and 1.25. Indeed, it is precisely in this range that participants steeply shift from near chance performance to near ceiling performance. This supports the claim that exploration is driven by expected information gain.

To test for a quadratic trend of ratio on number of flips, or an inverted U-shaped relationship between exploration and numerical ratio, we ran a model using both linear and quadratic ratio terms. This revealed a significant effect for both ratio (*beta* = -1.08, t = -3.49, p < .001) and ratio-squared (*beta* = .91, t = 2.91, p = .004). However, we found no relationship between average accuracy and the number of boxes flipped before decision (Figure 4). This

suggests that, rather than perceived performance or general motivation, participants' expected information gain drives their information seeking.

Conclusions

The current study investigated the relationship between the difficulty of numerical decisions and exploratory decisions. We found that adults' active search for additional information was the highest for trials with intermediate difficulty, and the lowest when the trials were either too easy or impossibly hard. Moreover, exploration has no clear relationship with numerical performance. These results suggest that numerical difficulty drives adults' exploratory decisions, showing a trade-off between cost of exploratory action and expected benefit from exploration.

Previous research has shown that infants seem to prefer an intermediate flow of information when exploring the environment (Kidd et al., 2012), and adults in novel or complex exploratory tasks explore the most when the task is at intermediate level of uncertainty (Kang et al., 2009; Baranes et al., 2014). These results have been taken to suggest that in learning and exploration, the observer have a tendency to optimize the cost of action and the gained information (Coenen et al., 2018). The current results extends this literature by suggesting that adults remain motivated to show such trade-off in their exploratory decisions even when using the primitive Approximate Number representations that have been active since infancy.

These results are consistent with both the idea that adults can balance the cost and benefit of exploratory actions, and that the rate of information gain drives exploratory behavior adults' numerical decision making. One possibility is that adults were making immediate decisions about whether to explore more solely based on the difficulty of each trial. Alternatively, it is possible that adults were dynamically adapting their exploratory decisions based on observed performance change, or their observed rate of learning, from previous explorations. Future research exploring the benefit of the exploratory actions, such as performance change with and without exploration, will help clarify the mechanisms by which adults make their exploratory decisions.

Where does this ability to dynamically adapt exploration to our own uncertainty come from? The similar U-shaped pattern in infants' attention suggests that infants are able to respond to probabilistic uncertainty in the environment (e.g. Kidd et al., 2012). However, it is possible that the ability to monitor the uncertainty in one's cognitive representations, such as numerical precision, may require more advanced metacognitive skills. Alternatively, infants may already come equipped with implicit representations of their uncertainty in numerical decisions. Recent work suggests that infants as young as 6 months old perform differently in a numerical change detection task as as the order of trial difficulty changes (Wang, Libertus, & Feigenson, 2018). It remains to be tested whether infants can adapt their exploratory behavior when using Approximate Number representations, and whether their exploration has the same kind of relationship with trial difficulty.

Another important question raised by the current study is whether active information seeking boosts numerical precision. In general, we found no relationship between overall accuracy and information seeking. It is possible that seeing the dot arrays more does not actually significantly impact people's accuracy at making numerical decisions. On the other hand, it remains possible that more complex interactions exist between information seeking and numerical precision. Future work examining the difference between people's numerical accuracy with and without information seeking will help test these possibilities.

Abstract

We present a novel statistical analysis of color categorization using a standard method from semantic typology. Our approach shows that crosslinguistic color naming data exhibits latent dimensions whose order of relative importance matches the evolutionary ordering of emergence of those distinctions. Moreover, we show that the importance ordering of these dimensions holds even when controlling for frequency of the distinctions by looking at languages within each stage of evolution. Additionally, we find that the extreme points of the latent color dimensions correspond well to a small set of "universal" focal colors. Thus we show that a simple mathematical method simultaneously derives a consistent match both to the evolutionary stages and to the universal foci.

Keywords: semantic universals; color naming; color evolution.

Introduction

Much work in cognitive science seeks to uncover the basis of human categorization of the world. Semantic typology in particular aims to discover crosslinguistic constraints and tendencies in the ways that lexical semantic systems parcel concepts into named categories. Research across a number of diverse domains – from color to spatial relations to cutting and breaking events (e.g., Berlin & Kay, 1969; Levinson et al., 2003; Majid et al., 2008) – have revealed seemingly universal dimensions that underlie the organization of such lexical categories. For example, there is substantial evidence that color lexicons are organized around a universal set of basic color categories, whose best exemplars – *focal colors*, or *foci* – are clustered within small areas of the perceptual color space (e.g., Berlin & Kay, 1969; Regier et al., 2005; though see, e.g., Roberson et al., 2000, for an alternative view).

The domain of color has been particularly fruitful in revealing such crosslinguistic commonalities. Indeed, research on color is unusual (if not unique) in semantic typology in having revealed another kind of universal as well – that of evolutionary stages of a domain-specific lexicon. Berlin & Kay (1969) proposed that, as the number of basic color terms increase in a language, the named color distinctions emerge in one of a small set of constrained orders; for example, separate terms for yellow and red appear in a language before green is split off from blue. This line of work has been extended to cover a broad range of data from many languages, and the specific proposal refined and adapted. While some counterexamples have been identified, and it has been recognized that some languages do not exhaustively partition the color spectrum, most extant languages largely follow a successive partitioning of the color space according to universal principles (see Kay et al., 2009, for a review).

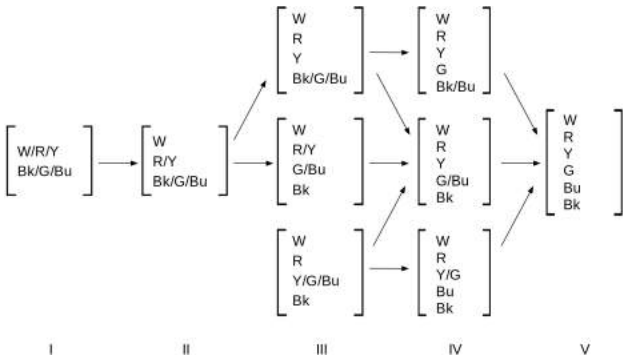

Figure 1: Evolutionary chart from Kay et al. (2009). W=white, R=red, Y=yellow, Bk=black, G=green, Bu=Blue.

Most evolutionary proposals focus on a core set of basic color categories, corresponding to the English terms *white*, *red*, *yellow*, *black*, *green*, and *blue*, because these 'primary colors' follow a consistent evolutionary path (Kay et al., 2009). Fig. 1 illustrates an influential proposal regarding the evolutionary sequence of languages, which we follow here. This diagram says that languages with only two color terms (Stage I) allocate those to the distinction between warm colors (White/Red/Yellow) and cool colors (Black/Green/Blue), while languages with three colors (Stage II) further distinguish White from Red/Yellow. Languages at Stages III through V can follow multiple pathways, depending on the further splits of Red, Yellow, Black, Green, and Blue.

Although modeling of crosslinguistic color data has revealed evidence of the various stages in Fig. 1 (e.g., Regier et al., 2007; Lindsey & Brown, 2009; Jäger, 2012), to our knowledge such work has not (yet) shown how the *ordering* of such stages could be derived from synchronic color naming data alone. Moreover, work on the evolutionary stages has typically focused on the partitioning of the space, and has not linked those stages to the nature and role of focal colors. That is, we know of no single model or method of analysis over the crosslinguistic color data that has derived both a consistent match to the evolutionary stages and to the universal focal areas, showing if or how these two concepts are linked.

Here we show that a standard analysis method from semantic typology, which has been used in work on color as well as

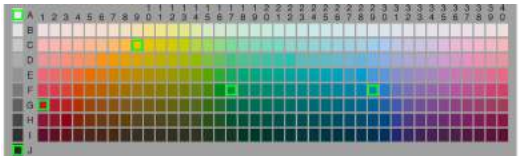

Figure 2: Munsell chart; universal foci (Regier et al., 2005)

in various other semantic domains, can simultaneously derive both the ordering of the evolutionary stages and the universal focal colors, revealing the latter as the drivers of the evolutionary distinctions. To preview our results, we use a simple statistical method to identify the important dimensions of the semantic space of color as represented by the crosslinguistic data. We find that the extremes of the identified dimensions correspond to focal areas of color, and, crucially, that the *importance ordering* of the dimensions corresponds to the *evolutionary ordering* of color distinctions. In addition, we perform the first analysis of subsets of languages at different evolutionary stages, and show that this importance ordering is not simply a by-product of the frequency of color distinctions in a mixed set of languages. We thus provide quantitative confirmation that synchronic color naming patterns reveal an underlying semantic space whose dimensional salience mirrors the evolutionary stages, with "anchors" in focal colors.

Color Data, Foci, and Evolutionary Stages

The World Color Survey (WCS; Kay et al., 2009, http://www.icsi.berkeley.edu/wcs/data.html) is a rich data set, along with a comprehensive qualitative analysis, that underlies much crosslinguistic analysis of color categories. Speakers of 110 diverse languages were surveyed, and languages were manually assigned to an evolutionary stage or transition between stages (cf. Fig. 1). The WCS contains two types of data. First, *naming data* was gathered by asking speakers to provide a single color term for each of the 330 color chips in the Munsell chart (see Fig. 2). Second, *focal data* was collected by asking speakers to select the most representative example, or focal color, of each term.

Both the focal and naming data of the WCS have played a prominent role in semantic typological analyses of color, which seek to derive semantic universals from crosslinguistic usage data. In particular, a body of work has attempted to go beyond qualitative analyses to provide precise mathematical underpinnings for such universals. Our work is in this vein, and we review related research below. Other quantitative analyses have attempted to link the semantic universals apparent from the WCS data to perceptual and/or communicative aspects of cognition. This is not the goal of our work here, but we refer to such research where relevant.

It is a striking finding that the distributions of the focal colors across all of the WCS languages cluster in small areas of the color space, corresponding to the six basic English focal colors, *white*, *red*, *yellow*, *black*, *green*, and *blue* (MacLaury, 1997; Regier et al., 2005; Lindsey & Brown, 2006, see Fig. 2). Some claim that these "universal" focal colors are cognitively privileged areas of the mental representation of color (Heider, 1972; Regier et al., 2005), which play a crucial role in the evolution of color systems (Berlin & Kay, 1969); others propose that they are only epiphenomena of the desired placement of color category boundaries (Roberson et al., 2000).

In their perceptual account, Jameson & D'Andrade (1997) suggest a middle ground in which the focal colors arise due to the nature of categorization in an irregular perceptual space. Abbott et al. (2012) operationalize this approach using Bayesian inference over perceptual color categories whose extents are determined by the WCS naming data. They find a good match between the representative members of these named color categories and the WCS focal data. This suggests that foci may be derivative from color categories whose optimal boundaries are driven by universal properties of the perceptual space (e.g., Jameson & D'Andrade, 1997; Regier et al., 2007). However, the relation of such foci to the evolutionary distinctions among colors is not clear.

The WCS data has also been explored as a source of insight into the evolutionary stages of color term systems, as exemplified in Fig. 1. Lindsey & Brown (2006, 2009) apply clustering techniques over naming patterns to reveal universal constraints over color categories, as well as color naming "motifs" (ways of partitioning the color space), some of which correspond to stages in the evolutionary hierarchy. Jäger (2012) takes a complex, multi-step approach to applying PCA to the WCS naming data, after transforming it in various ways. He derives partitionings of the six basic colors, many (but not all) of which match those of the evolutionary stages. While these approaches use quantitative analyses of the WCS to derive aspects of the evolutionary partitions, none of them derives an *ordering* over the partitions. (Indeed, Lindsey & Brown (2006) explicitly note that their work should not be interpreted as evidence of evolutionary sequencing from synchronic data.)

By contrast, Zaslavsky et al. (2018) combine WCS naming data with a perceptual semantics to derive an order over the emergence of color categories. They assume that color categories are created to optimally balance lexical accuracy with the size of the lexicon. As more color categories are added, their emergence roughly reflects the ordering of categories in color evolution. However, the reliance on perceptual salience leads to some mismatches with the evolutionary stages (overestimating the prominence of yellow), and the method does not address the role of focal colors in the ordering.

The wealth of research analyzing the WCS motivates our exploration of whether this rich synchronic color naming data can directly reveal patterns of evolutionary development, and shed light on the role of focal colors in those stages. We aim for a mathematical method of analysis that is simple and straightforward, with the intention that such an approach would be readily applicable to other semantic domains.

Our Approach

The approach we take in this work complements and seeks to fill in some of the gaps noted in the above body of research. Our goal is to derive the evolutionary sequence from WCS

data using a simple mathematical method – Principal Component Analysis (PCA) – that (along with other dimensionality reduction techniques) has been widely deployed in semantic typology, in diverse semantic domains including color (e.g., Majid et al., 2008; Jäger, 2012; Beekhuizen et al., 2014; Beekhuizen & Stevenson, 2018).

The novelty of our approach is two-fold. First, we extract latent dimensions of the WCS data *in order of importance*, yielding the first quantitative evidence of the evolutionary progression of color naming from the synchronic data. Second, we propose a natural interpretation of the "extremes" of the extracted dimensions as focal areas of color, which indeed show a strong match to empirical foci. Thus, we achieve a simultaneous match of the evolutionary ordering and the focal colors, which has not been shown before. Moreover, we do so with a very simple and straightforward use of PCA, in contrast to other methods that require much more involved mathematical transformations of the data (as in Jäger, 2012).

Our motivation is as follows. If most languages have followed a consistent and small set of orderings in the diachronic emergence of colors, those orderings must be determined by the relative importance of various perceptual/behavioral/cultural/communicative influences (e.g., Jameson & D'Andrade, 1997; Kay et al., 2009; Gibson et al., 2017; Holmes & Regier, 2017; Zaslavsky et al., 2018). Regardless of the source of these influences, if they play a role in the evolution of color systems, they may impact synchronic use of color terminology, and with the same relative importance. Note that this is not necessarily the case; for example, just because a language at Stage V has gone through Stages I through IV does not mean that the current color naming patterns of that language will reflect that a distinction made in an earlier stage (e.g., of Red vs. Yellow) is more important than a final distinction made in Stage V (e.g., of Green vs. Blue). That is, it is an open question whether the factors that exert evolutionary pressure to *create* new terms play a role in how terms are *deployed* in synchronic naming.

Experimental studies suggest that it may indeed be the case that evolutionary factors play a role in cognitive processing of colors by individuals. For example, Holmes & Regier (2017) found that English speakers show a categorical perception effect for the warm–cool distinction of Stage I, even though "warm" and "cool" are not basic color terms in English. Moreover, when English speakers group colors into K categories, the divisions they make roughly follow the evolutionary splits – i.e., with $K = 2$, they select a warm–cool separation, as in Stage I of evolution, with $K = 3$ they add a further distinction of white as in Stage II, etc. (Boster, 1986; Xu et al., 2013). Thus, English speakers are apparently sensitive to the evolutionary factors – and their relative ordering of importance – in color category processing.

Our goal here is to see whether actual color naming behavior, across the many diverse languages of the WCS, show this synchronic realization of the evolutionary influences. Specifically, given a suitable representation of the semantic space of synchronic color naming patterns, we use PCA over this data to extract dimensions of the data in order of importance, and examine whether those dimensions and their relative importance match the evolutionary stages proposed in the literature.

As a suitable representation of the color naming data, we follow a straightforward and standard practice in semantic typology. Specifically, we create a color chip by color term matrix using the color naming data from the WCS (Beekhuizen & Stevenson, 2018). Intuitively, such a matrix forms a semantic space over color, where each row can be viewed as a vector representation of the meaning of a color chip, as determined by the aggregate naming patterns in the data.

Applying PCA to such a matrix finds the latent dimensions characterizing the semantics of color across languages. Moreover, we take advantage of the interpretability of PCA dimensions, which means that points with a minimum or maximum value for a dimension are the most "extreme" example of the property that that dimension captures. Such points represent the "corners" of the data in the space (cf. Fig. 3), which are an indication of the key distinction each dimension is enforcing. We can thus examine these extremes to see if they correspond to the focal colors that have been proposed to "anchor" color categories (Regier et al., 2005).

Methods

Data matrices and PCA. We first create a color chip by term matrix over the naming data. Each cell records the (normalized) number of speakers in a language that used that term for that chip. This matrix compiles the naming data from all or selected subsets of languages in the WCS (as noted below). Thus we create matrices with 330 rows (one per chip in the Munsell chart) and up to 2223 columns (the number of color terms across all WCS languages).

We apply PCA to the resulting matrices to extract the most important dimensions. PCA identifies dimensions in the order along which the data shows the most variance, so the amount of variance accounted for represents the importance of that dimension. As we are looking for important dimensions that could relate to evolutionary development, we only consider dimensions that account for at least 5% of the variance in the data. (In almost all cases, this corresponded to a natural dropping off point in the accounted-for variance.)

For the first three such dimensions, we can plot the data for visualization purposes; i.e., we can plot the 330 color chips as represented by the first dimension of the PCA, by the first two, or by the first three. As shown in Fig. 3, such plots reveal the structure in the data that the PCA finds.

Determining the extreme points. To better understand the dimensions extracted by the PCA, we want to identify the *extreme points* of each. Conceptually, these are the maximally distinguishable points in the data on that dimension; in our visualizations in Fig. 3, these correspond to the endpoints or "corners" of the plotted data. In Fig. 3, the extreme points in 1D correspond to the minimum and maximum values on the x axis; the extreme points in 2D correspond to the corners of a triangle; the extreme points in 3D are the top of the pyramid

and the corners of its triangular base. As we will see in the results, such points generally correspond to focal colors.

We first collect the minimum and maximum points per dimension. However, because points can be tightly clustered at a "corner" of the space, we can end up with multiple extreme points when there is really only one "corner". For example, in the 2D plot in Fig. 3 (middle panel), the bottom right corner of the triangle is near the maximum for the x dimension *and* the minimum for the y dimension, so we might find two distinct points in that same small area. To avoid this, we consider all pairwise combinations of extreme points and merge those that are likely referring to the same "corners" of the space. Extreme points are considered to refer to the same "corner" if there is overlap in their $n = 15$ nearest neighbors, based on Euclidean distance. (We tried other values of n, which made little difference in the pattern of results.)

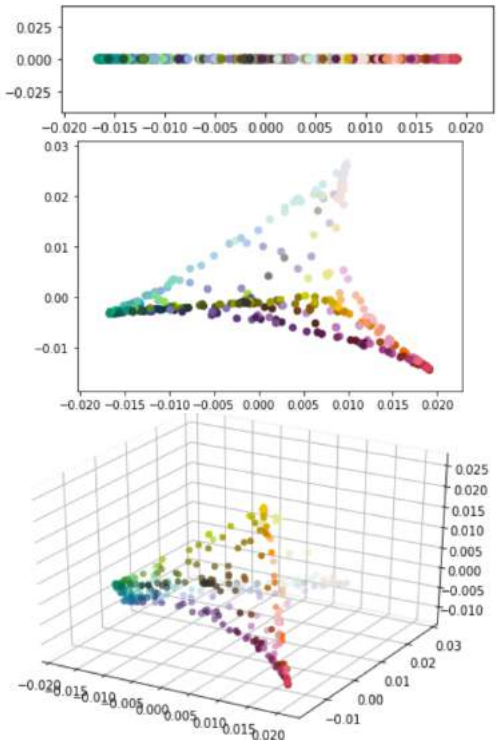

Figure 3: Plots of the 330 color chips in the 1D, 2D, and 3D PCA subspaces of the full WCS.

Visualizations of results. The results of our PCA analysis are a sequence of semantic subspaces defined by the extracted dimensions – the first (1D), the first+the second (2D), the first+the second+the third (3D), etc. – and the points that indicate the extreme "corners" of each subspace. To visually show the results, we plot the extreme points of each subspace (as triangles; or as diamonds for the merged points) in a Munsell chart, along with their closest neighbors (as circles whose size reflects their distance from the extreme point). These extreme point areas show the important color prototypes for each of the components of the PCA.

In addition, we visualize the extreme points as partitioning the PCA subspace, such that every color chip is allocated to the region of the space of its nearest extreme point. This yields a partitioned Munsell chart, with the number of partitions equal to the number of (merged) extreme points, or "corners", in the space. We label these partitions by the focal colors (green squares in the charts) occurring within them, whether they are extreme points or not. Thus each of the six focal colors is allocated to the region of its nearest extreme point, and we label a region by the focal colors it includes.

Fig. 4 shows examples of this visualization. For example, the White, Red, and Green extreme points shown in Fig. 4b for 2D correspond to the white, red, and green "corners" of the PCA plot for 2D shown in Fig. 3. The labels W, R/Y, and Bk/G/Bu correspond to the focal colors within each region as partitioned by the extreme points.

Analysis Over All WCS Languages

Using the methods above, our goal is to see whether a simple and straightforward application of PCA over the WCS naming data can simultaneously derive both the ordering of the evolutionary stages, as in Fig. 1, and the location of the universal foci, as in Fig. 2.

Results. We first apply our method over the full WCS color naming data. The first five extracted dimensions each account for more than 5% of the variance in the data; the results on the corresponding 1D–5D subspaces are in Fig. 4(a–e).

First, note that all of the primary extreme points for all dimensions of the PCA occur very close to the universal focal points of the 6 basic colors; see the triangles in Fig. 4. The extreme points corresponding to White, Black, and Green occur at the focus, Yellow and Blue adjacent to the focus, and Red two away from the focus. Fig. 4(f) shows the close match between our predicted focal colors and those of Abbott et al. (2012), who draw on both the color naming data and a representation of the named categories in perceptual space. It is important to emphasize that (as in Abbott et al., 2012) our results do not make use of the WCS focal color data, but only naming data. Given evidence for the universality of the focal colors as "anchors" for language-dependent naming of color regions, our results suggest that the extreme points of our PCA space are indeed meaningful in reflecting the important dimensions of color term systems in the WCS.

Second, and crucially, the importance ranking of dimensions in this all-languages data set shows a very strong match to the ordering of the evolutionary stages of Fig. 1, as indicated in the caption below each chart in Fig. 4(a–e). This is the first mathematical demonstration that synchronic color naming patterns reflect the relative importance of latent color dimensions that also underlie their evolutionary emergence.

Discussion. We have shown that a straightforward application of PCA over the WCS yields dimensions of the color naming data whose maximal/minimal values correspond to focal regions of color. That is, the universal foci appear to organize the dimensions along which the data shows the most variance. Moreover, these dimensions are extracted in the order of importance of the evolutionary distinctions among color terms, confirming that naming patterns in the WCS col-

(f) Foci in 5D, with our extreme points shown as triangles and the predicted foci of Abbott et al. (2012) as large circles.

lectively exhibit the synchronic influence of the evolutionary factors that shape the progression of color systems.

A legitimate question is whether our finding is simply the expected result of doing PCA over language data that includes languages at all the stages. Specifically, is it a simple frequency effect? That is, if languages at different stages are simply successively partitioning the data (rather than reorganizing colors in a way that changes earlier boundaries), then all languages have some boundary between warm and cool colors, all but Stage I languages have an additional boundary between white and the other warm colors, all but Stage I and II languages have another boundary between two more colors, etc. Thus, the PCA may be finding boundaries based on their frequency across languages at the different stages, rather than based on a true importance ordering.

A crucial observation that argues against this view is that the WCS contains no Stage I languages, and yet the warm–cool split of Stage I emerges as the first dimension in importance. That is: Although all languages in the WCS make *both* the warm–cool distinction of Stage I and the White–Red/Yellow distinction of Stage II, the warm–cool distinction emerges first in the PCA. This suggests that there is a detectable signal in the naming patterns that reveals the relative importance of an evolutionarily-earlier boundary over a later boundary, independently of their frequency in the data. To test this more directly, and across more stages, we next look at subsets of the languages of the WCS grouped by stage.

Analysis Over WCS Languages By Stage

We hypothesize that languages at each stage will show the same importance ranking of dimensions as found in the evolutionary progression, up to and including that stage. The set up here ensures that if we find that languages show evolutionarily-earlier distinctions as more important than later ones, this cannot be explained away as the data including languages at those earlier stages, thus skewing the frequencies toward the earlier distinctions.

Set up. In this analysis, we separately consider subsets of languages of the WCS that are in a single one of the identified evolutionary stages (Kay et al., 2009), yielding 7, 7, 41, and 14 languages at Stages II, III, IV, and V, respectively. (There are few documented Stage I languages, and none in the WCS. Also, we omit languages transitioning between stages, since they can show blends of behavior.) We perform the same PCA analysis as above, once over each of the four naming matrices limited to each stage, with the goal of seeing whether there is a match between the successive dimensions of each PCA analysis and the evolutionary stages.

Results. Tab. 1 presents the sequences of evolutionary stages revealed in the analysis of the subsets of languages by stage (omitting Stage V for space reasons). The table summarizes the color partitions in each subspace using the focal colors in each (we omit Munsell charts due to space reasons), and shows the best-matching stage from Fig. 1. (All and only dimensions accounting for $> 5\%$ of variance shown.)

Overall, the results confirm our hypothesis above: we find a very good match between the PCA analysis and the evolutionary diagram from all sets of languages, except those in Stage V. It is also the case that the majority of extreme points found in all the relevant dimensions of the four PCA analyses are at or very near focal colors. To summarize:

- All of Stages II, III, and IV show a very strong match to

Table 1: Sequences of focal colors in the Stages data.

Data set	1D subspace	2D subspace	3D subspace	4D subspace
Stage II languages	W/R/Y Bk/G/Bu ➔ **Stage I**	W R/Y Bk/G/Bu ➔ **Stage II**		
Stage III languages	W/R/Y Bk/G/Bu ➔ **Stage I**	W R/Y Bk/G/Bu ➔ **Stage II**	W R Y/warm–cool boundary G/Bu Bk ➔ **Stage III**[a,b]	W R Y G/Bu Bk warm–cool boundary ➔ **Stage III**[a,b]
Stage IV languages	W/R/Y/Bk G/Bu ➔ **Stage I**[c]	W R/Y/Bk G/Bu ➔ **Stage II**[c]	W R Y/Bk G/Bu ➔ **Stage III**[c]	W R Y G/Bu Bk ➔ **Stage IV**

[a] Stage III languages show a mix of the top and middle partitions of Stage III in 3D and 4D.

[b] Stage III languages show an additional warm/cool boundary color in 3D and 4D.

[c] Stage IV languages connect Bk with Y through the Brown region in 1D, 2D, and 3D.

the evolutionary stages.

- Stage III has, in addition to predicted extreme colors, a rainbow-like extreme area along the warm–cool boundary.
- Stage IV mostly matches the evolutionary stages, but with Yellow and Black connected through Brown in earlier dimensions. At 4D, there is a precise match to Stage IV.
- Stage V does not yield an ordering of dimensions that match the evolutionary stages. At 6D, all basic focal colors plus Purple have emerged as extreme regions.

Stage III data include languages from different sub-stages (column III in Fig. 1). Follow-up experiments with various subsets of Stage III languages reveal that the observed boundary color appears due to varying ways the different sub-stages divide up the G/Bu/Y region of color, in combination with the fact that one of the languages has an unusual basic color term for this warm–cool boundary region (Kay et al., 2009).

Stage V is a heterogeneous group, with languages having the 6 basic colors plus some number of other derived colors (13 of 14 have at least one derived color). We hypothesized that the variety in naming patterns for the non-basic colors may be swamping the signal from the basic colors. This may indicate a limitation of our method in dealing with a larger number of dimensions of color distinction. To test this, we performed the same PCA analysis over the 8 languages denoted as *approaching* Stage V (which have fewer derived colors). Here, the dimensions of the data emerged in order of the evolutionary stages, including the final stage at which Blue is distinguished from Green.

Discussion. To our knowledge, we are the first to apply a quantitative typological analysis to the languages of the WCS at the various evolutionary stages, as manually analyzed in Kay et al. (2009). Our findings provide strong support for the hypothesis that data from later stage languages can have structure that matches the evolutionary order of earlier stages. By separately analyzing languages at each specific evolutionary stage, we control for the potential frequency explanation of our results on the full WCS data set.

Further work will be required to determine the underlying causes of the cases of mismatches to the stages. Others have found, using more complex procedures, that the WCS data yield color groupings that largely, but not always, correspond to the manually derived partitionings of the color space (Lindsey & Brown, 2009; Jäger, 2012). Our method may be picking up on idiosyncratic patterns of naming, especially on smaller data sets. Regarding the Stage V data in particular, a possible shortcoming of our method is that it may not be sensitive enough to capture regularities beyond the six basic focal colors, which would be necessary to analyze this heterogeneous set of languages.

Conclusions

We present the first statistical analysis of color naming data that both shows a match between the evolutionary ordering of color systems and the importance ordering of informative dimensions of the data, and derives the focal colors from the extremes of those component dimensions. These results arise from a simple and straightforward application of PCA, a standard method from semantic typology for extracting salient dimensions from crosslinguistic naming patterns.

First, our approach reveals a quantitative importance ordering of latent dimensions of color semantics that strongly matches qualitative analyses of the evolutionary stages of color lexicons (e.g., Berlin & Kay, 1969; Kay et al., 2009). Specifically, we find that the color distinctions captured by each successive extracted dimension of the data largely correspond to the distinctions made in successive stages of color term evolution. Moreover, we show that the importance ordering of these dimensions holds even when considering languages at individual evolutionary stages, thus controlling for frequency of earlier vs. later distinctions in the data. Our work thus lends further evidence that speakers are sensitive to evolutionarily-important color distinctions that are not expressed directly by basic terms in their own language (cf. Boster, 1986; Xu et al., 2013; Gibson et al., 2017; Holmes & Regier, 2017).

Second, we find that the extreme points of the identified color dimensions correspond to a small set of focal color regions shown to occur across languages (e.g., MacLaury, 1997). Our work thus reinforces a growing body of research showing that focal colors are important dimensions of color space that serve as "anchors" for color categories (e.g., Regier et al., 2005). It has been proposed that focal colors arise at points of an irregularly-shaped perceptual space that maximize the distance between them (e.g., Jameson & D'Andrade, 1997; Regier et al., 2007). Although our method is agnostic as to the source of the latent dimensions (whether perceptual, and/or salience, as in Gibson et al., 2017, and/or communicative pressures, as in Zaslavsky et al., 2018), our results, like those of Abbott et al. (2012), show that the naming patterns of languages reflect the universal foci. Our approach further sheds light on the focal colors as extremes in the evolutionarily-important dimensions of color semantics.

Word-Learning Biases Contribute Differently to Late-Talker and Typically Developing Vocabulary Trajectories

Abstract

This study explores how the vocabulary growth trajectories of typically developing and late-talker children change in relation to their word learning biases. Forty late talkers and 44 typically developing toddlers visited the lab once a month for one year starting at about 18 months of age. Word-learning trajectories were tracked using a parent-reported vocabulary measure, and shape and material bias measures were collected using the novel noun generalization task each month. A two-level hierarchical linear model was utilized for the longitudinal analyses. Results indicate that, at the first visit, a stronger shape bias was significantly associated with a *larger* vocabulary in typically developing talkers. In late talkers, however, a stronger initial shape bias was associated with a *smaller* vocabulary. Over the course of the study, for every additional visit, stronger shape biases were associated with *larger* vocabularies in late talkers, but not in typically developing toddlers. Results for the material bias mirrored the shape bias results. These findings suggest different possible underlying mechanisms for the two groups of children, as well as avenues for the design of language interventions that might support young late talkers.

Keywords: vocabulary acquisition; word-learning bias; late talker; word learning

Vocabulary Acquisition

There is enormous variability in the vocabularies of young children just beginning to speak. By two years of age, an otherwise typically developing toddler may know as few as ten words or well over 300 (Fenson, 1993). These early differences in vocabulary size may lead to long term differences in learning and language skills (Rescorla, 2000). Understanding the mechanisms behind language development that give rise to these different trajectories is vital for informing further research and developing identification and interventions for those children who show delayed word learning.

As children learn words, they also learn important features of the objects represented by these words and how these features relate to word use in general. Children must learn the regularities in their world, such as all balls are round, and all toothpaste is, well, thick and pasty. Children's noun learning progresses from slow and laborious to fast and seemingly effortless. This may be due in part to understanding and taking advantage of the way languages organize categories in the world. For example, by their third year of life, children seem to know to generalize names for solid objects by shape, but names for nonsolid substances by material (Landau, Smith & Jones, 1988). These word learning biases are typically assessed using the novel noun generalization (NNG) task; the child is taught a novel name for a novel item and then asked which other items, matching the exemplar on one or more features, have the same name (Landau et al., 1988). These biases develop in tandem with vocabulary growth, such that when children accrue between 50 and 150 nouns, the tendency to attend to shape for solid objects emerges and becomes robust (Gershkoff-Stowe & Smith, 2004).

Late talkers are children who lag in their vocabulary size compared to their same-aged peers in the absence of any known developmental disorders. Although the label of "late talker" is not a clinical diagnosis in of itself, this group is often defined by being in the lower 25th percentile on productive vocabulary, which is typically measured by the MacArthur-Bates Communicative Inventory (CDI) (Fenson, 1993). However, different researchers use different cut-off points when classifying children as late talkers, ranging from the 10th to 30th percentile.

Evidence suggests that late talkers and typically developing children differ not only in their vocabulary size, but also in the way they learn new words. Thirty-month-old late talkers, when defined as falling at or below the 30th percentile on the CDI, show no or even opposite word learning biases compared to typically developing 30-month-olds do (Jones, 2003). Further, 30-month-old late talkers under the 10th percentile struggle learning new words through fast mapping (Weismer, Venker, Evans & Moyle, 2013). Even before they turn two, children in the top 25th percentile on productive vocabulary show different word learning biases than children in the bottom 25th percentile (Colunga & Sims, 2017). Specifically, these early talkers showed as strong a shape bias for solids as a material bias for nonsolids, whereas late talkers showed a robust shape bias for solids that might be overgeneralized to nonsolids. The fact that late talkers differ from typically developing children in their word-learning biases in the lab may mean that these children acquire language through different mechanisms.

The differences between late talkers and their typically developing peers have long-term impacts, with some late talkers showing persistent deficits in measures such as reading, writing, and oral language skills throughout elementary and middle school (Rescorla, 2000). Although

many of the children labeled late talkers as toddlers do "catch up" to their typically-developing peers, there is a clear need to better understand how late-talker trajectories develop over time, as well as the factors that may influence this development (Heilmann, Weismer, Evans & Hollar, 2005). However, it is unknown exactly how word-learning biases relate to vocabulary growth throughout development, as previous work has investigated these relationships cross-sectionally. For example, the finding that 18-month-old late talkers have a shape bias (Colunga & Sims, 2017) but 30-month-old late talkers do not (Jones, 2003), could be a result of the different task demands of the different novel noun generalization tasks used with these different age groups, or it may suggest something interesting about the different developmental trajectories of children who catch up versus children who remain late talkers between 18 and 30 months of age.

To understand word learning in typically developing and late talkers, word learning biases and vocabulary size need to be examined longitudinally. For example, are late talkers who show stronger word learning biases at 18 months more likely to make greater gains over time? Is the positive relationship between word learning biases and vocabulary size in typically developing children suggested by cross-sectional work also present longitudinally? Further, is that relationship similar among late talkers? By investigating the relationship between vocabulary size as well as both the shape and material biases during the course of development, we can begin to understand the mechanisms that may give rise to the different developmental trajectories. The present study will investigate vocabulary growth trajectories of children over a 12-month period and their relations to word learning biases.

Current Study

The overarching goal of this project is to understand how the vocabulary growth trajectories of typically developing and late-talker children develop vis-à-vis their word learning biases. To accomplish this, we track both the vocabulary and the word learning biases of toddlers over a period in which rapid vocabulary growth is typically observed, 16 to 30 months of age, on a monthly basis for a year. Late talkers were oversampled to account for their expected increased variability. To the extent that there exists a feedback loop between word learning biases and words learned, we would expect a positive relationship between these two measures. This relationship might change throughout development, such that the shape bias for solids is stronger and more strongly related to vocabulary growth early on, and the material bias for non-solids shows a different pattern of development in relation to vocabulary size. Furthermore, if typically developing and late-talker children differ in their learning mechanisms, not just on their vocabulary size, these relationships between word learning biases and words known may differ between the two groups of children.

This study is the first attempt to track, longitudinally, the relationship between word learning biases and vocabulary size in late talkers and typically developing children. Though previous work has documented the relationship between the shape bias and vocabulary composition cross-sectionally (Perry & Kucker, 2019) and longitudinally (Gershkoff-Stowe & Smith, 2004) in typically developing children, and other work had looked at vocabulary growth longitudinally in late talkers (Heilmann et al., 2005) and at the relationship between shape bias and vocabulary cross-sectionally in late talkers (Jones, 2003), this is the first attempt to document the development of both the shape and material biases, longitudinally, in both late talkers and typically developing children.

Method

Participants

One hundred and twelve children were recruited for this study; children were 16-18 months of age at the first visit (M = 17.69, SD = 0.93). Twenty-eight children growing up in bilingual households were excluded for the present analyses, as previous research suggests early differences in the developmental trajectories of vocabulary growth of monolingual vs. bilingual children (e.g., Thordardottir, 2011). Toddlers visited the lab once a month for 12 consecutive months. Seventy-nine of the 84 children attended at least 10 of the expected 12 visits. Forty monolingual children scored below the 25th percentile on the CDI at their first visit, and for the present analyses, these children will constitute the late talker group (CDI percentile M = 11.65, SD = 12.26). The typically developing group consisted of the remaining 44 children (CDI percentile M = 59.14, SD = 21.44). Participating children were screened for known sensory or cognitive developmental disabilities or disorders. Late talkers and their typically developing peers did not differ in their ages at visit 1 or on average throughout the study; $t(82) = 0.71$, $p = 0.48$, $t(82) = 0.73$, $p = 0.47$, respectively.

Materials

Children participated in the novel noun generalization task to assess both the shape and material biases at each visit. The stimuli consisted of a warm-up set made out of common objects, a novel solid test set, and a novel nonsolid test set. The warm-up set had an exemplar, a red plastic ball, two other balls (a tennis ball and a green and blue rubber ball), a plastic spoon, a toy carrot, and a toy cat.

Each solid set consisted of an exemplar and five novel choices; two that matched the exemplar in shape but differed in color and material, one that matched in color, one that matched in material, and another that matched in both color and material. The nonsolid set was analogous, consisting of an exemplar and five choices; two items matching the exemplar's material but differing in shape and color, a color match, a shape match, and a color and shape match.

There were three sets structured in the way described above. The three sets rotated through the study, visit 1 – set A, visit 2 – set B, visit 3 – set C, visit 4 – set A, such that each set was used every 3 months and a total of 4 times over

the 12 visits that encompassed the study.

The Macarthur-Bates Communicative Development Inventory Words and Sentences (CDI) was completed by parents on each visit. The CDI consists of a 680-word checklist asking parents to indicate which words their child *says*. Although the CDI is a parent report measure it has been shown to be reliable and related to performance on child-based vocabulary measures (Fenson, 1993).

Procedure

Children visited the lab once a month for 12 months. At each visit parents filled out a CDI form measuring their child's productive vocabulary. Upon consent, children participated in one rotation of the NNG task measuring their shape bias for solid objects and their material bias for nonsolids. The procedure was modeled after Gershkoff-Stowe and Smith (2004). In the warm-up phase, the experimenter presented all six toys to the child and allowed him or her to look at them and handle and touch them for 30s before removing them outside of the child's reach. The child was then shown the exemplar ball and told, "look at this ball." Then, each child was asked to "get a ball" or get "another ball." If the child failed to retrieve a ball, the child was asked one more time, and finally was told "here's another ball," handed the ball, and was instructed to get it one more time. If the child got one of the nonball distracter items, he or she was told, "that's not a ball, that's a ____", then the distracter was replaced on the tray, and the child was asked again, "is there another ball?" The goal of the warm-up phase was to familiarize toddlers with the procedure and the idea that the display might have multiple things that were or were not in the category.

The procedure during the test phase with the solid and nonsolid novel sets was the same, except without feedback. Children were shown the exemplar and told, "look at this dax" and then asked to "get a dax" or "get another dax" for the solid set or "get more dax" or "get some dax" in the nonsolid set. Children were asked to get another (or more) until they indicated that there were no more, allowing children to accept or reject as few or as many items as they desired. The solid set was presented before the nonsolid set, and a five-minute break and change in testing rooms took place in between the two tests to minimize carry-over effects.

Bias scores were coded by noting the order in which children chose items as members of the queried category. The first choice got three points, second choice two points, and so on. For the solid set, the weighted scores for the items not matching in shape were subtracted from the weighted scores for the two shape-matching objects, yielding a score from -5 to 5. Similarly, the material bias score for the nonsolid set was calculated by subtracting the weighted scores for the two items matching the nonsolid exemplar in shape from the scores for the items matching the exemplar in material.

Data Analysis

We employed a two-level hierarchical linear model to investigate our longitudinal data. We are able to quantify longitudinal growth trends and explore the variation in these trends across individuals. The "level 1" analysis estimates parameters within child, which in turn become the dependent variable for the "level 2" analysis assessing between-child variables. Number of words known, taken from the CDI, was the main outcome of interest across the analyses. Level 1 consisted of each visit within child, whereas level 2 quantified individual characteristics across children (e.g. talker type). We first graphed the trajectories of all children in the study to help visualize the data (*Figure 1*). we elected to use a linear growth description. The graph also indicates great variability in both the initial and ending vocabulary sizes of the children, as well as their trajectories throughout the study. Because of this, we will investigate not only fixed effects but the variance of the modeled growth curves.

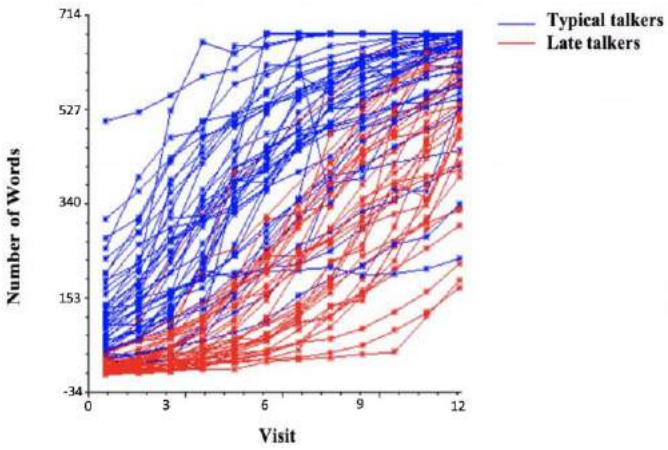

Figure 1: The raw data vocabulary trajectories for our full sample, color-coded by talker type. The x-axis is visit number, and the y-axis is the number of words the children produce from the CDI.

Model 1 Our first analysis seeks to describe the linear trajectories for all children in our sample, in order to establish a baseline for comparison. We centered Visit around visit one and allowed coefficients to vary at level 2. Figure 2 represents model 1 using the hierarchical linear modeling framework.

Level-1 Model: repeated observations of children

$$Vocab_{ti} = \pi_{0i} + \pi_{1i}(Visit_{ti}) + e_{ti}$$
$$where\ e_{ti} \sim iid,\ N(0,\ \sigma^2)$$

Level-2 Model: child characteristics

$$\pi_{0i} = \beta_{00} + r_{0i} \qquad r_{0i} \sim iid,\ N(0,\ \tau_{00})$$
$$\pi_{1i} = \beta_{10} + r_{1i} \qquad r_{1i} \sim iid,\ N(0,\ \tau_{11})$$

Figure 2: a representation of model 1 using the hierarchical linear modeling framework. This same structure will be used for analyses 2 and 3 as well, with added variables at level 1 and 2. For simplicity, we only present the general structure here.

Model 2 Our second analysis further investigates differences in growth trajectories between those children who were initially classified as late talkers (CDI < 25%) and those who were initially classified as typical talkers (CDI >25%). In our analysis, we examined the interaction between this talker type variable and both initial vocabulary size and linear growth. To do this, talker type status was placed at level 2 of the analysis as a between subjects variable, in order to predict the coefficients in our level 1 equation. Level 1 remained the same as in model 1. We centered our talker type variable to test the significance of both late and typical talker slopes separately.

Model 3a and b Our third analyses examine how the two word-learning biases of interest, shape and material, impact the number of words known by children both at visit one and over time. Here we investigate each bias separately. Further, we examine how these biases differentially impact the word learning trajectory for late talkers as compared to typical talkers. To do so, we add the bias score and the bias score by visit interaction to level 1 of our model. Level 2 remains similar to model 2, with talker type status predicting the intercept and visit coefficients. In addition, talker type is also placed in the level 2 equations for bias and the bias by visit interaction. Model 3a investigates the relationship between the shape bias for solid objects and vocabulary size at visit one and over the course of the study, whereas Model 3b does the same for the material bias toward nonsolid substances. A model including both shape and material bias, along with their interactions with each other and over visit, did not account for any more within-child variability in growth than models with either bias alone. Therefore, results will not be reported for such an analysis.

Results

Fixed affects for each model are presented in *Table 1* and variance components in *Table 2*.

Model 1

Results from model 1 indicate that, on average, children in our study had 63.27 words in their vocabularies at the first visit, or when 18 months old. For every month of the study, children, on average, accrued 47.05 new words, t(83)=28.51, p<.001. As expected, all children learned new vocabulary words as they aged. There was significant variability in both initial vocabulary size and visit slope; χ^2 (82, N=84) = 1554.80, p<.001, χ^2 (82, N=84) = 712.73, p<.001 respectively.

Model 2

Analysis 2 investigates differences in the word learning trajectories between late talkers and their typically developing peers (*Figure 3*). Typical talkers are predicted to have, significantly more words in their vocabularies at the first visit than late talkers; t(82)=8.99, p<.001. Both groups made significant vocabulary gains over time. Typical talkers were expected to add 48.19 words each visit, whereas late talkers were predicted to gain 45.53 words each month; t(82)=22.79, p<.001, t(82)=17.67, p<.001 respectively. In fact, vocabulary growth was not significantly different between the two talker types; t(82)=0.80, p=.427.

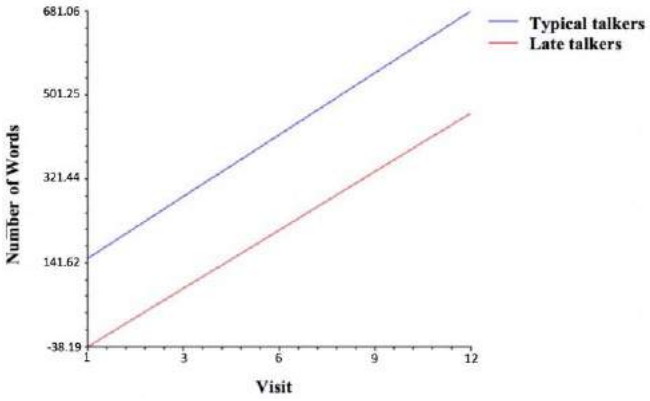

Figure 3: Predicted average vocabulary trajectory for typical and late talkers from model 2. Word-learning trajectories for both talker groups run parallel to each other

There is still significant variability in initial vocabulary size and linear growth; χ^2 (81, N=84) = 793.62, p<.001, χ^2 (81, N=84) = 710.86, p<.001 respectively. Knowing which talker type group a child belonged to did account for 51.85% of the variance between children's initial vocabulary sizes when compared to the first analysis. However, there was no appreciable difference in the variance of vocabulary growth from model 1 to model 2.

Model 3a – Shape Bias

Model 3a investigates how shape bias predicts both vocabulary size at visit one and over the course of the study (*Figure 4*). At the first visit, late talkers did not differ from their typically developing peers in shape bias scores; t(82)=1.61, p=.11. Controlling for shape bias score and its change over time, both late and typical talkers still, as in model 2, know significantly more words at each new visit. Typical talkers learn an average of 51.77 words a month and late talkers learn 41.84 words monthly on average; t(82)=21.18, p<.001, t(82)=16.75, p<.001. However, late talkers make significantly smaller gains in vocabulary size than their typical counterparts once shape bias and its changes over time were accounted for; t(82)=2.82, p<.01.

At the first visit, for every one-point increase in shape bias score, typical talkers were expected to know 6.05 more words, indicating that a stronger shape bias is significantly associated with a larger vocabulary in typically-learning talkers at the beginning of the study; t(82)=3.368, p<.001. In contrast, for every one-point increase in shape bias score, late talkers were predicted to initially know 7.44 fewer words -- for late talkers, a stronger initial shape bias was associated with a smaller vocabulary. This difference between shape

bias and vocabulary size was significantly different for the two groups at their first visit; t(82)=6.069, p<.001.

For every additional visit, a one-point increase in shape bias score predicted a significant 1.39 word decrease in vocabulary size for typical talkers; t(82)=-4.885, p<.001. However, by the 10th visit, 43% of typical talkers already knew at least 90% of the words on the CDI, indicating possible ceiling effects in the typical talker group. Late talkers, on the other hand, showed a significantly more positive relationship between shape bias scores and vocabulary size over the 12-month study period; t(82)=7.216, p<.001. For each visit and one-point increase in shape bias score, late talkers were expected to know 1.61 more words; t(82)=5.31, p<.001.

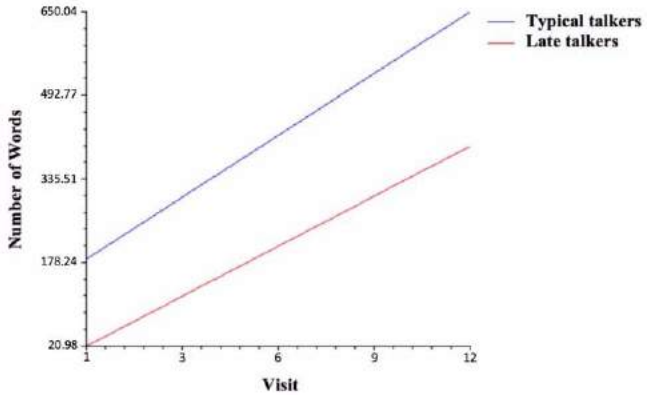

Figure 4: Predicted average vocabulary trajectory for typical and late talkers from model 3a. The words learning trajectories differ between late and typical talkers.

The inclusion of shape bias, its change over time, and how these variables differ between late and typical talkers in the model accounted for 8.7% of the within-child variability in vocabulary. However, there is significant variability in initial vocabulary size and growth; χ^2 (81, N=84) =455.60, p<.001, χ^2 (81, N=84)=475.46, p<.001 respectively.

Model 3b – Material Bias

Model 3b examines how the strength of a child's material bias predicts their vocabulary size at visit one and over the 12-month study period (*Figure 5*). At the first visit, late talkers did not differ from their typically developing peers in material bias scores; t(82)=1.02, p=.31. For a child with an average material bias strength at visit one and over time, both typical and late talkers are predicted to know significantly more words every month of the study, gaining 48.55 and 45.03 words, respectively; t(82)=23.07, p<.001, t(82)=17.50, p<.001. Further, these gains are not significantly different between the two groups; t(82)=1.06, p=0.291. This differs from when shape bias was controlled for, where late talkers did make significantly less gains in word knowledge than typical talkers.

At the first visit, for every one-point increase in material bias score, typical talkers are expected to know 4.32 more words, indicating a significant positive relationship between material bias and vocabulary size; t(82)=2.22, p<.05. The relationship between words known and material bias is significantly more negative for late talkers however; t(82)=3.54, p<.001. Late talkers are expected to know significantly less words (5.3) for every one-point increase in material bias; t(82)=-2.8, p<.01. This directly mirrors the results for shape bias.

The material bias by visit interaction also follows the same pattern as that for the shape bias. For every month aged, a one-point increase in material bias predicts a significant reduction in vocabulary size, by 0.95 words; t(82)=-3.06, p<.01. To note, this reduction in vocabulary size is not as large as the one for the shape bias, at a decrease of 1.39 words. Further, this relationship is significantly more positive for late talkers, as it was for the shape bias; t(82)=4.07, p<.001). For each month aged and a one-point increase in material bias score, late talkers are expected to know 0.92 more words; t(82)=2.72, p<.01. As the year goes by, a stronger material bias predicts more vocabulary gains for late talkers, but fewer gains for typical talkers.

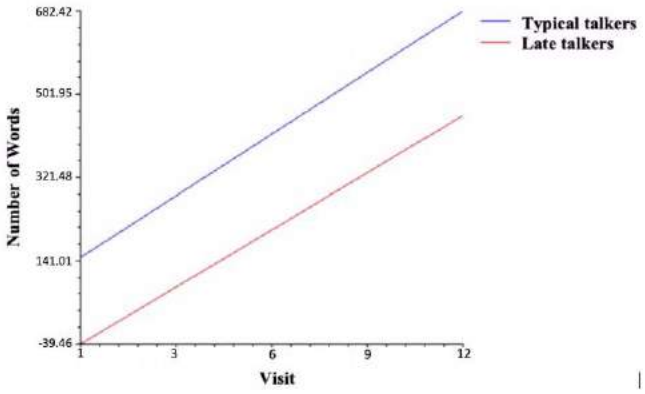

Figure 5: Predicted average vocabulary trajectory for typical and late talkers from model 2. The word-learning trajectories between late and typical talkers do not differ.

Including the material bias and its relationship with visit in the model accounts for about 5.9% of the variance at level one (as compared to 8.7% when shape bias was used). Variability in initial vocabulary size and linear growth are both significant χ^2 (81, N=84) =713.21, p<.001, χ^2 (81, N=84)=588.33, p<.001 respectively.

Table 1: Final estimation of fixed effects for the three analyses. Each intercept is the estimate for typical talkers. We indicate the coefficient for each variable followed by the significance (indicated *** p<.001, **p<.01, *p<.05). In parentheses are standard errors.

Discussion

The work presented here looks at the differential contributions of word learning biases to the developmental trajectories of typically developing children and late talkers, and in doing so provides important novel insights. First, word learning biases may not be equally advantageous to all children. At the beginning of the study, typically developing talkers show the expected positive relationship between shape bias score and vocabulary size, suggesting that a shape bias facilitates word learning, in line with decades of work by Linda Smith and colleagues (e.g., Smith, 2000). However, the relationship between word learning biases and vocabulary size among late talkers presents a different pattern.

It is important to note that late talkers and their typically developing peers do not differ in their initial shape bias scores. Although this may seem to contradict Jones' (2003) finding that 30-month-old late talkers do not show a consistent shape bias, that is not the case. Rather, these results complement Jones' by documenting a different point in the developmental timeline; participants in our study were at least a year younger at the beginning of our study. In addition, we used an age-appropriate novel noun generalization task different from that in Jones (2003).

In contrast to the documented positive relationship between the shape bias and vocabulary size in typically developing children, among late talkers there is a negative relationship between the strength of their shape bias and their vocabulary size at the beginning of the study. This intriguing finding suggests our measure of the shape bias might not be distinguishing different underlying mechanisms that these two groups of children might be using. For example, it is possible, given the specific novel noun generalization task we used, that late talkers are exhibiting a generalized shape bias that is not linked to learning new words, but instead simply to attending to shape more generally. The fact that this same pattern of results held also for the material bias, however, suggests that this is not the case, and that at the very least they can shift their attention depending on the physical characteristics of the objects in front of them. Another possible reason our specific shape bias measure might not be detecting different underlying mechanisms is that we do not test retention. It is possible that in the short term, late and typical talkers generalize novel nouns in the same way (though there are documented differences in their fast mapping abilities; Weismer et al., 2013), but typically developing children have an easier time remembering the

word-shape association over time, which would result in different rates of word learning in the real world.

Second, the relationship between word learning biases and vocabulary growth over time in the two groups of children might offer further clues. As the year goes by, we observe that among late talkers, increases in shape bias score is related to vocabulary gains. That is, the 18-month-olds who started as late talkers and grew up to have a robust shape bias by 30 months of age were likely not late talkers at all by that point. Here it is important to note that by the end of the study only seven out of the 39 children who started as late talkers, or about one in five, remained under the 25th percentile; about half of them were above the 50th percentile at the last visit. This could just be a function of the regular course of development, as it is well known that one of the difficulties of dealing with late talkers is that many of them will catch up without the help of any intervention as others will continue to struggle into their school years and beyond. In fact, Heilmann et al. (2005) suggest that the CDI can help identify children with low language skills up to the 11th percentile from children with normal language skills above the 49th percentile. Given that the majority of the late talkers in or sample (27/39) started the study under the 11th percentile mark, our rate of late talker recovery seems higher than expected. Is it possible that participating in this study helped late talkers acquire an effective shape bias? Whether that is the case or not, these findings suggest possible avenues for the design of language interventions that might support young late talkers.

On the other hand, for typically developing children, as the year goes by, increases in shape bias score are related to smaller vocabulary sizes. This unexpected finding is likely an artifact of typically developing children reaching ceiling performance in both the CDI and their word learning bias scores before the end of the study. Because the CDI is a finite set of about 700 words, the vocabulary curves of typical talkers artificially asymptote towards the end of the study, when in fact their vocabularies continue to grow as they acquire words beyond those listed in the CDI. One way to deal with this is to use open-ended diaries rather than vocabulary inventories to measure vocabulary. In addition, this would allow us to capture idiosyncratic differences in vocabulary composition in late talkers as well.

The present study, with the use of hierarchical analysis, sheds light on the differences in language acquisition between those who lag behind in vocabulary size, late talkers, and those that are developing typically. Although the present analyses are just a first step in understanding these trajectories, they suggest interesting targets for future work. With this knowledge, earlier identification of children at risk for delayed vocabulary acquisition, as well as the development of more targeted interventions for such children, might be possible.

Acknowledgments

We are grateful to the families of Boulder, CO, who participated and to the research assistants in the DACS Lab at the University of Colorado Boulder who collected the data. This research was supported by NICHD grant R01 HD067315 to Eliana Colunga.

Bayesian Pragmatics Provides the Best Quantitative Model of Context Effects on Word Meaning in EEG and Cloze Data

Abstract

We contrast three views of how words contribute to a listener's understanding of a sentence and compare corresponding quantitative models of how the listener's probabilistic prediction on sentence completion is affected in online comprehension. The Semantic Similarity Model presupposes that the predictor of a word given a preceding discourse is their semantic similarity. The Relevance Model maintains that utterances are chosen to maximize relevance. The Bayesian Pragmatic Model assumes a relevance-guided modulation of a word's lexical meaning that can be regarded as a Bayesian update of statistical regularities stored in memory. In addition to a Cloze test, we perform an EEG study, recording the event-related potential on the predicted word and take the N400 component to be inversely correlated with the word's predictive probability. In a multiple regression analysis, we compare the three models with regard to Cloze values and N400 amplitudes. The Bayesian Pragmatic Model best explains the data.

Keywords: Bayesian Pragmatics, EEG, N400, Cloze Test, Semantic Similarity, Relevance, Generative Lexicon, Probabilistic Prediction, Online Comprehension, Modulation, Predictive Completion Task

Introduction

A preceding discourse can influence the way words contribute to a listener's understanding of a sentence (Recanati, 2012). This contextual influence also affects a listener's implicit probabilistic predictions on the completion of a discourse in the process of online comprehension. The listener's implicit task of predicting the next word w_{n+1} following a discourse that consists of the word sequence $w_1 \dots w_n$ can be described by a predictive probability of the following form:

(1) $P(w_{n+1}|w_1 \dots w_n)$.

In an EEG study, Nieuwland and Van Berkum (2006) showed that discourse contexts can interact with the lexical animacy feature of concrete nouns. A preceding context with a peanut being fictitiously described as dancing and singing can, e.g., invert comparative predictive probabilities such that the predicate *(was) in love* now has a higher probability for the listener than the otherwise more likely predicate *(was) salted*. The inversion of comparative predictive probabilities was revealed by a crossing-over of the N400 components between the two conditions measured on the critical predicates. The N400 component is defined as a negatively-going deflection of the event related potential over centro-parietal electrodes occurring around 400ms after stimulus onset (Kutas & Federmeier, 2011). As reviewed by Kuperberg and Jaeger (2016), the N400 component measured on a word is typically inversely correlated with its conditional probability given the preceding context.[1] There are two dominant interpretations of the underlying neuro-cognitive functions reflected in the N400 component: the semantic integration (e.g., Hagoort, Baggio, Willems, 2009) and the lexical retrieval view (e.g., Brouwer, Crocker, Venhuizen, & Hoeks, 2017). On these views, a negative increase of the N400 amplitude reflects higher processing demands associated with either (a) the integration of the target word's meaning into the compositional meaning of a sentence, or, respectively, (b) the retrieval of the target word's lexical meaning from memory.

Neural network models of the N400's underlying neural mechanisms have been proposed (e.g., Brouwer et al., 2017), some of which take the correlation of the N400 component with its predictive probability as a key explanandum (Rabovsky, Hansen, & McClelland, 2018; Fitz and Chang, to appear).

What has remained unclear in the peanut study is which factors of the context are responsible for the crossing over of the N400 components. The Semantic Similarity View maintains that the contextual influence is due to the degree of the semantic similarity between parts of the discourse context and the words in the target sentence (Otten & Van Berkum, 2008). The semantic similarity between two expressions can be determined by statistical regularities on co-occurrences in large corpora, as described in Distributional Semantics. In the above example the expression *in love*, e.g., has a greater semantic similarity to words in the context story (e.g., *dancing*, *singing*) than *salted*.[2]

The Relevance View, in contrast, holds that the crossing-over and the associated changes in the listeners' predictions

§ MW and MU contributed equally.

[1] A problem for this interpretation of the N400 are so-called semantic illusions, where zero-Cloze cases do not yield an increase in the N400 amplitude (cf. Kuperberg, 2007; Bornkessel-Schlesewsky & Schlesewsky, 2008; Brouwer, Fitz, & Hoeks, 2012).

[2] Existing accounts in Distributional Semantics base semantic similarity values merely on co-occurrences of syntactically unstructured lexical primitives and have problems coping, especially, with certain logical contexts such as negation or negative quantifiers. It would thus not be surprising if semantic similarity values attained by existing Distributional Semantics accounts had problems predicting the N400 in those contexts (e.g., Urbach & Kutas, 2010; Nieuwland, 2016). However, ongoing research in Distributional Semantics attempts to also capture complex logical contexts.

Table 1. Example of stimuli with English translation (Experiments 1 & 2). In the 2 × 2 design, Agentive (+Alex) and Non-Agentive (– Alex) verbs are combined with a standard (AStdCtx) or a new context (ANewCtx). The word order of the target sentence in the English translation is adjusted to the German original.

are only due to relevance considerations, regarding the relation between the context and the target expression. In the process of comprehension, the listener may assume that the speaker has chosen a particular combination of words in the discourse to maximize relevance (Sperber & Wilson, 1996). In the above example, the preceding fictitious story appears to be more relevant if the noun *peanut* is interpreted as animate. Consequently, a completion with the predicate *in love* should be more probable than one with *salted*. The Relevance View might also be associated with the view that there are no identifiable word meanings in the mental lexicon, at all (Elman, 2004). Consequently, the notion of semantic similarities between lexical meanings would be void.

Both, the Semantic Similarity and the Relevance View contrast with the Bayesian Pragmatic View. The latter accounts for the rational cooperation between speaker and listener by Bayes's Theorem. The predictive probability is identified with the posterior probability of a word, which results from updating its prior probability with its likelihood. The prior is simply a function of the semantic similarity (reflecting overall statistical co-occurrences) between the target word and the words in the preceding context. By being able to update the prior, listeners can incorporate pragmatic considerations on speakers' intentions, such as the thrive for relevance, into to their interpretation and, consequently, adjust their predictions about speakers' continuation of a sentence. Bayesian pragmatics has been successfully used to explain results in behavioral experiments on simple referential games (Frank & Goodman, 2012), scalar implicatures (Degen, Tessler, & Goodman, 2015; Goodman & Stuhlmüller, 2013), gradable adjectives (Lassiter & Goodman, 2013; Qing & Franke, 2014), modal expressions (Lassiter & Goodman, 2015), and figurative meaning (Kao, Wu, Bergen, & Goodman, 2014). It has so far only been validated in EEG by Werning & Cosentino (2017).

In this paper, we test and compare the empirical adequacy of the three different views. For each of the views, a quantitative model of the listener's predictive probability of a word given a preceding discourse is developed. To feed the model with data, values for semantic similarity and relevance are attained. As a measure of semantic similarity, we use GloVe values (see below), a computer linguistic measure in the framework of Distributional Semantics. Values for relevance are collected via relevance ratings in an online questionnaire. To determine listeners' predictive probabilities, we perform two experiments with the same stimulus material: a forced-choice Cloze study employing an online questionnaire and an N400 study in EEG. In a multiple linear regression analysis, finally, the proportions of variance explained by each of the three models are compared with regard to both experiments.

Models

To design the experiment, we build on Pustejovsky's (1995) Generative Lexicon Theory, according to which the lexical entry of a concrete noun (e.g. *cake*) contains a "Qualia Structure", which, among others, specifies an Agentive component (e.g. *bake*). The Agentive component represents the typical way of bringing about the denoted object – it contrasts with the Telic component that relates to a typical purpose or function, e.g., *cake-eat* (Cosentino, Baggio, Kontinen, & Werning, 2017). Triggered by verbs like *begin* and *finish*, the Agentive component of a noun co-composes with the noun in sentence meaning composition (Werning, 2004, 2005). This explains why sentences such as (a) and (c) are typically understood as having the meaning of (b) and, respectively, (d):

(a) Granny finished the cake.
(b) Granny finished baking the cake.
(c) The artist began the statue.
(d) The artist began sculpturing the statue.

Since nouns often co-occur with verbs expressing their Agentive component – so-called Agentive verbs – the semantic similarity of a noun and the respective Agentive verb is usually high. For our stimuli, the high semantic similarity was explicitly confirmed by GloVe values (see below).

Each quadruple of our 2×2 experimental design $\{+\text{ALex}, -\text{ALex}\} \times \{\text{AStdCtx}, \text{ANewCtx}\}$ (see Table 1) was built around a fixed concrete noun n (*cream*). In condition +ALex as [opposed to −ALex] the critical word was chosen as a verb (*whip* [*draw*]) that expressed [did not express] the

Agentive component in the lexical entry of the preceding noun n and had a high [low] semantic similarity to it. In condition AStdCtx, a standard context preceded the target sentence, whereas in condition ANewCtx the preceding discourse sentence suggested a new way of bringing about the object. The semantic similarity between the verbs and each of the context sentences was held invariant over all four combinations of conditions.

The Semantic Similarity Model presupposes that the only predictor for the verb given its preceding discourse is the semantic similarity of the former to the latter (word frequency held constant). The predictive probability $P_n(v|c)$ of the verb v following the noun n given the preceding context sentence c is a monotonously increasing function f_n^+ of the semantic similarity $S(v,n)$ between the verb and the noun and the (however invariant) semantic similarity $S(v,c)$ between the verb and the context sentence c. Accordingly, the listener's predictive probability $P_n(v|c)$ hence comes to:

$$(2)\quad P_n(v|c) = f_n^+\,(S(v,n)).$$

The Relevance Model, in contrast, maintains that listeners assume that speakers aim at maximizing relevance by choosing their utterances. The sole predictor is the relevance of the situation expressed by the context sentence c for the action (expressed by the verb v) to be performed on the object (denoted by the noun n):

$$(3)\quad P_n(v|c) = g_n^+\,(Rel_n(c,v)).$$

The Bayesian Pragmatic Model allows listeners to update their priors regarding the verb following the noun with pragmatic considerations on speakers' intentions, thus, arriving at probabilistic predictions of the verb. The prior, i.e., $P_n(v)$, strictly increases with the semantic similarity between the verb v and the noun n. The update as described by the likelihood, i.e., $P_n(c|v)$, is modelled as the conditional probability of speakers' choice of a context c given their communicative intentions, namely, their intentions to attribute, to a protagonist, an action (denoted by the verb v) to be performed on a given object (denoted by the noun n). The speaker, in other words, has to choose a preceding context sentence (c) to let this action appear relevant such that the choice of c given v strictly increases with the relevance of c for v. This leads to the following identifications: $P(c|v) = g_n^+\,(Rel_n(c,v))$, $P_n(v) = f_n^+\,\big(S(v,n)\big)$, and by Bayes Theorem we get:

$$(4)\quad P_n(v|c) = K \cdot P_n(c|v)\,P_n(v) = K \cdot g_n^+\,(Rel_n(c,v)) \cdot f_n^+\,\big(S(v,n)\big).$$

The Bayesian update of the semantic similarity can be regarded as reflecting a relevance-guided modulation of the Agentive component in the lexical entry of the noun (Recanati, 2012).

Model Predictions. Both, Cloze values and the amplitude of the N400 component, can be assumed to correlate with the predictive probability $P_n(v|c)$. To model the two variables, we assume monotonous functional relations between $P_n(v|c)$ and the values of the Cloze test and, respectively, the N400 amplitude measured on v.

Account	Model
Bayesian Pragmatic View	$a\,Rel_n(c,v) + b\,S(v,n) + k$
Relevance View	$a\,Rel_n(c,v) + k$
Semantic Similarity View	$b\,S(v,n) + k$

Table 2. Linear parametric model predictions for Cloze values and the amplitude of the N400 component measured on the critical verb.

Logarithmization and subsequent linear approximation of the model predictions (2), (3) and (4) lead to the linear parametric model predictions described in Table 2. The negative logarithm of the predictive probability of a word has been interpreted as word surprisal and is directly correlated with the amplitude of the N400, measured on the word (Frank, Otten, Galli, & Vigliocco, 2015).

Experiment 1: Cloze Test

Method

Participants: Cloze Test. Forty German native speakers were recruited via Prolific. Three participants, who failed to have a high-school degree, and two further ones, who answered the test in below four minutes (estimated time: ten minutes), were excluded. Of the remaining thirty-five participants, 57.1% were male, 42.9% female. The average age was 30.20 years (SD=10.86).

Participants: Relevance Rating. Forty participants were recruited via Prolific. Of those, thirty-eight people were included which satisfied the requirement of being German native speakers and having attained a high school diploma.

General Material. For the forced-choice Cloze test and the relevance ratings, forty quadruples of the 2×2 design were generated in German (Table 1). Regarding the Cloze test, we used a forced-choice format to ensure that only Agentive verbs were available for comparison. The critical verbs did neither repeat, nor occur in context sentences.

$\langle +\text{ALex}, -\text{ALex}\rangle$-*verb pairs*. For each noun (e.g., *cream*), an +ALex verb (*whip*) and an −ALex verb (*draw*) were chosen so that the semantic similarity of the +ALex verb to the noun was .15 higher than that of the −ALex verb. $\langle +\text{ALex}, -\text{ALex}\rangle$-pairs did not differ significantly in frequency class (https://wortschatz.uni-leipzig.de/), nor in character length.

Context sentences. For each quadruple, a standard context was chosen (AStdCtx) that was highly relevant for the $\langle \text{n}, +\text{ALex}\rangle$ combination and less relevant for $\langle \text{n}, -\text{ALex}\rangle$. The new contexts (ANewCtx) were designed to reverse this order of relevance. The semantic similarity of $\langle \text{Context}, \text{Verb}\rangle$-pairs was not allowed to differ significantly over all four conditions. The character length of contexts AStdCtx and ANewCtx did not differ significantly either.

Fillers. Twenty filler discourses with congruent and twenty with incongruent $\langle \text{Noun}, \text{Verb}\rangle$-pairs were generated and had the same structure as the test material. The frequency

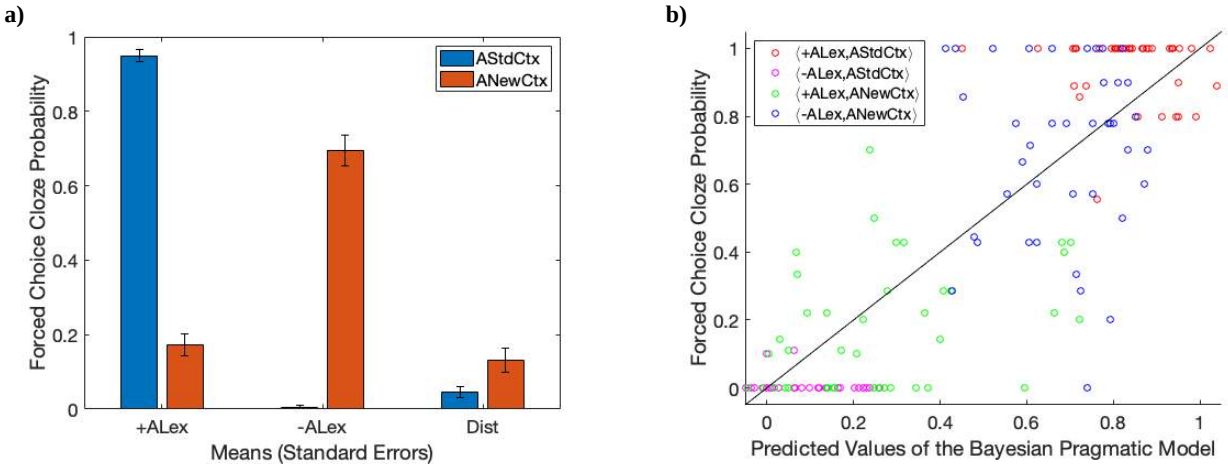

Figure 1. (a) Forced-choice Cloze probabilities. (b) Scatterplot for predictions of the Bayesian Pragmatic Model.

class and the length of the verbs did not differ significantly from the critical verbs of the test stimuli. Nor did the character length of the respective contexts differ significantly. *Semantic Similarity* was measured by an implementation of GloVe (Global Vectors, Pennington, Socher, & Manning, 2014) based on all articles from German Wikipedia and ca. three million news articles from Leipzig Corpora Collection (Goldhahn, Eckart, & Quasthoff, 2012).

Material and Design (Cloze Test). For the forced-choice Cloze test, the stimulus material was randomly distributed over four questionnaires in a counterbalanced way to avoid repetition. Context sentence and target sentence were presented as described in Table 1, with a blank instead of the critical verb. Subjects were instructed to choose the best fit among six alternative verbs. The alternatives always included the +ALex and −ALex verbs, as well as four alternative, agentive verbs drawn from the stimulus material not used in the questionnaire.

Material and Design (Relevance Ratings). The stimulus material including fillers was randomly distributed over four questionnaires in a counterbalanced way to avoid repetition. For each of the vignettes the context sentence surrounded by a box and marked as "A" was shown above the target sentence marked as "B", with the critical verb underlined. Participants were instructed to rate relevance on a 7-point Likert scale by answering the question: How plausible is the situation described in box A, given the action in sentence B.

Procedure. The Cloze test and relevance ratings were done using online questionnaires, via Qualtrics. The relevance ratings were preceded by two practice items.

Results and Discussion

Mean Cloze probabilities are summarized in Figure 1. The following results ensued: (1) $\langle +\text{ALex}, \text{AStdCtx}\rangle$ and $\langle -\text{ALex}, \text{AStdCtx}\rangle$ ($p < .0001$, $d = 9.01$), (2) $\langle -\text{ALex}, \text{ANewCtx}\rangle$ and $\langle -\text{ALex}, \text{AStdCtx}\rangle$ ($p < .0001$, $d = 2.65$), (3) $\langle +\text{ALex}, \text{AStdCtx}\rangle$ and $\langle +\text{ALex}, \text{ANewCtx}\rangle$ ($p < .0001$, $d = 3.88$), and (4) $\langle -\text{ALex}, \text{ANewCtx}\rangle$ and $\langle +\text{ALex}, \text{ANewCtx}\rangle$ ($p < .0001$, $d = 1.31$). To compare the Semantic Similarity, the Relevance and the Bayesian Pragmatic Models, we performed multiple regression analyses of Cloze data (see Table 3). The correlation between relevance ratings and corresponding similarity values was very small ($r = .10$).

The Bayesian Pragmatic Model was the clear winner according to BIC and AIC values, which take the unequal number of predictors into account. Within this model, the relevance values ($\beta = 1.01, p < .001$) and semantic similarity values ($\beta = .31, p < .01$) were significant predictors (for the scatterplot see Figure 1).

Experiment 2: EEG Study

Method

Participants. Twenty-eight participants were recruited. Two participants were excluded due to noisy EEG data and pain medication prior to the experiment. Of the resulting twenty-six participants, 30.8% were male, 69.2% female. The average age was 24.23 years (SD=3.40).

Design and Material. The stimulus material and fillers described in Experiment 1 were used. One of eight three-word phrases succeeded each target sentence (e.g., *und ist fröhlich* [and is happy]) to avoid the critical word being sentence final. Half of those appended phrases expressed positive and, respectively, negative emotional states, randomly chosen for each quadruple in a counterbalanced way.

The stimulus material was randomly split in two parts so that every context sentence and every critical verb appeared only once in each part. The two parts were administered to participants in two separate sessions, at least two weeks apart, to avoid carry-over and contrast effects. All participants had been presented with the entire stimulus material plus fillers. The order was counterbalanced. The complete set of fillers described in Experiment 1 was used in each session, resulting in eighty vignette (twenty per condition) and forty fillers (twenty congruent and twenty incongruent). The order was randomized.

Procedure. Each trial started with a fixation cross (1300ms) followed by the presentation of the context sentences. The context sentences were split up in roughly equal-sized chunks (character lengths: M = 17.91, SD =

Table 3. Model comparisons for the regression analysis of Cloze probabilities (Experiment 1) and EEG amplitudes (370–500ms, Experiment 2). The EEG Amplitude was averaged across electrodes CP1, CPz, CP2, P1, Pz and P2. AICc = Aikaike Information Criterion corrected for sample size. *p<.001.

3.41). Each chunk was presented for 1300ms with a random interval of 200–400ms.

The target sentence, including the three-word phrase, was then presented word by word. In order to allow for a sufficiently long time interval for measuring ERP components, the target word was always presented for 450ms followed by an inter-stimulus interval of 450ms. All other words in the target sentence were presented for either 400 or 450ms, with a random inter-stimulus interval of 250–450ms. 700ms after the vignette's last word, participants had to judge, on a keypad, whether the complete vignette – consisting of context and target sentence (including the three-word phrase) – was plausible. The left-right orientation was randomized. The plausibility judgment should ensure that participants read the stimulus material carefully. Three examples with clearly congruent and incongruent ⟨Noun, Verb⟩-pairs served as practice material, prior to the testing phase.

Electroencephalogram recording and data processing. A BrainAmp Acticap system was used to record the electroencephalogram (EEG) from 66 active electrodes including four electro-oculogram electrodes for monitoring horizontal and vertical eye movements. The Brain Vision Analyzer 2.0 was employed to filter the data, correct for eye movements via independent component analysis (ICA). We used automatic artifact rejection to remove an episode per electrode if the change in currency exceeded 150μV in a 150ms interval. In case more than 10 electrodes were affected, or the trial had been interrupted before the critical word occurred, the whole episode was removed.

ERP data on the critical word (for each participant and trial) was exported to Matlab and individual trials were sorted and averaged across participants for each of the 160 vignettes, based on the Fieldtrip format for EEG data.

Results and Discussion

Mean amplitudes in the interval 370–500ms for posterior-central electrodes (CP1, CPz, CP2, P1, Pz, P2) across the four conditions are described in Figure 2. Bonferroni-corrected t-tests revealed significant differences between (1) $\langle +\text{ALex}, \text{AStdCtx}\rangle$ and $\langle -\text{ALex}, \text{AStdCtx}\rangle$ ($p < .01$, $d = 1.80$), (2) $\langle -\text{ALex}, \text{ANewCtx}\rangle$ and $\langle -\text{ALex}, \text{AStdCtx}\rangle$ ($p < .01$, $d = 1.13$), and (3) $\langle +\text{ALex}, \text{AStdCtx}\rangle$ and $\langle +\text{ALex}, \text{ANewCtx}\rangle$ ($p < .05$, $d = .61$). However, no significant difference was found for (4) $\langle -\text{ALex}, \text{ANewCtx}\rangle$ and $\langle +\text{ALex}, \text{ANewCtx}\rangle$ ($d = .17$). For the respective ERP results as measured on the CPz see Figure 3.

To compare the Semantic Similarity, the Relevance and the Bayesian Pragmatic Models, we performed multiple regression analyses of the mean, baseline-corrected ERP in

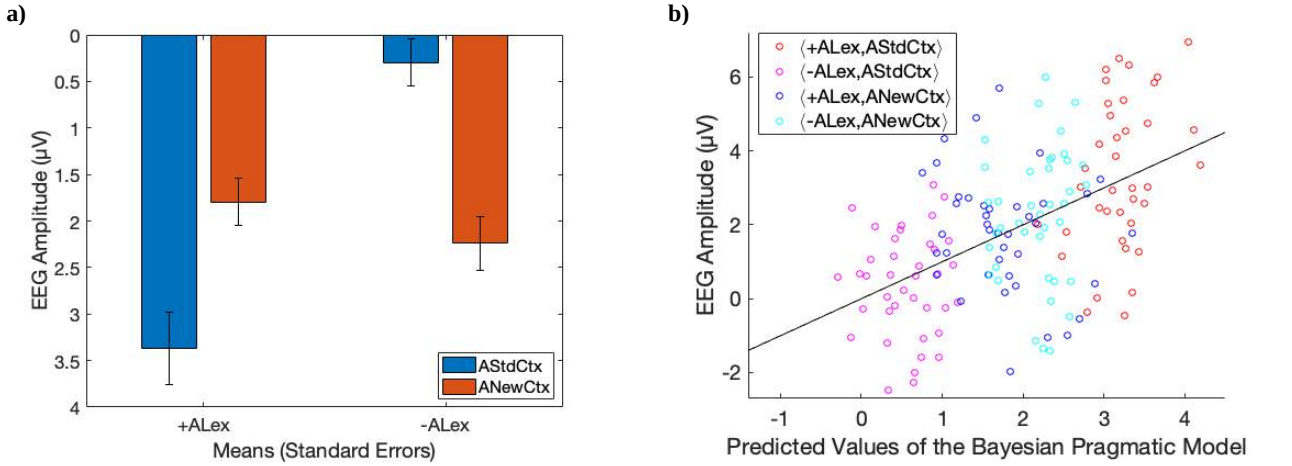

Figure 2. (a) EEG amplitudes (370–500ms, μV) for the pooled central-posterior electrodes (CP1, CPz, CP2, P1, Pz, and P2) after baseline correction. (b) Scatterplot for predictions of the Bayesian Pragmatic Model.

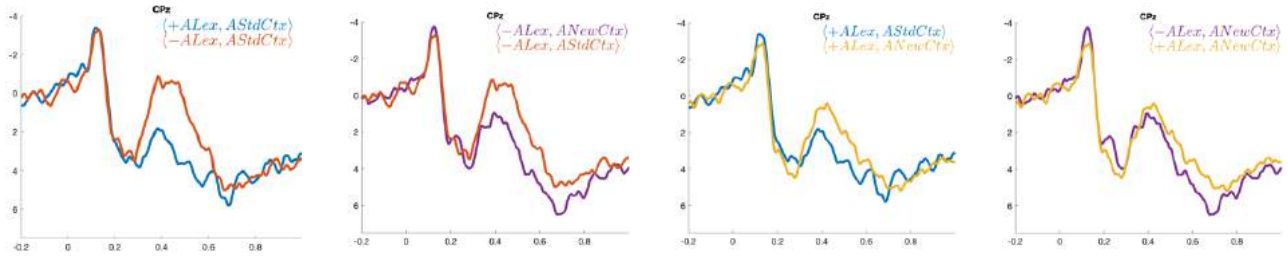

Figure 3. ERPs as measured on the CPz (µV).

the interval 370–500ms of the pooled posterior-central electrodes (see Table 3). Again, the Bayesian Pragmatic Model turned out as the clear winner according to BIC and AIC. Within this model, the relevance values ($\beta = 2.54, p < .0001$) as well as the semantic similarity values ($\beta = 2.81, p < .001$) were significant predictors. See Figure 2 for the scatterplot of the averaged N400 amplitudes and the values predicted by the Bayesian Pragmatic Model.

General Discussion

We contrasted three views of how words contribute to a listener's understanding of a sentence and compared three corresponding quantitative models of how the listener's implicit probabilistic predictions on the completion of a discourse is affected in online comprehension. The Semantic Similarity Model presupposes that the only predictor for a word given a preceding discourse is the semantic similarity between the two. The Relevance Model maintains that listeners assume that speakers aim at maximizing relevance by choosing their utterances. The Bayesian Pragmatic Model assumes a relevance-guided modulation of a word's lexical meaning that can be regarded as a Bayesian update of learnt statistical regularities stored in semantic memory.

To compare the explanatory power of the three models with regard to our Cloze and EEG data, we used the BIC and AIC criteria. Unlike r^2, BIC and AIC penalize for the unequal number of predictors. The clear winner in the comparisons, regarding both, the Cloze and EEG data, was the Bayesian Pragmatic Model. The Bayesian Pragmatic Model is not merely a combination of relevance and semantic similarity, but relates the two as the relevance-guided Bayesian update of a similarity-based prior probability. Interestingly, the two factors, relevance and similarity, did not contribute equally to the success of the Bayesian Pragmatic Model. Relevance outperformed semantic similarity, as indicated by the relative success of the Relevance over the Semantic Similarity Model. With regard to the EEG data, relevance explains 2.27 times as much variance as semantic similarity does. With regard to the Cloze data, however, this ratio is dramatically higher and equals 14.16. This pattern is also evidenced by comparing the EEG and the Cloze data with respect to the relative differences in BIC and AIC values of the three models. At first sight, this suggests that relevance is the dominant factor for the predictive probability of a word. A closer look reveals that semantic similarity still plays a larger role in truly incremental online comprehension, as observed in EEG, than in the Cloze test, which allows for backward-looking and untimed deliberation.

The lack of a significant difference of the ERPs in the time window of the N400 (370–500ms) for the comparison of the conditions ⟨+ALex, ANewCtx⟩ and ⟨−ALex, ANewCtx⟩ – with an effect size of only $d = .17$ – indicates that a greater semantic similarity value can compensate for a lower relevance value. This qualitatively illustrates the still prevalent importance of semantic similarity and thus the superiority of the Bayesian Pragmatic Model over the Relevance Model.

Our results also have clear implications for both the retrieval and the integration account of the N400. In light of our results, both approaches have to be modified to explicitly address the relevance-guided modulation of lexical meaning, described as updating by the Bayesian Pragmatic Model. Following the retrieval account, it will be the *modulated* lexical meaning of a preceding word that facilitates or impedes the retrieval of a subsequent word's meaning. Within the integration account, it is the *modulated* lexical meaning that determines the ease of integrating a subsequent word's meaning into the compositional meaning of the sentence.

A Trade-Off in Learning Across Levels of Abstraction in Adults and Children

Abstract

Learning about novel objects not only involves noticing information that makes the object unique, but also what makes objects the same. Yet, these two levels of learning involve different pieces of information, meaning that learning one well could come at the cost of the other. Moreover, children may categorize in a fundamentally different way, resulting in these levels of learning interacting differently. To investigate this, we had adults and children perform a categorization task followed by an item recognition test. We found that adults showed a trade-off, such that the ability to categorize items came at the cost of memory for those items. Using a subset of more unique lures, children's memory trended towards a trade-off with category learning. However, this was only observed among the older children. This suggests that adults' efficient learning comes at a cost, and this trade-off may start to appear in the elementary school years.

Keywords: cognitive development; category learning; abstraction; generalization; memory; selective attention

Background

Learning about objects goes beyond simply identifying unique features. We also learn abstract information, picking up on consistencies across objects. These different levels of abstraction are each informative in different ways, as the former provides details specific to an individual object while the latter facilitates categorization and generalization across objects. Given the discrepancy in the information learned, it seems likely that learning information really well at one level of abstraction might impede learning at the other, resulting in a trade-off in learning.

In fact, we know that categorical knowledge can impact memory in important ways. For instance, the Deese-Roediger-McDermott (DRM) paradigm has been found to show memory distortions in adults for words on a list when the presented words are categorically related. In this case, the category-level information that connects the words on the list causes memory distortions, a loss of memory of the specific words themselves (item-level information) and false memory for words that did not occur. This memory distortion is not seen when the word list is not categorical, suggesting that it is the abstraction of the category that is obscuring the details and producing distortions (see Brainerd, Reyna, & Ceci, 2008).

In addition, Sloutsky and Fisher (2004) found a drop in adults' memory for specific animals after participants sorted them categorically. When left uncategorized, memory for the individual animals was good, however following an induction task that required sorting the animals into species, memory for the individuals dropped to chance levels.

One possible explanation for this pattern of behaviour is the longstanding fuzzy-trace theory, in which abstraction necessarily involves a distillation of information to a vague, detail-free, gist representation (Brainerd & Reyna, 1990). In other words, abstraction is facilitated by a lack of detailed, item-level information. Similarly, the schema literature would suggest a comparable process in the organization of our knowledge, as schemas are abstract representations of something (be it a place, animal, social interaction) accumulated through experience that create expectations for the future (Mandler, 1984). Details from specific experiences are filtered out and consistencies are used to create a generic representation. Again, it is the loss of detailed information that makes a schema so generalizable.

Given this previous work and theory, there could be a trade-off in learning item-level and category-level information. Yet, work exploring this relationship has to date only included pre-existing categories and hasn't tackled whether a trade-off might occur *during* or in the service of category *learning*. It remains unclear how novel category learning would affect the interaction of item- and category-level information.

An eye-tracking study that assessed attention during a novel category learning task may provide some insight into this question (Rehder & Hoffman, 2005). In this study, as participants were learning to categorize the stimuli, they were found to fixate on all features of a stimulus. However, once they had successfully learned to categorize, they were found to fixate only on the diagnostic feature. This narrowing of focus would likely result in better categorization behavior, likely at the expense of learning about non-category relevant features of the objects, thereby producing a trade-off in object and category learning.

In contrast, when it comes to category learning, an abstract representation could still be formed not by ignoring irrelevant features of objects, but by learning *all* of the features of objects—both relevant and irrelevant—well. After all, abstracting to learn a category only necessitates learning the

relevant information for that category and not necessarily ignoring what is irrelevant. This approach to category learning would of course result in a different relationship with item memory: there would not be a trade-off.

There is some research suggesting that children may not demonstrate a trade-off in item-level and category-level information. For instance, in the DRM paradigm discussed above, adults consistently fall prey to false memories when the word lists are thematic. Interestingly, children do not succumb to the same memory distortions. In fact, this paradigm finds that young children have few false memories, with that number steadily increasing across the elementary school years and peaking in adulthood (Brainerd et al., 2008). In this case, children seem to have no thematic intrusions and remember the item-level information despite their category membership, resulting in no trade-off.

A similar result was found by Sloutsky and Fisher (2004), discussed above. Whereas the adults' memory for individual animals dropped after categorization, children's memory remained consistent. Here again, children maintained memory for the item information despite categorization. Given these findings, it is likely that children will similarly not show a trade-off during category *learning*, although the answer to this question is as yet unknown.

Along these lines, it has been suggested that instead of utilizing only the diagnostic dimensions, children categorize by including all item-level information (Sloutsky, 2010). Indeed, support for a holistic approach to categorization was found in children but not adults; adults were found to use only diagnostic features to categorize, while children were found to use the entirety of the item, basing their categorization on overall similarity (Smith & Kemler, 1977). This difference may reflect children's developing ability to selectively attend, as they are less successful at suppressing irrelevant information (Rueda, Posner, & Rothbart, 2005).

Furthermore, these differences in attention are likely to impact memory. For instance, during change detection and search tasks, children have also been found to have superior memory for task-irrelevant information compared to adults, suggesting that children's distributed attention facilitates memory for task-irrelevant information (Plebanek & Sloutsky, 2017). Together, these findings raise a final question. If children are attending to all available information when learning to categorize, will they retain item-level information despite successfully learning to categorize? In other words, might children be immune to the trade-off in item-level and category-level learning that we expect to see in adults?

To answer these questions, two experiments were performed, one with adults and one with children. In each, participants performed an A/B categorization task to measure category learning and a recognition memory test to measure item memory. To assess how specifically the items were remembered, half of the recognition foils were similar to the categorization stimuli along an orthogonal (not categorically-diagnostic) dimension, and half were dissimilar.

Experiment One

Methods

Participants Participants included 60 undergraduate students from the University of Toronto participating for course credit (M = 19.73 years, 76% female).

Materials and Procedure The category learning task consisted of 60 trial-unique trials of a feedback driven A/B sort task. Participants were instructed to sort "amoebas" into one of two categories based on the feedback given. They were not told what features defined category membership. Each stimulus was presented for 1.5 seconds or until a response was given, and stimulus presentation order was randomized between participants. The task was conducted on an Apple desktop computer using PsychoPy (Peirce, 2008).

The stimuli were designed to vary categorically along one dimension and orthogonally along two dimensions. Category membership was defined by distortions of two prototypical dot patterns shown below (Fried & Holyoak, 1984; Seger et al., 2000; Figure 1a). The 84 exemplars were generated by allowing dots a 7% chance of differing from the original. No exemplars were repeated across stimuli.

The orthogonal dimensions included colour and shape. Unique colours were randomly assigned, and shapes were created by making two extremely different shapes—generated from images of paint splatter—and morphing them together to varying degrees to create a series of related shapes (Figure 1b). All three dimensions were combined by placing the dot pattern in black on the coloured shape to create a total of eighty-four unique items (Figure 1d).

The item memory task consisted of a surprise item recognition test that always took place after the categorization task. In this recognition task, participants were asked if stimuli were present in the categorization task (old) or were new. Of the 48 stimuli presented at test, 24 were old, 12 were novel-shape lures, and 12 were same-shape lures. *Same-shape lures* were generated from the morphing procedure that was used to generate the categorization stimuli, but all twelve were unique and had not occurred during the categorization phase. Novel shape lures were created outside of the shape space used to generate the categorization stimuli, but were likewise generated from paint splatter images (see Figure 1c for examples). Order of presentation was randomized, and there was no time limit for response.

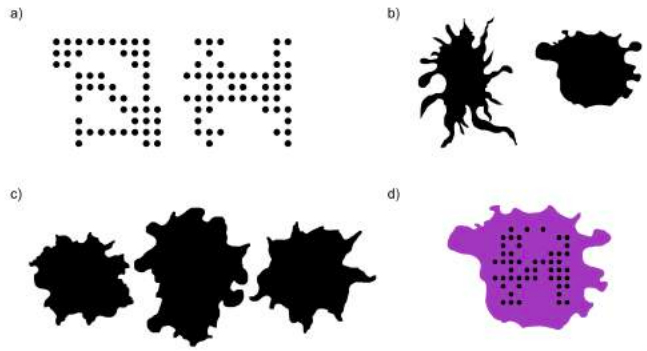

Figure 1: a) Diagnostic features defining category membership, b) Two shapes were morphed together to create a shape space, c) Novel-shape lures: Shapes were created outside of the shape space, d) An example of a complete stimulus: unique colours, shapes, and dot patterns were combined to create a set of completely unique stimuli.

Statistical Analysis We conducted all statistical analyses in R (R Core Team, 2017). Categorization accuracy was operationalized by calculating percentage correct in the category learning task. Item memory was calculated using d' (Z(hit rate) – Z(false alarm rate)), and scores were compared with chance using an independent-samples t-test. The general linear model was applied to all basic correlations, and general linear mixed-effects models were applied for analyses involving trial number using the lme4 package in R (Bates, Mächler, Bolker, & Walker, 2015). The fixed effects were categorization trial number and accuracy. Models contained random intercepts and slopes grouped by stimulus.

Results

Participants demonstrated learning in the categorization task, with accuracy increasing across trial number (β = 0.025, z = 9.793, p <.001) and an average overall accuracy of 76% (SD = 16.827). Similarly, participants demonstrated memory for the items at test, successfully distinguishing old items from new at a rate significantly different from 0 (M = 0.268, SD = 0.374; t(59) = 5.558, p <.001). As predicted, a tradeoff was also observed such that participants' categorization scores were negatively related to their recognition scores (F(1,58) = 14.31, p <.001, Figure 2). Thus, individuals who performed the categorization task better, had worse memory for exemplars.

To determine if memory was different for items that were categorized accurately from those that were not, we performed a t-test comparing the memory (d') for correctly and incorrectly categorized items. Memory was equivalent across correctly and incorrectly categorized items (t(495.18) = 0.463, p = 0.644). However, this relationship shifted over time, such that there was an interaction between memory for correctly and incorrectly categorized items and trial number (β = -0.016, z = -2.062, p = 0.039) such that memory for incorrectly categorized items moderately increased with an increasing number of trials (β = 0.001, z = 1.873, p = 0.061), and memory for correct trials moderately decreased with an increasing number of trials (β = -0.006, z = -1.648, p = 0.099).

To determine how specifically items were remembered, item memory was analyzed separately for novel-shape and same-shape lures by calculating d' using each as a unique false alarm score. A paired sample t-test determined that the two sets of scores were significantly different (t(59) = -7.643, p < .001). Using novel-shape lures, memory was significantly different from 0 (M = 0.7272, SD = 0.627; t(59) = 8.986, p <.001). Using same-shape lures, however, memory did not differ from 0 (M = -0.103, SD = 0.538; t(59) = -1.488, p = 0.142). Relating this to categorization performance across individuals, d' calculated using novel-shape lures was negatively correlated with categorization scores (F(1,58) = 25.7, p <.001), while d' calculated using same-shape lures was not (F(1,58) = 0.57, p = 0.453). Thus, the trade-off is only observed when using the novel-shape lures, for which there is evidence of memory.

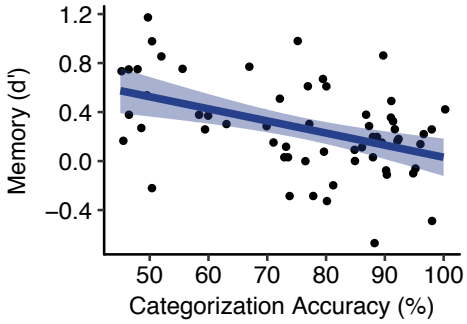

Figure 2: Item memory (d') by category accuracy (%). Each dot is an individual, the line signifies the slope and shading indicates standard error of the mean.

Discussion

As a group, participants successfully learned to categorize and remembered the items at post-test. Individual difference scores showed a trade-off between levels of learning such that those who performed well at the categorization task, performed more poorly at the item recognition task.

Participants failed to exhibit memory in comparison to the same-shape lures, but they did demonstrate memory when the lures were more distinct. Taken together, these data show that for adults, learning to categorize well impedes memory for items.

Experiment Two

Methods

Participants Participants included 61 children between the ages of 5- and 8- years old (M = 6.42 years, 48% female) recruited at a science museum. Exclusion criteria included lack of English skills to understand instructions, with one child meeting exclusion criteria.

Materials and Procedure The same two tasks were completed as in Experiment One, with a different, age-appropriate cover task. For the category learning task,

participants were told to sort two alien families onto their correct spaceship. Stimuli were presented for 3 seconds or until the participant responded. For the item memory test, 32 stimuli were presented randomly. Again, half were previously seen and half were new. Of the new, half were novel-shape lures and half were same-shape lures. Children were asked to verbally confirm their response after each button press. Tasks were completed on an Apple laptop using PsychoPy (Peirce, 2008).

Statistical Analysis We conducted the same analyses as Experiment One, as well as independent samples t-tests comparing adult and child scores.

Results

Children demonstrated learning in the categorization task, with accuracy increasing across trial number (β = 0.015, z = 6.619, p <.001). However, accuracy was significantly lower than adults (M = 65.889, SD = 17.664; β = -0.073, t = -3.399, p <.001, Figure 3). Children's item memory was poor: d' did not differ from 0 (M = 0.065, SD = 0.515; t(59) = 0.984, p = .329). Their item memory (d') was also significantly worse than adults (t(110) = 2.743, p = .007, Figure 4).

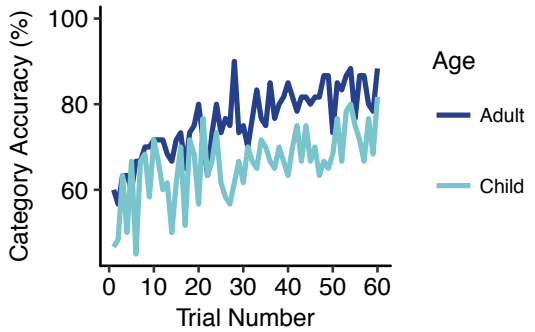

Figure 3: Category accuracy (%) by trial number and age group. The lines signify average group accuracy by trial. The dark blue line signifies the adult group, and the light blue line signifies the child group.

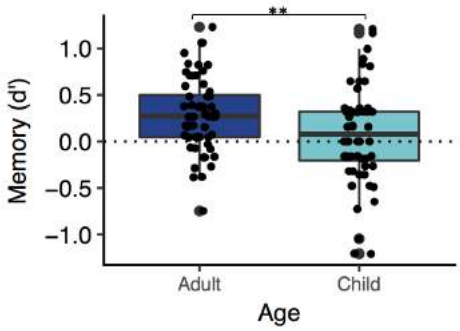

Figure 4: Item memory (d') by age group. d' is plotted separately for adults (dark blue) and children (light blue). The boxes signify the interquartile range and the whiskers signify the first quartile and below and the third quartile and above, respectively. The dotted line signifies chance, or no evidence of memory, and individual dots represent participants.

No trade-off was found between children's categorization accuracy and item memory (d') (F(1,58) = 1.766, p = .1891, Figure 5). Moreover, children's age was not found to interact with this relationship (F(3,56) = 0.647, p = 0.5885).

To determine if memory was different for items that were categorized accurately from those that were not, we performed a t-test comparing memory (d') for correctly and incorrectly categorized items. While not significant, we found a marginal difference in memory for correctly and incorrectly categorized items (t(690.2) = 1.950, p = .052), such that incorrectly categorized items were remembered moderately better. In addition, this relationship showed a trend toward shifting over time, with a trending interaction between time and accuracy (β = 0.013, z = 1.660, p = .097). Incorrectly categorized items were moderately better remembered at the beginning of the task, and correctly categorized items at the end of the task. While not significant, it is important to note that this relationship is the opposite pattern of that observed in adults.

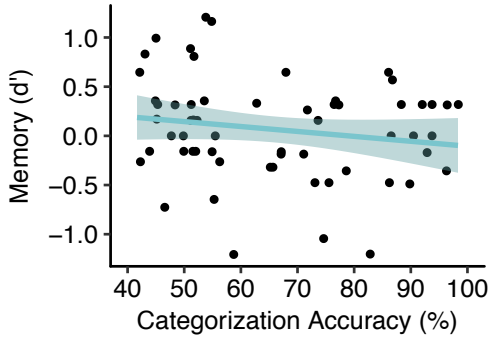

Figure 5: Child item memory (d') by category accuracy (%). Each dot is an individual, the line signifies the slope and shading indicates standard error of the mean.

To determine how specifically items were remembered, d' was calculated twice, once with each type of lure. Using a paired sample t-test, the two sets of scores were found to be significantly different (t(59) = -3.302, p = 0.002). When calculated with only novel-shape lures, memory was significantly different from 0 (M = 0.2701, SD = 0.822; t(59) = 2.547, p = 0.013), but memory did not differ from 0 when calculated with only the same-shape lures (M = -0.092, SD = 0.526; t(59) = -1.361, p = .179). While this is a similar pattern to that found in the adults, when compared to adults, the former was significantly lower (t(110.22) = 3.43, p <.001, Figure 6). Thus, children did show memory, but needed more distinct lures to demonstrate it, and it was poorer than that observed in the adults.

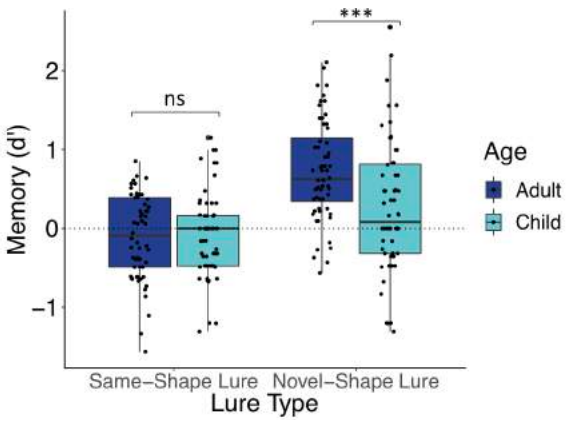

Figure 6: Item memory (d') calculated with novel- and same-shape lures across age group. The boxes signify the interquartile range and the whiskers signify the first quartile and below and the third quartile and above, respectively. The dotted line signifies chance, or no evidence of memory, and individual dots represent participants. The two left-hand boxes signify scores calculated with same-shape lures and those on the right signify scores calculated with novel-shape lures.

Looking at individual differences, d' calculated using novel-shape lures was not significant but had a moderate effect trending towards a trade-off with categorization accuracy, as more successful category learners had worse memory ($F(1,58) = 3.504$, $p = .0663$). No relationship was found between d' calculated with same-shape lures and categorization accuracy ($F(1,58) = 0.07289$, $p = .788$). The trade-off did not interact with children's age for d' calculated with the novel-shape lures ($F(3,56) = 1.618$, $p = 0.196$) or same-shape lures ($F(3,56) = 0.591$, $p = 0.623$). Nonetheless, to further assess the impact of children's age on the trade-off, we broke the children into two age groups: 35 5- and 6-year old children (young) and 25 7- and 8-year old children (old). Upon analyzing the trade-off in each group, the moderate effect found in the novel-shape lures continued in the old children ($F(1,23) = 3.303$, $p = 0.082$), but disappeared in the younger children ($F(1,33) = 0.790$, $p = 0.380$, Figure 7). No relationship between categorization accuracy and d' calculated with the same-shape lures was found in the old ($F(1,23) = 0.094$, $p = 0.762$) or young children ($F(1,33) = 0.182$, $p = 0.672$).

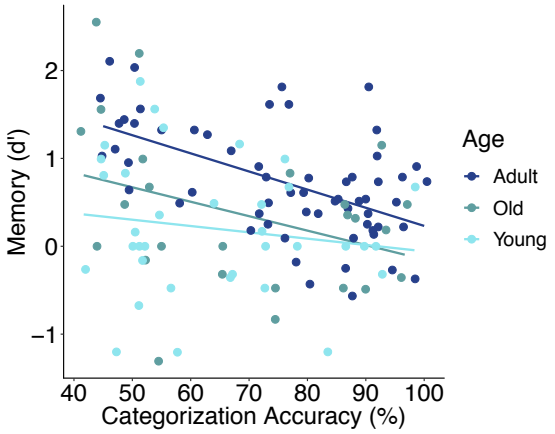

Figure 7: Item memory (d') by category accuracy (%) across adults, 7-8 year olds ("Old"), and 5-6 year olds ("Young"). Each dot is an individual, and the lines signify the slope. Adults are represented in dark blue, older children in teal, and young children in light blue.

Discussion

Although children learned to categorize, their memory for items was very poor overall. Like adults, children had no memory when compared to the same-shape lures but demonstrated memory when compared to the novel-shape lures, suggesting that they could only distinguish new and old items when the lures were distinctive.

Item memory did not significantly predict category learning, which is not surprising given how low children's memory was. However, a moderate effect was observed when d' was calculated with only the novel-shape lures, such that category learning scores were negatively correlated with memory (d'). Finally, this trend was only present in the older, 7- and 8-year old children but was not found in the younger, 5- and 6-year old children.

General Discussion

Building off of prior research showing a trade-off in pre-existing category knowledge and item memory, we found that a trade-off also occurs during the process of learning new categorical structures. For the adults, there was a cost to category learning, as those who performed well at the category learning task demonstrated worse memory for the items at post-test. This effect was driven by the more distinct lures, as memory for the similar lures was overall quite poor. In comparison, the children did not show a trade-off in category learning and item learning. However, when d' was calculated using only the distinct lures, a moderate effect was observed. This effect was found to be driven by the older, 7- and 8-year old children. When divided into two age groups, the moderate trade-off was observed in the older children, but there was no trade-off found in the younger, 5- and 6-year olds. These data may point to adults and young children approaching categorization in different ways.

While the mechanism at play remains unclear, a selective attention account provides an explanation for the pattern of data observed in adults. Selective attention is a top-down

process that not only directs attention to *relevant* information, but also suppresses *irrelevant* information (Pashler, Johnston, & Ruthruff, 2001). In a categorization task, the relevant information is the diagnostic feature, while the remaining information is irrelevant. Indeed, as discussed above, upon learning what defines a category, learners have been shown to fixate their gaze on the diagnostic feature (Rehder & Hoffman, 2005). In the current task, successful category learners likely fixated on the dot pattern while suppressing the irrelevant, item-level information. Given that unattended information is not remembered well (Simons, 2000), this could explain the successful learners' poor memory performance. Conversely, the poor category learners may have failed to learn which feature was diagnostic, thereby never selectively attending to it and, thereby continuing to attend to item-level information.

In comparison, it is less clear what mechanism best accounts for the children's pattern of behaviour, as they displayed only a moderate trade-off and, more specifically, only in the older children when calculating memory using the most distinctive lures. One possibility is that the younger children are utilizing a holistic, similarity-based categorization style, leading to a lack of trade-off. In comparison, the older children may be beginning to shift from this categorization style towards a more adult-like style focused on a diagnostic feature. A developmental shift in this age group would account for the moderate trade-off observed.

Prior research suggests that young children may categorize based on overall item similarity (Smith & Kemler, 1977), and if this were the case, children would attend to all features equally instead of selectively attending to a single feature. As such, their item memory would not drop upon categorization. Interestingly, Smith and Kemler (1977) found that this approach to categorization was consistently used among 5-year olds, but results were more ambiguous among 8-year olds. Perhaps the ambiguity reflects the beginning of adult-like categorization, and explains the moderate trade-off that we see here.

Indeed, a shift away from holistic processing would reflect the developmental course of selective attention, as the ability to filter irrelevant information has been found to improve across the elementary school years (Enns & Akhtar, 1989). An increase in selective attention would facilitate a more adult-like approach and result in a trade-off between category learning and item memory. Future research assessing the role of selective attention and its developmental course on the trade-off would help clarify the mechanism behind the patterns of behaviour observed in each age group.

Interestingly, children's memory was quite poor overall, which is not aligned with a holistic processing approach. Prior studies found children to have superior memory to adults for item-level information since they processed more information overall (e.g., Sloutsky & Fisher, 2004; Plebanek & Sloutsky, 2017). However, it is also well established that children have poor memory compared to adults (Ghetti, Angelini, & Annunzio, 2008; Rubin, 2000), and the adult group's item memory was not particularly strong either. It may be the case that children learned to categorize in a different way than the adult group but did not have the memory capacity to demonstrate it.

Alternatively, children's poor memory may not reflect poor memory overall, but may be symptomatic of poor pattern separation. Work by Ngo, Newcombe, & Olson (2018) found that 4-year olds were significantly worse than 6-year olds and adults at distinguishing old items from very similar items, irrespective of overall memory scores. Due to the similarity across items in the current study, it is possible that the younger children were disproportionately unable to discriminate the items. While unclear at this time, boosting children's memory in the future by increasing discriminability between items would help us to better understand how category learning and item memory interact across development.

The different patterns of learning across categorization trials in the adult and child groups suggest that the groups could be using different learning strategies. First, adults remembered incorrectly categorized items better towards the end of the task, while children remembered them better towards the beginning and moderately better overall than correctly categorized items. It may be the case that with increased learning across trials, errors became rare and surprising to adults and were, thus, remembered better. In comparison, children's heightened memory for errors throughout may reflect their tendency to respond more reactively than adults (Chatham, Frank, & Munakata, 2009), the surprise of which could have a memory boosting effect throughout.

Second, adults remembered correctly categorized items better towards the beginning of the task while children remembered them better towards the end. Given our assertion of increased selective attention with category learning in the adult group, it follows that correctly categorized items would be remembered more poorly towards the end of the task after learning had occurred and irrelevant information became unattended. Since children showed the reverse pattern in memory, this may provide further support for a more holistic approach to categorization than one of selective attention. This pattern would suggest that children maintain distributed attention throughout the task, as their memory for task-irrelevant information does not drop. The boost in memory observed towards the end may be a simple recency effect. Whatever the explanation, these divergent patterns of learning show that adults' and children's online categorization performance impacts memory.

Across the lifespan, our approach to learning changes as our needs change. Children are still figuring out what information is important, so it makes sense that they would attend to much of the information available. On the other hand, adults have a good sense of what information to prioritize and so attend to only what they deem informative. Inevitably, this means that a certain amount of information is always going to be missed. These findings make clear that we are always only seeing a piece of the picture, but perhaps we did not all start out that way.

Acknowledgments

We would like to thank Meg Schlichting, Katherine Duncan, Tess Forest, Michael Dubois, Alexandra Decker, and the rest of the Finn lab for all your help and support. We would also like to thank the Ontario Science Centre, Child Study Centre, NSERC and SSHRC, as well as the reviewers for their helpful commentary and feedback. Finally, a special thank you to all the parents and children who made this research possible.

The Role of Prior Beliefs in The Rational Speech Act Model of Pragmatics: Exhaustivity as a Case Study

Ethan Wilcox[1] and **Benjamin Spector**[2]

[1]Department of Linguistics, Harvard University, wilcoxeg@g.harvard.edu
[2]Institut Jean Nicod, Département d'études cognitives, ENS, EHESS, PSL University, CNRS , benjamin.spector@ens.fr

Abstract

This paper examines the interaction between prior beliefs and pragmatic inferences, focusing on exhaustivity effects. We present three experiments that tests how prior beliefs influence both interpretation and production of language, and compare the results with the predictions of the Rational Speech Act model, a Bayesian model of linguistic interpretation. We find that prior beliefs about conditional probabilities have no affect on language production, but do affect interpretation, producing *anti-exhaustivity* effects. We find that the RSA model achieves a relatively good fit both for the human production and interpretation data, but only for highly-implausible utterance costs.

Keywords: Pragmatics, Rational Speech Act model, Exhaustivity.

Introduction

The interpretation of linguistic utterances in context depends on the prior beliefs of speakers and hearers. For instance, if someone says "Mary visited a cardiologist today", one will infer that Mary is more likely than a random person to have a heart-related medical condition. It is easy to account for such inferences as a probabilistic inference: the hearer starts with a prior probability distribution over possible world states, and then conditionalizes this distribution with the new information that Mary visited a cardiologist today. Typically, though, pragmatic inferences go well beyond what can be predicted with such a simple model of linguistic interpretation. They also involve, for instance, reasoning about *other sentences* that the speaker could have uttered given some assumptions about their communicative goals (Grice, 1975). For instance, if I'm asked a question such as *Among Peter, Mary and Sue, who attended the show today?*, an answer such as *Mary did* tends to trigger the inference that the others did not, even if there is no expectation that what any of them does depends on what the others do. Such *exhaustivity effects* are typically accounted for in terms of Grice's maxim of quantity: if in fact both Peter and Mary had attended the show, a knowledgeable speaker would say that rather than just talking about Mary.

Now, in some situations these two types of effects (effect of prior beliefs, exhaustivity effects) are pitted against each other. For instance, we might know that Peter and Mary are a couple, who usually go out together, so that, upon learning that Mary attended the show, one would assign a high probability to the possibility that Peter did too, which would go against the exhaustivity effect just mentioned.

The Rational Speech Act Model (RSA) is a model of pragmatic reasoning which integrates both the role of prior beliefs and that of pragmatic reasoning about alternative utterances (Frank & Goodman, 2012). It can in principle make very precise predictions about their interactions. The RSA model views the speaker as being engaged in a trade-off between two goals: maximizing informational content and minimizing the cognitive cost of an utterance. As we will see shortly, in the baseline RSA model, this trade-off is affected in a drastic way by the prior beliefs shared by listeners and speakers, to the extent that, in some situations, an *anti-exhaustivity effect* is predicted: in some cases, the utterance *Mary did*, in the above context, is expected to be the best message to use to convey that both Mary and Peter attended the show, and thus to be interpreted in this way. However, because an RSA model has several free parameters, it is difficult to assess a) whether it is compatible with a given set of data, and b) whether it provides an *explanatory* account of the data. The goal of this paper is to gather data about the effect of priors on exhaustivity effects, both for interpretation and production, and to assess how well the baseline RSA model can account for these data in a principled way.

Degen et al. have already tested the effect of priors on pragmatic interpretation within the RSA framework, focusing on a similar but different type of inference, namely the inference from *some* to *not all* (Degen, Tessler, & Goodman, 2015). We will discuss the relationship between our study and Degen et al. (2015) in the next section.

The Rational Speech Act Framework and exhaustivity effects

In the basic RSA model, we start from a *literal listener* L_0 who has a prior probability distribution over worlds and knows the literal meanings of sentences. When hearing an utterance u, L_0 updates her prior distribution by conditionalizing it with the proposition expressed by the literal meaning of u. Then we define a speaker S_1 who wants to communicate her beliefs to L_0 and knows how L_0 interprets sentences. S_1 is characterized by a utility function U_1 such that the utility of a message u if S_1 believes w is *increasing* with the probability that L_0 assigns to w after updating her distribution with u, and *decreasing* with the *cost* of u. A *rationality parameter* α determines the extent to which S_1 maximizes her utility. Next, we define a more sophisticated listener, L_1, who, when receiving a message u, uses Bayes's rule to update her prior distribution on worlds, under the assumption that the author of u is S_1. A speaker S_2 is then defined exactly like S_1, except that now S_2 assumes that she talks to L_1, not L_0. And so on.[1].

[1]See Bergen, Levy, and Goodman (2016) for the mathematical description of the model.

Now consider a case where world states are individuated by the truth-values of two propositions A and B (for instance *Mary attended* and *Peter attended*), and where the available utterances are A, B, A *and not* B, B *and not* B and A *and* B. Consider a situation where the speaker wants to communicate the world state $\{A\}$ (where A is true and B is false) . She can choose between the two messages A and A *and not* B. While A is less informative than A *and not* B, it has nevertheless a significant probability of use, because it is less costly. Upon hearing A, the first-level pragmatic listener L_1 will reason as follows, if the priors are sufficiently uniform across world states. The message is only compatible with two world states, namely $\{A\}$ And $\{A,B\}$. But the the speaker is more likely to mean $\{A\}$ than to mean $\{A,B\}$. If she wanted to communicate $\{A,B\}$, there were two other possible messages, namely B and A *and* B. B is furthermore no more costly than A, and A *and* B is costly but also more informative. In contrast with this, if she wanted to communicate $\{A\}$, there was only one other possible message, namely A *and not* B, and furthermore this message, while more informative, is very costly (more than A *and* B). As a result, it is likely that the intended meaning was in fact $\{A\}$, and the exhaustivity effect is derived.

However, things can change drastically with non-uniform priors. Imagine now a speaker who wants to communicate $\{A,B\}$. She has a choice between using the messages A, B, A *and* B. While the latter message is the most informative, it is also more costly than the two others. Suppose further that the prior conditional probability of B given A is very high. The literal listener L_0, upon hearing A, will assign a high probability to the world state $\{A,B\}$. In this case, A may turn out to have a higher utility than A *and* B for S_1: it is quite good at communicating the world state $\{A,B\}$ (given the priors), and it is less costly than A *and* B. Furthermore, with such non-uniform priors, a speaker who would want to communicate $\{A\}$ might be very unlikely to use the message A: despite the fact that A is less costly than A *and not* B, it is so poor at conveying the intended world state (due to the priors), that the speaker now has an extra incentive to use the costly sentence A *and not* B. Now, upon hearing A, the pragmatic listener L_1 will reason as follows. The intended world state is either $\{A\}$ or $\{A,B\}$. If the latter, S_1 was in fact quite likely to use A. If the former, the speaker was more likely to use A *and not* B. So the intended world state is probably $\{A,B\}$. This time an *anti-exhaustivity effect* is derived (Roni Katzir, p.c.). However, this prediction is highly sensitive to the values of the free parameters of the model (rationality, costs).

Degen et al. (2015) discuss a related case. The RSA model, under a broad range of values for the free parameters, predicts that when the conditional probability of an *all*-statement given the truth of the corresponding *some*-statement is very high, *some* is going to be used to convey *all* and to be so understood. Degen et al. consider a discourse such as: *Max threw fifteen marbles in the water. Some of the marbles sank*. Because we expect all marbles to sink, this is a case where the prior probability of $\forall$ (the world where all marble sank) is very high, and where the basic RSA model predicts that the sentence will in fact convey that all marbles sank. But the experimental results show that actual listeners typically derive a *some but not all*-reading. In Degen et al.'s model, unlike in the basic RSA model, the pragmatic listener is uncertain about the speaker's beliefs about the listener's priors. Even if $\forall$ has a very high prior probability for the listener, the pragmatic listener L_1 assigns a substantial probability to the possibility that the speaker believes that the literal listener L_0 is in fact entertaining uniform priors over world states. So the pragmatic listener L_1 has a higher-order prior probability distribution over the set of first-order prior distributions (over world-states) that the speaker might attribute to the literal listener L_0. When processing a sentence, this listener updates both her probability distribution over worlds and her higher-order probability distribution over the set of priors that the speaker is considering. The proposed model is such that when hearing *some*, the listener concludes that the speaker probably believes that the listener is using uniform priors, and as a result *some* ends up conveying $\exists\neg\forall$. Simulations show that in order to obtain this result, the pragmatic listener L_1 must view the speaker (S_1) as believing that there is a high probability that the literal listener's prior distribution over world states is uniform. For the range of values that are typically used in RSA models for α (somewhere between 1 and 10), this probability must be substantial (Degen et al. report that it has to be equal to .5 to achieve the best fit with experimental data). Given this, a conceptual limitation of this account is that it models the listener as believing that the speaker views the listener as likely to be unaware that marbles typically sink when thrown into water (despite the fact that the priors over world states that Degen et al. collected show that people do in fact expect that when marbles are thrown into water, they will all sink). But no empirical evidence is provided to support these assumptions, and so it is not clear that much is gained compared to a model that would simply ignore the actual priors and take as input relatively uniform priors.

Now, in the case of exhaustivity effects, the situation is even more extreme. In the *some-all* case, the *all* sentence is no more costly than the *some*-sentence. Because of this, even with extremely biased priors, a fully rational speaker would always choose *all* to convey *all*, since it is still more informative than *some*, and would never use *some* (*some but not all* would be used to convey $\exists\neg\forall$). For this reason, with very high values for α (corresponding to a very rational speaker), a correct result is derived in Degen et al.'s model, even if the probability that the speaker assigns to the possibility that the listener does not expect all marbles to sink is very low (but still positive). In the exhaustivity case, avoiding the anti-exhaustivity effect is harder, because the message A *and* B is more costly than the message A, and so will not necessarily be the message used by a fully rational speaker who believes A *and* B, if the prior conditional probability of B given A is very high (the gain in informativity provided by A *and* B compared to A might be too small to justify the extra cost). Even with

a fully rational speaker, for a broad range of reasonable cost values, there exist contexts where the speaker is predicted to use *A* to mean *A and B*. In this paper, we will compare the predictions of the baseline RSA model with experimental data pertaining to exhaustivity and anti-exhaustivity effects.

Independently of this theoretical goal, our contribution is to provide experimental data pertaining to cases where priors are biased against the exhaustive reading of a sentence *A* in the context of *Which of A and B is true?*.

Human Judgement Experiments

To test the effect of priors on human linguistic judgements, we conducted three online experiments. Each experiment involved a simple scenario in which a character was moving furniture from her apartment onto the street, and questions were asked about what the character was able to move or how she was likely to report the progress of her moving to a friend. Experiments were hosted on IbexFarm. Participants were recruited on Amazon Mechanical Turk.[2]

Experiment 1: Priors

As this work aims to test the effect of priors on human linguistic judgements, our first experiment gathered prior probabilities for two scenarios, which were used in later experiments. In the priors experiment subjects were shown a scenario in which a character is moving her apartment and tests the weight of two furniture items. The character picks up one item, at which point respondents were asked whether they thought she could pick up the second item as well. Input format were forced-choice, yes/no radio buttons. The experiment was divided into two conditions: In the first, High Conditional Probability condition, the character was shown picking up a chair and asked whether she could also pick up a footstool, which was visually about half the size. In the second, Low Conditional Probability condition participants saw the character picking up the footstool and asked if they thought she could also pick up the chair. Participants were asked two simple comprehension questions at the end of the experiment, and only responses from participants who answered both correctly were used. We collected 60 responses, of which 57 (95%) were usable. The proportion of respondents who selected yes in each condition was taken as the population-level prior on conditional probability in each case.

The results can be seen in Fig. 1, on the left-hand panel. Error bars represent binomial 95% confidence intervals using the binconf function in R on default settings (Wilson method). A Fishers Exact Test indicates that participants were significantly less likely to endorse the yes response in the Low Conditional Probability condition (p=0.02225).

Experiment 2: Elicitation

We conducted a second experiment to test the effect of priors on the elicitation of simple conjunctives. If humans subjects incorporate priors in their utterance and endorsement of simple conjunctives, then we expect the relative rate of the conjoined utterance ("A and B") to be lower in high-conditional probability contexts, where P(B‖A) is very high (because in this case the utterance A is quite good at communicating the $A \wedge B$ world state (which we will denote by $\{A,B\}$ henceforth). Furthermore, we also expect that, if they want to communicate the world $A \wedge \neg B$ (which we will now notate$\{A\}$), there will be less likely to use the message A in the high-probability condition, and more likely to use *A and not B*.

In this setup, participants were shown the same 'moving' scenario from the previous experiment, involving a chair, a footstool and a character who tells a friend that she would move 'everything I can' down to the curb. In the subsequent panel participants were shown the character with the furniture she was able to move depending on the condition to which the participant was assigned, which are enumerated in Table 1, along with the condition name and a *tag*, with which we refer to the condition in charts and figures. Participants are asked to endorse an utterance that they think the character would use to describe the situation to a friend, who has prior familiarity with the items, over the telephone. Input were force-choice radio buttons with six possible utterances: 'I moved the chair', 'I moved the footstool', 'I moved the chair but not the footstool', 'I moved the footstool but not the chair', 'I moved the chair and the footstool' and ' I moved the footstool and the chair.'

Experimental Stimuli	Tag	Condition Name
Chair + Footstool	{A,B}	[BOTH, HIGH PROB]
Chair	{A}	[SINGLE, HIGH PROB]
Footstool + Chair	{A,B}	[BOTH, LOW PROB]
Footstool	{A}	[SINGLE, LOW PROB]

Table 1: Elicitation Experimental Conditions

Following the critical question, we asked two simple comprehension questions and whether the participant was a native speaker of English. Only data from those respondents who answered both correctly and identified as a native English speaker were used. The experiment was given to 174 subjects, of which 126 (72.4%) answered the follow-up questions satisfactorily. A further 33 subjects were filtered as repeat subjects from one of our other experiments, bringing the total number of responses to 93.

The results from this experiment can be seen in Figure 1, in the middle panel, with world state on the x-axis and the proportion of "A and B" responses on the y-axis. Red dots represent proportion of "A and B" responses in the high probability condition, blue dots the low probability condition; error bars represent 95% confidence intervals. Endorsements of the "A and B" utterance were near floor in the $\{A\}$ world (m=0.02, m=0.11 in the High Probability and Low Probability conditions, respectively). However, the endorsements were not at ceiling in the $\{A,B\}$ world state (m=0.68, m=0.84 in the High Prob and Low Prob conditions, respectively).

[2]Experiments were pre-registered online at http://aspredicted.org/blind.php?x=7qm9pz

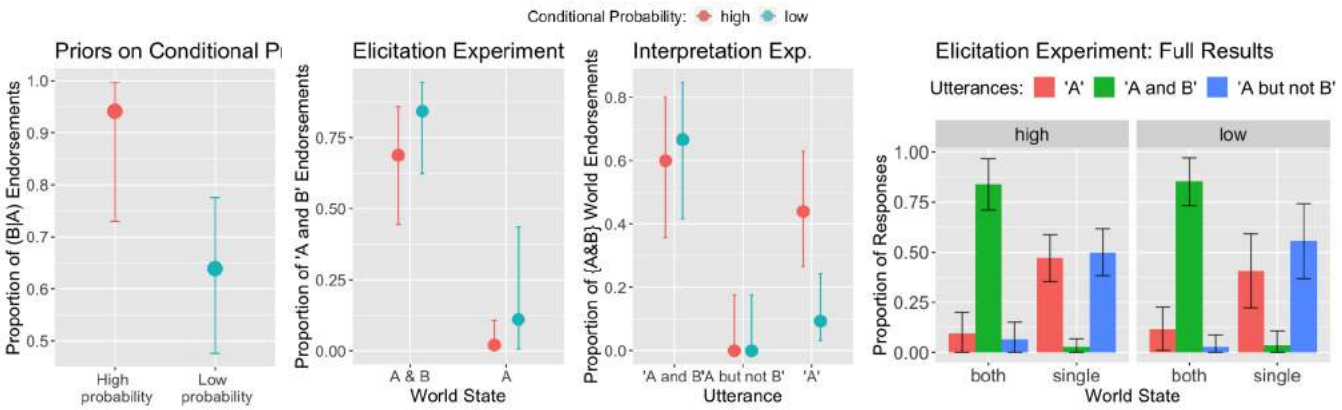

Figure 1: Human Judgements from the Online Study

To test whether priors on conditional probability had an effect on utterance endorsement, we fit a linear model to the data using the proportion of 'A and B' responses as our dependent measure, and experimental conditions as predictors, which were coded using 1/-1. We found a main effect of WORLD STATE, whereby participants were less likely to endorse "A and B" in the $\{A\}$ world ($p<0.001$), as expected. However, we found no interaction between world state and prior conditional probability ($p=0.507$), which is visually evident from the fact that both prior probability conditions fall within each other's confidence intervals. In fact, the relative rate of "A and B" endorsement in the high and low conditional probability conditions, ran counter to our expectations, with respondents marginally less likely to endorse the relevant utterance in the high conditional probability condition. Note that while the subjects in this study were willing to use 'A' to endorse the {A,B} world, their rates of endorsement in both conditions (between 15-32%) were well below their expectation of P({A,B}|{A}) (between 65-95%).

In addition to our pre-registered analyses, we conducted a follow-up analysis to assess whether the priors on conditional probability affected the rate of endorsements for the exhaustified utterances, 'A but not B.', in order to communicate the world $\{A\}$ The results for all utterance endorsements can be seen in Fig. 1, on the far right panel. As the conditional probability increases, we might expect the rate of endorsements for the exhaustified utterance (the blue bar) to increase in the SINGLE condition, given that the bare utterance, 'A' might be quite bad at communicating $A \wedge \neg B$. Our pre-registered analysis, which examines only the rate of endorsement for the 'A and B' utterance, would not capture these dynamics.

In order to assess the impact of conditional probability priors on the rate of the exhaustified utterance we fit a linear regression model using the proportion of exhaustified ('A but not B') utterance endorsements as our dependent variable and utterance types as our predictors. We found a main effect of world state ($p < 0.001$) whereby exhaustified utterances were less likely to be endorsed in the BOTH condition (as fully expected), but no significant interaction between world state and conditional probability ($p = 0.515$).

Experiment 3: Interpretation

Experimental Stimuli	Tag	Condition Name
"The chair and the footstool"	'A and B'	[BOTH, HIGH PROB]
"The footstool and the chair"	'A and B'	[BOTH, LOW PROB]
'The chair but not the footstool"	'A but not B'	[ONLY, HIGH PROB]
"The footstool but not the chair"	'A but not B'	[ONLY, LOW PROB]
"The chair"	'A	[SINGLE, HIGH PROB]
"The footstool	'A'	[SINGLE, LOW PROB]

Table 2: Interpretation Experimental Items

The third experiment aimed to test the effects of prior conditional probability on utterance interpretation. The RSA model predicts that human subjects will be more likely to interpret the utterance 'A' as referring to an {A,B} world in cases where P(B|A) is higher.

For this experiment, participants were shown the same 'moving' scene as in the others. A character commits to moving 'what I can lift' down to the curb, and tells a friend what she is capable of lifting depending on the condition to which the subject was assigned. There were six conditions, corresponding to six possible utterances: 'I can lift the chair and the footstool','I can lift the footstool and the chair', 'I can lift the chair but not the footstool', 'I can lift the footstool but not the chair', 'I can lift the chair', 'I can lift the footstool'(cf. Table 2).

In the subsequent slide, participants see the character by the curb, with a grayed-out area where the furniture would be, are told that the character 'has moved all the items she can lift down the curb', and are asked to select which items they believe have been moved down. They are provided with a visual reference of the furniture items, scaled to size, at the bottom of the screen. The input form was a check box, and

in the instructions to the experiment participants were told that they could check as many or as few of the boxes as they wished.

Following the critical question, participants were asked two comprehension questions and whether or not they were a native speaker of English. The survey was given to 475 participants of which 338 (71%) answered the follow-up questions satisfactorily. Another 77 were filtered out, as they were repeat responders from the previous experiment, leaving the total number of responses analyzed to 261.

The results from this experiment can be seen in 1, on the right-hand panel. The utterance types are on the x-axis, with the proportion of respondents who checked both boxes (thereby endorsing the {A,B} world) on the y-axis. Red dots indicate responses for the high conditional probability condition, blue for the low conditional probability condition. Error bars indicate 95% confidence intervals. The proportion of {A,B} world endorsements is at floor when respondents heard the "A but not B" utterance, as predicted. However, when respondents heard the "A and B" utterance, endorsements of the {A,B} were relatively low (m=0.6, m=0.66 in the high and low probability conditions, respectively). This means that when respondents read "I will move what I can lift down to the curb" followed "I can lift the chair and the footstool down", and are then told that the character moved all the furniture he could lift, they are willing to endorse a world where only one had been moved (the footstool in 72% of the cases). We believe this behavior is partly due to the experimental setup: subjects may expect the character to do as little work as possible without the help of her friend, who they were told would assist in the moving process later on. We had initially thought that the commitment to 'move what I can lift' would ensure that modalized sentence of the form 'I can do X' would be interpreted as implying that the character did X, but this result suggests that this was not always the case.

To test whether the conditional probability had an effect on the rate of {A,B} world endorsements, we fit a linear regression model using experimental conditions as predictors. We found a significant main effect of ONLY utterances and SINGLE utterances ($p<0.001$ for both), whereby subjects were less likely to endorse the {A,B} world for these two conditions. In addition, we found an interaction between the prior probability and the SINGLE utterance types ($p=0.0144$), whereby participants were more likely to endorse the {A,B} world in the high conditional probability after hearing the non exhaustified utterance. Overall these results indicate that gradient prior probabilities gradiently affect utterance interpretation, raising the question why we did not observe a similar gradience in the elicitation experiment.

Model Fit

We fit the vanilla Recursive Speech act Model presented in (Frank & Goodman, 2012) to the human data we collected, with one level of recursion depth (that is, we fit S_1 and L_1).

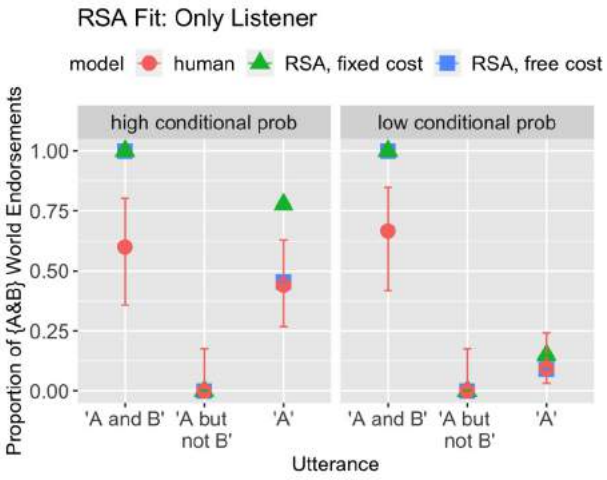

Figure 2: RSA Model fit with fixed cost (green triangles) and free cost ratios (blue squares) to human judgements (red circles).

The model has three possible world states: {A}, {B} and {A,B}. World {A} had a prior of 0.32, world {B} had a prior of 0.14 and world {A,B} had a prior of 0.54, rendering $P(\{A,B\} \mid \{A\}) = 0.8$, close to the human *high conditional probability* prior, and $P(\{A,B\} \mid \{B\}) = 0.63$, close to the human *low conditional probability* prior. The model includes seven messages: 'A', 'B', 'A but not B', 'B but not A', 'A and B' and 'null', which is defined as true in every situation, and was assigned a fixed cost of 100. 'A' and 'B' were assigned a cost of 0.[3] The costs of 'A and B' (c_1) and 'A but not B' (c_2) were free parameters, as was the rationality parameter, α.

In order to assess how well the RSA model captured the human judgements, we conducted four fits, which are summarized in Table 3. Each fit was made by iterating through a wide range of alphas and cost parameters (0-20 for each). This technique guarantees that we found a locally optimal fit within the range of cost and optimally parameters typically seen in the rest of the Recursive Speech Act literature (Scontras, Tessler, & Franke, 2017). In the fixed cost ratio fits, the cost for "A but not B" must be greater than but could not be more than 2 times that of "A and B". This constraint makes sense if we view cost as reflecting, for instance, the number of logical operators in a sentence, or the number of words used. Thus, we wanted to see if an fit existed with cognitively plausible relative costs between these two types of utterances. But we also relaxed this constraint in the 'free cost' fit, where the only constraint that the the cost of "A but not B" is higher than that of "A and B".

The results for the listener-only fit can be seen in Figure 2. Here, the x-axis is the possible utterances, and the x-axis is the proportion of respondents who endorsed the {A,B} world (in the human case) or the posterior distribution on the {A,B} world (in the model case). The left panel represents the high

[3] In the RSA model, it is the *difference* between relative costs that matters: adding a fixed constant to each cost value has no effect.

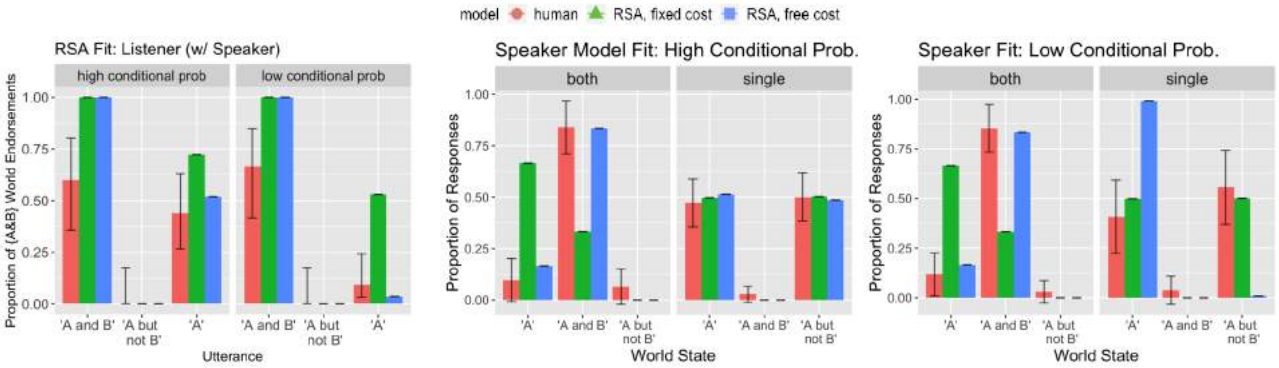

Figure 3: RSA Model fit with fixed-cost ratios (green) and free cost ratios (blue) to human judgements (red).

Name	Layers	Restrictions	α	c_1	c_2	MSE
Fit 1	L_1	$c_2 < 2 * c_1$	9.19	1.57	3.17	0.097
Fit 2	L_1	$c_1 < c_2$	5.52	0.010	8.42	0.068
Fit 3	L_1, S_1	$c_2 < 2 * c_1$	0.01	0.27	0.54	0.092
Fit 4	L_1, S_1	$c_1 < c_2$	7.97	0.01	1.59	0.059

Table 3: Summary of The Four Fits and Optimal Parameters

conditional probability condition and the right panel the low conditional probability condition. The vanilla RSA's meaning function constrains the listener's posterior for utterances 'A and B' and 'A but not B' such that all probability is assigned to the {A,B} world and the {A} world, respectively. Therefore, it is entirely the model's posterior on the 'A' utterance that determines the relative goodness of the fit. For the restricted cost ratio fit (green triangles) the best model is able to match human behavior in the low conditional probability condition, but favors the {A,B} much more greatly than do human respondents in the high conditional probability condition (the green triangle is well above the red error bars), resulting in a mean squared error of 0.097. When the restriction on relative costs is relaxed (blue squares) the model is able to achieve a very precise fit, with a mean squared error of 0.0678. The reason why the free-cost fit is able to perform significantly better than the fixed cost fit is that it can assign much higher relative cost to "A but not B" than to "A and B".

For example, in Fit 2 the utterance "A but not B" is 840 times more costly than the utterance "A and B". This results in strong model performance because high relative cost of the exhaustified utterance counterbalances its informativity at communicating the $\{A\}$ world. This renders the 'A' utterance a good choice to communicate the $\{A\}$ world, despite the strong priors on the $\{A, B\}$. Furthermore, the low cost of "A and B" ensures that it will be chosen often in the $\{A, B\}$ world, even in the high-probability condition.

The results for Fits 3 and 4, which fit both the speaker and listener layers, can be seen in Figure 3, with the listener layer graphed at left and the speaker layer graphed in the center and right images. For the listener layer, the x-axis shows utterances, and the y-axis posterior probability endorsements for the {A,B} world. For the speaker layer, the facets represent the different worlds conditions and the x-axis shows the possible utterances, with the relative proportion assigned to each utterance (for the RSA models) or proportion of endorsements (for the human) on the y-axis.

As to performance of the model: in the restricted cost ratio fit (the green bars) the performs only moderately well. For the ten critical conditions where the posterior distributions are not constrained to either 100% of 0%, the best fit falls outside of the human judgements' 95% confidence intervals 6 times, resulting in a mean squared error of 0.092. For the free cost model (blue bars) the model is able to perform slightly better, falling outside of the human judgements' 95% confidence intervals only twice (both in the {A} world, low probability condition). This fit gives an MSE of 0.059. Two remarks are in order. First, in the free cost model, "A but not B" is 158 times more costly than the utterance "A and B". Second, the best model achieves a good fit for the listener and for the speaker in the high-probability condition, but drastically underestimates the rate of endorsement of "A but not B" in the low probability condition as a way to express the $\{A\}$-world.

Discussion

The results of the interpretation experiment establishes that prior probabilities modulate exhaustivity effects, as is expected under the RSA approach. In our data, they do so for interpretation, but not for production. The RSA model can achieve a good fit with our experimental data for the interpretation experiment only with implausible parameters. With the kind of cost values that are typically assumed (cf. fixed cost fit), it overestimates the effect of prior probabilities. When we relax constraints on costs, an excellent fit is achieved, but the cost of "A but not B" has to be 832 times that of "A and B". When we want to fit both interpretation and production, the best model drastically underestimates the use of sentences such as "A but not B" - precisely because it assigns it an extremely prohibitive cost. Note that we are only evaluating the baseline RSA model. More sophisticated models have been proposed within the RSA framework, and we are not evaluating those. What our results suggest is that a key ingredient of the baseline RSA model, namely the tradeoff between infor-

mativity and cost, which predicts a huge influence of priors on interpretation and production, might make it hard to capture both interpretation and production data. On the interpretation side, the model needs to assign a very high cost to *A but not B*, but then on the production side, the model predicts that *A but not B* is not usable.

That being said, this conclusion is provisional, as caution is in order when interpreting the results we present here. We only tested two different conditions, in one type of scenario, and the data are somewhat noisy (cf. the high rate of rejection of $\{A, B\}$ after hearing "I can do A and B"). The fact that we used modal sentences when we collected priors and in the interpretation task is a limitation of this study.[4] Future work is needed to a) gather additional and less noisy data so as to reach more reliable conclusions, b) construct alternative models, including refined versions of the baseline RSA model, which could then be compared to it.

[4] In another experiment that we do not present here, we collected judgments for non-modal sentences in near-identical scenarios, and we got a much higher endorsement (85%) for the $\{A, B\}$ world for the conjunctive sentence *A and B*.

Phonological Cues to Syntactic Structure in a Large-Scale Corpus

Ethan Wilcox
Harvard University, Cambridge, Massachusetts, United States

Abstract

The Prosodic Bootstrapping Theory (PBT) states that prosodic and phonetic cues assist infant language learners to segment the speech stream into words and assemble those words into phrase structures. However, many of the studies demonstrating a link between prosody and syntax were conducted on small data sets and on a narrow range of syntactic structures. This work uses a state-of-the-art parser to syntactically annotate the BU Radio News Corpus of around 16,000 diverse sentences, which are prosodically tagged and annotated. A decision tree classifier was fit, using six prosodic features and achieving 87% accuracy at differentiating words internal to major syntactic phrases vs. words that mark phrase boundaries. However, the models tested are unable to differentiate between phrasal categories based on prosodic information alone. These results provide new evidence in support of the Prosodic Bootstrapping Theory, suggesting it is possible to identify phrasal boundaries based on prosodic information alone.

The Accuracy of Causal Learning over 24 Days

Abstract

Humans often rely on past experiences stored in long-term memory to predict the outcome of an event. In traditional lab-based experiments (e.g., causal learning, probability learning, etc.), these observations are compressed into a successive series of learning trials. The rapid nature of this paradigm means that completing the task relies on working memory. In contrast, real-world events are typically spread out over longer periods of time, and therefore long-term memory must be used. We conducted a 24 day smartphone study to assess how well people can learn causal relationships in extended timeframes. Surprisingly, we found few differences in causal learning when subjects observed events in a traditional rapid series of 24 trials as opposed to one trial per day for 24 days. Specifically, subjects were able to detect causality for generative and preventive datasets and also exhibited illusory correlations in both the short-term and long-term designs. We discuss theoretical implications of this work.

Keywords: causal learning; probability learning; illusory correlation; long-term memory; smartphone

Introduction

Every day we use our experiences to make inferences. For example, is your new medication improving an ailment or causing a negative side-effect? Does meditating have a positive impact on your mental health? If we can accurately predict the outcomes of our experiences and actions, we can use this information to behave adaptively in the world.

Trial-by-trial learning paradigms, in which cue-outcome pairs are presented to subjects sequentially, are used extensively to study learning across many different fields including causal learning, probability learning, fear learning, stereotype formation, associative learning with non-human animals, and others. The trial-by-trial paradigm is supposed to simulate an important aspect of the world: most of our experiences occur sequentially over time, rather than in a summarized form. Typically the 'inter-trial-interval', the time between trials, is a couple seconds. However, we contend that there are few real-world learning situations that involve experiencing repeated cue-outcome pairs separated by seconds, perhaps with a few exceptions (e.g., flipping through records rather than first-hand experiences).

The goal of the current study is to compare trial-by-trial learning in the normal rapid format vs. trial-by-trial learning in which the trials are spaced out once per day. Day-by-day learning simulates many natural processes (e.g., does a medicine have an influence on a health outcome, does exercising have an influence on sleep, etc.). Importantly, whereas working memory is believed to support learning in short timeframes, long-term memory must take over when learning occurs over many days. In the current study we investigated how effectively people are able to learn cue-outcome relations across multiple days.

Trial-by-Trial Causal Learning

Prior research has evaluated how people detect causation from data shown over a successive series of trials. In a typical experiment, participants observe data in which the putative cause and the outcome are either present or absent. This information can be organized into a 2x2 table where each cell *A-D* represents the number of times that the cause/outcome combination occurs for a particular dataset (see Figure 1). Most often, participants are shown the data rapidly, for example two or three seconds per trial. After observing the entire dataset, subjects judge the degree to which the cause influences the outcome.

		Outcome: Present	Outcome: Absent
Cause	Present	*A*	*B*
	Absent	*C*	*D*

Figure 1: A 2x2 table depicting the four possible types of data in a traditional binary design.

One normative model of causation is the Δ*P* rule, a measure of contingency that suggests an optimal way to infer causation is by comparing the probability of the outcome in the presence of the cause and the probability of the outcome in the absence of the cause: $\Delta P = A/(A+B) - C/(C+D)$. When Δ*P* is positive, the causal relationship is generative. When Δ*P* is negative, the causal relationship is preventive.

Although prior research suggests that people are able to discriminate generative vs. preventive causation (Shaklee & Mims, 1982), individuals sometimes exhibit biases in causal reasoning. One such bias, "illusory correlation" or "illusory causation", occurs when people inaccurately infer causation when no causal relationship exists.

An "A-cell bias" is when individuals believe that a causal relation exists merely because of a high number of A-cell trials (e.g., Kao & Wasserman, 1993). In the A-cell bias condition in Table 1, even though there is zero relation between the cue and outcome (the outcome occurs with a chance of .625 regardless of whether the cue is present or absent, so $\Delta P = 0$), people tend to infer that they are positively correlated. An "outcome density bias" is when people incorrectly assign causation to a dataset in which the overall probability of the outcome is high (Table 1), even though the

probability of the outcome is the same (.75) whether the cause is present or absent, so $\Delta P = 0$ (e.g., Jenkins & Ward, 1965).

Table 1: Cell Frequencies for the 4 Datasets

Dataset	*A*	*B*	*C*	*D*	ΔP
Generative	9	3	3	9	0.5
Preventive	3	9	9	3	-0.5
Outcome-Density	9	3	9	3	0
A-cell	10	6	5	3	0

Causal Learning and Memory

Many causal learning experiments use rapidly successive trial-by-trial paradigms. In the real world, however, you would not experience each data point in rapid succession. This raises a number of challenges for long term memory. For example, imagine learning whether going to yoga improves your mood; some days you do yoga and other days you do not. After a few weeks, would you be able to remember the days you did or did not do yoga? Could you remember your mood on those days? How might your memories for these events impact your ability to detect causation? Would you be more susceptible to biases such as illusory correlations? Currently, there is no research on how well people can learn causal relations over long timespans.

One basis for making hypotheses about causal learning in long timeframes is research on short timeframes that has increased working memory (WM) demands. Studies have found stronger illusory correlations in a rapid trial-by-trial paradigm (higher WM demands) than in a "summary" paradigm (lower WM demands) in which all the trials are presented simultaneously (Kao & Wasserman, 1993). Adding a distractor task on top of the trial-by-trial paradigm leads to less accurate judgments (Shaklee & Mims, 1982), and older adults with lower WM have less accurate causal learning (Mutter & Pliske, 1996). If causal learning is worse when WM is taxed, we expected learning to get even worse when long-term memory must be used to assess causation. Still, people are often able to navigate the world successfully, suggesting a reasonable causal-learning ability when relying on long-term memories to make inferences. This raises the question: how well can we learn causal relations across many days?

Summary of Current Study

In the current study, we investigated the implications of learning a cause-effect relationship quickly from a rapid sequence of trials vs. learning the same relationship over an extended period of time – one trial per day for 24 days. We investigated how subjects learned about four causal relations using different datasets: generative, preventative, 'outcome-density', and 'A-cell' (Table 1).

The motivation for studying the generative and preventive datasets was to determine whether or not participants were capable of detecting a causal relationship or if learning is hampered when the experiences occur spread out in time. Because memories might be noisier in the long-term condition, we predicted that participants' judgments might be closer to zero, implying a weaker causal relationship.

For the A-cell and outcome density datasets, we wanted to assess the effect of long-term memory on illusory correlations. Prior research mainly found exaggerated illusory correlations with increased WM demand, so one hypothesis was that illusory correlations would be exaggerated in the long-term condition. Another hypothesis was that, if memories of the experiences are weaker in the long timeframe condition, then the judgments might actually be closer to zero – more accurate.

Methods

Participants

There were 476 participants. The main requirements were owning a smartphone and intending to complete the entire study; however, we mainly targeted college students to have a similar sample to most other causal learning studies and since they frequently use smartphones. Participants were paid $30 if they successfully completed the entire study.

Our goal was to have around 400 participants, 100 for each of the 4 datasets in the long timeframe condition. The large number was used because the four datasets need to be analyzed separately, and to have power to detect small effects. The final data analyses included 409 participants after dropping 13 participants who admitted to writing down data during the study, 1 who was not trying during the task, 39 due to a programming error, and 14 who skipped too many days of the long timeframe task.

Datasets

Participants learned about five datasets: four short-timeframe (generative, preventative, A-cell, and outcome density) and one long-timeframe (one of the four from the short-timeframe

Table 2: Example Datasets for a Subject

Task Order	Day	Length	Dataset	Context	Valence	Authenticity
1	1	Short	A-Cell*	Restaurant	Positive*	Real*
2	1	Short	Preventive	House	Negative	Vitamin
3	1-24	Long	A-Cell*	Library	Positive*	Real*
4	25	Short	Generative	Street	Positive	Vitamin
5	25	Short	Outcome Density	Park	Negative	Real

Note. *Matched short and long timeframe conditions.

condition). This design allowed for a within-subjects comparison of one of the four datasets across the long vs. short conditions (see Table 2 for an example). By having subjects learn all four datasets in the short timeframe condition, it also reduces the likelihood that subjects were aware that one of the short timeframe datasets was the same as the long timeframe dataset. Each dataset consisted of 24 trials ordered randomly. The two illusory correlation datasets were previously used by Kao and Wasserman (1993).

Procedure

Participants completed the entire study on their own smartphones by logging into our website created with our PsychCloud.org framework. The procedure for the short-term and long-term tasks were identical, except that subjects observed one trial per day in the long timeframe condition, and they did trials back-to-back in the short timeframe condition. On Day 1 of the study, participants completed two short-term tasks and began Day 1 of the long-term task.

On Days 2 – 24, participants received automated text-message reminders at 10am, 3pm, and 8pm to complete their daily trial for the long-term task and stopped receiving reminders if they had already participated that day. They returned to the lab on Day 25 to complete the remaining short-term tasks and receive payment. The order of the short-term tasks was randomized so that participants completed the short version of the long-term task either on Day 1 or on Day 25 - before or after the long-term task.

Within a Trial Each task consisted of 24 trials in which participants were told whether or not the putative cause was present or absent. A number of procedures were taken to facilitate encoding, including asking subjects to verify the state of the cause and effect (rather than just observe them), and to spend extra time to look each image. Each trial proceeded as described in the following example, which uses the 'Facebook' cover story – other cover stories are explained below. In the Facebook cover story, subjects were asked to judge whether using Facebook during their lunch break improves or worsens or has no influence on their mood, based on the hypothetical dataset.

At the beginning of each trial, subjects were shown a contextual image. These images allowed us to ask a number of episodic memory questions that are not analyzed in this report. In the Facebook cover story, they saw an image from the inside of a restaurant and were told "This is the scene from your lunch break." After three seconds, an icon and text were superimposed over the contextual image to show the presence or absence of the cause (e.g., whether they used or did not use Facebook during their lunch break). They pressed a radio button to confirm the state of the cause and could not move on until selecting the correct button (e.g., Facebook vs. No Facebook). Next, they pressed a radio button to predict the effect as present or absent (e.g., Very Sad Mood vs. Normal Mood). They received text feedback for whether their prediction was correct or incorrect and an icon representing the effect was superimposed on the image. After clicking the correct radio button to verify the state of the effect, subjects were instructed to "Take a couple of seconds to imagine this scene", which was displayed for an additional four seconds.

At the end of a trial in the short timeframe condition, subjects were permitted to move on to the next trial. In the long timeframe condition, subjects were told that their task was over and to come back to the website the following day. Once a trial was over, the website did not allow subjects to see the data for that trial or prior trials, not even by clicking the back button on their web browser.

Figure 2. Screenshot of the end of a trial.

After Trial 24 (either immediately afterwards for the short timeframe condition, or on Day 25 in the long timeframe condition), participants judged the strength of the causal relationship. First, they answered whether the cause (Facebook) "improves or worsens or has no influence" on the effect (mood). If participants said the cause had no influence, they were assigned a causal judgment of 0. If they responded "improve" or "worsen", they answered "How strongly does [the cause] [improve/worsen] [the effect]?" on a scale of 1 (*very weak*) to 10 (*very strong*), which produced a scale from -10 to +10. In this report we only discuss the judgments after Trial 24, though subjects also made similar judgments before Trial 9 and before Trial 17.

In addition to the causal strength judgments, participants also made a number of other judgments, for example, memories of the number of experienced cells of types A, B, C, and D (before Trials 5, 13, 21, and after Trial 24), as well as a number of judgments about the memories for the contextual images after Trial 24. These measures will not be analyzed in the current report due to space.

Cover Stories Since subjects learned about five cause-effect relations, we created the following five authentic '*contexts*', randomly assigned to the five tasks so that each was viewed as a separate learning task: the relation between using Facebook during lunch in a *restaurant* and mood, eating a

healthy dinner in a friend's *house* and having an upset stomach, using notecards to study in a *library* and grades on a daily quiz, biking to work on *city streets* and productivity at work, and bringing your dog on a walk in a *park* and stress. The five stories were chosen so that it would be plausible for the cause to either improve or worsen the outcome; the influence of prior beliefs will be analyzed in other reports.

Because this study is the first to use a long timeframe paradigm, is unlikely to be replicated, and is focused on external validity, we conducted two manipulations of the cover stories. Specifically, we manipulated the "authenticity" and "valence" of the cover stories. If subjects in the long timeframe condition exhibited very poor learning, we wanted to rule out some potential explanations and to know how to best design future studies. Although we will explain the manipulations here, they are not of primary importance and will not be analyzed in this report.

First, though it is typical in causal learning studies to use entirely novel and abstract cover stories to minimize the influence of prior beliefs, we worried that abstract stimuli could be hard to remember in a long timeframe condition.[1] For this reason, we manipulated the 'authenticity' of the cover stories. The 'authentic' cover stories were the five stories mentioned previously. In the 'novel' cover stories, we used the same effects but replaced the causes with a hypothetical vitamin that a subject took on some days but not others (e.g., does the vitamin have an influence on mood, upset stomach, etc.). The matched short-term and long-term datasets were assigned to different contexts but were matched on authenticity. Of the four short timeframe conditions, two were assigned to 'novel' vitamin cover stories and two were assigned to authentic cover stories (Table 2).

Second, we manipulated the 'valence' of the effect; whether the presence of the effect is good or bad.[2] The absence of the effect was always described as normal (e.g., normal mood, normal grade on a quiz, etc.). The presence of the effect was described as either very good or very bad (e.g., very happy or very sad; very good grade or very bad grade, etc.). For participants in the negative valence condition, we reverse coded their causal strength judgments, so positive causal strength means "improved" for the positive valence condition and "worsened" for the negative valence condition. The matched short-term and long-term datasets were assigned the same valence. Of the four short-term conditions, two had positive and two had negative valence (see Table 2). Authenticity and valence are not analyzed due to space.

Participation Before starting the experiment, participants were told that if they missed more than three days in the long timeframe task, the study would be terminated and that they would not be paid. 462 (97%) participants successfully completed the study. On any given day, 83% of subjects participated before the 3pm reminder, 96% before the 8pm reminder, and 99% by midnight. If a subject missed one, two, or three days, the subsequent days were automatically pushed back the appropriate number of days.

The causal strength judgments and other measures for the long timeframe task occurred during the second in-lab testing session. We worked hard to have subjects come back to the lab for the second in-lab testing session on Day 25, one day after the last trial in the long timeframe condition. Of the 409 subjects in the final analyses, 83% returned to the lab on Day 25. If they skipped one day of the long timeframe task, sometimes this session occurred on the same day as their 24th trial (13%). If the session had to be moved, sometimes it occurred two (3%) or three (1%) days after the last trial. Overall, the protocol was followed with high fidelity.

Results

Causal Strength Judgments

In this paper, we only analyzed data from the matched short-term and long-term conditions. We analyzed the generative ($N = 98$), preventive ($N = 102$), A-cell ($N = 105$), and outcome density ($N = 104$) conditions separately.

Average causal strength judgments are presented in Figure 3. Significance values above each column indicate whether the value was significantly different from zero. The significance value above the horizontal lines indicates whether the judgments in the short and long-term conditions were significantly different from each other. We calculated Bayes Factors (*BF*) for each t-test, where a $BF > 1$ is support for the alternative hypothesis and a $BF < 1$ is support for the null. Often *BF*s > 10 (or < 1/10) are considered "strong" evidence for the alternative (or null), *BF*s > 30 or < 1/30 are considered "very strong" and *BF*s >100 or < 1/100 are considered "extreme" (e.g., Lee & Wagenmakers, 2013).

Generative and Preventive Conditions First, we wanted to assess whether participants were capable of detecting causation in the generative and preventive conditions. For the generative dataset, causal judgments were significantly different from zero in both the short-term condition, $t(97) =$

[1] For example, we suspect that in short learning tasks using novel stimuli, subjects might use other cues such as the position of stimuli on the screen rather than the semantic meanings of the cues. Such alternative methods of learning might be less salient in the long timeframe condition. Instead, we thought that semantically meaningful cause-effect relations might be easier to remember and also have higher external validity.

[2] Most studies on causal learning use cues that are either present or absent. Presence/absence of the cause and the effect is theoretically important in some theories of causal learning (e.g., Cheng, 1997). Further, the definition of the cells as A-D only makes sense with cues that are present/absent (not "high"/"low" or "2"/"1", etc.; see Figure 1). In order to stick close to prior studies and to be able to study the A-cell bias, we used present/absent cues. However, one consequence of using presence/absence is that most outcomes have an implicit valence of being good or bad. For example, many prior studies have used outcomes like the presence/absence of a headache (bad) or of a flower blooming (good). We did not want to arbitrarily use outcomes of one particular valence, or to confound valence with cover story. Furthermore, valence can influence the strength of illusory correlations (Mullen & Johnson, 1990). For all these reasons, we counterbalanced the valence of the cover story.

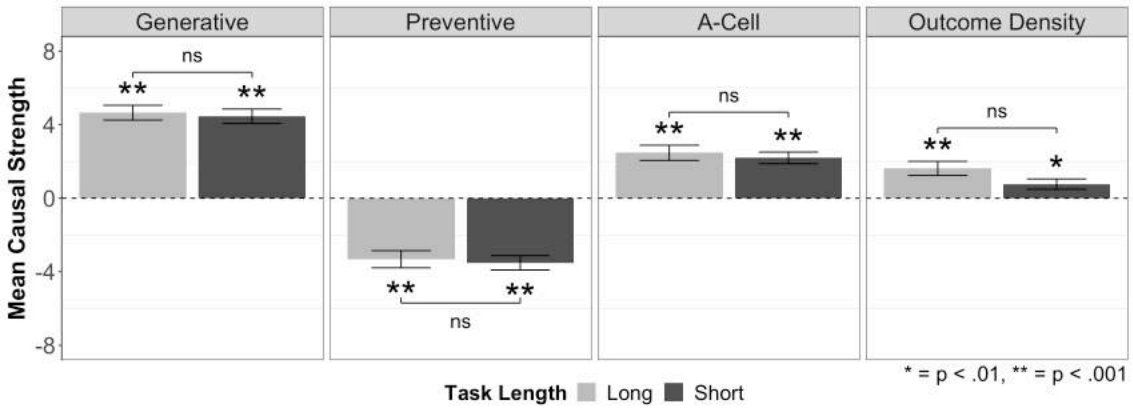

Figure 3: Average causal strength judgments after reviewing 24 trials. Error bars indicate standard error.

11.27, $p < .001$, $d = 1.14$, $BF = 2.13 * 10^{16}$, and the long-term condition, $t(97) = 11.53$, $p < .001$, $d = 1.17$, $BF = 7.37 * 10^{16}$. For the preventive dataset, judgments were less than zero in both the short-term, $t(101) = -9.03$, $p < .001$, $d = -0.89$, $BF = 5.72 * 10^{11}$, and long-term condition, $t(101) = -7.13$, $p < .001$, $d = -0.71$, $BF = 6.05 * 10^{7}$.

We predicted that for both the generative and preventive datasets, causal judgments would be closer to zero in the long-term condition because participants' memories would be noisier. However, paired t-tests revealed no significant differences between judgments in the short-term and long-term conditions for either the generative, $t(97) = -0.37$, $p = .707$, $d = -0.04$, $BF = 0.12$, or preventive datasets, $t(101) = -0.33$, $p = .741$, $d = 0.03$, $BF = 0.12$. Thus, participants were just as capable of detecting causation in the short and long timeframe conditions.

Illusory Correlation Conditions In the outcome-density and A-cell datasets, an optimal causal judgment would be zero. In line with our predictions, we found significant illusory correlations for both datasets**.** For the A-cell dataset, causal judgments were significantly greater than zero in both the short-term, $t(104) = 7.13$, $p < .001$, $d = 0.70$, $BF = 6.75 * 10^{7}$, and long-term, $t(104) = 6.11$, $p < .001$, $d = 0.60$, $BF = 6.36 * 10^{5}$, conditions. We found similar results for the outcome-density dataset; judgments were also positive and significantly different from zero in the short-term, $t(103) = 2.73$, $p = .008$, $d = 0.27$, $BF = 3.60$, and long-term, $t(103) = 4.23$, $p < .001$, $d = 0.41$, $BF = 341.33$, conditions.

We hypothesized that the illusory correlations could be either exacerbated or diminished in the long timeframe condition. However, there were no differences between causal judgments in the short and long-term conditions for the A-cell dataset, $t(105) = -0.67$, $p = .500$, $d = 0.07$, $BF = 0.13$. Illusory correlations appeared slightly stronger in the long-term condition for the outcome-density bias dataset, but this trend only approached significance, $t(104) = -1.87$, $p = .065$, $BF = 0.45$, with a small effect size of $d = 0.18$. These results suggest that illusory correlations in traditional trial-by-trial experiments are similar to what we observe in a long timeframe task.

Predictive Strength

Another way to measure learning, aside from causal strength judgments, is through subjects' predictions of whether the outcome was present or absent each day. To ensure that participants had observed enough experiences to make predictions, we analyzed the predictions from Trials 13 – 24.

We transformed participants' predictions into a measure of causal strength by subtracting the probability that they predicted that the outcome would be present given the absence of the cause from the probability that the outcome would be present given the presence of the cause. This measure of "predictive strength" is conceptually similar to ΔP. These results are displayed in Figure 4.

Generative and Preventive We found very similar results using subjects' predictions to assess learning as from their causal strength judgments. In the generative condition, predictive strength was significantly greater than zero for both the short-term, $t(97) = 11.58$, $p < .001$, $d = 1.17$, $BF = 9.01 * 10^{16}$, and long-term conditions, $t(97) = 12.47$, $p < .001$, $d = 1.26$, $BF = 6.32 * 10^{18}$. In the preventive condition, predictive strength was significantly less than zero in both the short-term, $t(101) = -11.87$, $p < .001$, $d = -1.18$, $BF = 6.77 * 10^{17}$, and long-term conditions, $t(101) = -9.38$, $p < .001$, $d = -0.93$, $BF = 3.12 * 10^{12}$. We found no difference in predictive strength between the short-term and long-term conditions for either the generative, $t(97) = -0.36$, $p = .718$, $d = -0.04$, $BF = 0.12$, or preventive, $t(101) = -0.49$, $p = .623$, $d = -0.05$, $BF = 0.12$, datasets. In sum, participants learned to accurately predict the effect, to the same extent, in both conditions.

Illusory Correlation Conditions In the A-cell bias condition, we found a similar pattern of results to the strength judgments. Subjects did infer an illusory correlation; they were more likely to predict the effect as present when the cause was present in both the short-term, $t(104) = 3.66$, $p < .001$, $d = 0.36$, $BF = 51.08$, and long-term condition, $t(104) = 3.66$, $p < .001$, $d = 0.36$, $BF = 50.64$. Furthermore, we found no difference between predictions in the short-term vs. long-term conditions, $t(104) = -0.66$, $p = .512$, $d = 0.06$, $BF = 0.13$.

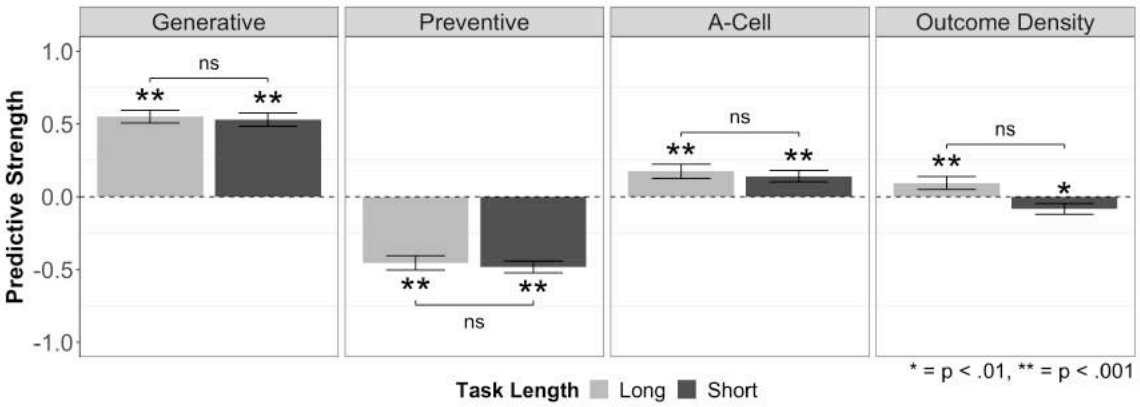

Figure 4: Δ P calculated from predictions about the effect given the cause. Error bars indicate standard error

In the outcome-density condition, the predictions were significantly negative in the short-term condition, $t(103) = -2.24$, $p = .028$, $d = -0.22$, $BF = 1.17$. However, they were significantly positive in the long-term, $t(103) = 2.13$, $p = .036$, $d = 0.21$, $BF = 0.94$, and the difference was statistically significant, $t(103) = -3.60$, $p < .001$, $d = -0.35$, $BF = 42.20$.

This difference was only marginally significant for the causal strength analyses, and the causal strength judgments for the short timeframe were significantly positive, not negative. Because this is the only difference between the two conditions, and it was only found for predictive strength (not the causal strength judgments) in the outcome density condition (not the other illusory correlation condition), we do not want to over-interpret it.

Discussion

We sought to evaluate the external validity of traditional trial-by-trial causal learning experiments by comparing trial-by-trial learning when presented rapidly vs. one trial per day for 24 days. Presumably the former relies on working memory, whereas the latter requires long term memory. Our findings suggest that people are capable of learning generative and preventive causal relationships and also exhibit illusory correlations when learning causal relations over 24 days. Critically, we found few differences between the short-term and long-term tasks, and in fact most of the Bayes factors were roughly 8 to 1 in favor of the null.

From a practical perspective, this research provides an optimistic perspective on the validity of the trial-by-trial paradigm as a simulation of causal learning that occurs in the real world across longer periods of time. Assessing the external validity of this paradigm is important given that it has been used in hundreds of published studies on causal learning, and many thousands of studies when including studies of probability learning and other related topics.

From a theoretical perspective, we find it striking that there are so few differences in learning across the short and long timeframe condition. We intentionally used large samples to have the power to detect small effects. The robust learning in the long timeframe condition is surprising considering that participants completed the long-term trials outside of the lab and likely participated with many distractors and interruptions, comparable to everyday causal learning. Still, we hypothesized that the learning in the long timeframe condition would be plagued by considerably worse learning due to noisy memories. The fact that we found few differences raises a number of questions.

One question has to do with how learning occurs (e.g., Bornstein et al., 2017). Are subjects recording individual episodic memories and using them for causal learning? Or are they merely encoding them as generic events of the four cell types? Or are they using a process more similar to reinforcement learning in which an estimate of the strength of the relation between the cause and outcome gets updated as new evidence is experienced? Some of these questions can be addressed with our contextual image memory questions.

Another question is how well long-term memory can support other types of learning. It is possible that a single cause-effect relation is simple enough for long-term memory to robustly support learning, but that long-term memory might not be able to support more complex cause-effect relations (e.g., with multiple causes or long delays). We are actively studying such questions.

This research also has potential implications for whether learning and memory processes are fundamentally the same for shorter vs. longer timeframes. In associative learning, there is a debate about "timescale independence or invariance" (Gallistel & Gibbon, 2000), in which learning phenomena tend to replicate if the sequence is stretched or compressed. In memory, there are debates about the similarities and differences in short vs. long-term memory (e.g., Cowan, 2008) and whether memories across short and long timespans can be modeled with the same forgetting curves (e.g., Wixted & Ebbesen, 1991). Perhaps researchers invested in these debates may be able to use these results.

More generally, we believe that the current research provides an important step towards generalizing current learning paradigms to more real-world settings. The current findings are optimistic in terms of how well the paradigm generalizes; however, future research may also reveal areas in which standard learning paradigms generalize poorly.

Abstract

Studies of human expertise suggest that experts and novices "see" problems differently. Experts not only acquire a body of domain-specific strategies and knowledge, but also learn to quickly identify when those concepts apply to problems within the domain. We propose modeling these elements as an iterative process of domain-specific language (DSL) learning, while jointly training a neural network to recognize when learned concepts apply to new problems. We show that the algorithm solves problems more accurately and quickly than either a neural network alone, or a model that simply acquires new concepts without learning when to use them. We also examine the implicit problem representations learned by the neural network recognition model, and find that they increasingly come to reflect abstract relationships between problems, rather than surface features, as the model acquires domain expertise. Abstract

Neuropsychological investigations with frontal patients have revealed selective deficits in selecting the relational answer to pictorial analogy problems when the correct option is embedded among foils that exhibit high semantic or visual similarity. In contrast, normal age-matched controls solve the same problems with near-perfect accuracy regardless of whether high-similarity foils are present (in the absence of speed pressure). Using more sensitive measures, the present study sought to determine whether or not normal young adults are subject to such interference. Experiment 1 used eye-tracking while participants answered multiple-choice 4-term pictorial analogies. Total looking time was longer for semantically similar foils relative to an irrelevant foil. Experiment 2 presented the same problems in a true/false format with emphasis on rapid responding and found that reaction time to correctly reject false analogies was greater (and errors rates higher) for those based on semantically or visually similar foils. These findings demonstrate that healthy young adults are sensitive to both semantic and visual similarity when solving pictorial analogy problems. Results are interpreted in relation to neurocomputational models of relational processing.

Keywords: Analogy, semantics, perception, interference, eye-tracking, reaction time

Introduction

Relational reasoning—inferential processes constrained by the relational roles that entities play rather than the specific features of those entities—is a hallmark of human cognition. The basic components of relational processing have been investigated using a wide variety of analogy tasks. The simplest format for analogies involves four terms, expressed as either words or pictures, in the form *A:B::C:?*, where the task is to complete the analogy by selecting the best *D* term from a small set of options. By varying the alternative options, it is possible to assess the degree to which analogical reasoning is influenced by foils that pit semantic and/or visual similarity of individual

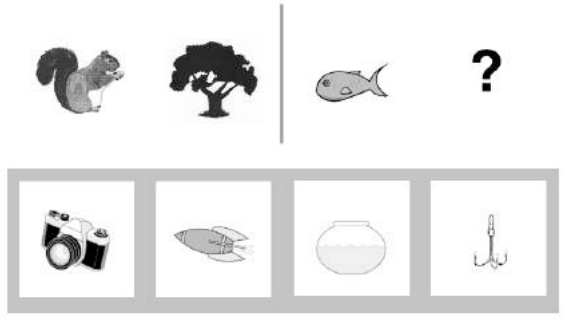

Figure 1. Example of a 4-term pictorial analogy with four alternatives, used in the present experiments (from Krawzcyk et al., 2008).

concepts or objects against relational similarity between pairs of concepts or objects. In the example shown in Figure 1, the task is to select the analogical option (*fish bowl*, based on the relation "lives in" that matches the *A:B* relation) from among a semantic distractor similar to the *C* term (*fish hook*), a visual distractor (*rocket*) and an unrelated option (*camera*).

Krawczyk et al. (2008) administered a set of picture analogies (from which the example shown in Figure 1 is drawn) to neuropsychological patients suffering from frontotemporal lobar degeneration (FTLD) and age-matched neurotypical controls (mean age approximately 60 years). Some of these problems were adapted from an earlier set created by Goranson (2002), and hence are dubbed the Goranson Analogy Test (GAT). In the study by Krawczyk et al., problems were administered one at a time, without speed pressure. In one problem set the options included distractors as in Figure 1; in an alternative set the semantic and perceptual distractors were replaced by two additional unrelated options.

For the set with similar distractors, patients with frontal-variant FTLD were correct on only 49% of the problems, rising to 84% correct for the set without similar distractors. An additional group of patients with temporal-variant FTLD showed a similar level of impairment regardless of whether similar foils were present, suggesting a general semantic deficit (see also Morrison et al., 2004). When similar distractors were present the patients with frontal damage selected similar distractors (mainly semantic, but also visual) more often than control participants. Indeed, the control group achieved near-perfect accuracy (98% correct). Thus, frontal damage appeared to selectively impair the ability to inhibit responding to pictorial analogy problems on the basis of superficial object similarity.

The near-perfect performance of the control participants in solving pictorial analogies even in the presence of similar distractors raises the question of whether and how cognitively unimpaired adults screen out object similarity (both semantic and visual) so as to focus on similarity of relations. Adults sometimes respond on the basis of object similarity when comparing more complex visual scenes (Markman & Gentner, 1993; Walz et al., 2000); however, the simple format of four-term pictorial analogies may allow non-relational information to be filtered out at a very early processing stage, so that choice of the analogical solution is not influenced by the presence of similar but non-relational foils. Alternatively, more sensitive measures may reveal evidence of response competition based on different varieties of similarity.

In two experiments, we investigated this question by administering versions of the GAT analogies used by Krawczyk et al. (2008) to healthy young adults. Eye-tracking methods provide one avenue for investigating online processing that occurs during analogical reasoning prior to making an overt decision (Gordon & Mozer, 2006; Glady, French, & Thibaut, 2016; Hayes, Petrov, & Sederberg, 2011; Vendetti et al., 2017). Accordingly, in Experiment 1 we collected data on gaze durations for the various response options while solving the GAT problems.

Another potentially more sensitive measure is reaction time (RT) to solve analogies under speed pressure. In Experiment 2 we changed the format of the GAT problems from four-alternative forced choice to true/false. For each of the original problems, each of the three foils was used to create a false picture analogy in the form *A:B::C:D*. In addition, participants were instructed to respond as quickly as possible. If semantic and/or visual similarity is screened out easily, then the various types of false analogies should take about the same length of time to reject. However, if college students are unable to avoid processing more superficial types of similarity, then decisions about false analogies in which the *D* term is similar (semantically or visually) to the *C* term may be relatively slow and error-prone.

Experiment 1

If superficial similarity intrudes into analogical reasoning for healthy adults, then they may spend more time looking at semantic and/or visual distractors than at an unrelated option.

Method

Participants. Participants were 32 undergraduates (24 female), mean age 20.4 years (range: 17–34) from the University of California, Los Angeles (UCLA), with normal or corrected to normal vision. They received course credit for participating.

Materials. Picture analogies were based on the 18 GAT problems used by Krawczyk et al. (2008). Two of these served as practice items, and 16 as experimental items. As in the Krawczyk et al. study, two sets of the 16 problems were created, one of which included similar foils and one of which replaced the semantic and visual foils with unrelated options.

Procedure. Pictorial analogies were presented on a computer screen one at a time. The size of each individual image (framed by a gray box) was 128 x 128 pixels (one-tenth of the screen width). A fixation cross was presented for 2 s, followed by the problem. The problem remained on until the participant pressed one of four response keys (corresponding to letters F, G, H, and J) to indicate which of the four alternatives was the correct analogical solution. When a response was made, the screen showed the reverse grayscale image for .25 s, after which the next trial began. Instructions did not emphasize speed of responding. During the experiment eye-tracking data were recorded using an Eyelink II gaze tracker (SR Research Ltd., Mississauga, Ontario, Canada), running under Eyelink Toolbox, PsychToolbox, and MATLAB on dual PCs. No feedback was provided.

For each participant, eight problems were included in the set with similar distractors (Distractor condition), and the other eight in the set with only unrelated foils (No-Distractor condition). Assignment of problems to set was counterbalanced across participants, as was the order of the four response options for each problem. Presentation order of the problems was randomized for each participant.

Results

Data were missing for one participant, who was excluded from analyses. Accuracy overall was 92% correct and did not vary reliably across the Distractor and No-Distractor conditions.

To guide analyses of eye movements, an invisible square of size 192 x 192 pixels around each individual image was defined as the location of that image. Figure 2 presents an example of a pattern of eye movements for an individual analogy problem in the Distractor condition.

To provide evidence of a possible pre-decisional influence of superficial similarity, we focused on dwell time (i.e., total looking times summed across all fixations) for each response option. Figure 3 plots the mean dwell time for each option in both the Distractor and No-Distractor conditions.

Participants' mean total time looking for each of the three foil images, in descending order, was: semantic foil (522 ms, *SE* = 38.2), visual foil (518 ms, *SE* = 54.9), and unrelated foil (404 ms, *SE* = 31.1). Overall, there was significant variation in dwell times depending on the foil condition, $F(2,60) = 3.93$, $p = 0.025$, $\eta^2 = .12$. Individual comparisons between conditions are reported with Bonferroni-corrected *p*-values. Semantic foils had longer dwell times relative to unrelated foils, $t(30) = 3.67$, $p < .001$, $\eta_P^2 = .31$.

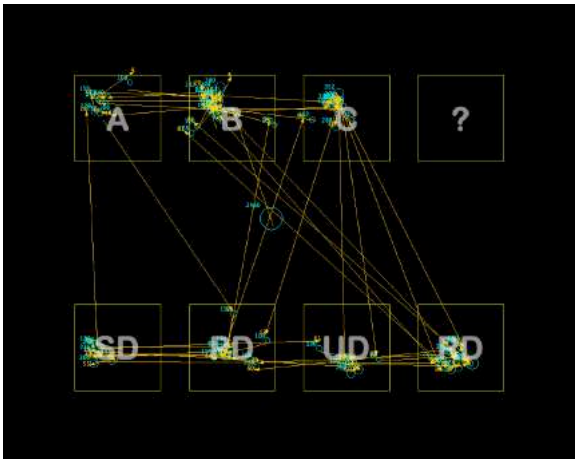

Figure 2. Example of pattern of eye movements during solution of a picture analogy. The above boxes (not visible to participants) indicate regions around the four images in the problem (*A*, *B*, *C*, *?*) and the four response options: semantically similar (S), visually similar (P), unrelated (U), and relational (R, the correct response). The D on each option label indicates this trial is from the Distractor condition.

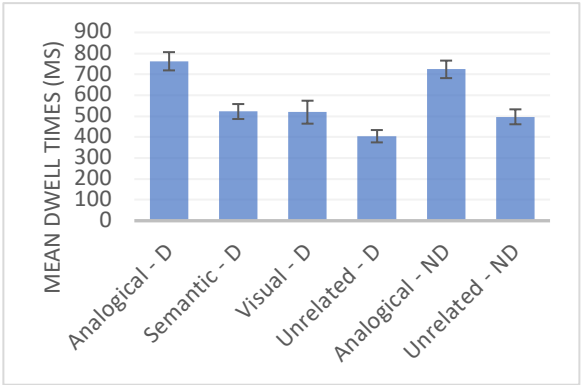

Figure 3. Total dwell time for each type of response image. The dwell time for Unrelated–ND is the mean across the three unrelated options provided in the No-Distractor condition. Error bars indicate +/- 1 standard error of the mean.

Visual foils also tended to have longer dwell times relative to unrelated foils. However, due to greater error variance in the visual foil condition, the latter difference was not reliable after the Bonferroni correction, $t(30) = 2.24$, $p = .098$, $\eta_P^2 = .14$. Dwell times for the two types of similar foils did not differ, n.s.

The eye-tracking data from Experiment 1 provide clear evidence that healthy adults are influenced by the presence of semantic and possibly visual distractors. Although response accuracy was high even in the presence of distractors, participants looked longer at semantically similar foils than at an unrelated option, suggesting that participants were sensitive to superficial similarity prior to making a decision.

Experiment 2

Experiment 2 used the same basic GAT analogies as in Experiment 1 but changed the format from 4-alternative forced choice to true/false. Instead of eye-tracking, the main dependent measure was RT to evaluate the problems under speed pressure.

Method

Participants. A total of 60 UCLA undergraduates (83% female) participated in the experiment. Their mean age was 20.8 years (range: 18–28), with normal or corrected to normal vision. They received course credit for participating.

Materials and Procedure. The experiment was conducted using a computer to display problems and record responses. The materials were based on the GAT problems used by Krawczyk et al. (2008). Each original problem was used to generate four true/false

problems, each showing four pictures. As shown in Figure 4, in each problem the *A:B* pair appeared at the top of the display and the *C:D* pair on the bottom. The *D* picture was either the correct analogical response (true), the semantic foil (false), the visual foil (false), or the unrelated option (false). Thus 25% of the problems were true analogies and 75% were false.

A set of four practice problems was created, using two of the GAT problems plus two additional problems taken from other sources. For the actual test trials, 16 analogy sets were created, one from each of the remaining 16 GAT problems. Figure 4 shows one of these sets. This procedure resulted in a total of 64 analogy problems. Each participant solved all 64 problems (i.e., a within-subjects design). To control for order effects the items were counterbalanced in the following way. The 16 sets were randomly assigned in equal numbers to Group A, B, C, or D. Thus, there were a total of 4 sets in each of the groups. Then, four test combinations were formed (I, II, III, IV). Combination I included only the items in Group A that had the analogical option, items in Group B that had the semantic foil option, items in Group C that had the visual foil option, and items in Group D that included the unrelated choice. Combinations II–IV were formed in the same basic manner, completing the counterbalancing of the four problems in each set. The presentation order of combinations I–IV was then counterbalanced across participants. Finally, the order of items within each combination was randomized for each participant.

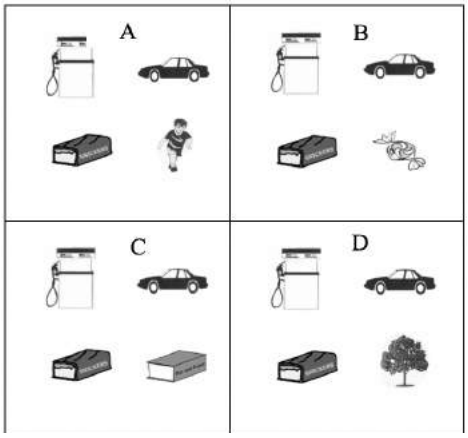

Figure 4. Example set of true/false picture analogies used in Experiment 2, created from the four alternatives of a single GAT problem. In each problem the *A:B* pair appears on top and the *C:D* pair on the bottom. The *D* term varies across problems. Panel A: Analogical (true); Panel B: semantic (false); Panel C: visual (false); Panel D: unrelated (false).

Participants were instructed to respond as quickly as possible while avoiding errors. They were told to press the *v* key to indicate "true" and the *n* key to indicate "false". Before the actual test trials, participants completed the four practice items (illustrating each of the four basic problem types) and were given feedback after each one. The correct answer was presented for 3,000 ms. No feedback was provided after test trials. On each test trial, a fixation cross appeared in the center of the screen for 1,000 ms before presentation of the analogy problem. The analogy problem remained visible until a response was made. The screen then went blank for 1,000 ms, after which the next fixation cross was presented.

Results

Both error rates and RTs for correct trials were analyzed. In Experiment 1, where the task was a four-alternative forced choice without speed pressure, error rates were low. In Experiment 2, by contrast, the speeded true/false task led to a substantial error rate. The mean error rate was 25% for analogical (true) problems, 48% for the problems with a semantic foil (false), 16% for the problems with a visual foil (false), and 7% for the problems with an unrelated foil (false). For the three types of false problems, a one-way within-subjects ANOVA was highly significant, $F(2, 118) = 150.31$, $p < .001$, $\eta^2 = .72$. Error rates were higher for the semantic foils than the unrelated foils, $t(59)=13.63$, $p < .001$, $\eta_P^2 = .76$. Error rates were also higher for the visual foils than the unrelated foils, $t(59)=5.42$, $p < .001$, $\eta_P^2 = .33$. Finally, semantic foils produced more errors than visual foils, $t(59)=12.66$, $p < .001$, $\eta_P^2 = .73$.

Figure 5 presents the mean correct RTs for each problem type. On average, participants took 3,047 ms to correctly verify problems with the analogical completion, 3,396 ms to correctly reject problems with the semantic foil, 2917 ms to reject those with the visual foil, and 2,518 ms to reject those with the unrelated foil. A within-subjects one-way ANOVA provided strong evidence for variation in RTs among the three types of false analogies, $F(2, 58) = 34.98$, $p < .001$, $\eta^2 = .37$. A Bonferroni correction was again applied to pairwise comparisons between foil conditions. False problems with semantic foils took longer to reject than those with unrelated foils, $t(59) = 6.62$, $p < .001$, $\eta_P^2 = 0.43$. Those with visual foils also yielded longer RTs compared with unrelated foils, $t(59) = 6.27$, $p < .001$, $\eta_P^2 = .40$. Finally, problems with semantic foils produced longer RTs than those with visual foils, $t(59) = 4.46$, $p < .001$, $\eta_P^2 = .77$.

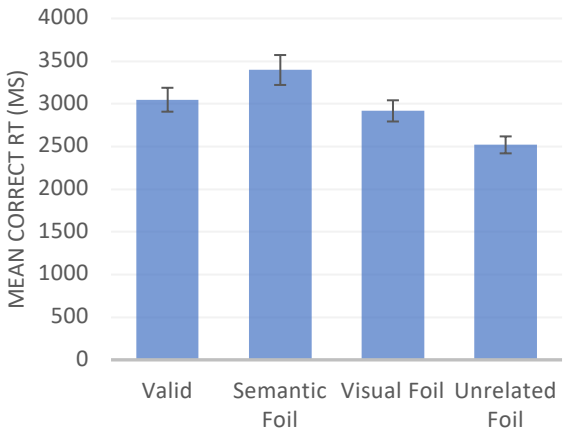

Figure 5. Mean correct RT for each type of picture analogy problem (Experiment 2). Error bars indicate +/- 1 standard error of the mean.

Discussion

The goal of the present study was to assess whether or not healthy young adults are influenced by semantic and/or visual similarity of distractors when solving four-term picture analogy problems. Previous work had indicated that in the absence of speed pressure, healthy older adults show little if any tendency to actually choose similar distractors over the correct, analogical option (Krawczyk et al., 2008). One possibility is that for reasoners with a fully functional frontal cortex, any tendency to select similar distractors is successfully inhibited (Morrison et al., 2004; Knowlton et al., 2012). But an alternative possibility is that healthy adults are able to reason by analogy without evoking a more superficial strategy based on comparing the similarity of *C* and *D* terms, so that superficial similarity simply does not enter into the analogical decision process.

Employing two different methods, the present study found evidence that college students are in fact influenced by both semantic and visual similarity when solving picture analogies. Using a four-alternative forced choice paradigm, in Experiment 1 we tracked eye movements while college students solved picture analogies in the absence of speed pressure. We found that dwell time (total looking time) was elevated for semantic (and possibly visual) foils during the period prior to selection of a response, even though the presence of similar distractors had little impact on the final choice. This finding suggests that similar distractors tended to draw extra attention, even though they were almost always rejected in favor of the analogical solution.

Experiment 2 examined solutions of the same basic picture analogies after they were recast in a true/false format and administered with instructions that emphasized speed of responding. In this situation, the similar distractors (especially the semantic foil) strongly influenced performance by college students. False analogies containing a semantic distractor as the *D* term were often erroneously judged to be true and took longer to correctly reject than any other condition. False analogies based on visual distractors also yielded higher error rates and higher correct RTs than did false analogies based on unrelated *D* terms.

The much more salient impact of similar distractors in Experiment 2 may be related to two ways in which its design differed from that used in both Experiment 1 and in the previous neuropsychological study by Krawczyk et al. (2008). First, speed pressure may be critical. When pressed to respond quickly, as in Experiment 2, there may not be time for inhibitory processes to effectively suppress a tendency to base decisions on superficial similarity.

Second, the true/false format used in Experiment 2 may also have played a role. In the four-alternative forced choice set-up, all options are simultaneously available for comparison, and a common criterion can be applied on an individual trial to determine the "best" alternative (e.g., Lu, Wu, & Holyoak, 2019; Lu, Liu, Ichien, Yuille, & Holyoak, 2019). In the true/false set-up, by contrast, each option has to be evaluated in isolation, and a criterion must be set on each trial to decide whether the analogy is "good enough" to respond "true". Since feedback was never given in our experiments, participants may have been uncertain about the appropriate criterion (especially since the ratio of true and false analogies was unbalanced). Given that the analogies were best solved on the basis of semantic relations, problems including a semantic lure (i.e., those in which the *C* term is semantically related to the *D* term, but not in the same way that *A* is related to *B*) may have often passed the subjective decision criterion, resulting in errors.

Taken together, the present findings seem to rule out the hypothesis that superficial similarity plays no role in analogical reasoning for healthy adults. Depending on test conditions, semantic and visual lures may have relatively subtle effects (a tendency to attract visual attention) or extremely salient effects (generating either errors or slow correct responses).

It would seem, therefore, that our results favor the standard view that analogical reasoning is susceptible to interference from a non-analogical strategy of simply evaluating the similarity of the *C* and *D* terms, without reference to the *A:B* relation. However, another alternative deserves consideration. The analogy "game" bases the correct answer on the most specific possible relation(s) in common across *A:B* and *C:D* (e.g., for the analogy shown in Figure 1, the specific relation "lives in" links squirrel to tree and

also fish to fishbowl). But suppose relations emerge in a gradual fashion during the reasoning process, rather than simply being retrieved in an all-or-none fashion. Then the *A:B* and *C:D* relations may at first be vague or incomplete, and only over time reach full specificity. Early in this process of relation encoding, the active relation between *A:B* may be something very general (e.g., a squirrel is somehow related, either semantically or visually, to a tree). At this point, one or both of the foils may match the crude *A:B* relation about equally well as the analogical answer (e.g., a fish is associated with a fishbowl, and similar visually to the pictured rocket). Under this view, speed pressure may force the reasoner to choose the "best" answer before the relations are fully encoded, at a point in time when the analogical answer and the similar foils may be comparable in their degree of match to the partially-encoded *A:B* relation.

This alternative account of interference implies its source may not be a rival non-analogical strategy (e.g., simply comparing *C* and *D* while ignoring *A:B*). Rather, interference may emanate from the analogy process itself, if a fast decision is required when relations are as yet poorly encoded. Future research should attempt to test these alterative accounts of how superficial similarity can infiltrate a process that aims to focus on relations.

Abstract

Perseveration, or stickiness parameters have been added to reinforcement-learning (RL) models to capture autocorrelation in choices. Here, we systematically examined whether perseveration terms simply improve a models ability to fit noise in the data, thereby making them overly flexible. We simulated data with basic versions of a Delta and Prediction-Error Decay model with no perseveration terms added, and for half of the simulated data sets we added random noise to expected RL values on each trial. We then performed cross-fitting analyses where the simulated data sets were fit by the basic data-generating models as well as extended models with perseveration terms added. The addition of perseveration terms improved model fit, particularly when noise was added to the simulation process. Parameter recovery was generally poorer for the extended models. These results suggest simpler models may be more useful for prediction and generalization to novel environments, as well as for theory development.

Generalization as diffusion: human function learning on graphs

Abstract

From social networks to public transportation, graph structures are a ubiquitous feature of life. How do humans learn functions on graphs, where relationships are defined by the connectivity structure? We adapt a Bayesian framework for function learning to graph structures, and propose that people perform generalization by assuming that the observed function values diffuse across the graph. We evaluate this model by asking participants to make predictions about passenger volume in a virtual subway network. The model captures both generalization and confidence judgments, and provides a quantitatively superior account relative to several heuristic models. Our work suggests that people exploit graph structure to make generalizations about functions in complex discrete spaces.
Keywords: Function Learning, Graph structures, Gaussian Process, Generalization, Successor Representation

Introduction

Most of function learning research has focused on how people learn a relationship between two continuous variables (Mcdaniel & Busemeyer, 2005; Lucas, Griffiths, Williams, & Kalish, 2015; DeLosh, Busemeyer, & McDaniel, 1997). How much hot sauce should I add to enhance my meal? How hard should I push a child on a swing? While function learning on continuous spaces is ubiquitous, many other relationships in the world are defined by functions on discrete spaces. For example, navigating a subway network and constructing a bookshelf both require representation of functions mapping discrete inputs (subway stops and configurations of components) to continuous outputs (passenger volume and probability of success). Likewise, language, commerce, and social networks are all defined partly by discrete relationships. How do people learn functions on discrete graph structures?

We propose that a diffusion kernel provides a suitable similarity metric based on the transition structure of a graph. When combined with the Gaussian Process (GP) regression framework, we arrive at a model of how humans learn functions and perform inference on graph structures. Using a virtual subway network prediction task, we pit this model against heuristic alternatives, which perform inference with lower computation demands, but are unable to capture human inference and confidence judgments. We also show that the diffusion kernel can be related to prominent models in continuous function learning and models of structure learning. This opens up a rich set of theoretical connections across theories of human learning and generalization.

Computational Models of Function Learning

Based on a limited set of observations, how can you interpolate or extrapolate to predict unobserved data? This question has been the focus of human function learning research, which has traditionally studied predictions in continuous spaces (e.g., the relationship between two variables; Busemeyer, Byun, DeLosh, & McDaniel, 1997). Function learning research has revealed how inductive biases guide learning (Kwantes & Neal, 2006; Kalish, Griffiths, & Lewandowsky, 2007; Schulz, Tenenbaum, Duvenaud, Speekenbrink, & Gershman, 2017) and which types of functions are easier or harder to learn (Schulz, Tenenbaum, Reshef, Speekenbrink, & Gershman, 2015).

Several theories have been proposed to account for how humans learn functions. Earlier approaches used rule-based models that assumed a specific parametric family of functions (e.g., linear or exponential; Brehmer, 1974; Carroll, 1963; Koh & Meyer, 1991). However, the rigidity of rule-based learning struggled to account for order-of-difficulty effects in interpolation tasks (Mcdaniel & Busemeyer, 2005), and could not capture the biases displayed in extrapolation tasks (DeLosh et al., 1997).

An alternative approach relied on similarity-based learning, using connectionist networks to associate observed inputs and outputs (DeLosh et al., 1997; Kalish, Lewandowsky, & Kruschke, 2004; Mcdaniel & Busemeyer, 2005). The similarity-based approach is able to capture how people interpolate, but fails to account for some of the inductive biases displayed in extrapolation and in the partitioning of the input space. In some cases, hybrid architectures were developed to incorporate rule-based functions in a associative framework (e.g., Kalish et al., 2004; Mcdaniel & Busemeyer, 2005) in an attempt to gain the best of both worlds.

More recently, a theory of function learning based on GP regression was proposed to unite both accounts (Lucas et al., 2015), because of its inherent duality as both a rule-based and a similarity-based model. GP regression is a non-parametric method for performing Bayesian function learning (Schulz, Speekenbrink, & Krause, 2018), has successfully described human behavior across a range of traditional function learning paradigms (Lucas et al., 2015), and can account for compositional inductive biases (e.g., combining periodic and long range trends; Schulz et al., 2017).

While the majority of function learning research has studied continuous spaces, many real-world problems are discrete (Kemp & Tenenbaum, 2008). In a completely unstructured discrete space, the task of function learning is basically hopeless, because there is no basis for generalization across inputs. Fortunately, most real-world problems have structure

(Tenenbaum, Kemp, Griffiths, & Goodman, 2011), which we can often represent as a connectivity graph that encodes how inputs (nodes) relate to each other (see Kemp & Tenenbaum, 2008, for a similar argument). By assuming that functions vary smoothly across the graph (a notion we formalize below), functions can be generalized to unobserved inputs. Although this idea has been studied extensively in machine learning, it has not yet fully permeated into studies of human function learning.

Goals and Scope

We describe a model of learning graph-structured functions using a diffusion kernel. The diffusion kernel specifies the covariance between function values at different nodes of a graph based on its connectivity structure. When combined with the GP framework, it allows us to make Bayesian predictions about unobserved nodes. Even though previous work has investigated how people learn the relational structure of a graph (Kemp & Tenenbaum, 2008; Kemp, Tenenbaum, Griffiths, Yamada, & Ueda, 2006; Tomov, Yagati, Kumar, Yang, & Gershman, 2018), or infer properties of unobserved inputs (Kemp & Tenenbaum, 2009; Kemp, Shafto, & Tenenbaum, 2012), less is known about how people learn functions in discrete spaces with real-valued outputs.

We present an experiment where participants are shown a series of randomly generated subway maps and asked to predict the number of passengers at unobserved stations to test our model of function learning on graphs. In addition, we collected confidence judgments from participants. We compared the GP diffusion kernel model to heuristic models based on nearest-neighbor interpolation.

Function Learning on Graphs

We can specify a graph $G = (\mathcal{N}, \mathcal{E})$ with nodes $n_i \in \mathcal{N}$ and edges $e_i \in \mathcal{E}$ to represent a structured state space (Fig. 1a). Nodes represent states and edges represent connections. For now, we assume that all edges are undirected (i.e., if $x \to y$ then $y \to x$).

The diffusion kernel (Kondor & Lafferty, 2002) defines a similarity metric $k(s,s')$ between any two nodes on a graph based on the matrix exponentiation of the graph Laplacian:

$$k(s,s') = e^{\alpha L}, \tag{1}$$

where L is the graph Laplacian:

$$L = D - A, \tag{2}$$

with the adjacency matrix A and the degree matrix D. Each element a_{ij} is 1 when nodes i and j are connected, and 0 otherwise, while the diagonals of D describe the number of connections of each node. The graph Laplacian can also describe graphs with weighted edges, where D becomes the weighted degree matrix and A becomes the weighted adjacency matrix.

Intuitively, the diffusion kernel assumes that function values diffuse along the edges similar to a heat diffusion process (i.e., the continuous limit of a random walk). The free parameter α governs the rate of diffusion, where $\alpha \to 0$ assumes complete independence between nodes, while $\alpha \to \infty$ assumes all nodes are perfectly correlated.

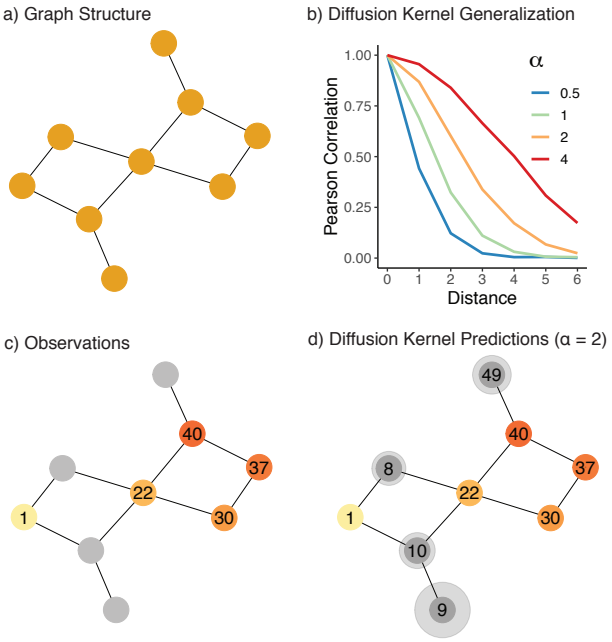

Figure 1: Graph-structured function learning. **a**) An example of a graph structure, where nodes represent states and edges indicate the transition structure. **b**) A diffusion kernel is a similarity metric between nodes on a graph, allowing us to generalize to unobserved nodes based on the assumption that the correlation between function values decays as an exponential function of the distance between two nodes. The diffusion parameter (α) governs the rate of decay. **c**) Given some observations on the graph (colored nodes), we can use the diffusion kernel combined with the Gaussian Process framework to make predictions (**d**) about expected rewards (numbers in grey nodes) and the underlying uncertainty (size of halo) for each unobserved node.

From the similarity metric defined by the diffusion kernel, we can use the GP regression framework (Rasmussen & Williams, 2006) to perform Bayesian inference over graph-structured functions. A GP defines a distribution over functions $f : \mathcal{S} \to \mathbb{R}^n$ that map the input space $\mathcal{S}$ to real-valued scalar outputs:

$$f \sim \mathcal{GP}(m,k), \tag{3}$$

where $m(s)$ is a mean function specifying the expected output of s, and $k(s,s')$ is the covariance function (kernel) that encodes prior assumptions about the smoothness of underlying function. Any finite set of function values drawn from a GP is multivariate Gaussian distributed.

We use the diffusion kernel (Eq. 1) to represent the covariance $k(s,s')$ based on the connectivity structure of the graph, and follow the convention of setting the mean function to zero, such that the GP prior is fully defined by the

kernel.

Given some observations $\mathcal{D}_t = \{\mathbf{y}_t, \mathbf{s}_t\}$ of observed outputs $\mathbf{y}_t$ at states $\mathbf{s}_t$, we can compute the posterior distribution $p(f(s_*)|\mathcal{D}_t)$ for any target state s_*. The posterior is a normal distribution with mean and variance defined as:

$$m(s_*|\mathcal{D}_t) = \mathbf{k}_*^\top (\mathbf{K} + \sigma_\varepsilon^2 \mathbf{I})^{-1} \mathbf{y}_t \quad (4)$$

$$v(s_*|\mathcal{D}_t) = k(s_*, s_*) - \mathbf{k}_\star^\top (\mathbf{K} + \sigma_\varepsilon^2 \mathbf{I})^{-1} \mathbf{k}_* \quad (5)$$

where $\mathbf{K}$ is the $t \times t$ covariance matrix evaluated at each pair of observed inputs, and $\mathbf{k}_* = [k(s_1, s_*), \ldots, k(s_t, s_*)]$ is the covariance between each observed input and the target input s_*, and σ_ε^2 is the noise variance. Thus, for any node in the graph, we can make Bayesian predictions (Fig. 1e) about the expected function value $m(s_*|\mathcal{D}_t)$ and also the level of uncertainty $v(s_*|\mathcal{D}_t)$.

The posterior mean function of a GP can be rewritten as:

$$m(s) = \sum_{i=1}^{t} w_i k(s_i, s) \quad (6)$$

where each s_i is a previously observed state and the weights are collected in the vector $\mathbf{w} = \left[k(\mathbf{S}_t, \mathbf{S}_t) + \sigma_\varepsilon^2 \mathbf{I}\right]^{-1} \mathbf{y}_t$. Intuitively, this means that GP regression is equivalent to a linearly-weighted sum using basis functions $k(s_i, s)$ to project observed states onto a feature space (Schulz, Speekenbrink, & Krause, 2018). To generate new predictions for an unobserved state s, each output y_t is weighted by the similarity between observed states s_t and the target state s.

Connections to Function Learning On Continuous Domains

The GP framework allows us to relate similarity-based function learning on graphs to theories of function learning in continuous domains. Consider the case of an infinitely fine lattice graph (i.e., a grid-like graph with equal connections for every node and with the number of nodes and connections approaching continuity). Following Kondor and Lafferty (2002) and using the diffusion kernel defined by Eq. 1, this limit can be expressed as

$$k(s, s') = \frac{1}{\sqrt{(4\pi\alpha)}} \exp\left(\frac{-|s - s'|}{4\alpha}\right), \quad (7)$$

which is equivalent to a Radial Basis Function (RBF) kernel. Models similar to the RBF kernel are prominent in the literature on function learning in continuous domains (Busemeyer et al., 1997; Lucas et al., 2015). The RBF kernel has also been used to model how humans generalize about unobserved rewards in exploration tasks (Wu, Schulz, Speekenbrink, Nelson, & Meder, 2018). Thus, the RBF kernel can be understood as a special case of the diffusion kernel, when the underlying structure is symmetric and infinitely fine.

More broadly, both the RBF and diffusion kernel can be understood as instantiations of Shepard's (1987) "universal law of generalization" in a function learning domain, by expressing generalization as an exponentially decaying function of the distance between two stimuli. Shepard famously proposed that the law of generalization should be the first law of psychology, while recent work has further entrenched it in fundamental properties of efficient coding (Sims, 2018) and measurement invariance (Frank, 2018).

Heuristic Models

We compare the GP model to two heuristic strategies for function learning on graphs, which make predictions about the rewards of a target state s_* based on a simple nearest neighbors averaging rule. The *k-Nearest Neighbors* (kNN) strategy averages the function values of the k closest states (including all states with same shortest path distance as the k-th closest), while the *d-Nearest Neighbors* (dNN) strategy averages the function values of all states within path distance d. Both kNN and dNN default to a prediction of 25 when the set of neighbors are empty (i.e., the median value in the experiment).

Both the dNN and kNN heuristics approximate the local structure of a correlated graph structure with the intuition that nearby states have similar function values. While they sometimes make the same predictions as the GP model and have lower computational demands, they fail to capture the connectivity structure of the graph and are unable to learn directional trends. Additionally, they only provide point-estimate predictions, and thus do not capture the underlying uncertainty of a prediction (which we use to model confidence judgments).

Experiment: Subway Prediction Task

We used a "Subway Prediction Task" to study how people perform function learning in graph-structured state spaces. Participants were shown a series of graphs described as subway maps, where nodes corresponded to stations and edges indicated connections (Fig. 2). Participants were asked to predict the number of passengers (in a randomly selected train car) at a target station, based on observations from other stations.

Methods and procedure

We recruited 100 participants ($M_{age} = 32.7$; $SD = 8.4$; 28 female) on Amazon MTurk to perform 30 rounds of a graph prediction task. On each graph, numerical information was provided about the number of passengers at 3, 5, or 7 other stations (along with a color aid), from which participants were asked to predict the number of passengers at a target station and provide a confidence judgment (Likert scale from 1-11). The subway passenger cover story was used to provide intuitions about graph correlated functions. Additionally, participants observed 10 fully revealed graphs to familiarize themselves with the task and completed a comprehension check before starting the task. Participants were paid a base fee of $2.00 USD for participation with an additional performance contingent bonus of up to $3.00 USD. The

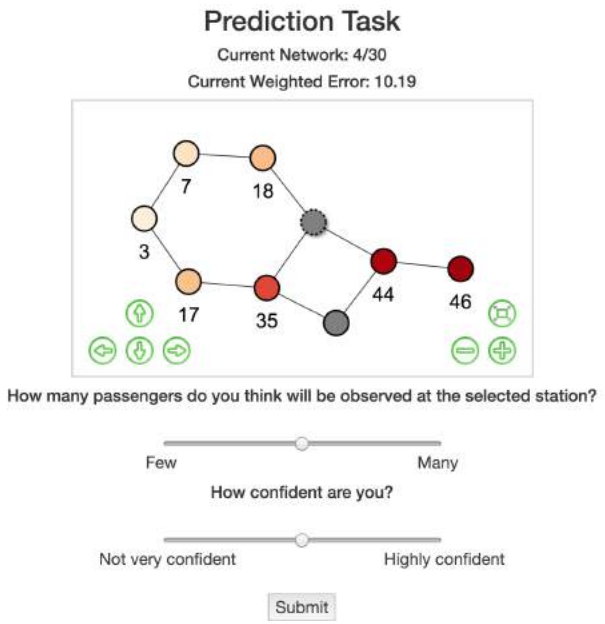

Figure 2: Screenshot from the Subway Prediction Experiment. Observed nodes (3, 5, or 7 randomly sampled nodes depending on the information condition) are shown with a numerical value and a corresponding color aid (darker indicates larger values). The target node is indicated by the dashed line, and dynamically changes color and displays a numerical value when participants move the top slider. Confidence judgments were used to compute a weighted error (i.e., more confident answers having a larger contribution), which was used to determine the performance contingent bonus.

bonus payment was based on the mean absolute judgment error weighted by confidence judgments: $R_{bonus} = \$3.00 \times (25 - \sum_i \tilde{c}_i \varepsilon_i)/25$ where $\tilde{c}_i$ is the normalized confidence judgment $\tilde{c}_i = \frac{c_i}{\sum c_j}$ and ε_i is the absolute error for judgment i. On average, participants completed the task in 8.09 minutes ($SD = 3.7$) and earned \$3.87 USD ($SD = \$0.33$).

In each of the 30 rounds, a different graph was sampled without replacement. We used three different information conditions (observations $\in [3,5,7]$; each used in 10 rounds in randomly shuffled order) as a within-subject manipulation determining the number of randomly sampled nodes with revealed information. In each round, participants were asked to predict the value of a target node, which was randomly sampled from the remaining unobserved nodes.

All participants observed the same set of 40 graphs that were sampled without replacement for the 10 fully revealed examples in the familiarization phase and for the 30 graphs in the prediction task. We generated the set of 40 graphs by iteratively building 3×3 lattice graphs (also known as mesh or grid graphs), and then randomly pruning 2 out of the 12 edges. In order to generate the functions (i.e., number of passengers), we fit a diffusion kernel to the graph and then sampled a single function from a GP prior, where the diffusion parameter was set to $\alpha = 2$.

Results

Figure 3 shows the behavioral and model-based results of the experiment. We applied linear mixed-effects regression to estimate the effect of the number of observed nodes on participant prediction errors, with participants as a random effect. Participants made systematically lower error predictions as the number of observable nodes increased ($\beta = -.11$, $t(99) = -6.28$, $p < .001$, $BF > 100$[1]; Fig. 3a). Repeating the same analysis but using participant confidence judgments as the dependent variable, we found that confidence increased with the number of observable nodes ($\beta = .16$, $t(99) = 11.3$, $p < .001$, $BF > 100$; Fig. 3b). Finally, participants were also able to calibrate confidence judgments to the accuracy of their predictions, with higher confidence predictions having consistently lower error ($\beta = -.19$, $t(99) = -9.0$, $p < .001$, $BF > 100$; Fig. 3c). There were no substantial effects of learning over rounds ($\beta = .01$, $t(99) = 0.47$, $p = .642$, $BF = 0.2$), suggesting the familiarization phase and cover story were sufficient for providing intuitions about graph correlated structures.

Model comparison

We compare the predictive performance of the GP with the dNN and kNN heuristic models. Using participant-wise leave-one-out cross-validation, we estimate model parameters for all but one judgment, and then make out-of-sample predictions for the left-out judgment. We repeat this procedure for all trials and compare predictive performance using Root Mean Squared Error (RMSE) over all left-out trials.

Figure 3d shows that the GP made better predictions than both the dNN ($t(99) = -4.06$, $p < .001$, $d = 0.41$, $BF > 100$) and kNN models ($t(99) = -7.19$, $p < .001$, $d = 0.72$, $BF > 100$). Overall, 58 out of 100 participants were best predicted by the GP, 31 by the dNN, and 11 by the kNN. Figure 3e shows individual parameter estimates of each model. The estimated diffusion parameter α was not substantially different from the ground truth of $\alpha = 2$ ($t(99) = -0.66$, $p = .51$, $d = 0.07$, $BF = 0.14$), although the distribution appeared to be bimodal, with participants often underestimating or overestimating the correlational structure. Estimates for d and k were highly clustered around the lower limit of 1, suggesting that averaging over larger portions of the graph were not consistent with participant predictions.

Finally, an advantage of the GP is that it produces Bayesian uncertainty estimates for each prediction. While the dNN and kNN models make no predictions about confidence, the GP uncertainty estimates correspond to participant confidence judgments ($\beta = -.10$, $t(99) = -3.39$, $p < .001$, $BF > 100$; linear mixed-effects model with participant as a random effect).

[1] β is the standardized effect size $\in [-1,1]$ and we approximate the Bayes Factor using bridge sampling (Gronau, Singmann, & Wagenmakers, 2017) to compare our model to an alternative intercept only null model, where both models were hierarchical regressions but only the alternative model contained the variable of interest as a regressor.

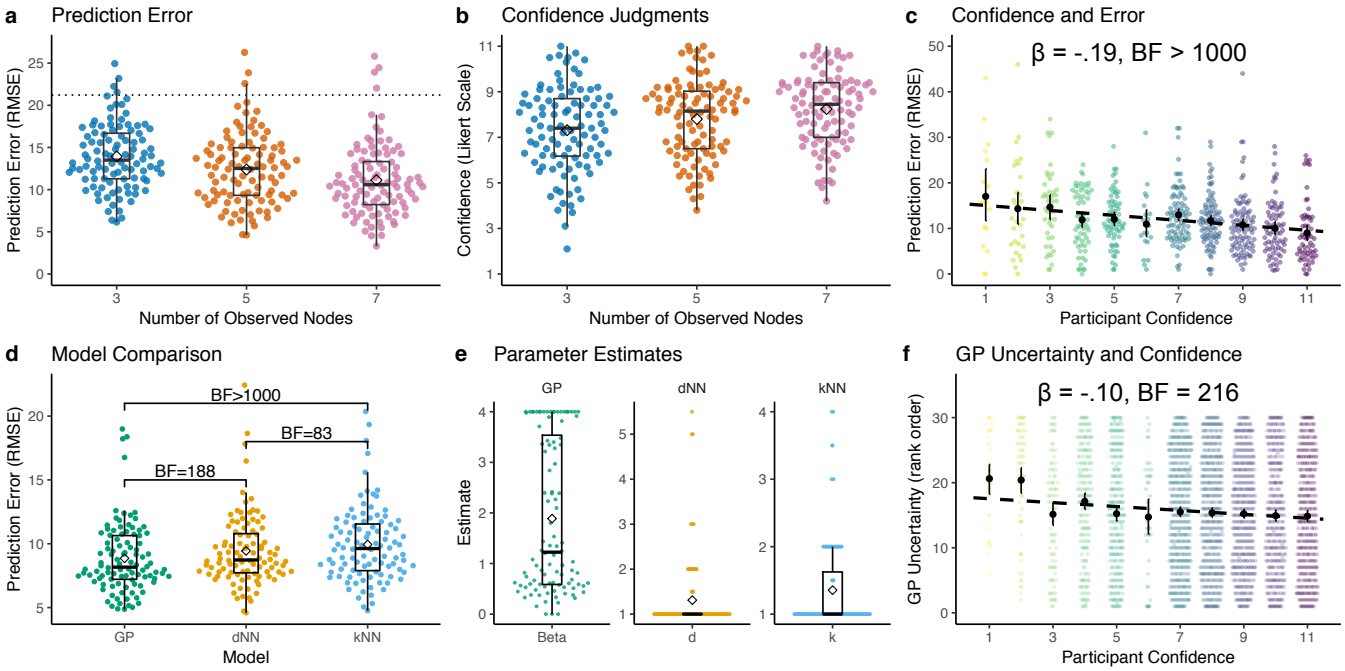

Figure 3: Results. **a-b**) Participant judgment errors and confidence estimates. Each dot is a single participant (averaged over each number of observed nodes), with Tukey boxplots and diamonds indicating group means. The dotted line in **a**) is a random baseline. **c**) Judgment error and confidence. Each colored dot is a participant (averaged over each confidence level), dashed line is a linear regression, with black dots and error bars indicating group means and 95% CI. We report the mixed-effects regression coefficient and Bayes Factor above. **d**) Cross-validated model comparison between the Gaussian Process with diffusion kernel (GP), d-nearest neighbors (dNN), and k-nearest neighbors (kNN). Each point is a single participant with a Tukey boxplot overlaid and diamonds indicating group means. Comparisons are for a Bayesian one-sample t-test, where the null hypothesis posits no difference between models and assumes a Cauchy prior with the scale set to $\sqrt{2}/2$. **e**) Parameter estimates, where each dot is the mean cross-validated estimate for each participant, with Tukey boxplots and diamonds indicating group means. **f**) GP uncertainty estimates (rank ordered within participant) and participant confidence judgments (Likert scale). Dotted line is a linear regression, with black dots and error bars indicating mean and 95% CI. We report the mixed-effects regression coefficient and Bayes factor (see text for details).

Discussion

How do people learn about functions on structured discrete spaces like graphs? We show how a GP with a diffusion kernel can be used as a model of function learning that produces Bayesian predictions about unobserved nodes. Our model integrates existing theories of human function learning in continuous spaces, where the RBF kernel (commonly used in continuous domains) can be seen as a special limiting case of the diffusion kernel. Using a virtual subway task, we show that the GP was able to capture how people make judgments about unobserved nodes and is also able to generate uncertainty estimates that correspond to participant confidence ratings.

Related work

Previous work has also investigated how people perform inference over graphs (Kemp & Tenenbaum, 2009, 2008; Shafto, Kemp, Baraff, Coley, & Tenenbaum, 2005; Tomov et al., 2018). Whereas these studies were geared towards probing how people inferred underlying structure (Kemp & Tenenbaum, 2008) and how (implicit or explicit) representations of structure influenced causal property judgments (Kemp & Tenenbaum, 2009; Shafto et al., 2005), the goal of our Subway Prediction Task was to study how people perform functional inference given explicit knowledge of a relational structure. Thus, our study can be seen as a real-valued extension of the experiments presented in Kemp and Tenenbaum (2009) and Shafto et al. (2005), where we explicitly present the underlying structure and modeled both participants predictions and their confidence judgments simultaneously.

Our approach also has formal similarities to Kemp and Tenenbaum (2008, 2009), who used a kernel defined as $k(s,s') = (L + \frac{I}{\sigma^2})^{-1}$ to generate feature vectors over structured representations, in order to approximate a prior over properties distributed across the graph. This kernel is a reformulation of the regularized Laplacian kernel[2] (Zhu, Lafferty, & Ghahramani, 2003), which belongs to the same broad framework of regularization operators (Smola & Kondor, 2003) as the diffusion kernel (Eq. 1), with both providing similar inductive biases of smoothness over the graph struc-

[2] $k(s,s') = (I + \sigma^2 L)^{-1}$

ture.

Future Work and Limitations

Currently, we have only studied how people learn functions on spatial representations of graph structures, where all nodes and edges are visible simultaneously. However, people can perform inferences over discrete structures that are more conceptual such as social hierarchies (Lau, Pouncy, Gershman, & Cikara, 2018) or causal connections (Rothe, Deverett, Mayrhofer, & Kemp, 2018). Given that the GP framework can be used to compare how people learn functions over different (i.e., spatial and conceptual) domains (Wu, Schulz, Garvert, Meder, & Schuck, 2018), comparing functional inference over conceptual and spatial graphs seems like promising extension for future studies.

Additionally, one could also assess the suitability of the diffusion kernel as a model for more complex problems, such as multi-armed bandit tasks with structured rewards (e.g., Schulz, Franklin, & Gershman, 2018) and in planning problems, where exploration plays a fundamental role. One advantage of the GP diffusion kernel model is that it makes prediction with estimates of the underlying uncertainty. Whereas many models of generalization only make point-estimates about the value of a state, the GP framework offers opportunities for using uncertainty-guided exploration strategies (e.g., Auer, 2002).

One limitation of the diffusion kernel is that it assumes *a priori* knowledge of the graph structure. While this may be a reasonable assumption in problems such as navigating a subway network where one can simply look at a map, this is not always the case. In contrast, the SR can learn the graph structure through experience (using prediction-error updating). Thus, the connection between the SR and the diffusion kernel presents a promising avenue for incorporating a plausible process model of structure learning.

Conclusion

We show that GP regression, together with a diffusion kernel, captures how participants learn functions and make confidence ratings on graph structures in a virtual subway prediction task. Our model opens up a rich set of theoretical connections to theories of function learning on continuous domains and models of structure learning and property induction.

Abstract

Sentence comprehension in part involves introducing, storing, and retrieving information about individuals. Natural languages provide various means for performing this computational work. One popular idea is that indefinite noun phrases provide instructions for updating the discourse model by adding a new discourse referent, while definite noun phrases presuppose the existence of a discourse referent available in memory, as well as instructions for retrieving it. When no antecedent is available, the definite's presupposition fails to be satisfied, resulting in the so-called 'presupposition failure' and pragmatic infelicity. However, under certain conditions, definite noun phrases *can* felicitously be used even when no antecedent is available in memory. In such cases, a conversational repair strategy called 'presupposition accommodation' can rescue the discourse by adding the required referent. It is natural to expect greater processing costs for adding a discourse referent with a definite than with an indefinite: although both involve the process of adding a referent, definites go through a stage of presupposition failure and a subsequent decision to accommodate. The experimental challenge has been to apply a method sensitive enough to detect expected costs in discourse, even when the participant is unaware of the presupposition failure and repairs it rapidly. The present study addresses this challenge by using EEG to capture temporally fine-grained processing differences between definite and indefinite noun phrases when both introduce new discourse referents in plausible and implausible contexts. Our main finding is that definite noun phrases elicit the Left Anterior Negativity (LAN) effect, compared to indefinite noun phrases, both in implausible contexts where there is a sense of oddness and in perfectly coherent contexts. We take this as evidence of a specific cognitive stage at which presupposition failure is detected and when an accommodation decision occurs. This also supports the idea that, when encountering a definite, the LAN is tightly linked to working memory processes involving the search for discourse elements that are presupposed to exist in memory. When none are found, definites are subsequently accommodated and bridged to other entities in the discourse.

Keywords: discourse; presuppositions; context; accommodation; EEG

Introduction

Presuppositions in natural language are commonly viewed as pieces of information that impose constraints on the contexts in which they are triggered. Just as pronouns like "she" require that the context furnish a (uniquely) salient female, presuppositions require that the context entail them. For example, consider a command like (1):

(1) # After you read this paper, go call the waiter.

The sentence in (1) is strange when uttered out of the blue. It is strange for the same reason that *go call her* is strange when there is no salient female in the context. The sentence has been uttered in a context that is missing something that the sentence needs - in this case, a uniquely salient waiter. We refer to such cases as 'presupposition failure': the failure is technical (i.e., the context does not entail the presupposition), and this technical failure leads to a discourse failure. Note that there is nothing inherently odd about the sentence in (1); it is odd when the context in which it is uttered fails to provide a waiter as antecedent for the definite phrase *the waiter*. If we introduce a waiter into the prior context, meaning that there

is no longer any technical presupposition failure, the oddness disappears:

(2) A waiter and a cook came by and left a flyer. After you read this paper, go call the waiter.

Note also that the oddness disappears when we change "the" to "a"; since the latter has no presuppositions, there is no threat of presupposition failure, and hence none of the oddness that is experienced in (1).

(3) After you read this paper, go call a waiter.

You might not know why the speaker is telling you to call a waiter, but nothing has gone wrong as far as language itself is concerned.

This connection between presupposition and the prior context is the centrepiece of the so-called "satisfaction theory" of presupposition (e.g., Karttunen, 1974; Stalnaker, 1974; Heim, 1983). Its basic assumption is that a sentence S with presupposition p, S_p, may be used in context c only if c 'satisfies' p, i.e., only if $c \subseteq p$. The satisfaction theory adds additional auxiliary assumptions to deduce predictions about presupposition projection, that is, about the presuppositions of complex sentences. For example, it predicts that $\neg S_p$ presupposes p but that *if T then* S_p presupposes $A \rightarrow p$ (e.g., Heim, 1983). We will limit our attention to atomic sentences here.

A *prima facie* challenge for the satisfaction theory comes from the observation that it is often possible to felicitously use S_p even when c does *not* satisfy p. In other words, there appear to be instances of technical presupposition failure without any sense of a higher discourse failure. For example, consider the following text (modified from Singh, Fedorenko, Mahowald, & Gibson, 2016):

(4) I went to a restaurant last night. The waiter yelled at me.

In (4), the context in which *the waiter* is uttered does not entail that there was a waiter. It is plausible, of course, that there should be waiters in the restaurant, but this information is not strictly entailed by the context. Nevertheless, there is no hint of oddness here.[1]

The satisfaction theory explains the contrast between (4) and (1) by appealing to what is called 'presupposition accommodation' (Lewis, 1979). When addressees hear or read a definite description like *the waiter* in a context that does not furnish an antecedent, they face a choice: they can either accommodate the required presupposition; that is, they can 'quietly and without fuss' (Von Fintel, 2008) adjust the context by adding the missing presupposition, or they can let the discourse come to a crashing halt. If the context is one that makes it reasonable to accommodate, say if the presupposition is unsurprising or uncontroversial, then cooperative speakers will recognize that they should keep the discourse running and will therefore simply accommodate.[2] Viewed in this light, accommodation is a repair mechanism that can fix a context so that technical presupposition failure – the failure to initially find the required antecedent – does not become pragmatic presupposition failure. By 'pragmatic presupposition failure' we mean that the context does not get amended and the discourse is interrupted because the definite noun phrase is unable to do its job. It is considered bad conversational practice to rely on accommodation when the presupposition is somehow noteworthy. If the addressee faces the choice of having to either let the discourse crash because of pragmatic presupposition failure, or accommodate a presupposition that is surprising, controversial, or otherwise hard to incorporate into the context, then the addressee would rightly feel that the speaker is asking too much of them.

The appeal to accommodation has been controversial (e.g., Gazdar, 1979; Van der Sandt, 1992; Gauker, 1998; Abbott, 2006). The satisfaction theory predicts that the addressee has passed through a stage of processing at which technical presupposition failure was detected but was then overcome by the accommodation repair. However, there is no trace of this failure detection in our conscious awareness, and it would be desirable to find a way to measure whether accommodation is real and whether it is indeed triggered by a stage of technical presupposition failure.

Previous psycholinguistic studies have found that S_p is easier to process in contexts that satisfy p than in contexts that do not (e.g., Haviland & Clark, 1974; Crain & Steedman, 1985; Burkhardt, 2006; Schwarz, 2007). This might be thought to lend support to the satisfaction theory. However, this processing difference may not be about presupposition accommodation itself; instead, it could have arisen from the fact that in contexts in which p is not satisfied, there is an extra step of adding p to the context. This additional step may have been responsible for the extra costs whether or not there is any purported technical presupposition failure from which the addressee may choose to recover using accommodation (see Singh et al., 2016 for discussion).

To control for this, we would need a minimal pair that would also involve adding p to the context, but through assertion rather than presupposition accommodation. Indefinite articles provide the required contrast:

(5) I went to a restaurant last night. A waiter yelled at me.

[1] A reviewer raises the question about the relative appropriateness of "I went to a restaurant last night. The waiter yelled at me" and "I went to a wedding. The bride talked to me." Weddings typically have one and only one bride, while there may be no waiters or many waiters at a restaurant, and the reviewer suggests that these considerations might lead to differences in appropriateness judgments. We are not aware of work on this, and we hope to return to it in future work. We intentionally designed contexts that would (i) allow multiple referents, such as multiple waiters – this is that indefinites could also be used in these contexts), with one being uniquely salient (e.g., the waiter who serves you).

[2] Heim (1982) argued that with definites, there must be a prior discourse referent that the definite can 'bridge' to (in the sense of Clark, 1975). For example, in (4) the introduced waiter can 'bridge' to the restaurant mentioned in the first sentence, such that *the waiter* is roughly understood as 'the waiter at the restaurant', and typically with further identifying features (e.g., the waiter who served you at the restaurant – see Note 1).

In both (4) and (5), the existence of a waiter is added to the discourse context (e.g., Heim, 1982). For example, suppose with Heim (1982) that discourse referents can be thought of as file cards that can be introduced, referred to, or taken out of the 'file' that collects the discourse information as it accumulates. An indefinite noun phrase such as *a waiter* simply adds a new file card with 'is a waiter' on it. A definite like *the waiter* scans the file to find a file card with 'is a waiter' on it. If one exists, it refers to it; if it doesn't, then either communication fails, or the missing file card is accommodated. This is what appears to happen in (4). Thus, the processing of both (5) and (4) involves adding a file card corresponding to a waiter, but only in (4) do you also go through a stage of recognizing that something is wrong with the context (there is no antecedent file card). The addition of a (file card corresponding to a) waiter is then an accommodation response to this recognition; we will sometimes use 'referents' and 'antecedents' when we mean file cards, as they are probably more familiar, but it is worth noting that file cards are the underlying technical object that is being manipulated (see Heim, 1982). What we would like, then, is to test whether there is indeed a stage at which the processing mechanism seeks but fails to find an antecedent for *the waiter*, and then repairs for this by accommodating one. The satisfaction theory predicts that there should be such stages; presumably the performance system executes these computations demanded by the competence system, and if so, we might expect to find reflexes of them during language processing.

Singh et al. (2016) performed an online incremental stops-making-sense (SMS) task to examine participants' appropriateness judgments about indefinite and definite noun phrases in plausible contexts like (4) and (5) as well as in implausible contexts like the following:

(6) I went to a jail last night. {A/the} waiter yelled at me.

They found a main effect of plausibility, such that implausible conditions had more and earlier SMS judgments. This was unsurprising, given that implausible information is generally harder to process than plausible information (e.g., Trueswell, Tanenhaus, & Garnsey, 1994; Gibson & Perlmutter, 1998). More interestingly, they found an interaction, such that implausible definites had earlier and more SMS judgments than implausible indefinites. This provides support for the claim that accommodation is subject to stricter requirements than assertion. In particular, it is inappropriate to force your addressee to accommodate implausible information as a presupposition; such information is better expressed as an assertion so that your addressee is at least given the opportunity to challenge it (e.g., Soames, 1989; Heim, 1992; Beaver, 2001; Von Fintel, 2008).

However, together with appropriate auxiliary assumptions about how the competence theory is realized in performance (see above), it is plausible that the satisfaction theory would expect accommodation difficulty relative to indefinite controls not only in implausible contexts but also in plausible contexts (though cf. Stalnaker, 2002). There is technical presupposition failure in both plausible and implausible contexts. Pragmatic presupposition failure of course is more easily averted in plausible contexts than implausible ones. Thus, the enhanced difficulty of implausible definites makes sense. However, the predicted stage of technical failure in plausible contexts did not reveal itself. Perhaps the method was inappropriate for detecting such a stage, if there is one. We have seen that accommodation is not sensed as odd or costly when the presupposition is sufficiently supported in the context. Thus, it is perhaps not surprising that participants' SMS judgments did not differentiate between plausible definites and plausible indefinites. It remains an open question, then, whether an empirical cognitive account can be found for when the absence of an expected antecedent is noticed and when we decide to accommodate in response.

We explored this question by means of an electroencephalography (EEG) study using materials from Singh et al. (2016). We give a comprehensive account of our materials and methods momentarily, but briefly our goal was to compare definites and indefinites in contexts in which both would have the effect of introducing a new discourse referent into the context. The relevant difference between the two is that definites presuppose the existence of an object in memory and aim to retrieve it while indefinites introduce a new object into memory. Ideally, we want these objects to be the same, or as close to that as possible. That way, any detected difference between the two could be plausibly attributed to the assumption that definites introduce the desired object only when the search for it fails. We wanted to see if we could find an EEG signature of this hypothesized failure and repair. Previous EEG studies comparing definites and indefinites did not isolate this difference between definites and indefinites. Experiment 2 of Anderson and Holcomb (2005) had a definite and indefinite condition but the definite in these cases *had* an antecedent and the indefinite (as it does) introduced a new discourse referent. Schumacher (2009), building on Burkhardt (2006) (which investigated definites alone), included a definite given condition and an indefinite given condition (in which an indefinite NP in the second sentence has a matching indefinite NP in the first sentence); but the latter texts are odd (for reasons we discuss shortly), and hence the definite and indefinite are not properly matched, and in any event, this 'given' condition breaks our desired symmetry under which definites and indefinites both introduce a new discourse referent in all conditions.

Methods

Participants

Thirty-four participants were recruited from Carleton University. As compensation for participating in the experiment, students received 3% class credit towards a first-year cognitive science course. All students were English speakers between the ages of 18 and 24.

Materials

We used shortened versions of all 128 sentence pairs from Singh et al. (2016) as our experimental stimuli. The sentence pairs were divided evenly into four blocks using a Latin Square design as illustrated in Table (1):

Table 1: Sample stimuli

Indefinite Plausible:
Philip went to *a pool* on Tuesday evening.
A swim instructor insulted him there.
Definite Plausible:
Philip went to *a pool* on Tuesday evening.
The swim instructor insulted him there.
Indefinite Implausible:
Philip went to *a laboratory* on Tuesday evening.
A swim instructor insulted him there.
Definite Implausible:
Philip went to *a laboratory* on Tuesday evening.
The swim instructor insulted him there.

Procedure

Participants sat in a Faraday cage in front of a computer monitor and were instructed to read all sentence stimuli for comprehension. Using PsychoPy, all stimuli were presented visually in the center of the monitor in white letters against a grey background. A practice session consisting of four trials was completed before beginning each session. The first sentence in the sentence pair appeared in full for 3000 ms, followed by 100 ms of a blank screen. Our critical noun phrase (e.g., "the lion") in the second sentence of the pair then appeared on screen for 600 ms, followed by another 100 ms of a blank screen. The remaining non-critical segments of the second sentence, which had an average length of three words, appeared for 400 ms. All participants saw all items in all conditions, counterbalancing block orders.

EEG Recording

A 128-channel HydroCel Geodesic Net was used to record continuous EEG signals against Cz as reference, at a sampling rate of 250 Hz, with Net Station 4.3.1. Electrode impedance was kept below 5 kOhms.

Data Analysis

Data from two participants were excluded due to excessive noise during EEG recording. Four channels (E68, E73, E88, E94) were removed prior to preprocessing as is common for high-density electrode nets (to allow the plug-in of other external biometric devices). EEG recordings were re-referenced offline to the average and digitally filtered with a low-pass of 0.5 Hz and a high-pass of 30 Hz. Filtered data were then epoched from 500 ms before to 1000 ms after the critical noun phrase.

Subject data were preprocessed using a combination of EEGLAB 14.1.2 (Delorme & Makeig, 2004) and custom-written MATLAB scripts. Independent component analysis (ICA) in EEGLAB was used to first remove eye-blinks and other physiological noise. The CleanLine toolbox (Mullen, 2012) was used to reduce drift. Channels that were three standard deviations away from the mean, based on a power spectrum threshold, were removed. Lastly, an automatic component rejection was performed using the MARA toolbox (Winkler, Haufe, & Tangermann, 2011).

Following previous literature, two time windows were selected for analysis: 300-500 ms and 500-700 ms after onset of the critical noun phrase. This allowed us to examine the N400/P600 complex (Burkhardt, 2006), as well as the LAN effect (Kutas & Federmeier, 2007). Using the EEGLAB Darbeliai extension, event-related potentials were computed for the 1000 ms after stimulus onset relative to a 100 ms pre-stimulus baseline for each participant, for each condition, from electrodes clustered in each of the following four regions: left anterior (F3/F7/FC3/FT7), right anterior (F4/F8/FC4/FT8), left posterior (P3/T5/CP5/T5), and right posterior (P4/T6/CP6/T6).

For statistical analyses, mean amplitude data were submitted to linear mixed-effects models using the lme4 package (Bates, Mächler, Bolker, & Walker, 2014) in R (R Core Team, 2013). Significance testing was done using the lmerTest package (Kuznetsova, Brockhoff, & Christensen, 2017). In both time windows of interest, our models evaluated mean amplitude as a function of a three-way interaction among Plausibility (plausible, implausible), Definiteness (definite, indefinite), and Electrode Region (left anterior, right anterior, left posterior, right posterior). Participant was included as a random factor. We performed planned comparisons between our four conditions (Definite Plausible, Indefinite Plausible, Definite Implausible, Indefinite Implausible) if significant interactions were found between region and definiteness or plausibility. Pairwise contrasts were investigated using the emmeans package in R (Lenth, 2018) and p-values were adjusted using the Bonferroni correction.

Results

300-500 ms time window: We found a significant interaction between Region and Definiteness ($F(3, 1946) = 5.64$, $p < .001$). In particular, the Definite - Indefinite condition contrast in the group of left anterior electrodes was significant (beta = -.37, t = -5.24, $p < .001$) (Figure 1). This general determiner effect was further corroborated by a scalp map of the same left anterior electrodes in the 300-500 ms time window, averaged across all participants for each condition (Figure 2). We further found a significant difference in the Definite Implausible - Indefinite Implausible

contrast in the same region (beta = -.35, t = -3.59, p = .002), which was reflected in greater negativity elicited by definite noun phrases (e.g., "the lion") compared to indefinite noun phrases (e.g., "a lion") (Figure 3). Similarly, in the plausible context, the Definite Plausible - Indefinite Plausible contrast revealed a significantly more negative deflection for definite noun phrases (beta = -.37, t = -3.81, $p < .001$) (Figure 4).

500-700 ms time window: In the left anterior, we again found a significant interaction between Region and Definiteness ($F(1, 1946) = 22.17$, $p < .001$). Contrast analyses were significant for Definite - Indefinite (beta = -.22, t = -4.05, $p <$ .001) (Figure 1), as well as for Definite Implausible - Indefinite Implausible (beta = -.30, t = -3.86, $p < .001$) (Figure 4).

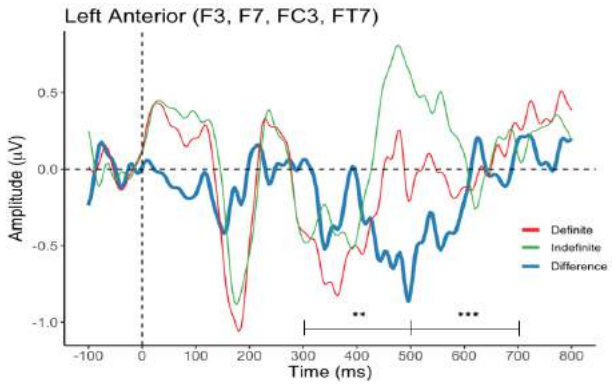

Figure 1: Significant negative-going ERP elicited by the Definite condition relative to Indefinite condition in the 300-500 ms time window in left anterior electrodes, reminiscent of the Late Anterior Negativity (LAN). Significant divergence between the two conditions continues into the 500-700 ms time window.

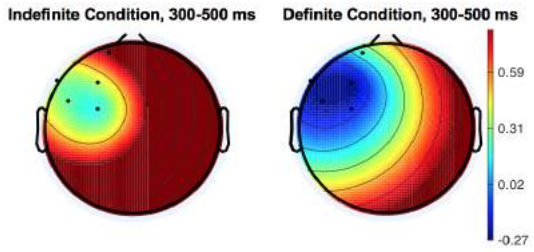

Figure 2: Scalp map of left anterior electrodes for Indefinite (left) and Definite (right) conditions in the 300-500 ms time window.

Discussion

Our study used EEG to explore the consequences of processing definite and indefinite noun phrases in plausible and implausible sentence contexts. Our goal was to test both types of determiners together, to isolate the crucial stages of presupposition failure and accommodation of a new discourse

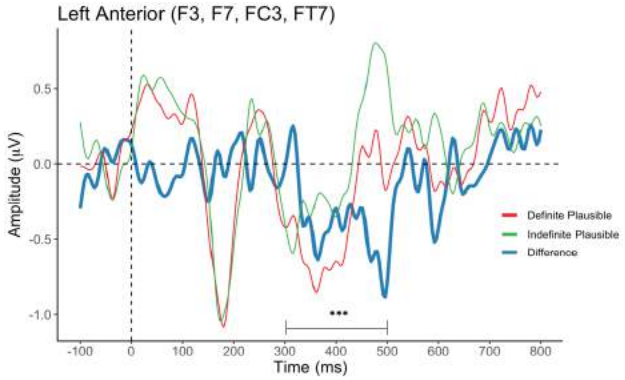

Figure 3: Greater negativity elicited by the Definite Plausible condition relative to the Indefinite Plausible condition in the 300-500 ms time window.

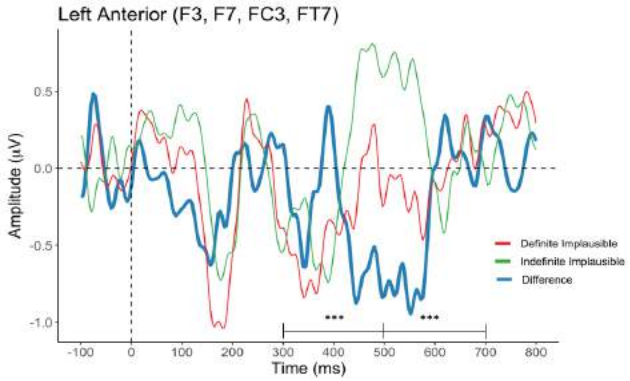

Figure 4: Greater negativity elicited by the Definite Implausible condition relative to Indefinite Implausibl in the 300-500 ms time window. Significant divergence between the two conditions continues into the 500-700 ms time window.

referent (see our earlier discussion of Burkhardt, 2006 and Schumacher, 2009; see also Hirotani & Schumacher, 2011). While Schumacher (2009) also investigated definite and indefinite phrases together, the pragmatic appropriateness of the phrase pairs in that task was not stable across contexts. For example, consider a given definite text like *Peter has recently visited a speaker in Munich. He said that the speaker had been very nice*. The text is coherent and there is no sense of oddness. This cannot be said of the indefinite given counterpart: *Peter has recently visited a speaker in Munich. He said that a speaker had been very nice.* This text is decidedly odd, confirmed by offline data reported in Schumacher (2009). Presumably, the oddness is due to so-called *Maximize Presupposition!* effects (e.g., Heim, 1991; Singh, 2011), which essentially demand that the speaker use a presuppositional alternative (like a definite) when its presupposition is satisfied instead of a non-presuppositional minimal variant (like an indefinite). *Maximize Presupposition!* has been proposed to explain the oddness of sentences like *A sun is*

shining; the definite variant is preferred because of *Maximize Presupposition!* (see also Note 1). Similarly, in the case under current consideration, the indefinite *a speaker* would be ruled out in favour of *the speaker* (if the same speaker is intended), or in favour of *another speaker* (if a different speaker is intended).

In our study, the definite/indefinite pairs are both either appropriate or both inappropriate in their given contexts (cf. stimuli norming results in Singh et al., 2016). There is no influence of *Maximize Presupposition!* because there is no 'given' context. All conditions required the addition of a new discourse referent, and hence were expected to not differ with respect to the P600 (given the findings in Burkhardt, 2006; Schumacher, 2009). Somewhat to our surprise, our results showed a greater positive deflection for indefinites than definites in the implausible context during the 500-700ms window. This might suggest a P600, but we are not confident that it is since the P600 is typically found over parietal lobes (e.g., Osterhout & Holcomb, 1992). Whatever this effect's proper classification, the difference does not replicate the finding in Schumacher (2009) that definites and indefinites both generate a late positivity (a P600 in her studies) that indexes the addition of a discourse referent. The difference here might be teaching us that by this stage the accommodation for the definite has already occurred, or that the introduction of referents via assertion is different than via accommodation, and the late positivity we found for indefinites indexes only assertive updates.

Here we tentatively suggest that by that late stage the accommodation for the definite has already taken place. According to the satisfaction theory, assertions are updates to the context, and the presuppositions in a context get updated by the assertion. Thus, there is an implied temporality: presuppositional matters are resolved prior to assertive updates (hence the *pre-*). Thus, it is conceivable that the accommodation step occurs early, right after the detection of the technical presupposition failure. Perhaps this bundle of computations is what our left-lateralized frontal negativity for definite noun phrases in the 300-500ms window was indexing. This Left Anterior Negativity (LAN) has been found in previous studies of (in-)definiteness (e.g., Anderson & Holcomb, 2005; Schumacher, 2009), but for reasons discussed earlier it is hard to interpret such findings because the contrasts between definite and indefinite conditions were not quite minimal. More generally, the LAN has been linked to processes of working memory resources that involve 'reactivating' previous entities or forming dependencies between new and old entities (see e.g., King & Kutas, 1995; Kirsten et al., 2014, among others). We tentatively propose here that the detection of presupposition failure and accommodation are among the computations the LAN indexes. Note that definites involve the search for entities in memory ('reactivation'), and that accommodation when no antecedent is found typically involves 'bridging' the new entity to a previous entity (e.g., linking 'the waiter' to the previously mentioned restaurant – see also Note 2).

The design of our study was based on a previous stops-making-sense task that investigated temporal decisions during the silent reading of definite and indefinite phrases in contexts that varied in plausibility (Singh et al., 2016). Based on the results of that study, we initially expected sentences with implausible contexts to result in a semantic violation that would be captured by the N400, relative to sentences with plausible contexts. Our results did not support this expectation. There may be several reasons for this. First, our stimuli did not include traditional semantic violation phrases that are used elsewhere in the N400 literature (e.g., *He spread the warm bread with socks*, Kutas & Hillyard, 1984). The process of reading an otherwise well-formed phrase in an implausible context (e.g., "the lion" in the context of a restaurant) may not map directly onto the process of reading semantic violation phrases, which typically are incoherent. Our implausible texts are not incoherent like the traditionally studied ones; they are merely implausible, and this distinction might be relevant to the N400 component. Second, unlike our instructions, the stops-making-sense task used in Singh et al. (2016) explicitly required participants to make judgments about nonsense. This may have led participants to pay greater attention to coherence and sensibility than our instructions. Third, it is possible that there is a lag between the time at which the brain first detects implausibility/incoherence and the time at which our minds become consciously aware of this, and the N400 may be sensitive to the first and not necessarily the second.

Our results thus sharpen Schumacher's finding that the LAN appears to be associated with failure to find an appropriate antecedent when triggered by a uniqueness presupposition, i.e., *the*. By removing 'given' conditions, and the need to compare context updates, we have isolated the cognitive cost associated with technical presupposition failure and accommodation: the brain registers it as a LAN effect. If this is correct, we would expect the LAN to show up in other environments that require accommodation but which are not odd. For example, *The psychology department is facing a crisis. Both of their neuroscientists left* should elicit a LAN relative to *The psychology department is facing a crisis. All of their neuroscientists left*.

Abstract

There are plenty of opportunities for life-long learning but people rarely seize them. Game elements are an increasingly popular tool to keep students engaged in learning. But gamification only works when it is done properly. Here, we introduce the first principled approach to gamifying learning environments. Our feedback mechanism rewards students' efforts and study choices according to how beneficial they are in the long run. The rewards are conveyed by game elements that we call "optimal brain points". In our experiment, these optimal brain points significantly increased the proportion of participants who attempted to learn a difficult skill, persisted through failure, and succeeded to master it. Our method provides a principled approach to designing incentive structures and feedback mechanisms for both educational games and online courses. We are optimistic that this can help people overcome the motivational obstacles to self-directed life-long learning.

Keywords: gamification; artificial intelligence in education; persistence; educational games; incentive structures

Introduction

As the technological development accelerates, self-directed life-long learning is becoming critically important. Massive Open Online Courses (MOOCs) and other digital resources provide unprecedented opportunities for life-long learning. However, only about 15% of the students who enroll in a MOOC actually finish it (Jordan, 2019). One of the reasons might be that learning something new often requires confronting one's own incompetence and persisting through several failed attempts to understand a new concept or do something new. Many people tend to irrationally avoid such hardships (Urdan & Midgley, 2001; Baker et al., 2008) even though they are often necessary to master new skills (Ericsson, Krampe, & Tesch-Römer, 1993). People who have become experts in using an outdated tool by doing the same work in the same way for many years may be especially resistant to learning how to use a new tool because in the short-run it is much more comfortable for them to exploit their outdated expertise than to become a novice again.

When students are given choices in online courses or educational software they sometimes procrastinate on learning something new by repeatedly practicing skills they already know (Baker, Corbett, & Koedinger, 2004; Mostow et al., 2002).

To help student's overcome such motivational obstacles, educational software increasingly relies on game elements, such as points, levels, and badges, to encourage continued engagement with the learning materials (Kapp, 2012; Dicheva, Dichev, Agre, & Angelova, 2015; Huang & Soman, 2013). The trend of gamification has outpaced the development of an adequate theoretical foundation, and it has been noted that gamification is often ineffective and sometimes even harmful (Toda, Valle, & Isotani, 2018). This raises the question how the incentive structures of digital learning environments such as educational games and online courses should be designed to optimally incentivize good study choices and effective learning strategies.

The points students receive in educational games usually convey performance feedback. But making performance feedback more gameful does not address the fundamental problem that – in the short run – performance feedback might discourage trying to learn something new. Rather, by making student's failures more salient to them, gamified performance feedback can have a negative effect on their study choices – thereby making things worse rather than better (Shute, 2008). O'Rourke, Haimovitz, Ballweber, Dweck, and Popović (2014) argue that to address this problem, gamification should give students "brain points" that reward effort and persistence rather than performance. In support of this view, they found that incentivizing students' effort and learning strategies in an educational game significantly increased their persistence and the total amount of time they spent in the game. However, the hand-crafted incentive system was imperfect and could be exploited by discovering easy ways to earn brain points without doing the hard work of learning a new skill (O'Rourke, Peach, Dweck, & Popovic, 2016). The high prevalence of students "gaming the system" across many intelligent tutoring systems (Baker et al., 2008) underlines that designing good incentives by hand is hard and fallible. This illustrates the deeper issue that we lack a principled theory for designing reward structures in learning systems that incentivize learning properly.

Recent work has begun to establish such principles in the domain of decision-support (Lieder & Griffiths, 2016; Lieder, Chen, Krueger, & Griffiths, 2019). There, the basic idea of this approach is to align the immediate reward of each decision with its long-term value. This addresses the problem that people's decisions are usually overly swayed by the anticipated immediate outcomes (e.g., the unpleasantness of strug-

gling with a difficult math problem vs. the fun of watching a YouTube video) rather than their long-term consequences (e.g., the benefits of a good education). This, so called, *present bias* (O'Donoghue & Rabin, 1999) manifests in a wide range of sub-optimal, short-sighted decisions and problems such as impulsivity and procrastiation that have been explained in terms of hyperbolic discounting and temporal motivation theory (Steel & König, 2006; Steel, 2007).

Considering people's present bias, the real world is far from being an optimal learning environment because the immediate reward for practicing a new skill is usually failure and negative feedback – when it should be something much more positive, namely the value of learning. Conversely, neglecting skill development in favor of exploiting existing skills is usually rewarded because it leads to higher immediate productivity. This suggests that the present bias could be one of the major reasons why students often quit studying too soon or procrastinate on learning a difficult skill – especially when this requires persisting through a series of failed attempts. This suggests that the optimal gamification approach developed by Lieder et al. (2019) might also be applicable to support students' study choices in MOOCs and educational games.

Here, we leverage the framework of optimal gamification (Lieder & Griffiths, 2016; Lieder et al., 2019) to develop a formal mathematical theory of optimal incentives for self-directed learning and an automatic method for computing such incentives from basic assumptions about the skills to be learned and the process of skill acquisition. To achieve this, we develop a mathematical model of the value of practice and apply optimal gamification to it. Our method can be used to automatically compute *optimal* brain points that encourage learning behaviors that are consistent with the growth mindset that the intervention by O'Rourke et al. (2014) was meant to encourage. We postulate that optimal brain points can not only increase the amount of time students invest into learning, as has been demonstrated for hand-designed brain points (O'Rourke et al., 2014), but also their learning outcomes. We test this prediction in a behavioral experiment that simulates a scenario where people have to choose between exploiting their old skill (Skill 1) or learning a new skill (Skill 2) that would allow them to solve a recurring task more efficiently.

We found that participants incentivized with optimal brain points were less likely to give up on trying to learn a new skill, became more likely to master it, and consequently performed better at their tasks. This suggests that our method for computing optimal brain points can help us overcome the pitfalls of incentivizing students study choices manually.

These findings suggest that our principled approach to incentivizing skill acquisition can help people overcome the motivational challenges of self-directed learning and could be used to make educational games and online courses more effective and to avoid the pitfalls of previous attempts to gamify education. Optimal brain points are a principled way to incentivize good study choice and might be able to help students develop a growth mindset (Dweck, 2008).

The plan for this paper is as follows: We first derive the long-term value of practicing a new skill using a simple model of skill acquisition. Next, we translate the value of practice into an optimal gamification method for encouraging skill acquisition. We then evaluate the efficacy of this method in a behavioral experiment mimicking the motivational obstacles to life-long learning. We conclude with the implications of our findings for designing educational games and directions for future work.

Quantifying the value of practice

When should you complete a task using the skills you already have and when should you try to learn a better way to accomplish it? If you would like to invest into learning a new skill, which one should you pick? And if trying to learn this skill is proving difficult, then how long should you keep trying before you give up and do it in the old, familiar way? To help people make these difficult choices, we derive the value of practicing an unfamiliar skill.

The first step of our derivation postulates a simplistic but general and tractable model of skill acquisition through trial and error. If a task has k potential solutions – only one of which is correct – then the probability of discovering the skill in the first attempt is $\frac{1}{k}$. Conversely, the probability that the first attempt will fail is $\frac{k-1}{k}$. After a failure the probability of success increases to $\frac{1}{k-1}$.

Based on this probabilistic model, we can describe skill acquisition as a Markov Decision Process (Sutton & Barto, 1998)

$$M_{\text{skill}} = \{\mathcal{S} \times \mathcal{D}, \mathcal{A}, \gamma, T, r\} \tag{1}$$

where $\mathcal{A}$ includes one action for each skill, $\mathcal{S}$ is the set of all possible skill levels the learner could attain through practice and $\mathcal{D} \subset \mathbb{N}_0$ denotes how much more work is required to complete the current task. The learner's skill level $\mathbf{s_t} \in \mathcal{S}$ reflects how close they are to having mastered each of n different skills at time t and how likely they are to succeed at the task by using each of those skills in their next attempt. We formalize it by the tuple $(k_1, k_2, \cdots, k_n)$ where k_i is the number of potential ways in which the i^{th} skill might work given what the learner knows so far. The transition matrix T encodes that unsuccessfully attempting skill i decreases k_i by 1 and that discovering how it works sets k_i equal to 1. It also encodes how the successful application of each skill would reduce the amount of work required to complete the task and that unsuccessful attempts do not decrease it. The reward function $r((\mathbf{s_t}, d_t), a_t, (\mathbf{s_{t+1}}, d_{t+1}))$ encodes the immediate effort of using or attempting to learn a skill and the value of completing the current task. For simplicity, we assume that the cost of each action is -1 and add the value of completing the current task when d changes to 0. Finally, $1-\gamma \in [0,1]$ is the probability that the current type of task will become obsolete in the next time step.

Abstracting away the details of how specific skills are acquired makes this model very general and broadly applicable. It can therefore be used to incentivize student effort in

any learning context. Our model can either be applied out of the box or tailored to specific learning contexts by measuring how specific learning activities increase the probability that the student will successfully learn a particular skill and plugging the measured probabilities into the model's transition matrix T .

Having modelled the process of skill acquisition as an MDP allows us to leverage standard dynamic programming methods (Sutton & Barto, 1998) to compute the value of practice. For instance, we can apply the value iteration algorithm to compute $V^{\star}((\mathbf{s},d))$ – which is the value of having the skill set s when the current task has difficulty d – and $Q^{\star}((\mathbf{s},d),a)$ which is the value of choosing action a (e.g., trying out a new tool versus reusing an old one). To work out under which conditions it is worthwhile to invest in extending one's skill set, we can then translate these value functions into the value of practice which we define as

$$\mathrm{VOP}\left((\mathbf{s},d),a\right) = Q^{\star}\left((\mathbf{s},d),a\right) - V^{\pi_{\text{stop learning}}}\left((\mathbf{s},d)\right), \quad (2)$$

where $V^{\pi_{\text{stop learning}}}$ is the expected return of the strategy that always exploits existing skills without making any investment into learning new skills.

The simplicity of our model allows us to derive the value of practice analytically for the dilemma of choosing between exploiting a mastered skill and attempting to learn a new skill that would make you more effective. When the value of completing the task is g, the mastered skill achieves it in d time steps, and the to be learned skill could achieve it in 1 time step, then the value of practicing the second skill is

$$\begin{aligned}\mathrm{VOP}\left((k_2,d),a_2\right) = {} & \frac{1}{k_2}\cdot\left[(g-1)+\gamma\cdot V^{\star}(((1,1),d))\right] \\ & + \left(1-\frac{1}{k_2}\right)\cdot\left[\gamma\cdot V^{\star}((1,k_2-1),d)-1\right] \\ & - V^{\pi_{\text{stop learning}}}\left(((1,k_2),d)\right),\end{aligned} \quad (3)$$

and the value of ceasing to learn and exploiting Skill 1 is

$$V^{\pi_{\text{stop learning}}}\left((\mathbf{s},d)\right) = g\cdot\frac{\gamma^{d-1}}{1-\gamma^{d}} - \frac{1}{1-\gamma}, \quad (4)$$

where $\frac{\gamma^{d-1}}{1-\gamma^{d}}$ is the expected number of times one can complete the task using only Skill 1, and $-\frac{1}{1-\gamma}$ is the expected cumulative cost of using the skill. This allows us to characterize under which conditions it is valuable to invest in learning a new skill and under which conditions it is better to exploit the skills one already has.

As shown in Figure 1, we found that the value of practice decreases with the relative effectiveness of the skill one has already mastered ($\frac{d_2}{d_1}=\frac{1}{d}$ if d_1 and d_2 are the number of time steps it takes to complete the task with Skill 1 vs. Skill 2 respectively in this example), but increases with the expected number of times one will have to perform the task in the future (i.e., $\frac{1}{1-\gamma}$). This means that learning a new skill becomes more valuable the more often it might be useful in the future and becomes less worthwhile the more effective the skill is that one has already mastered. By quantifying these effects, the value of practice reveals under which conditions it is worthwhile to learn something new (green-blue) and under which conditions it is better to stick with what one already knows (orange-red). Since the recommendations of our mathematical framework appear to be intuitively correct, we proceed to apply our model of the value of practice to automatically incentivize people's study choices. Furthermore, future work might leverage Equations 2–4 to assist people with decisions about their personal or professional development.

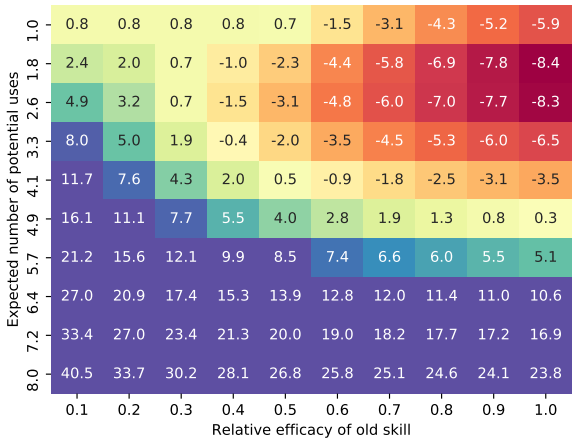

Figure 1: The value of practice. Each square of this heat map shows the difference between the value of attempting to learn a new skill versus exploiting an old skill (colors and numbers) depending on relative efficacy of the old skill (x-axis) and the expected number of occasions on which either skill could be used (y-axis; increasing from top to bottom).

An optimal gamification method for incentivizing skill acquisition

Optimal brain points. Having quantified the value of practice with the skill acquisition MDP defined above, we can now use it to incentivize learning behaviors according to their expected contributions to the learner's competency. Formally, the expected increase in the value of the learner's skill set s achieved by action a is

$$\Delta V(\mathbf{s_t},a) = \gamma\cdot\mathbb{E}[V^{*}(\mathbf{S_{t+1}})|\mathbf{s_t},a] - V^{*}(\mathbf{s_t}),$$

where the random variable $\mathbf{S_{t+1}}$ denotes the learner's skill set after performing action a and $V^{\star}$ is the optimal value function of the skill acquisition MDP defined above. The discount factor γ accounts for the possibility that the practiced skill might become obsolete.

The value of learning by doing is twofold: it increases the value of the learner's skill set (ΔV) and it produces potentially

valuable outcomes ($r(\mathbf{s_t}, a)$). Our optimal brain points capture both sources of value, that is

$$\text{BrainPoints}(\mathbf{s}, a) = \Delta V(\mathbf{s}, a) + r(\mathbf{s}, a). \quad (5)$$

The way in which optimal brain points are constructed is a direct application of the optimal gamification method developed by Lieder et al. (2019). It satisfies the necessary and sufficient conditions of the *shaping theorem* (Ng, Harada, & Russell, 1999) which thereby guarantees that the resulting incentives do not encourage sub-optimal learning strategies. Rather, by using the value of the learner's skill set ($V^\star$) as the basis for constructing the brain points, they are making optimal study choices immediately rewarding. We predict that they should therefore help learners overcome the present bias and invest more in acquiring difficult skills that will benefit them in the future. In the next section, we test this hypothesis with a simple behavioral experiment.

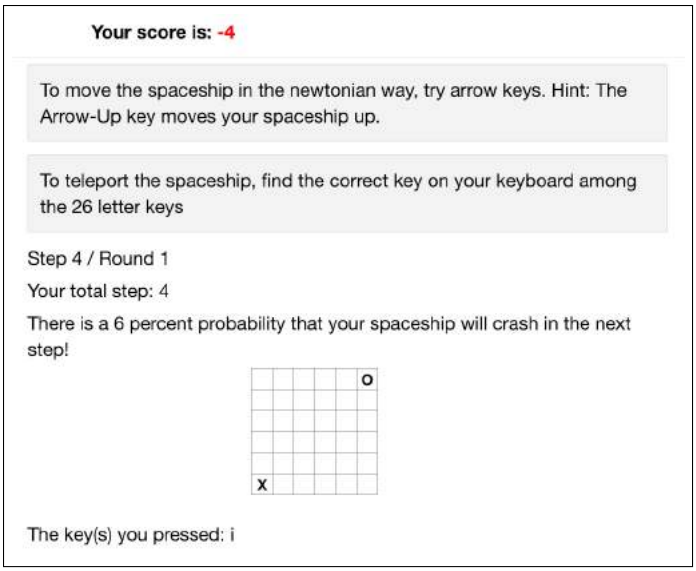

Figure 2: Screenshot of the spaceship game.

Optimal brain points improve learning and performance

To evaluate the potential of our approach to help people overcome the motivational obstacles to learning new skills, we conducted an online experiment where people repeatedly solve a task and can choose to either solve it using a skill that they already possess (Skill 1) or try to learn a new skill that, once mastered, would allow them to solve the task more efficiently (Skill 2). The experimental group received optimal brain points for their choices between exploiting Skill 1 versus attempting to learn Skill 2 whereas the control condition received no brain points. We predicted that a) most participants in the control condition would neglect investing the time and effort necessary to acquire the new skill – even if their investment in learning would pay off in the long run, and b) that optimal brain points can help them overcome this irrational bias.

Methods

We ran our experiment using psiTurk (Gureckis et al., 2016). We recruited a total of 450 participants from Amazon Mechanical Turk between 15:30 EST and 18:30 EST on January 19, 2019, and we restricted the worker region to the United States of America. Participants received \$0.75 for about 6 ± 2 minutes of work and could earn a bonus of up to \$1 (average bonus \$0.10, standard deviation \$0.10) for their performance in the task. Of our 450 participants, 226 were assigned to the control condition and 224 were assigned to the experimental condition with optimal brain points according to psiTurk's counterbalancing method.

Experimental paradigm. We created the *Spaceship Adventure* game shown in Figure 2 and used it to evaluate the efficacy of optimal brain points. The game world is a board with 6×6 cells. The task for the participants is to control the spaceship so as to move from its initial position (0, 0) to its destination (5, 5). Participants play the game for several rounds. After each time they arrive at the destination, the game board is reset and the spaceship is returned to its initial position.

The instructions inform participants that they will be playing the game for multiple rounds. Participants are also informed that there are two modes of moving the spaceship: The spaceship can be moved one step at a time whereas an unknown letter key could be used to teleport the spaceship directly to its final destination. Each step (using the arrow keys or trying out a new letter key) incurs a cost of -1, whereas reaching the destination earns a reward of $+20$. Following each round there was a 6% chance that the game would end and a 94% chance that it would continue (i.e., $\gamma = 0.94$) and participants were informed about that.. The two skills involved in the game are using the arrow key to move the spaceship forward one square at a time (Skill 1) and teleporting the spaceship directly to the destination using one of the 26 letter keys (Skill 2). For each participant the letter key that would teleport their spaceship was independently selected at random before they started their first round and remained the same until the end of their last round.

In the control condition, the only points being shown were the cost of controlling the spaceship and the reward for reaching the goal. In the experimental condition, participants additionally received the optimal brain points described above. Brain points were given for each of the participant's choices between exploiting Skill 1 versus attempting to learn Skill 2. As illustrated in Figure 3, brain points were conveyed using a color-coded score that was accompanied by the image of a brain. The first time, the participant received brain points, those were explained as conveying the value of learning a new skill. To make the brain points more rewarding, a pleasant crystal sound, which is often used to convey a sense

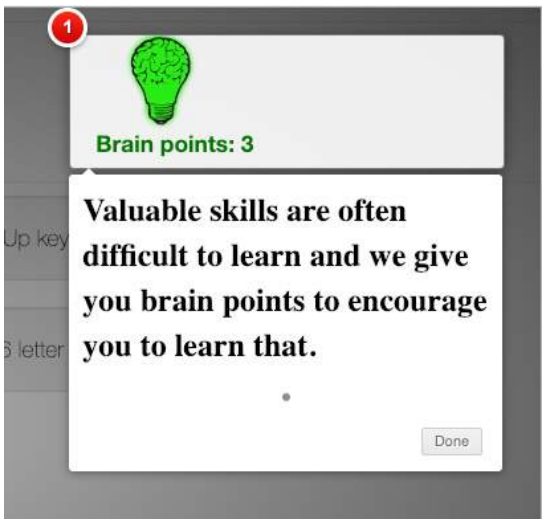

Figure 3: Screenshot illustrating the brain points a participant would receive for trying Skill 2 in the first step.

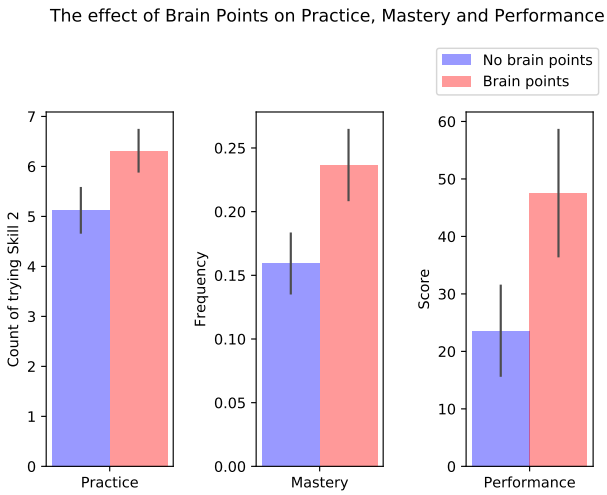

Figure 4: Effect of brain points on practice, learning, and performance. The left bar chart shows the average number of times that people who tried to teleport (skill 2) at least once attempted to figure out how it works until they discovered it or gave up. The middle bar chart shows the proportion of participants in either condition who succeeded to learn skill 2 by discovering which letter key would teleport their spaceship to its target location ("Mastery"). The right bar chart shows the average total score by condition. The error bars represent the standard error of the mean for the bar charts on Practice and Performance and the standard error of the proportion for the Mastery bar chart.

of enlightenment when the players find something valuable in a video game, was played when the number of brain points increased, whereas an unpleasant sound, which could be intuitively perceived as something shrinking, was played when it decreased. Additionally, in both conditions a cheerful sound is played when the spaceship reaches its destination. The brain points score was cumulative as is customary in computer games.

Our code, the experiment, and the data are available on the Open Science Framework at `https://osf.io/k6wjp/`.

Results

As predicted, we found that, when left to their own devices, 42% of the participants never even tried to learn Skill 2 and relied exclusively on Skill 1, although learning Skill 2 could have allowed them to reap higher rewards; that is always attempting Skill 2 would have yielded 154 points on average whereas always exploiting Skill 1 yielded only 8 points on average. This highlights that while there are some situations where people adequately invest into exploring new things (Wilson, Geana, White, Ludvig, & Cohen, 2014), the choice between solving a recurring task with a skill one has already mastered versus using trial-and-error to learn a new skill to be able to handle future occurrences of the task more efficiently might not be one of them for many people.

Encouragingly, we found that optimal brain points significantly increased the proportion of people who attempted to learn the difficult skill (i.e., teleportation, henceforth "Skill 2") from 32% to 46% of participants who had not already tried it in the first step ($\chi^2(1) = 5.74, p = .0165$)[1].

As illustrated in Figure 4, optimal brain points also increased the amount of effort people invested into acquiring Skill 2 from 2.8 to 3.9 attempts on average ($t(448) = 2.52$, $p = .006$; the median number of attempts were 1 and 2 respectively, $Z = 2.59$, $p = .0048$). Furthermore, our optimal brain points also made the people who tried learning Skill 2 at least once more persistent, doubling their median number of additional attempts at learning Skill 2 from 2 to 4 ($Z = 2.49$, $p = .0064$; 4.1 vs. 5.3 on average, $t(448) = 1.86$, $p = .0323$). As a consequence, the proportion of participants who mastered Skill 2 increased from 15% to 24% ($\chi^2(1) = 3.77, p = .0523$), and their average total score doubled from 24 points to 48 points ($t(448) = 1.74, p = .0414$).

These findings suggest that optimal brain points successfully motivated our participants to learn the more difficult skill and thereby improved their learning outcomes and performance.

Conclusion

We derived the expected value of attempting to learn a new skill and translated it into an optimal feedback mechanism for encouraging students to persist in learning valuable skills. Our results suggest that optimal brain points could be useful for helping people overcome the motivational obstacles towards life-long learning. Its basic idea is to reward people's efforts to learn a new skill according to the long-term value of having mastered it and the expected progress towards mas-

[1] We excluded the first action from this analysis because the conditions are identical up until the first feedback is displayed after the participant's first action.

tery.

Our principled computational method for incentivizing learning might become part of the theoretical foundation for the gamification of digital learning environments such as MOOCs or educational games. We hope that the approach illustrated in this article will eventually help people overcome the motivational obstacles that stand in the way of life-long self-directed learning.

Our admittedly simplistic experiment was merely the first step towards evaluating the potential of optimal brain points for increasing student effort. Follow-up experiments should use more naturalistic skill acquisition paradigms and evaluate the proposed feedback mechanism against simpler, heuristic approaches to the gamification of learning environments (Huang & Soman, 2013; Dicheva et al., 2015; Kapp, 2012; O'Rourke et al., 2014). Before we can make any practical recommendations randomized field experiments will have to evaluate our intervention with real students learning real skills.

Future work will evaluate the practical utility of our optimal feedback mechanisms for increasing the student retention rates of MOOCs, encouraging students to use educational games and intelligent tutoring systems more effectively, and building apps that facilitate deliberate practice. These applications may use our method as it is or refine its model of skill acquisition with domain-specific learner models.

While there is a lot of value in being able to motivate students to practice a specific skill inside a digital learning environment, it would be even more valuable if we could help them internalize the value of learning new skills. Future work will therefore investigate whether giving people optimal brain points for their efforts to learn a new skill in one environment can also improve their motivation to learn other skills in different environments and help them develop a growth mindset (Dweck, 2008).

Abstract

This paper presents an embodied conversational agent framework as a controlled environment to test components of empathy. We implement levels of emotional contagion which includes mimicry and affective matching along with necessary communicational capabilities. We further demonstrate an examination of these foundational behaviors in isolation, to better understand the effect of each level on the perception of empathy in a social conversational scenario with a human actor. We report three studies where the agent shows levels of emotional contagion behavior during (1) the listening act in comparison with baseline backchanneling behavior (2) additional verbal response matching simple emotional storyline (3) the verbal response to the human actor performing complex emotional behaviors. Results revealed that both mimicry and affective matching behaviors were perceived as more empathic than the baseline listening behavior, where the difference between these behaviors was only significant when the agent verbally responded to complex emotional behaviors.

Empathy; Emotional Contagion; Mirroring; Affect Matching; Affective Computing; Social Interaction; Embodied Conversational Agents

Introduction

Empathy, as the capability to understand and react to the emotions of another (Iacoboni, 2011; Coplan & Goldie, 2011), is a complex behavior that arises from the interaction of these basic affective mechanisms with higher-level cognitive functions (de Waal & Preston, 2017). Emotional contagion is said to be the foundation of empathic capacity, as it includes innate and automatic synchronization of the motor and affective responses during an interaction (Hatfield, Cacioppo, & Rapson, 1994). Behaviors such as mimicry and affective matching are levels of the emotional contagion that results from the innate capability of resonating with the other during social interaction.

The literature suggests the sustained act of mimicry results in a feeling of the mimicked emotion and affective matching through muscular feedback (Hatfield et al., 1994; Hatfield, Bensman, Thornton, & Rapson, 2014), while categorizing both behaviors as emotional contagion. Others use affect matching as a highly connected but distinct phenomenon to the mimicry, pointing out the differences between the subjective quality of experience in the emotional contagion and the automatic matching of expressions in mimicry (Hess & Fischer, 2014). However, both ideas converge on the foundational role of mimicry and affect matching in empathic behavior. This notion is consistent with the Perception-Action-Model (PAM) (Preston & De Waal, 2002) and the Russian Doll model of empathy (de Waal, 2007), which integrates the neuroscience studies on mirror neurons as a baseline for the hierarchical levels of empathy mechanisms. However, it is difficult to study the levels of emotional contagion in isolation.

Research efforts often rely on behavioral experiments, neuroscientific techniques (EEG, fMRI) and pathology studies conducted to understand the effects of emotional contagion during social interactions (Hess & Fischer, 2014; Hatfield et al., 2014). As an alternative, computational empathy studies have recently gained attention in a way to simulating the empathy mechanism within the agent and examining empathic responses of the users towards the agent (Paiva, Leite, Boukricha, & Wachsmuth, 2017; Yalçın & DiPaola, 2018). The perception of empathy in artificial agents is shown to increase the length of the interaction (Leite, Castellano, Pereira, Martinho, & Paiva, 2014), user performance (Partala & Surakka, 2004), user satisfaction (Prendinger, Mori, & Ishizuka, 2005), and lead to more trust (Brave, Nass, & Hutchinson, 2005). These findings suggest that equipping interactive systems with empathic capacity would not only improve our understanding of the interaction between cognitive and affective processes in the human mind but may also help us enhance our interaction between artificial systems.

In this work, we use the simulation approach to study empathic behavior in virtual agents and try to understand the differences between the levels of emotional contagion behavior and the perception of empathy during a conversation. We examine the basic emotional contagion capabilities in an embodied conversational agent (ECA) in order to evaluate the perception of empathy during mimicry and affect matching behaviors. We present an agent framework and implementation with necessary communicational capabilities as a baseline. In the following section, we will present our implementation for an ECA that incorporates different levels of emotional contagion as a foundation for empathic capacity. Next, we will demonstrate three experiments that examine the effect of these levels on the perception of empathy during a social interaction scenario with a human actor. Our approach and results show the potential of computational empathy studies as a reliable alternative to test mechanisms for empathic behavior in isolation.

Agent Behavior

Our empathy framework is implemented in an embodied conversational agent that is capable of responding to an emotional conversation with the user using verbal and non-verbal behaviors. Our socially situated 3D virtual character system can perform a set of behavioral acts and context-specific dialogue in response to the speech and video input received from the user (see (Yalçın, in press) for a detailed explanation of the framework). Inputs are gathered using a standard webcam and a microphone. We use the Smartbody behavior realizer (Thiebaux, Marsella, Marshall, & Kallmann, 2008), that can provide face and body gestures, gaze, and speech output for virtual characters. We use the standard Behavior Markup Language (BML) (Kopp et al., 2006) as the basis for the two way connection between the framework and the behavor realizer.

The implementation includes mimicry and affect matching behaviors as the foundational capabilities of empathy in combination with basic conversational capabilities such as backchanneling. In order to achieve this, our system incorporates a perceptual module, a behavior controller and a behavior generation module. The visual and verbal input from the user is processed through the perceptual module, reasoned within the behavior controller according to the selected empathy mechanism and prepared for a behavioral output in the behavior manager before being displayed in the ECA.

Low-level empathic behaviors, such as mimicry and affective matching require a fast response to the emotional stimuli presented by the interaction partner. The fundamental components of this first level of empathic behavior include the perception of emotion, representation of emotion and expressing emotion. This cycle is realized with Perceptual Module and Controller and Behavior Generation modules of our system.

Perceptual Module

The perceptual module is responsible for handling the input received from the user and creating internal representations of these inputs to be used by the controller. Currently, our system is capable of handling audio, video and textual inputs to be used in recognition systems. The audio input includes verbal signals from the user to be recognized as speech and pauses. The initiation, pauses and termination in the speech signal are used to provide information about the dialogue state as well as backchannel timing.

Emotion recognition is a sub-module within the perceptual module that is specialized for emotion recognition and fusion processes. Here, three types of modalities can be used for further processing using the first level of recognition from the perceptual module: facial emotion recognition, tone analysis and speech emotion recognition. During listening, emotion recognition is based on the facial gestures and tone analysis, which is derived from the video and speech inputs for immediate listening feedback. After the speech signal from the user ended, the complete utterance is also being processed in speech emotion recognizer for emotion detection based on the textual output of the speech recognizer. Outputs from this sub-module are used by the behavior controller depending on the dialogue state as well as the selected empathy mechanisms.

Behavior Controller

The behavior controller module is a central unit in the framework which provides a link between inputs and the outputs. It decides which input channel or information to be used depending on the state of the conversation, required empathy mechanisms and the behavioral capabilities of the agent. It is also responsible for providing the information necessary to the behavior manager module to prepare verbal and non-verbal behavior. The Controller acts as a decision-making component, which determines behavioral choices concerning the percepts of the agent and its internal state. Currently, the behavior controller provides a link between the perception-action mechanisms as a key component in computational empathy (de Waal, 2007). During a conversation, the agent should decide which behavioral state it is in depending on the user input: listening, thinking, speaking or waiting. According to the state of the interaction (listening, speaking, thinking and waiting) and the current emotional value (arousal, valence and emotion category), the controller assigns the proper behavior categories to the behavior generation component.

If the user is speaking, the agent should be in the listening mode. Here, the agent is expected to provide proper backchanneling to the user as well as the emotional feedback depending on the empathy mechanisms. After the speech of the user is over, the speech signal should be sent to the dialogue manager component through the controller with the assigned emotional value. The agent will be in thinking mode during the processing of this input by the dialogue manager component. The prepared output sentence will then be sent back to the controller to be sent to the behavior manager which will prepare the output behaviors including face gestures, body gestures and the verbal response to be presented in the speaking mode. After the speech behavior of the agent is done, the waiting or idle mode will be activated until the user speaks again. This cycle can be interrupted via the controller at any stage.

Behavior Generation

The behavior generation module is responsible for preparing the output for the virtual character depending on the emotion, dialogue state and speech information received from the behavior controller. During listening behavior, this module is relatively passive in preparing behaviors. It uses the backchanneling signal to select an appropriate head nod for the agent and a facial expression. When these behaviors are sent and consumed by the behavior realizer, the behavior generation module receives a signal back that indicates the behavior was successfully generated by Smartbody system.

Method

In this paper, we used the simulation approach to study low-level empathic behavior in virtual agents to show the differences between the levels of emotional contagion behavior in the perception of empathy. We examined the effect of mimicry and affect matching behavior on perceived empathy during conversational interaction using three studies.

Participants

Participants for all three experiments were recruited using Amazon's Mechanical Turk platform and were paid for their participation to the study. Because we were focusing on the emotional expressions during verbal communication, we only included participants who had English as their first language. Additionally, users that participate with mobile devices and tablets were excluded to ensure a consistency in the display quality.

A total of 84 subjects participated in the studies. 36 participants with ages ranging from 20 to 60 (M=37.6, SD=10.7) completed the first study. 19 of the participants were male and 16 of them female, while 1 participant defined themselves as 'other'. 24 subjects participated in the second study with ages ranging between 21 and 64 (M=36.17, SD=10.82). 10 of the participants were female and 13 of them male, while 1 participant defined themselves as 'non-binary'. The last study included 24 participants with ages ranging between 23 and 59 (M=37.82, SD=10.64), 12 Male and 12 Female.

Procedure

Studies followed the same procedure, where the participants are asked to evaluate the recorded interaction between the agent and a human (see Figure 1). The interaction scenario consists of a student/participant expressing an emotional story to the agent. We have chosen three stories inspired by the work of Omdahl (Omdahl, 2014), that includes three basic emotion categories: anger, joy and sadness. Other basic emotions such as fear, surprise and disgust were not considered for this study due to the involvement of facial action units that controlled mouth movements during the expression of these emotions. Furthermore, we selected the emotions that would be consistent with the facial emotions, that would not provide an advantage to the affective matching over mimicry.

All of the experiments were deployed in Amazon's Mechanical Turk environment using scripts written in Python 3.6 with psiturk and jspych libraries. Each of the studies takes about 10 minutes to complete. Participants were first shown a test video and were asked to answer two questions about the visual and verbal content of the video, to make sure they can hear and see the videos that are displayed. This was required for the workers to participate in the study.

Each participant is then displayed a short video clip of an interaction, where the agent and a student are shown in a video-conferencing scenario in different conditions (see Figure 1). During the interaction, the student in the video talks about an emotional story in one of three basic emotions: joy, sadness and anger. After displaying each video, the participant is asked to report what the story in the video was about, and also the main emotion of the user and the virtual agent. This is done to make sure the participants are paying attention to the video clips. The participants then evaluated the perceived empathy of the agent towards the student. The perceived empathy of the agent is evaluated by using a modified version of the Toronto empathy questionnaire (Spreng, McKinnon, Mar, & Levine, 2009) which is a 16-item survey that originally is used as a self-report measure. Each item on the questionnaire are scored in a 5-item likert scale (Never = 0; Rarely = 1; Sometimes = 2; Often = 3; Always = 4), where half of the items are worded negatively. Scores are summed to derive total for the perceived empathy and can be varied between -32 to +32. Similar evaluations were suggested by Paiva and colleagues (Paiva et al., 2017), as a modification of Davis's Interpersonal Reactivity Index (Davis et al., 1980).

Figure 1: An image from the video chat between the student and the avatar. Here, the student (left) converses with the avatar.

We used repeated measures design, where each participant is shown all levels of agent behavior in emotional contagion. The type of the interaction study and the order of the conditions are counterbalanced accordingly.

Experiment Conditions

Experiment conditions include three distinct agent behaviors that signifies levels of emotional contagion mechanisms in the empathy framework.

The baseline behavior of the agent is the backchanneling behavior, which is activated depending on the pauses during the speech signal from the audio input component in the perceptual module. In the following subsections, we will provide a detailed examination of three different listening behaviors depending on the level of empathic behavior of the agent: backchannel only, mimicry with backchannel, affective matching with backchannel.

Backchanneling as baseline behavior Listener behavior in humans include backchannels such as head nods, fa-

cial feedback, short vocalizations or a combination of them (Yngve, 1970). These behaviors might show information about listener agreement, acknowledgment, turn-taking or attitude (Schroder et al., 2012; Cassell, Bickmore, Campbell, & Vilhjálmsson, 2000). Backchannel feedback can occur due to change in pitch, disfluency or loudness of the speech signal, as well as shifts in speaker's posture, gaze and head movements (Maatman, Gratch, & Marsella, 2005). In our current implementation we included backchanneling based on the pauses during speech, which is a form of disfluency in the speech signal (Maatman et al., 2005). Information about pauses are extracted from the perceptual module and sent to the controller, which in turn is used to trigger backchanneling as head nods. More advanced methods of adding backchannel that are compatible with the valence of the interaction partner or adding specific facial expressions such as smile, would have interfere with the empathy mechanisms that we would like to test. Therefore, we omitted these behaviors from the baseline behavior.

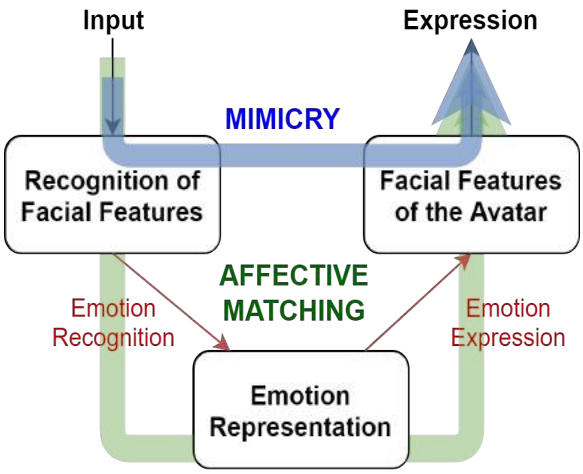

Figure 2: Two paths for emotional contagion. Basic emotional communication competence that results in low-level empathic capabilities of mimicry and affective matching by following distinct routes during the interaction process.

Mimicry Mechanism Mimicry is the lowest level of empathy behavior in our empathy model. It is achieved by a direct mapping between the gestures of the user to the gestures of the agent without being assigned to any type of emotional category. Facial mimicry behavior during listening is a result of mapping the perceived facial action units (AUs) extracted from the perceptual module, to the AUs of the embodied agent in the behavior generation module. The amount, duration and speed of these AUs match the perceived values of the interaction partner without any regulations. In order to avoid mimicking of the lip movements during the speaking of the user, we removed direct mapping of AU18 (lip puckerer), AU26 (jaw drop) and AU24 (lip pressor). As a side-effect of this modification, certain emotions that requires these AUs (fear, surprise and disgust) were not properly expressed. In order to avoid bias, interactions that include these emotions were not used during the evaluation of the system for this study. However, this drawback should be noted for future studies.

After the listening cycle, the agent will sustain the mimicry behavior until it retrieves a response from the dialogue manager. The dialogue manager will then retrieve an emotionally neutral response, due to the lack of emotional representation that is needed to be acquired during the interaction.

Affective Matching Another type of low-level or affective empathy behavior is affective matching (de Waal & Preston, 2017). It is achieved by the emotion recognition and the emotion expression cycle that is connected through emotion representation. As it can be seen in Figure 2, the facial features are mapped to the representation of the basic emotion categories which in turn triggers the facial expressions of the agent that represents those emotions. The amount, duration and speed of these expressions depend directly on the values from the perceived emotions. In contrast to the mimicry behavior, this allows the agent to present and regulate emotions that are better perceived by the users. Moreover, excluded emotion categories in mimicry can be used without the disturbance of the AUs that control mouth muscles as explained in the previous section.

After the listening cycle, the agent will give an emotional feedback that reflects the overall emotion of the interaction partner until it retrieves a response from the dialogue manager. In the affective matching condition, the dialogue manager is able to use the representation of the interaction partner's emotions to pick an emotional response. Without the effect of the higher level emotion regulation capabilities, the agent will pick a response that reflects the emotion of the interaction partner.

Study 1

In order to evaluate the perception of empathic behaviors we compared the listening behavior of the agent in backchannel, mimicry and affective matching conditions. For our study, we used within subjects design where three conditions of agent behavior are shown to the same subject for the evaluation. The conditions are baseline backchanneling behavior, mimicry with backchanneling and affective matching with backchanneling during only the listening act. We used three emotional stories told by the same person, which displays three different emotions as the main theme: joy, sadness and anger. Each video starts with a neutral remark, that is followed by the emotional story.

The experiment counterbalanced on the order of the type of interaction (backchannel, mimicry, affect matching), and the order of type of emotional story (angry, sad, happy). 36 (6x6) different conditions presented to subjects.

Evaluation In the evaluation of the first study, Mauchly's Test of Sphericity indicated that sphericity had not been vio-

lated, X2(2) = 1.748, p = .417. A one-way repeated measures ANOVA was conducted to compare the effect of (IV) level of emotional contagion behavior on (DV) the perception of empathy in backchanneling, mimicry, and affective matching conditions. The results showed that perceived empathy is significantly effected by the type of listening feedback F(2, 70)= 16.721 $p < .0001$, 95%CI (see Figure 3). Pairwise comparisons showed backchannel feedback only (M=-5.47, SD=12.45) is perceived to have significantly lower empathy than both mimicry ($p < .001$) and affective matching ($p < .0001$). However, listening behavior with mimicry (M=5.16, SD=10.64) and affective matching (M=8.22, SD=13.72) did not have any significant difference (p = .18).

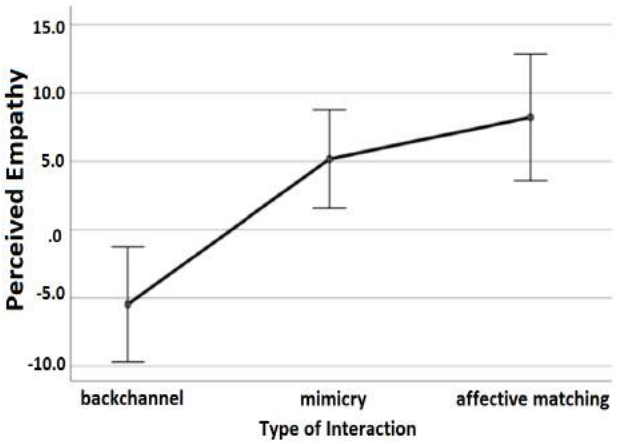

Figure 3: Results of our study showed significant differences in the perceived empathy levels between backchannel, mimicry and affective matching behavior (95%CI).

Study 2 and Study 3

Following up the first study, we further examined the effect of the verbal feedback produced by the dialogue manager in both mimicry and affect matching conditions. Our hypothesis is, due to the effect of emotional representation during the affect matching mechanism, the verbal response behavior of the avatar will be perceived as more empathic. However, this result might show difference when the interaction partner shows more complex emotions, where the context and information about the overall emotion representation is required to understand the semantics of the behavior. Therefore, we conduct two additional studies where one is focused on simple emotions and the other examines the effect of complex emotional behavior. For the following experiments, the participants were asked to evaluate the interaction stories, where the agent listens to different types of emotional stories told by the interaction partner and verbally reacts to it. As the first study showed significant differences over the baseline backchanneling behavior, the following studies did not compare the baseline behavior to emotional contagion.

In both conditions the listening behaviors of the agent will be the same as the first study, which showed no significant difference. The behavior of the agent between will differ from the first study in terms of verbal feedback during the conversational cycle. In the mimicry condition, the agent will produce an emotionally neutral feedback such as "I understand" or "I know what you mean" while sustaining the reflective facial expression of the interaction partner. In the affect matching condition, due to the additional information the dialogue manager will receive from the emotional representation of the interaction partner, the agent will produce an emotionally charged sentence. The emotional category of this sentence will be the same as the emotions of the interaction partner. For example, a happy story will trigger a happy remark such as "That sounds wonderful", an angry story will trigger a response such as "That is really frustrating", and a sad story will trigger a sad response such as "I am sorry to hear that".

The third experiment focused on more complex emotional stories, where the human actor will talk about two scenarios mentioning a dog and a plant. In the dog scenario, the actor will go through excitement, disgust, worry and happiness emotions while mentioning a story about their new pet dog. In the plant scenario, the actor will go through neutral, surprise, worry and happiness emotions while mentioning a story about their friend's plant. The listening behavior of the agent will be matching the emotions both in mimicry and affective matching conditions. Similar to the second study, mimicry condition will result in a generic verbal response from the agent while affective matching condition will give an emotionally charged feedback due to emotional representation.

The second experiment counterbalanced on the order of the type of interaction (mimicry, affect matching), and the order of the type of emotional story (angry, sad, happy). 12 (2x6) different conditions presented to subjects. The third experiment is also counterbalanced on the order of the type of interaction (mimicry, affect matching), and the order of the type of emotional story (dog, plant). 4 (2x2) different conditions presented to the subjects. Both experiments followed the same procedure as the first study.

Evaluations In the second study, one-way repeated measures ANOVA was conducted to compare the effect of (IV) level of emotional contagion behavior on (DV) the perception of empathy in mimicry, and affective matching conditions. The results showed that perceived empathy is not significantly different between mimicry (M=7.62, SD=11.66) and affect matching (M=9.5, SD=8.03) conditions F(1, 23) = 1.030, p = .321.

Following up these results, in the third study, one-way repeated measures ANOVA was conducted to compare the effect of (IV) level of emotional contagion behavior on (DV) the perception of empathy in mimicry, and affective matching conditions during the interaction with complex emotional behavior. The results showed that perceived empathy is significantly different between mimicry (M=0.75, SD=10.45) and affect matching (M=7.21, SD=9.98) conditions F(1, 23) = 7.731, p = .011 (see Figure 4).

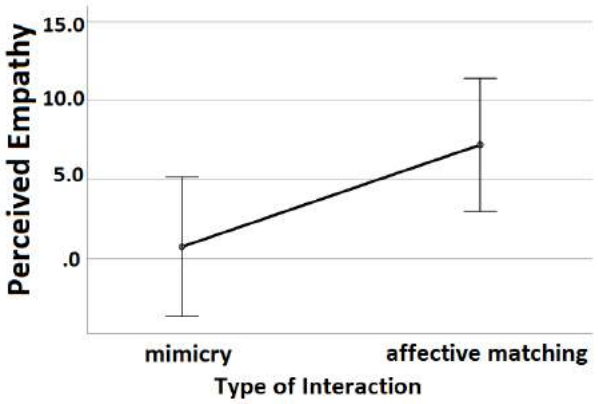

Figure 4: Results of the third study showed significant differences in the perceived empathy levels between mimicry and affective matching behavior in complex emotional interaction (95%CI).

Discussion

The results of the studies showed a significant difference in the perception of empathy between the baseline backchanneling behavior and the emotional contagion behavior during the listening act. As expected, the perceived empathy was significantly higher in the emotional contagion behavior with respect to the baseline behavior in the first study. However, there was no significant difference between the different levels of empathic behavior (mimicry and affective matching) in this experiment. This result is a direct consequence of the similarity in the expressions of these two conditions during listening.

Even though mimicry and affect matching behaviors have important differences in terms of processing of input information, the real-time expressions of these behaviors during listening behavior show dramatic similarities. During the listening act, mimicry captures the facial expressions of the interaction partner and reflects them using the same facial muscles. In affective matching behavior, instead of copying the facial muscles, the system copies the emotions perceived from these facial expressions. As the emotions are expressed as a result of the facial muscles, these two behaviors are expected to show very similar expressions.

One advantage of affective matching that it allows the expression of emotions that are more suitable to the virtual agent, while any emotion will be expressed in terms of the virtual agent's repertoire instead of the expressions of the conversation partner. Moreover, affective matching allows processing of other input channels to conclude the emotion of the interaction partner, such as voice stress, the context of the speech and body expressions. However, the first and second studies only included simple emotions, and therefore such an effect was not present.

Another distinction between mimicry and affect matching conditions is present during the verbal response after the listening act is completed. This response is created by examining the overall emotion of the story told by the interaction partner. As mimicry behavior does not provide the representation of the emotions of the interaction partner, the virtual agent cannot generate a response that is aligned to that emotion. In contrast, the verbal response for the affective matching behavior can be generated from the emotion representation (see Figure 2 for a comparison of these two strategies). Study 2 and 3 are designed to show this distinction.

Interestingly, Study 2 did not show a significant difference between the mimicry and affect matching behaviors for simple emotional stories, where we see a significant difference in Study 3. In these studies, there are two main differences between mimicry and affective matching conditions: the content of the verbal response, and the facial emotions shown during the verbal response. In mimicry condition, the verbal response is generic where the affect matching condition generates an emotionally appropriate response. The facial expressions in mimicry response are sustained regardless of the overall emotions, where the affect matching condition generates facial expression based on the overall emotional representation for the whole story. The difference between the two studies was the emotional complexity of the overall story told by the interaction partner.

We argue that the mimicry response for the simple emotional stories in Study 2, did not show a significant difference on the perception of empathy due to the match between the overall emotion of the story and the sustained facial expression. Where in Study 3 the sustained emotion of the mimicry response was contrasting the overall emotions of the story, due to the complexity of the emotions presented by the interaction partner. We further examined the comments provided by the participants on how they perceived the behavior of the agent in response to the story told by the interaction partner. The comments of the participants in Study 2 showed that the mimicry condition is seen as "understanding" and "sympathy", where the affective matching behavior is seen as "concerned" and "empathy". In contrast, in Study 3, participant comments on the behavior of the virtual agent included descriptions such as "confused" and "indifferent", where the affect matching response was seen more as "attentive", "understanding" and "empathy". However, this distinction should be examined more systematically before reaching to a conclusion.

Overall, these results show that low-level emotional contagion behaviors of the agent during conversational interaction lead to an increased perception of empathy. Additionally, the results show that higher levels of emotional contagion behavior are perceived as more empathic behavior when the interaction includes more complex emotional behaviors. The proposed framework shows promise in providing a foundation to examine the perception of higher levels of empathic behavior during an interaction.

Conclusion and Future Work

Artificial systems provide means to test the empathy theories while allowing the manipulation of parameters in a controlled and isolated way. In this work, we proposed an embodied conversational agent framework to test empathy components and demonstrated three studies that evaluate the foundational empathy mechanisms along with basic communication behaviors. We found that during listening, mimicry and affective matching behaviors are perceived significantly more empathetic compared to backchannel behavior. We also found that the difference between the two levels of affective contagion only significant while the interaction involves complex emotional behaviors, where the context of the interaction is crucial for producing matching behavior. Our framework and the results of our initial study shows promising results that allows for easy integration and testing of higher level components of empathy. The suggested framework, study and evaluation methods shows the potential as a reliable alternative to test mechanisms for empathic behavior in isolation.

Our contributions were to provide a framework, implement the baseline behavior for real-time interaction with a highly realistic conversational avatar, and provide the first study for testing the theoretical assumptions. We hope this baseline for is useful the emerging community of researchers that study empathy in artificial agents and that it can be expanded through this framework and evaluation methods.

Mouse Tracking Measures Reveal Cognitive Conflicts Better than Response Time and Accuracy Measures

Takashi Yamauchi (takashi-yamauchi@tamu.edu), Anton Leontyev, Moein Razavi
Department of Psychological and Brain Sciences
College Station, TX 77843 USA

Abstract

Mouse-tracking is said to provide a real-time record of decision making in a conflict situation (Stillman, Shen, & Ferguson, 2018); yet precise benefit of this method is unknown. Using two versions of the attention network task (ANT-R) (Fan et al., 2009), we investigated the extent to which mouse movement measures capture cognitive conflicts created in flanker and Simon tasks. The movement measures collected in the augmented ANT-R (mouse movement condition) were responsive to both flanker and Simon incongruency but response time and accuracy measures in the regular ANT-R (key-press condition) were responsive primarily to flanker incongruency only. The mouse movement measures were also sensitive to interaction effects involving incongruency and gender, trial order and congruency sequence, while response time and accuracy in the regular ANT-R (key-press condition) were mostly insensitive to these interactions. These results suggest that mouse movement measures are more perceptive to cognitive conflicts.

Keywords: mouse-cursor movement; cognitive conflict; cognitive control; flanker and Simon effect

Introduction

One of the major goals of cognitive science is to elucidate the mental mechanism of cognitive operations (i.e., reverse engineering, Marr, 1981), and developing analytic tools that aide this endeavor has been a main preoccupation in cognitive science. Nearly all theoretical debates in the field involve the assessment and interpretation of behavioral data that these tools provide. Bayesian cognitive models, linear mixed effect models, model-based and model-free experimental designs and tasks are geared to help inference of perceptual, cognitive, and affective mechanisms that enable complex human behavior (Barr, Levy, Scheepers, & Tily, 2013; Daw, Gershman, Seymour, Dayan, & Dolan, 2011; Lee & Wagenmakers, 2014).

Ironically, these sophisticated theories and models are based on the age-old dependent measures—how fast and accurately the subject presses a computer key. Yet, it is unclear how reliable these measures are as analytic tools. The problem is that, until recently, cognitive science has had few other viable measures of human behavior.

Using two versions of the attention network task (ANT-R, Fan et al., 2009)—one that primarily measures response time and accuracy through a key press and the other that uses mouse tracking, we compared the extent to which these measures capture cognitive conflicts created in flanker and Simon tasks.

Detecting cognitive conflicts in motor behavior: Mouse-cursor tracking

The theoretical foundation of the mouse-cursor motion research originated from Michael Spivey's conceptualization of human cognitive processing (Spivey, 2007). Traditional theories suggest that cognitive functions such as reasoning, decision making, and problem solving result from symbol manipulations, and computational algorithms for perception, decision, and action are explained by procedures transforming one representational state to another (Marr, 1981). Spivey conceptualizes cognitive functions as a fluid process where probabilistically weighted perceptual-cognitive processing units interact continuously.

Instrumental in Spivey's continuous cognition theory is a series of experiments that measure goal-directed action and decision making (i.e., choice reaching). In a typical choice reaching task, two competing options are pitted against each other (2AFC) and participants are instructed to select one of the choices by clicking on a button by the computer mouse. Unlike a traditional 2AFC task where response time and accuracy are key dependent measures, a choice reaching task has the subject navigate the computer cursor to select a button. By analyzing the navigational path of the cursor from the initial starting position to the end position, researchers found that trajectory features such as AUC (area under the curve) and MAD (maximum absolute deviation) (the degree of deviations from the straight line connecting the starting position to the end position) reveal the subject's perceptual, cognitive, and social conflicts in the decision process (Maldonado, Dunbar, & Chemla, 2019).

The findings in support of this principle come from a broad range, including numerical judgment (Xiao & Yamauchi, 2015), categorization (Dale, Kehoe, & Spivey, 2007), inductive reasoning (Yamauchi, Kohn, & Yu, 2007), linguistic judgment (Spivey, Grosjean, & Knoblich, 2005), racial and gender judgment of morphed face pictures (Freeman & Ambady, 2009; Freeman, Pauker, Apfelbaum, & Ambady, 2009), attitudinal ambivalence toward certain topics (e.g., abortion) (Schneider et al., 2015; Wojnowicz, Ferguson, Dale, & Spivey, 2009), uncertainty in economic choices (Calluso, Committeri, Pezzulo, Lepora, & Tosoni, 2015), and among others (see for review, Freeman, 2018; Stillman et al., 2018; Yamauchi, Leontyev, & Wolfe, 2017). Studies have shown that mouse movement measures can capture semantic incongruency that is processed subliminally

(Xiao & Yamauchi, 2014, 2015, 2017); they even allow automated recognition of emotion, gender and feelings of computer users (Yamauchi & Xiao, 2018; Yamauchi & Bowman, 2014).

One critical question is exactly how well these "continuous" motor measures capture cognitive conflicts as compared to traditional response time and accuracy measures. Is there any advantage of assessing motor measures to study executive control? To address this question, we employed two versions of the attention network task (Fan et al., 2009) and compared the extent to which different dependent measures—traditional response time and accuracy measures and mouse-cursor movement measures—capture flanker and Simon effects.

Cognitive Conflicts in ANT-R

Because attention plays a pivotal role in a wide range of perceptual, cognitive and affective behavior (Posner & Rothbart, 2007), the attention network task provides an ideal testbed to investigate how well cognitive conflicts are reflected in different dependent measures.

The attention network theory (Petersen & Posner, 2012) posits that there are three separate but interactive functions of attention—alerting (being vigilant), orienting (selecting stimuli), and executive control (resolving conflict). A revised version of the attention network task (ANT-R, Fan et al., 2009) has been used widely to probe the interaction and integration of these attention functions, especially cognitive conflicts. The task combines the flanker task (Eriksen & Eriksen, 1974) and the Simon task (Simon & Berbaum, 1990) and creates different types of cognitive conflict (Figure 1). In a flanker task, conflicts are generated by surrounding arrows pointing opposite to the center (target) arrow. In a Simon task, conflicts are created by the stimulus location presented opposite to the center (target) arrow (Figure 1). In both cases, the task of the participant is to indicate the direction of the target (center) arrow.

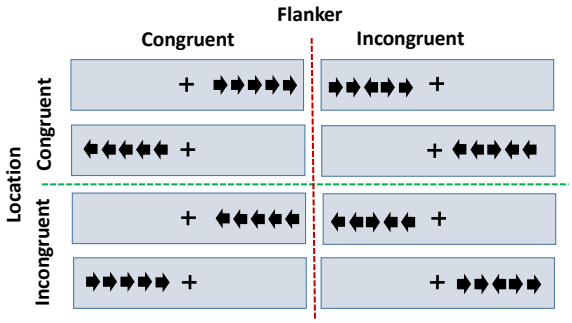

Figure 1: Illustration of flanker and Simon (location) tasks. Flanker congruent and flanker incongruent stimuli are shown in the two columns. Location congruent and location incongruent stimuli are shown in the four rows. The task is to identify the left-right direction of the target (center) arrow.

We devised two versions of the attention network task—traditional and augmented—and contrasted how well traditional response time and accuracy measures and mouse-cursor movement measures can capture the flanker and Simon effects. The traditional attention network task collects only response time and accuracy. Here the subject is to indicate their responses by pressing a designated computer key. The augmented version of the attention network task is identical to the traditional version, except that subjects indicate their response by clicking a button presented on the screen. For this, the subject has to navigate the mouse from the bottom of the screen and press the button. In the augmented version, the x-y coordinate location of the cursor is recorded every 15ms.

(a) (b)

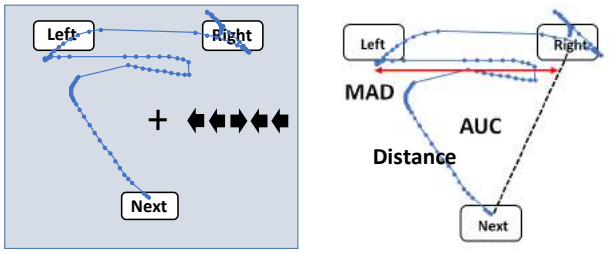

Figure 2: (a) An illustration of an augmented ANT-R trial in the mouse movement condition. To indicate the left/right direction of the target (center) arrow, the participant moves the cursor from the center of the Next button to the final posisiton. The trajectory of the cursor is shown for illustrative purpose and were invisible to participants. (b) AUC (area under curve) is the area enclosed by the trajectory and the straight line connecting the starting position and the end position. MAD (maximum absolute deviation) is the signed maximum absoluite deviation from the direct path. Distance is the sum of Euclidean displacements of the cursor at each sampling point (dots).

The critical question addressed here is how well these depend measures collected from the traditional and augmented ANT-R tasks can capture cognitive conflicts (Figure 1). Although researchers claim the advantage of mouse-cursor measures over traditional measures in extracting cognitive conflicts, this idea has never been explicitly tested. By contrasting the two types of the attention network task, the experiment described below investigate this question directly.

Experiment

The flanker and Simon effects are known to produce robust conflict effects (Eriksen & Eriksen, 1974; Stillman et al., 2018). Although the traditional ANT-R is well suited for the assessment of a flanker-type conflict, the task fails to capture a Simon effect (Fan et al., 2009). Indeed, the Simon effect is particularly difficult to replicate unless the stimulus allows explicit spatial coding (Hommel, 2011). With its emphasis on spatial coding (Figure 1), we predict that the augmented ANT-R are suitable for the assessment of both flanker and Simon effects.

What is unknown is the nature of the effects. Both flanker and Simon effects are subject to contextual factors, such as gender and sequential modulation. The flanker and Simon effects are generally larger in women than men (Stoet, 2017); they are also subject to the trial order. For example, flanker and Simon effects are smaller when two incongruent stimuli are shown in sequence (Egner, 2017). The question addressed here is how well these contextual impacts are reflected in the four dependent measures. If mouse-cursor movement measures are more sensitive than traditional response time and accuracy measures, these interaction effects should be well captured by the mouse-cursor movement measures as compared to the response time and accuracy measures collected in the key-press condition.

Method

Participants Participants (*N*=261) were undergraduate students who enrolled in an introductory psychology course. Participants participated in the experiment for course credit. These participants were randomly assigned to one of two between-subjects conditions—the key-press or mouse movement conditions (key-press = 135, female = 105 male = 30; mouse movement = 126, female = 92, male = 34).

Procedure We employed a revised version of the attention network task (ANT-R, Fan et al., 2009). The ANT-R task is a combination of an arrow flanker (Eriksen & Eriksen, 1974)(Eriksen & Eriksen 1974) and a Simon task (Simon & Berbaum, 1990). A stimulus consisted of five arrows—one center arrow sandwiched by four arrows (two arrows placed both sides). The task of the participant was to indicate the left-right direction of the center arrow (i.e., target arrow). Stimuli (five arrows) were shown either the left or right side of the monitor and the direction of the target arrow was either congruent or incongruent to side arrows (Figure 1).

The key-press and the mouse movement conditions were identical except for one critical point. In the key-press condition, participants indicated the left-right direction of the center arrow by pressing the left or right arrow keys on the keyboard. In the mouse movement conditions, participants used the mouse to indicate the left-right direction of the center arrow. In this condition, two buttons were placed on top left or top right corner of the screen and participants had to navigate the cursor to press the button. (Figure 2a).

ANT-R also incorporates different attention cues (rectangular boxes), which were shown before the presentation of the stimulus at (Figure 3). No cue, double cue, invalid cues, and valid cues were randomly assigned. Because no impacts of attention cues were observed in the present study, the procedure and results involving attention cues are not discussed further.

Altogether each participant received 144 trials, which were divided into eight possible combinations of flanker congruency (congruent, incongruent) and location congruency (congruent, incongruent) and target direction (left, right) (18 trials for each condition and see Figure 1). Eight stimuli in each combination were shown 18 times (8 x 18 = 144), comprising of 144 trials. The order of presenting individual stimuli was determined randomly.

The schedule of stimulus presentation is illustrated in Figure 3. A blank screen with a square is shown; 500ms after the subject clicks the Next button, a fixation sign appears and remains on the screen between 2000ms to 12000ms. The duration between the offset of the target and the onset of the next trial (the cue is shown) varied (approximating an exponential distribution, 2000 to 12,000ms, mean 4000ms). A cue is shown for 100ms. Another fixation is shown for 0, 400, or 800ms (uniform random). A target figure is shown for 500ms. At the onset of the target frame, the cursor is placed at the center of the next button in the mouse movement condition.

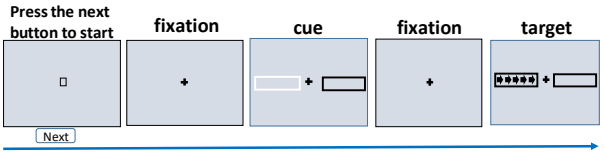

Figure 3: A trial sequence of an ANT-R trial. As the subject press the Next button, a fixation sign appears, followed by a cue, and another fixation sign. Soon after a target frame flashed for 500ms.

Prior to the experiment, all participants received a minimum of 24 practice trials. In the practice trial, corrective feedback was provided after each trial. Practice trials ended when the accuracy was 90% or above in the last 24 trials or a maximum of 48 trials. In 24 practice trials, all possible combinations of flanker congruency, location congruency, and target directions. No cue, double cue, invalid cues, and valid cues were randomly assigned.

Design The experiment had a 2(flanker; congruent, incongruent) x 2(location; congruent, incongruent) x 2 (block order; early, late) x 2 (gender; male, female) design. The key-press and the mouse movement conditions were analyzed separately. Dependent measures in the key-press condition were response time and accuracy (error rate). Dependent measures in the mouse movement condition were AUC, MAD and distance. To analyze the impact of trial sequence, we introduced another factor, congruency sequence (cog_seq; congruent, incongruent), which indicate a congruent or incongruent condition of the stimulus given right before the current stimulus.

To compare the efficacy of the dependent measures, we applied linier mixed-effects models (LMEMs), which are particularly suited to detect population-level systematic effects of manipulations while controlling random variations stemming from individual participants and stimuli. Following the suggestion by Barr et al. (2013), we applied a maximal random-effects structure that was allowed by the experimental design with four fixed factors with two levels; flanker (congruent, incongruent), location (congruent, incongruent), trial order (early, late), and gender (female, male) and two-way interactions among the factors combined with subject-specific random intercepts and item-specific

random intercepts. The first three factors, flanker, location, and trial order are within-subjects variables and gender is a between-subjects variable.

Trials that took longer than and equal to 5000 milliseconds and trials shorter than and equal to 100ms were removed from our data analysis. Outliers were removed using the median-based procedure suggested by Wilcox (p. 77, Wilcox, 2003) (9% of the trials were removed in the key-press condition and 7% of the trials were removed in the mouse movement condition). To ensure that each dependent variable was approximately normally distributed in a similar degree, we transformed each dependent variable with ordered quantile transformation using R package bestNormalize. For all LMEM analyses, we used R packages lme4 and afex, and all dependent variables were rescaled to -1 to 1 (mean = 0). All trajectories were time-normalized using linear interpolation method (101 constant time steps, and see Spivey et al., 2005). We used R package mousetrap (Kieslich & Henninger, 2017) for time normalization and feature extraction (AUC, MAD, and distance).

Result

We first report the results from LMEM analysis followed by a direct comparison of effect sizes. Summaries of these results are shown in Table 1 and Figures 4-6. Following this analysis, we report the impact of congruency sequence.

Table 1: *p*-values from LMEM ANOVA

	RT	Accuracy	AUC	MAD	Dist.
flanker	****	****	****	****	****
location	(**)		****	****	****
flanker x location	(****)	+		+	****
flanker x blkOrder	*		****	***	**
location x blkOrder			+	**	****
flanker x gender			+	*	
location x gender			*	*	

Note. $^{+}p < .10$. $*p < .05$. $**p < .01$. $***p < .001$. $****p < .0001$. Dist. = Distance. (*) opposite direction (congruent > incongruent)

Response time. The response time measure in the key-press condition was quite robust in capturing the flanker effect; $F(1, 172.9) = 662.4$, $p<0.0001$. However, this measure was ineffective for the Simon (location) effect. Although we found a significant main effect of location, the direction of the effect was opposite—participants took longer for location-congruent stimuli than location-incongruent stimuli; $F(1, 172.5) = 7.6$, $p<0.01$. A similar significant "opposite" Simon effect was reported in the Fan et al. (2009) study. The flanker-location interaction effect was significant; $F(1, 132.41) = 17.7$, $p<0.001$.

In general, response time was not very effective in capturing interaction effects. Except for the flanker by block order interaction ($F(1, 17474.4)= 4.2$, $p<0.05$), no other

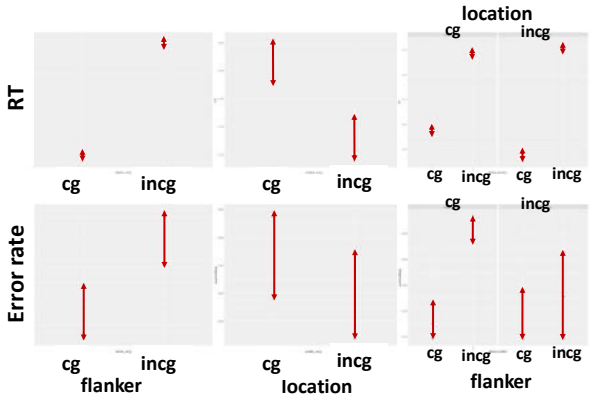

Figure 4: Mean response time (RT) and error rate (accuracy) with flanker (cg=congruent, incg=incongruent, left), location (center), and flanker by location (right) interactions. The arrows represent 95% CI.

interaction effects were significant; location x block order, $F(1, 17473.6)=1.5$, $p=0.22$; flanker x gender, $F<1.0$; location x gender, $F<1.0$ (Figure 4).

Accuracy (error rate) Accuracy (error-rate) was effective in capturing the flanker effect, but not the location (Simon) effect; flanker, $F(1, 133) = 43.0$, $p<0.0001$; location, $F(1, 133) = 1.4$, p=0.24; flanker x location, $F(1, 133) = 2.9$, $p=0.09$. No other interaction effects were observed in accuracy; flanker x block order, $F(1, 133) = 1.0$, $p=0.32$; location x block order, $F(1, 133) = 2.0$, $p=0.16$; flanker x gender, $F<1.0$; location x gender, $F<1.0$ (Figure 4).

AUC (Area under curve). AUC was effective in capturing both the flanker and location (Simon) effects very well. This measure was also sensitive to interaction effects involving gender and block order; flanker, $F(1, 198.9) = 371.9$, $p<0.0001$; location, $F(1, 199.2) = 898.8$, $p<0.0001$; flanker x location, $F<1.0$; flanker x block order, $F(1, 16714.4) = 16.0$, $p<0.0001$; location x block order, $F(1, 16709.2) = 2.9$, $p=0.09$, flanker x gender, $F(1, 16567.9)=3.2$, $p=0.07$; location x gender, $F(1, 16570.9) = 6.3$, $p<0.05$.

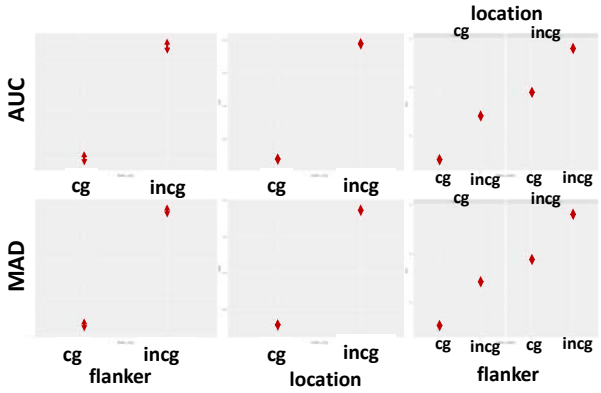

Figure 5: Mean AUC and MAD with flanker (cg=congruent, incg=incongruent, left), location (center), and flanker by location (right) interactions. The arrows represent 95% CIs.

MAD (Maximum Absolute Deviation). MAD was sensitive to flanker and location (Simon) effects, as well as interactions between these terms and block orders; flanker, $F(1, 209.9) = 518.9$, $p<0.0001$; location, $F(1, 210.0)=885.5$, $p<0.0001$; flanker x location, $F(1, 209.8) = 3.3$, $p=0.07$; flanker x block order, $F(1, 17226.3)=12.1$, $p<0.0005$; location x block order, $F(1, 17218.3) = 6.8$, $p<0.01$; flanker x gender, $F(1, 17074.7) = 4.0$, $p=0.05$; location x gender, $F(1, 17075.8) = 4.3$, $p<0.05$.

Distance. Distance responded well to flanker and location effects; flanker, $F(1, 215.3)=214.2$, $p<0.0001$; location, $F(1, 215.3)=109.1$, $p<0.0001$; flanker x location, $F(1, 214.5) = 17.6$, $p<0.0001$. This measure was also sensitive to interactions between these terms and block order; flanker x block order, $F(1, 15822.2) = 9.5$, $p<0.002$; location x block order, $F(1, 15818.9) = 22.7$, $p<0.0001$, but not gender; flanker x gender, $F(1, 15698.3) = 1.2$, $p=0.28$; location x gender, $F<1.0$.

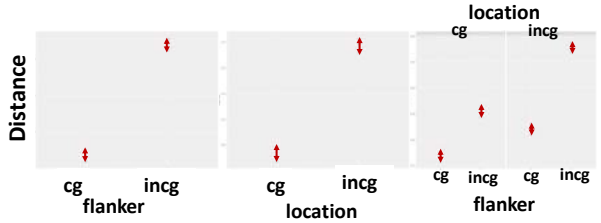

Figure 6: Distance with flanker (cg=congruent, incg=incongruent, left), location (center), and flanker by location (right) interactions. The arrows represent 95% CI.

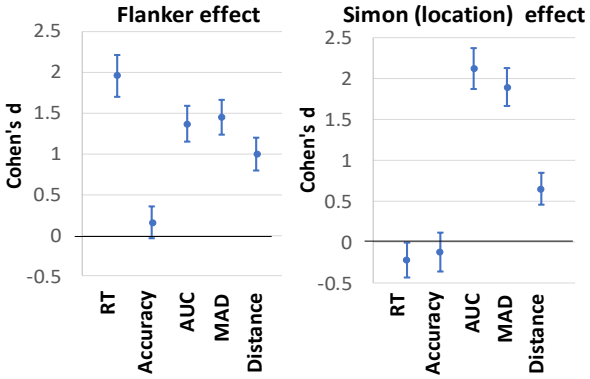

Figure 7: Effect sizes (95% CIs) of flanker (left) and Simon (location) effects. Following Cumming (p. 290, 2012), effect sizes and their CIs for congruent and incongruent conditions were calculated as independent groups.

Effect sizes We compared effect sizes of the flanker and location (Simon) effects captured by the five dependent measures (Figure 7). We observed a large effect size of the flanker effect in the response time measure, as compared to AUC, MAD, and distance; for all comparisons Z's> 2.9, p's<0.001. However, both response time and accuracy measures were ineffective for the location (Simon) effect. In contrast, the effect sizes obtained in the mouse-cursor movement measures were considerably above chance level (Figure 7).

Congruency sequence effects Another important characteristic of cognitive conflict is congruency sequence effects. Flanker and Simon effects are generally smaller when two incongruent stimuli are shown in sequence (Egner, 2017). We examined sequence effects with another factor, congruency sequence (cog_seq; congruent, incongruent), which informs whether preceding stimuli were congruent or incongruent (e.g., flanker (cog, incog) x seq(cog, incog)). This analysis shows that congruency sequence effects were well captured by AUC, MAD, and distance, but not response time and accuracy (Table 2); flanker x seq, RT and accuracy, F's<1.0; AUC, MAD, distance, F's>37.0, p's<0.0001; location x seq, RT and accuracy, F's<1.0; AUC, MAD, F's<1.0; distance, $F(1, 162.4)=4.2$, $p<0.05$ (Table 2).

Table 2: *p*-values for congruency sequence effects

	RT	Acc.	AUC	MAD	Dist.
flanker x seq			****	****	****
location x seq					*

Note. $^{+}p < .10$. $^{*}p < .05$. $^{**}p < .01$. $^{***}p < .001$. $^{****}p < .0001$. Dist.=Distance, seq=congruency sequence, RT=response time, Acc.=accuracy (error rate)

Discussion

The cursor movement measures, AUC, MAD, and distance, collected in the mouse-movement condition were responsive to incongruency created in flanker and Simon (location) tasks but response time and accuracy measures in the key-press condition were primarily responsive to flanker incongruency but not location (Simon) incongruency. The mouse movement measures were also sensitive to interaction effects involving incongruency and gender, trial order and congruency sequence, while response time and accuracy in the key-press condition were mostly insensitive to these interactions. These results suggest that the mouse movement measures, as compared to traditional response time and accuracy measures, are more perceptive to flanker and Simon (location) effects.

Researchers have advocated that mouse tracking measures are advantageous for the examination of cognitive conflicts (Freeman, 2018; Stillman et al., 2018). Our results provide empirical support for this idea: the mouse movement measures are statistically more sensitive to various aspects of cognitive conflicts than traditional response time and accuracy measures.

Our results are also consistent with recent findings that performance-based behavior tests for cognitive control (e.g., go/No-go task and stop signal task) can be improved with augmentation of mouse movement measures. Although go/No-go and stop signal tests have been applied widely for the assessment of mental disorders (e.g., ADHD), these tests are ineffective in assessing sub-clinical populations (Toplak, West, & Stanovich, 2013). By augmenting regular go/No-go or stop signal tasks with mouse movement measures,

Leontyev et al. (Leontyev, Sun, Wolfe, & Yamauchi, 2018) demonstrated that these cognitive tests become more reliable in separating individuals with weak and strong symptoms of ADHD-related impulsivity.

Given that the mouse motion measures allow more nuanced examination of cognitive conflict, mouse-tracking measure helps further our theoretical understanding of cognitive control. For example, determinants, boundary conditions, and neural correlates of the congruency sequence effect have been developed, revised and evaluated primarily on the basis of how well the theory accounts for response time and accuracy performance (Egner, 2007). Our results show that different dependent measures can produce different outcomes. In this vein, the validity of these theories (e.g., bottom-up associative theory and top-down control-based theory) can be reexamined with mouse-tracking measures.

Conclusion

For decades, scientific analysis of human behavior has been made mainly on the basis of how fast and accurately an individual responds to a task. Response time and accuracy has served as the primal dependent measures and formidable theories have been developed from these two measurements. The results from this study show that these traditional measures can be supplemented with motor measures, and the mouse-cursor motion analysis provides a viable analytic tool to probe cognitive conflict.

A perspective-change based account of creativity evaluation: An investigation in simile assessments

Abstract

Why do people experience something as creative? We propose a perspective-change based account of creativity evaluation. Drawing upon structure mapping theory (Gentner, 1983), we show that people evaluate a simile to be creative when they spontaneously (Study 1) or are induced (Study 2) to experience a change in perspective. This account further predicts that people are unlikely to find a simile creative if they are unable to form a working perspective, as is in the case of anomalies. In addition, a simile is unlikely to be evaluated as creative when people's initial perspectives are sufficient to interpret the simile, as in the case of literal statements. We further show that repeated use of the same perspective suppresses the experience of perspective change and thus reduces creativity perception (Study 3).

Keywords: creativity evaluation; analogy; simile; perspective-change; structure mapping theory

Introduction

Author J. K. Rowling apparently received many rejection letters for her first Harry Potter novel. Stories abound in academia about seminal, award-winning papers that were initially rejected by journals. Innovation requires more than just generating creative ideas—it also requires being able to evaluate ideas. Consequently, creativity evaluation is a critical and challenging step in the innovation process (Mueller, 2017). However, our knowledge of how lay people form creativity judgments is still limited (Zhou, Wang, Bavato, Tasselli, & Wu, 2019). This paper contributes by proposing and providing initial tests of a perspective-change based account of creativity evaluation.

We focus on perspective change following a proposal that evaluating creative ideas is somewhat like generating creative ideas (Cronin & Loewenstein, 2018). There is a long tradition in creativity research emphasizing the key role of changing one's perspective, discussed variably as, for example, the reorganization of cognitive structures (Mumford & Gustafson, 1988), breaking set (Boring, 1950), restructuration (Duncker & Lees, 1945), deviation from habitual use of knowledge (Luchins, 1960), and transformation (Boden, 2004). These ideas are related to work beyond the creativity literature on conceptual change (Chi, 2009) and re-representation (Gentner & Wolff, 2000). Following terminology from Page (2008) and Cronin and Loewenstein (2018), we describe it as perspective change. Briefly, as any mental representation is a partial rather than a complete account, it necessarily only provides a perspective on whatever is being represented. It follows then that adopting a particular mental representation of a situation leaves open the possibility of changing to an alternative mental representation that is both appropriate to the situation and incompatible with the first mental representation. The possibility pursued here, building on the argument by Cronin and Loewenstein (2018), is that if the process of generating creative ideas involves a change in perspective, then it might also be the case that when the process of forming an interpretation of an item leads us to change our perspective, we are likely to perceive the item to be creative. Thus, the proposal is that creativity evaluations rest at least in part on the process of forming interpretations, and that process echoing the process of generating creative ideas.

To explore this perspective change account of creativity evaluation, we asked participants to evaluate similes: A is like B. Prior work has established that such statements can convey fresh analogies, anomalies, or mundane literal similarities or class inclusions (Bowdle & Gentner, 2005; Gentner, 1989). The perspective change account of creativity evaluation makes predictions about each case. Specifically, a simile is unlikely to be judged creative if people cannot form a coherent interpretation of it—that is, if it is an anomaly. A simile is unlikely to be judged creative if people's initial, default interpretation is apt—that is, if it is a mundane literal similarity comparison or class inclusion. In contrast, a simile is likely to be judged creative if people's initial, default interpretation is not apt but they are able to find an alternative interpretation that is appropriate—that is, it is experienced as a fresh analogy.

To further examine the role of perspective change, we draw upon the habituation paradigm (Rankin et al., 2009) to show that repeated exposure to a perspective can lead to diminished perspective change and thus reduces creativity evaluation.

Study 1: Spontaneous Perspective Change

Method

Participants This study involved 147 students from a mid-west university who participated in the study for course credit (49% male, $Mean_{age}$ = 20.65, SD_{age} = 2.11, 48.30% white, 5.44% black, 41.50% Asian, 4.68% other). No participant was excluded from the analysis.

Materials and Design We generated five groups of similes, with each group using the same target and three different bases. The five targets were: diamond, crib, snowflake, pencil, and closet. Drawing upon the structure mapping framework for analogy (Gentner, 1983), we composed three types of

similes for each of the five targets: 1) anomaly, e.g., a crib is like seaweed; 2) literal similarity, e.g., a crib is like a bed; 3) analogy, e.g., a crib is like a cocoon.

Participants saw the 15 similes twice. First, they rated them for creativity on a 7-point Likert scale (1="highly uncreative", 7="highly creative"). Next, they categorized each statement as: "nonsensical", "a literal comparison", "a metaphor". Participants gave ratings of perspective change by being asked the extent to which the statement made them think differently about the target in the statement on a 5-point Likert scale (1 = "Not at all differently", 5 = "Extremely differently"). Participants also wrote down their interpretations of the statements.

Results and Discussion

Table 1 provides descriptive data. Consistent with the materials design, most of the anomalies, literal similarity statements, and analogies were categorized by participants as such ("Nonsensical," "Literal" and "Metaphor"; bold numbers in Table 1).

Creativity evaluations and perspective-change scores are presented in the rows of Table 1. As expected, aggregating across items, we found that the analogy type ($Mean_{All3} = 4.84$) was evaluated to be more creative than the anomaly type ($Mean_{All1} = 3.74$), $F(1, 1468) = 171.64$, $p < .00$ as well as the literal type ($Mean_{All2} = 2.62$), $F(1, 1468) = 852.80$, $p < .00$. The same pattern held for perspective-change scores. The analogy type ($Mean_{All3} = 2.56$) was rated as more perspective-changing than the anomaly type ($Mean_{All1} = 1.77$), $F(1, 1468) = 164.88$, $p < .00$ as well as the literal type ($Mean_{All2} = 1.33$), $F(1, 1468) = 554.7$, $p < .00$.

We also analyzed creativity evaluations and perspective-change scores for the similes by how participants categorized, and so presumably how they experienced, them (Table 1). Aggregating across items, planned contrasts showed that items categorized by participants as metaphors ($M = 5.18$, $SD = 1.38$) were evaluated to be more creative than items categorized as nonsensical ($M = 3.36$, $SD = 1.62$), $F(1, 1320) = 400.07$, $p < .00$, $\eta^2 = 0.23$. They were also evaluated to be more creative than items categorized as literal ($M = 2.72$, $SD = 1.51$), $F(1, 1320) = 842.3$, $p < .00$, $\eta^2 = 0.39$. A similar pattern held for the perspective change ratings. Similes that participants categorized as metaphors ($M = 2.84$, $SD = 1.13$) were rated as more perspective-changing than those categorized as nonsensical ($M = 1.30$, $SD = 0.93$), $F(1, 1320) = 733.21$, $p < .00$, $\eta^2 = 0.36$ They were also rated as more perspective-changing than similes categorized as literal ($M = 1.46$, $SD = 0.82$), $F(1, 1320) = 627.07$, $p < .00$, $\eta^2 = 0.32$.

The consistency in the patterns between creativity evaluations and perspective-change scores held not just in the aggregate but also at the level of individual items. The correlation between creativity evaluations and perspective change scores was high, $r = 0.50$, $p < .00$.

Taken together, these findings are consistent with the possibility that people evaluate similes to be creative to the extent that they formed interpretations that differed from how they usually interpreted the target.

Table 1: Categorizations, creativity evaluations, and perspective change scores in Study 1

List	Category (%)			Creativity			P-change		
	Ns	Lit	Met	Ns	Lit	Met	Ns	Lit	Met
All1	**71**	6	23	3.41	3.5	4.81	1.32	2.5	2.94
All2	12	**85**	3	3.08	2.52	3.57	1.46	1.29	2.24
All3	8	12	**80**	3.68	4.05	5.07	1.35	2.44	2.70

Note: Ns-Nonsensical, Lit-Literal, Met-Metaphor; 1, 2, and 3 denotes nonsensical, literal, and metaphor, respectively. Note that Ns, Lit, and Met denote participants' categorizations, whereas 1, 2, and 3 denote the intended type of statement in the design of the materials.

This was seen in the highest creativity evaluations being given to those similes intended as analogies as well as in the high correlation between creativity evaluations and perspective-change scores. But perhaps the most compelling aspect of the data is that it was not the similes themselves that mattered so much as participants' own categorizations of the similes. The same simile could be and were categorized differently by different participants. What was perceived to be an anomaly by some was perceived to be a metaphor by others, and the perspective-change scores and creativity evaluations followed from those subjective interpretations.

Taken together, the results of Study 1 found that a simile is likely to be evaluated as creative to the extent that people experience a change in perspective as they form an interpretation of the similarities between the target and the base. This is initial evidence consistent with a perspective-change based account of creativity evaluation—that what drives creativity judgments is experiencing a perspective change in the course of forming an interpretation of the item one is evaluating.

Study 2: Induced Perspective Change

Study 2 builds on Study 1 by randomly assigning individuals to conditions that should encourage or discourage them from experiencing a change in perspective (cf., Day & Asmuth, 2017). Specifically, before participants evaluated an anomalous simile, they first read a short paragraph. That paragraph contained information that was either relevant or irrelevant to comprehending the simile as an analogy. Thus, we sought to enable participants to form a coherent change in perspective or limit them from doing so, and as a result encourage or hinder them from perceiving the simile to be creative.

Method

Participants We recruited 237 participants from Mturk (45% male, $Mean_{age} = 37.59$, $SD_{age} = 12.22$, 78.90% white, 11.39% black, 7.17% Asian, 2.53% other). Participants qualified for the study if they were located in the United States and had an approval rate above 95% in previous ''Human Intelligence Tasks" (HITs) on MTurk. None of the participants was excluded from the analysis.

Materials and Design Participants saw one of two similes: (1) Pigeons are like snowflakes, or (2) Seaweed is like a crib. Before reading the simile itself, they first read a paragraph that was either relevant or irrelevant to interpreting the target of the simile in a way that supports interpreting the simile as an analogy.

Specifically, for participants assigned to evaluate the simile about pigeons, they read one of the two paragraphs:

Pigeons often move together and descend to the ground, blanketing it and changing its color. At some times of year, out in the countryside it seems that the wind brings pigeons and covers the roofs with the feathered creatures. Or go to a town square at certain times of day or the year and soon you may find that pigeons gradually cover the entire square (relevant information condition*).*

Pigeon is a French word that derives from the Latin pipio, for "peeping", based on the sounds the birds make. Pigeons are a common species. They are stout-bodied birds with short necks and slender bills. Pigeons primarily feed on seeds, fruits, and plants. Most pigeons lay one or two eggs at a time, and both the male and female pigeons care for the young (irrelevant information condition).

For participants assigned to evaluate the simile about seaweed, they read one of the two paragraphs:

Fish sometimes benefit from the protection provided by seaweed. The ribbons of seaweed extending upwards from the sea floor form a safe space in which fish can place their eggs. Seaweed provides a shelter for the baby fish. They can rest in the protected space that the seaweed provides. When baby fish outgrow their seaweed home, they can explore the open waters until they are ready to lay eggs of their own (relevant information condition).

Seaweed is a popular snack. All seaweed food is low in calories and fat. Dried seaweed comes in various flavors and is sold in sheets, flakes, or handy snack packs. Fresh seaweed, on the other hand, is commonly sold as an ingredient in prepared foods like sushi or seaweed salad. Canned seaweed snacks are also becoming trendy now; you can easily find them in the refrigerated section of the supermarkets (irrelevant information condition).

After reading these passages and rating them for how informative they were, participants then saw the target simile. Specifically, they rated how creative the simile was on a 5-point Likert scale (1= "Not at all creative", 5= "Highly creative"). They also categorized each simile ("nonsensical" or "metaphor"), provided perspective change ratings by indicating the extent to which the simile made them think differently about the target on a 5-point Likert scale (1 = "Not at all different", 5 = "Extremely differently"), and wrote interpretations.

Results and Discussion

As predicted, the initial passages that participants read influenced their interpretations of the similes and their judgments of creativity. Specifically, for the simile about pigeons, participants assigned to the relevant information condition rated it as more creative than those in the irrelevant information condition ($Mean_{relevant}$ = 3.08, $SD_{relevant}$ = 1.21, $Mean_{irrelevant}$ = 2.34, $SD_{irrelevant}$ = 1.22, t = 3.33, p < .00, Cohen's d = 0.61). In addition, a higher proportion of participants categorized the simile as a metaphor in the relevant information condition than in the irrelevant information condition ($Metaphor_{relevant}$ = 68%, $Metaphor_{irrelevant}$ = 30%, χ^2 = 17.61, p < .00, φ = 0.38). Lastly, participants assigned to the relevant information condition also rated the simile as more perspective-changing than those in the irrelevant information condition ($Mean_{relevant}$ = 2.59, $SD_{relevant}$ = 1.12, $Mean_{irrelevant}$ = 1.97, $SD_{irrelevant}$ = 1.08, t = 3.12, p < .00, Cohen's d = 0.57).

The same pattern was found for the simile about seaweed. Specifically, compared to participants assigned to the irrelevant information condition, those assigned to the relevant information condition rated the simile as more creative ($Mean_{relevant}$ = 3.26, $SD_{relevant}$ = 1.17, $Mean_{irrelevant}$ = 1.84, $SD_{irrelevant}$ = 1.20, t = 6.51, p < .00, Cohen's d = 1.20), were more likely to categorize it as a metaphor rather than a nonsensical statement ($Metaphor_{relevant}$ = 75%, $Metaphor_{irrelevant}$ = 12%, $\chi 2$ = 46.47, p < .00, φ = 0.63), and rated it as more perspective-changing ($Mean_{relevant}$ = 2.72, $SD_{relevant}$ = 1.06, $Mean_{irrelevant}$ = 1.67, $SD_{irrelevant}$ = 1.16, t = 5.22, p < .00, Cohen's d = 0.97).

Study 2 found that providing participants with particular information about the target in a simile could encourage them to see a coherent, novel metaphor in what otherwise would likely have been an anomalous statement. This was likely to be experienced as a change in perspective and likely to have led to considering the simile to be creative. Thus, in inducing a perspective-change and prompting evaluations of creativity, this study offers further support for perspective change playing a role in the process of forming creativity evaluations.

Study 3: Suppressed Perspective Chang

Study 3 tests whether minimizing a perspective change will lead to lower evaluations of creativity. If experiencing a change in perspective contributes to judging something to be creative, then continuing with an existing perspective could dampen judgments of creativity. For example, examining several items in a row could provide an opportunity to compare judgments of the same item when it is either distinct from what has come before and so a change in perspective, or in line with what has come before and so consistent with the existing perspective.

A variety of research examines sequences of judgments of potentially similar and potentially different items, ranging from research using a habituation paradigm (Rankin et al., 2009), to research on deviant items (Sakamoto & Love, 2004), to work on expectation violations (Loewenstein, 2019). We used work on repetition-break structures (Loewenstein & Heath, 2009; Loewenstein, Raghunathan & Heath, 2011) to design sequences of items. The repetition-break structure allows us to identify items that are likely to be experienced as a perspective change: the first item and the break item. It also allows us to identify items that are likely to be experienced as consistent with the existing perspective: the second and any subsequent items that are highly similar to the first one. Thus, we can use sequencing to lead to either a diminished perspective change and therefore diminished

creativity judgments, or a perspective change and therefore expected creativity judgments.

The study uses sequences of similes, some of which are arranged using the repetition-break structure. For a given target in a simile, we generated two sets of bases incorporating two distinctive perspectives. We used three similar bases to establish an initial repetition pattern, and then broke this pattern by contrasting this set of three similes with a fourth simile that whose base drew from a different perspective. In this way, for each target we are able to create two distinctive interpretations of it. Thus, we expected an evaluation experience that can be described by the following process: initial exposure to perspective A → habituation to perspective A with the second and third exposures → initial exposure to a different perspective B. It is at the last stage of this evaluation process that we expect to observe the switch from perspective A to a second different perspective B, and so be experienced as a perspective change.

If the experience of a perspective change underlies creativity evaluation as we proposed, we should expect to see the following patterns: First, the gradual habituation to a perspective will result in reduced ratings of creativity. Through repeated exposure to similar bases incorporating the same perspective, the initial perspective will be gradually assimilated into participants' knowledge structure and thus should lose its freshness. Since it can no longer induce any departure from or change to participants already existing interpretations regarding the target, similes incorporating this perspective will be perceived as less creative. We therefore predict that there will be a decrease in creativity and perspective-change ratings over the course of encounters with the first, second, and third simile.

Second, in the repetition break condition, given that the last simile conveys a second perspective of the target that is different from the first one, we should observe that comprehending the fourth simile will induce a change in perspective—switching from one way of interpreting the target to another way. As a result of this experienced perspective-change, we predict that there will be a jump in creativity and perspective-change ratings for the last simile.

Method

Participants We recruited 428 participants from Mturk. There were 14 participants who failed the attention check. They were excluded, leaving 414 in the final sample (44% male, $\text{Mean}_{\text{age}} = 36.91$, $SD_{\text{age}} = 12.31$, 78.83% white, 7.79% black, 6.81% Asian, 6.38% other). Unless otherwise noted, inclusion of the 14 participants did not change any of the results reported below substantially. Participants qualified for the study if they were located in the United States and had an approval rate above 95% in previous ''Human Intelligence Tasks" (HITs) on MTurk. This sample size was determined using G*Power (Faul, Erdfelder, Lang, & Buchner, 2007), based on a priori power analysis by setting 80% statistical power with an effect size of 0.50, which was obtained through pilot studies.

Materials and Design To generate similes that can be organized in the repetition break structure, we conducted several rounds of pretests. Our final materials included similes with two targets: (1) poverty and (2) marriage. For each target, we generated two sets of bases, with four bases in each set. Each set of bases are synonyms or phrases with similar meanings, such that they are centered around one specific interpretation of the target (i.e., a perspective). The two perspectives for interpreting poverty were that it is a destructive, spreading influence (i.e., poverty is like an infection/an illness/a disease/a virus) and that it is a barrier (i.e., poverty is like a fence/a barricade/a moat/a wall). The two perspectives for interpreting marriage were that it is a thrilling activity (i.e., marriage is like skydiving/bungee jumping/parachuting/hang gliding) and that it is a nurturing activity (i.e., marriage is like growing flowers/caring for your lawn/farming/gardening).

We used a 3 (three structure conditions) by 2 (two targets) by 2 (two sets of bases) design. The first factor is structure, which has three conditions: repetition break, consistent, and baseline. Using "poverty is like a virus" as an example, this simile conveys the interpretation that poverty is destructive and contagious. In the repetition break condition, three similes conveying the other interpretation of poverty were presented in a sequence prior to it (i.e., poverty is like a fence/a barricade/a moat/a wall). This way, when appeared at the fourth position, the focal simile "poverty is like a virus" constituted a break from the initial perspective for poverty.

In the consistent condition, the preceding three similes conveyed the same perspective (i.e., poverty is like an infection/an illness/a disease) as the ending simile, such that the focal simile "poverty is like a virus" is a continuance of rather than a break from the initial perspective. In this condition the focal simile in the fourth position is consistent with the preceding perspective. Lastly, in the baseline condition, the focal simile "poverty is like a virus" was presented on its own without any preceding similes about poverty.

Across the three conditions, our focus is on comparing the creativity and perspective-change ratings for the focal simile— "poverty is like a virus". We expect that: (1) the consistent condition will generate lower creativity and perspective-change ratings than the baseline condition; (2) the consistent condition will generate lower creativity and perspective-change ratings than the repetition break condition; and (3) given that the standing-alone condition provides us with a baseline level of how creative and perspective-changing the focal simile is, we expect to see that the repetition break condition will lead to a jump in perceived creativity and perspective-change of the focal simile such that the ratings are restored to a level comparable to that in the baseline condition.

The second factor in our design was the target (i.e., poverty vs. marriage). We chose to use two rather than just one target in order to show that the pattern of creativity evaluation we predicted did not hinge on the idiosyncrasies of one specific simile target, and that the effect of perspective-change can be generalized to similes with various targets.

In a similar spirit, for each target, we fully counterbalanced the position of the two perspectives, such that each perspective was placed as the opening one (i.e., the repetition stage) in one condition and the ending one (i.e., the break

stage) in another condition. Our intention is to show that the pattern of creativity evaluation we predicted did not rely on one specific perspective being in a specific position. Regardless of the specific content of a perspective, it is the cognitive experience of viewing it as either a continuance of or a break from the already existing perspective that predicts how creative people perceive it to be.

In the current study we have four focal similes: poverty is like a virus/a wall, and marriage is like gardening/hang gliding. Each of the four focal simile is presented in three different structures: repetition break, consistent, and baseline. We thereby generated a total of 12 conditions. In each condition, participants were asked to rate one (i.e., the baseline condition) or four similes (i.e., consistent condition and repetition break condition) for creativity (1 = "not at all creative", 5 = "extremely creative") and perspective-change (1 = "not at all perspective-changing", 5 = "extremely perspective-changing").

In the repetition break and the consistent conditions, the focal simile always appeared at the fourth position. Given that the focus of the current study is on examining the experience of switching from one coherent interpretation to another one, being able to understand a simile and form a perspective in the first place is therefore an important prerequisite. Thus, we gave participants the option of marking a simile as non-sensical if they failed to form an interpretation of it ("this simile doesn't make sense to me"), in which case they were excluded from the analysis.

Results and Discussion

The creativity ratings showed that the consistent condition generated the lowest level of creativity (M = 2.07, *SD* = 0.95), lower than both the baseline condition (M = 2.70, *SD* = 1.07, $t = 7.13$, $p = 0.000$, Cohen's $d = 0.62$) and the repetition break condition (M = 2.89, *SD* = 1.09, $t = 9.06$, $p = 0.000$, Cohen's $d = 0.80$). Although we didn't predict to see a significant difference across the repetition break condition and the baseline condition, results showed that while the difference was small in absolute magnitude (i.e., 0.19), it reached statistical significance level ($t = 2.02$, $p = 0.04$, Cohen's $d = 0.18$). These are overall effects of the structure condition; there were no reliable effects or interactions due to the particular targets or bases so we collapsed across them.

Analysis of perspective-change ratings showed a similar pattern, such that the consistent condition generated the lowest level of perspective-change (M = 1.80, *SD* = 1.12), lower than both the baseline condition (M = 2.45, *SD* = 1.20, $t = 5.43$, $p = 0.000$, Cohen's $d = 0.47$) and the repetition break condition (M = 2.50, *SD* = 1.33, $t = 6.82$, $p = 0.000$, Cohen's $d = 0.60$). There was no difference across the repetition break condition and the baseline condition ($t = 1.52$, $p = 0.13$, Cohen's $d = 0.13$)[1].

Figure 1 shows the ratings for similes in each of the four positions, and once again there were no effects or interactions due to the particular targets or bases. As we predicted, creativity and perspective-change ratings declined from position 1 to position 4 in the consistent condition. On the contrary, in the repetition break condition we observed a decline over the first three similes but a jump in the last one. Switching from the initial perspective to a different one restored the perceptions of creativity and perspective-change to a level comparable to that in the baseline condition.

Taken together, Study 3 provided evidence largely in support of our predictions that repeated exposure to the same perspective will result in reduced creativity perception, whereas breaking from one perspective to another one (i.e., a perspective-change) will lead to an increase in creativity perception to the baseline level. This is evidence in support of the general proposition that the experience of a perspective-change underlies creativity evaluation.

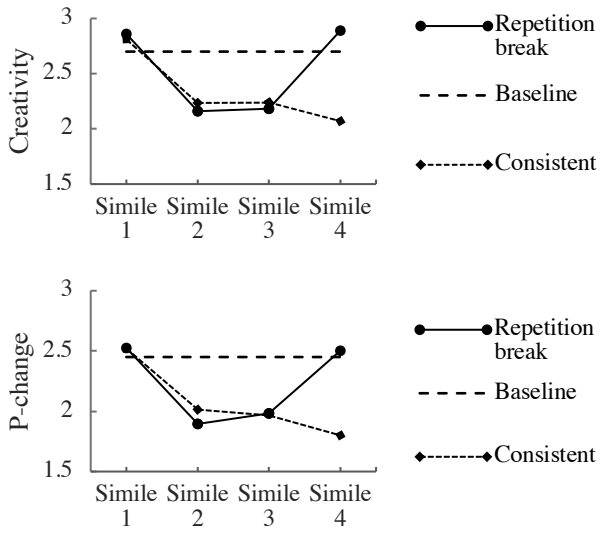

Figure 1: Results in Study 3

General Discussion

The proposal that some kind of change in perspective is involved in generating creativity has long drawn the attention of theorists, but there has been much less said about the process of evaluating creativity. We outlined and tested the beginnings of a perspective change account of creativity evaluation. Three studies found strong relationships between a simile prompting changes in perspective and evaluating the simile to be creative.

Critical to the account was specifying that an item, such as a simile, is likely to be experienced as creative if in the process of comprehending it people experienced a change in perspective. We followed existing research on changes in representation within the cognitive science literature, particularly work on analogy and comparison, to provide plausible specifications of what a change in perspective might involve and what might make a change more and less compelling. Other approaches could also be useful. Our intent was not to delve into accounts of mental representation

[1] Inclusion of the 14 participants who failed the attention check yielded marginally significant difference in perspective-change across the repetition break condition (M = 2.68, *SD* = 1.19) and the baseline condition (M = 2.51, *SD* = 1.20, $t = 1.15$, $p = 0.09$, Cohen's $d = 0.14$).

but rather to emphasize why doing so could advance research on creativity evaluations.

The current results offer initial support for the value in thinking about perspective change as a driver of creativity evaluations. Using both spontaneous (Study 1) and induced (Study 2) changes in perspective, we found consistent evidence that a simile is likely to be judged creative if it is experienced as a new way to interpret the target. Further, we also found (Study 3) that repeated use of the same perspective suppresses the experience of perspective change and thus reduces creativity perception. Taken together, these studies indicate that the process of forming an interpretation of an item, and the kind of interpretation we form, influences our evaluation of its creativity.

Focusing on the cognitive process of forming and changing perspectives opens a new area for research on creativity evaluation. Most work has focused on whether an item is novel and useful for a community or domain (e.g., Amabile, 1983, 1988, 1996; Cropley & Cropley, 2010; Oldham & Baer, 2012; Runco & Jaeger, 2012; Shalley, Zhou, & Oldham, 2004; Sternberg & Lubart, 1999; Woodman, Sawyer, & Griffin, 1993). The current work shifts the focus of creativity judgments from the product to the process—from the characteristics (i.e., novelty and usefulness) of the item to the work of making sense of the item and the perspective that results.

In emphasizing the forming and changing of perspectives, this work opens up new ways to think about the role of expertise and culture in shaping creativity evaluations. There might be expertise needed to appreciate an item as creative, as absent that expertise on might not change perspective or perceive the change to have much potential. There might be cultural assumptions that resonate or impede the change in perspective. These are cognitive issues, and they also lead to considerations around attitudes and values. Creativity evaluations are, after all, judgments about worth.

Developing an account of creativity evaluations resting on perspective change provides an opening. The considerable amount of research on knowledge and knowledge change in cognitive science is not always or even usually at the center of discussions about creativity. Yet it may hold significant potential to help advance such discussions. As researchers whose central task is innovation, we are aware of the imperfect evaluations generated by grant review panels, journals, and promotion review committees. It is clear that deepening our understanding of the creativity evaluation process is consequential. It is likely to be similarly consequential for all the other domains of innovation in our societies.

Abstract

Research has suggested that perceivers automatically categorize faces based on gender and race but gaps remain regarding whether effects emerge at encoding or recall and the extent to which they are reducible to perceptual similarities (since faces from the same category are generally more similar to each other). We address these limitations using change detection paradigms adapted from visual working memory literature where one face from an array of faces changes to a face from the same or a different gender or racial category. We show that individuals are considerably faster and more accurate to identify changes that cross a category boundary, even when controlling for a range of perceptual differences and subjective features of faces. Our results suggest that social category information is automatically encoded in visual working memory in a format that is not reducible to lower-level perceptual features.

The Effect for Category Learning on Recognition Memory: A Signal Detection Theory Analysis

Abstract

Previous studies have shown that category learning affects subsequent recognition memory. However, questions remain as to how category learning affects discriminability during recognition. In this three-stage study, we employed sets of simulated flowers with category- and non-category-inclusion features appearing with equal probabilities. In the learning stage, participants were asked to categorize flowers by identifying the category-inclusion feature. Next, in the studying stage, participants memorized a new set of flowers, a third of which belonged to the learned category. Finally, in the testing stage, participants received a recognition test with old and new flowers, some from the learned category, some from a not-learned category, some from both categories, and some from neither category. We applied hierarchical Bayesian signal detection theory models to recognition performance and found that prior category learning affected both discriminability as well as criterion bias. That is, people that learned the category well, exhibited improved discriminability and a shifted bias toward flowers from the learned relative to the not learned category.

Keywords: category learning; recognition memory; signal detection theory; Bayesian modeling

Introduction

Memory research has shown that prior learning experience affects recognition memory. It is often thought that prior learning is encoded into knowledge structures or *schemas* (Bartlett, 1932). In turn, schemas increase recognition of schema-inconsistent information compared to schema-consistent information, while also increasing false alarms to schema-consistent lures compared to schema-inconsistent lures. Because schema acquisition takes time and learning experiences vary among people, most recognition memory tasks have employed either within-subject designs for pre-acquired schemas (Graesser & Nakamura, 1982) or between-subject designs for individuals with different expertise (Castel et al, 2007). As such, traditional experimental designs do not easily allow manipulation of schema acquisition in a way that enables us to assess their effect on recognition memory performance.

A number of recent studies have unveiled strong connections between schematic and categorical knowledge, leading many researchers to postulate profound similarities in the cognitive processes underlying schematic and categorical learning (Sakamoto & Love, 2004). To contribute to the integration of schematic and categorical learning, and to further explore the effects of prior learning on recognition memory, De Brigard et al. (2017) recently employed a set of computer-generated stimuli (flowers) to explore how learning a novel category affects participants' recognition memory for items from the learned category relative to items from a category they did not learn. However, the studies reported by De Brigard et al. (2017) left several unanswered questions. In particular, the findings could not differentiate between discriminability changes for items from the learned category and a change in response bias because their experiments did not include foils of both learned and not-learned categories, and thus could not provide measures of discriminability and bias for all options. In addition, De Brigard et al.'s (2017) findings did not discriminate between those who learned best and those who learned least during the category-learning phase, potentially obscuring effects on discriminability in recognition memory.

To explore these issues, in the present study we used a modified version of De Brigard et al.'s (2017) paradigm in which flowers from learned and non-learned categories appeared in the learning and study phases with equal probability. Additionally, the current study included lures from both learned and not-learned categories during the recognition test. As such, we were able to implement full hierarchical Bayesian signal detection theory (SDT) models to data from all participants, as well as separate people by the strength of their learning. This modified experimental paradigm, and the SDT models with which the results are analyzed, enables us to further understand the effect of category learning on recognition memory.

Category Learning and Recognition Experiment

Participants

113 individuals participated via Amazon Mechanical Turk (https://www.mturk.com) for monetary compensation. All participants were from the United States and had at least 100 approved hits and overall hit rate $\geq$ 95%. Three participants were excluded because of failure to follow instructions or terminated the experiment in the middle, so data were analyzed with the remaining 110 individuals. All participants

were provided informed consent under a protocol approved by the Duke University IRB.

Materials

Stimulus consisted of MATLAB (2018b)-generated flowers from De Brigard et al. (2017). Flowers varied across five dimensions, with each dimension taking one of three possible values: number of petals (4, 6, or 8), color of petals (blue, green, or yellow), shape of center (circle, triangle, and square), color of center (orange, purple, or turquoise), and number of sepals (1, 2, or 3). Figure 1 illustrates three examples of flowers with different combinations of the features (see further details in De Brigard et al., 2017).

Procedure

We closely followed the procedure from the fourth experiment in De Brigard et al. (2017), with some modifications (see below). The experiment had three phases: learning, study, and test. At the beginning of each phase participants read the instructions for 90s.

Figure 1. Examples of MATALB-generated flowers. From left to right: 4 blue petals- orange circle center -1 sepal; 6 green petals- purple triangle center-2 sepals; and 8 yellow petals- blue square center-3 sepals. See more in De Brigard et al., 2017.

In the learning phase, participants were told they would see a flower on the screen and will have to determine whether or not it belonged to the species *avlonia*. Participants were told that avlonias differed from other flowers in one simple way (e.g., only avlonias have four petals), and their task was to find out what the simple way was. At the beginning of the learning phase, participants were informed of all five possible dimensions—number of petals, color of petals, etc.—across which flowers may vary and saw two example flowers for illustration. They then made binary choices "yes" or "no" on each trial to categorize each flower by pressing "y" or "n", respectively, and there were 54 trials in total. Immediately after their responses, feedback with the word "Correct" or "Incorrect" was displayed. Participants were ensured that they could guess at the beginning but eventually they would find out the simple way that made a flower an avlonia. Each participant was assigned to a category-inclusion feature consisting of one possible value from one of the five dimensions. Additionally, participants were also assigned a "Not-learned" category, defined by a value of a different dimension, of which participants were never informed or given feedback. Both of these assignments were counterbalanced across participants. In all phases of the experiment, all values of all stimulus features did not differ in their statistical properties, such that flowers having the learned feature (i.e., that were avlonias) appeared on one-third of the trials, while the other two-thirds of the trials included flowers displaying the other two values of the Learned category-inclusion feature. Likewise, one-third of the trials presented flowers in the Not-learned category, while the other two-thirds of the trials included flowers with the other two values of the Not-learned category-inclusion feature. Importantly, the category-inclusion features for the Learned and Not-learned categories were independent, such that one-ninth of all flowers were in both the Learned and the Not-learned categories (Both condition), two-ninths of all flowers were in the Learned category but not the Not-Learned category (Learned condition), two-ninths of all flowers were in the Not-learned category but not the Learned category (Not-learned condition), and four-ninths of all flowers were in neither the Learned nor the Not-learned category (Neither condition). Table 1 summarizes the distribution of values for the Learned and Not-Learned category-inclusion features.

In the study phase, participants were asked to memorize 18 flowers. Each flower was shown alone for 5s followed by a 1s blank. Of the 18 flowers, four were in the Learned category but not the Not-Learned category (Learned), four were in the Not-learned category but not the Learned category (Not-Learned), two were in both categories (Both), and eight were members of neither category (Neither). To incentivize memorization, participants were told that they would receive an extra bonus for remembering above 85% of the stimuli. None of these 18 flowers were presented during the learning phase (Table 1).

Finally, in the testing phase, participants were told that they would see 54 flowers, one on each trial, and that their task was to remember whether or not stimuli were shown before in the study phase by pressing "yes" or "no". Of the 54 flowers, 18 were *old*—i.e. were presented in the studying phase—while the remaining 36 were *new*. Of these new flowers, four were from the Learned category only, four were from the Not-learned category only, two were from Both, and eight were from Neither. Of note, these new flowers were not shown during the study phase. All flowers were presented randomly and each trial was self-paced.

In sum, there were four types of trials in these three phases. Table 1 illustrates some possible combinations of Learned and Not-learned features. For each subject, one-third of trials included the learned category inclusion feature, which was chosen randomly from the three possible values from one of the five dimensions. Orthogonally, one-third of the trials included a not-learned category inclusion feature, i.e., the value of a dimension that could define a category of which participants were not aware of. This not-learned category inclusion feature was chosen randomly from the values belonging to the remaining four dimensions different from the dimension with the learned category inclusion feature. Membership in the Learned and Not-learned categories was independent of one another.

Table 1: Examples of possible combinations of Learned and Not-learned feature. Each row indicates one possible combination for one participant. A_1, A_2 and A_3 indicate three

possible values (denoted by 1, 2, and 3) of one randomly selected dimension out of five dimensions (denoted by A, B, C, D, and E; here we use only A and B for illustration purpose) -- number of petals, color of petals, shape of center, color of center, and number of sepals. B_1, B_2 and B_3 indicate three possible values of another randomly selected dimension out of the remaining four dimensions. Both condition has learned category inclusion feature and not-learned category inclusion feature features, and Neither condition does not have learned category inclusion feature or not-learned category inclusion feature features. The number of trials shown in the table is for learning and testing phases only. The number of trials for each feature during the study phase is 2 (not shown).

Learned feature	Not-learned feature	Number of trials	Probabilities
A_1	B_1	6	1/9
A_1	B_2	6	1/9
A_1	B_3	6	1/9
A_2	B_1	6	1/9
A_2	B_2	6	1/9
A_2	B_3	6	1/9
A_3	B_1	6	1/9
A_3	B_2	6	1/9
A_3	B_3	6	1/9

Results

Learning. We measured the learning performance by calculating the percentage of correct responses in the learning phase (Figure 2). We found participants were, in general, able to detect the single feature that categorized avlonias. The overall accuracy rates for both stimuli during the last twenty trials were 82.3%. Note that because we do not inform participants of the feature in advance, they necessarily begin at 50% accuracy at the beginning of the learning phase.

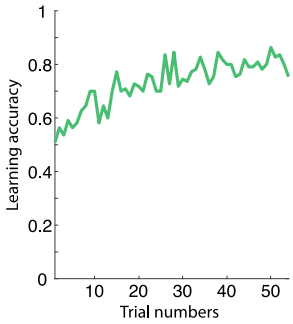

Figure 2. Learning performance during learning phase.

Memory Accuracy. We analyzed hit and false alarm (FA) rates separately for flowers of each type (Figure 3). To examine the learning effects for the four conditions (i.e., flowers that belong to the Learned category, Not-learned category, Both categories, Neither category), we implemented a two-way Bayesian repeated measures ANOVA. People exhibited increased hit rates for stimuli containing learned features included in Learned (M_{Hit} = 0.65, SD_{Hit} = 0.28) and Both (M_{Hit} = 0.70, SD_{Hit} = 0.35) conditions during the testing phase, but not toward stimuli not including those features in Not-learned (M_{Hit} = 0.56, SD_{Hit} = 0.28) and Neither (M_{Hit} = 0.58, SD_{Hit} = 0.22) conditions (Figure 2 and Table 2). We followed up with Bayesian paired samples t-tests which showed evidence supporting that hit rates in the Learned condition were higher than those in the Not-learned (BF_{10} = 2.15) and Neither conditions (BF_{10} = 1.70), but not in the Both condition (BF_{10} = 0.25) (See the scale of evidence in Jeffreys, 1998). Similarly, there was evidence indicating that hit rates for the Both condition were higher than those in the Not-learned (BF_{10} = 135.38) and Neither condition (BF_{10} = 30.56). Hit rates in the Not-learned condition were not different from the Neither condition (BF_{10} = 0.14). Also, there was weak evidence for FA rates in the Learned condition (M_{FA} = 0.59, SD_{FA} = 0.24) being higher than for the Not-learnsed (M_{FA} = 0.53, SD_{FA} = 0.23; BF_{10} = 0.43) and Neither condition (M_{FA} = 0.53, SD_{FA} = 0.19; BF_{10} = 0.61). We found no evidence for differences in other pairs of conditions (Both condition: M_{FA} = 0.57, SD_{FA} = 0.30).

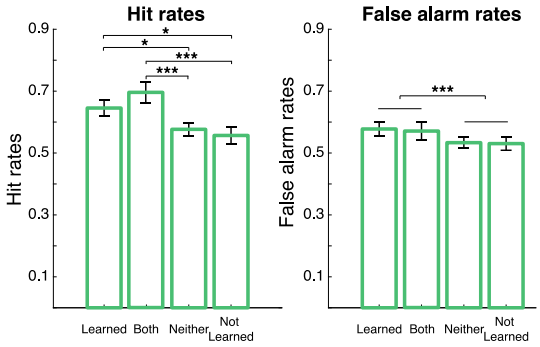

Figure 3. Hit and false alarm rates during testing phase. Left panel: hit rates. Right panel: false alarm rates. Stimulus with the category-inclusion value appeared in the Learned and Both conditions, and not in the Neither and Not-Learned conditions. * BF_{10} > 1, *** BF_{10} > 10.

Table 2: Bayesian repeated measures ANOVA

Rates	Best models	BF_{Model}	BF_{10}
Hit	Learned	11.02	6.93×10^3
False Alarm	Learned	13.93	32.35

BF: Bayes Factor.

We followed up with Bayesian paired samples t-tests which showed evidence supporting that hit rates in the Learned condition were higher than those in the Not-learned (BF_{10} = 2.15) and Neither conditions (BF_{10} = 1.70), but not in the Both condition (BF_{10} = 0.25) (See the scale of evidence in Jeffreys, 1998). Similarly, there was evidence indicating that hit rates for the Both condition were higher than those in the Not-learned (BF_{10} = 135.38) and Neither condition (BF_{10} = 30.56). Hit rates in the Not-learned condition were not different from the Neither condition (BF_{10} = 0.14). Also, there was weak evidence for FA rates in the Learned condition (M_{FA} = 0.59, SD_{FA} = 0.24) being higher than for the

Not-learned (M_{FA} = 0.53, SD_{FA} = 0.23; BF_{10} = 0.43) and Neither condition (M_{FA} = 0.53, SD_{FA} = 0.19; BF_{10} = 0.61). We found no evidence for differences in other pairs of conditions (Both condition: M_{FA} = 0.57, SD_{FA} = 0.30).

To explore the effect of category learning separately on response bias and discriminability (e.g., d'), we conducted a hierarchical Bayesian parameter estimation analysis within a SDT framework. To that end, we fit the accuracy data from three groups, i.e., (1) *all* participants (n = 110), (2) *experts*, i.e., participants whose accuracy of the last twenty learning trials was greater than or equal to 80% (n = 66), and (3) *non-experts*, i.e., participants whose accuracy of the last twenty learning trials was less than 80% (n = 44), to a SDT model in which the parameters were estimated using a hierarchical Bayesian approach (Lee, 2008). As such, two parameters of discriminability were estimated: (1) the sensitivity, d', that is measured by the distance between the signal and noise distributions indicating the discriminability of the signal trials from the noise trials; and (2) the criterion or bias, c, that is measured by the distance between the actual criterion used for responding and the unbiased criterion (i.e., $d'/2$).

The hierarchical model of SDT is able to partially pool individual parameters by taking into account group-level distributions, thus yielding more reliable estimates than non-hierarchical, full individual difference models. In this model, individual parameters are drawn from group-level (normal) distributions with estimated means and standard deviations. The model assumes that the estimated means quantify discriminability and criterion-bias for each of the four conditions, and precision quantifies the similarity among individual behavior.

In this implementation, our SDT model has four parameters per condition, reflecting properties of the average subject and how the subjects vary: mean discriminability μ_d, precision of discriminability τ_d, mean criterion μ_c, and precision of criterion τ_c. The prior on the mean discriminability was set to be very wide so as to be uninformative over the range of reasonable d' values (i.e., 0-4), with only a slight pull toward 0, consistent with previous research. Specifically, individual d_i was drawn from a normal distribution with mean and precision $\mu^d \sim N(0, 0.001)$ and $\tau^d \sim Gamma(0.001, 0.001)$, respectively. Individual c_i was then drawn from the normal distribution with two group-level parameters $\mu^c \sim N(0, 0.001)$ and $\tau^c \sim Gamma(0.001, 0.001)$. We implemented the hierarchical SDT model in JAGS, a sampler that utilizes a version of the BUGS programming language (Version 3.3.0) called from MATLAB (The MathWorks, Inc., Natick, Massachusetts, United States). Posterior distributions were approximated by 3 Monte Carlo Markov Chain methods with 5000 samples from each chain, after a burn-in of 1000 samples. Convergence of chains was evaluated with the $\hat{R}$ statistic.

We first estimated the mean sensitivity and mean criterion-bias for each condition by calculating the posterior distributions of hit and FA rates for all participants--group (1). We found that in the Learned condition, this was skewed toward 1 for both hit and false alarm rates, significantly above the other three conditions (Figure 4A), indicating the people had both more hits and more false alarms in this condition. Furthermore, for participants from group (2, expert-learners), hit and FA rates in both Learned and Both conditions were skewed toward 1, significantly above than those under Not-learned and Neither conditions (Figure 4B), whereas for participants from group (3, non-expert-learners) there were no differences (Figure 4C), suggesting the main effect was driven by the expert-learners.

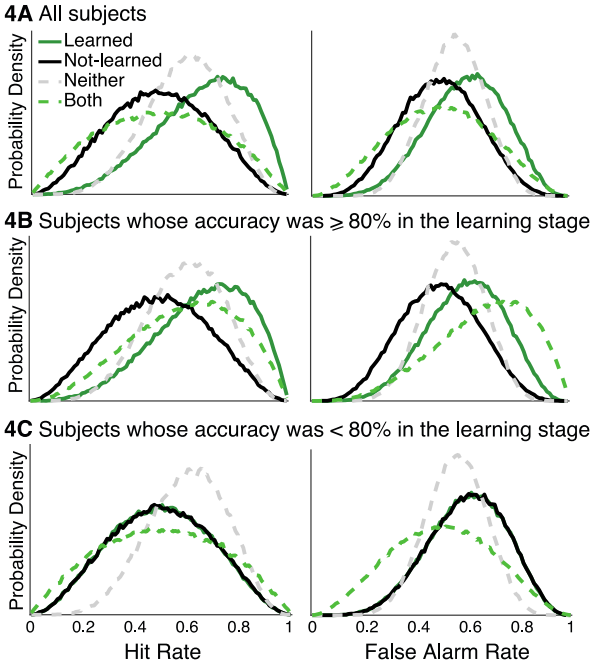

Figure 4. Posterior distribution of hit and FA rates for each of the four conditions.

To further investigate differences in discriminability/bias we performed a two-way Bayesian repeated measures ANOVA on estimated individual sensitivity and criterion-bias measures from each group. For individual sensitivity/d' of all subjects (1), we found main effects for Learned and Not-learned categories as well as their interaction, while for criterion-biases, we only found a main effect for the Learned category. For group (2, expert-learners), we found a significant main effect for the Learned category and a significant interaction between the Learned and Not-learned categories for both sensitivity and criterion-bias measures. For individual sensitivity of group (3, non-expert-learners), we found main effects for Learned and Not-learned categories as well as their interaction, while for criterion-biases we did not observe main effects of categories or their interaction (Table 3). These results indicate that participants who clearly excelled at learning the category during the learning stage—which we here operationalize as those participants whose accuracy for the last twenty trials was above 80%—were more sensitive to (i.e., increased discriminability/d') other flowers in this category and also and tended to say 'old' more often for these in general (i.e.,

Learned and Both conditions) compared to flowers not in the category (i.e., Not-learned and Neither conditions).

Follow-up Bayesian paired sample t-tests on sensitivity and criterion-bias for participants from group (1)—i.e. all participants—showed decisive evidence supporting that the sensitivity d_i for the Learned condition ($d_{Learned} = 0.18 \pm 0.05$) was higher than for the other three conditions ($d_{Not-learned} = 0.07 \pm 0.11$, $d_{Neither} = 0.12 \pm 0.03$, $d_{Both} = 0.38 \pm 0.18$), while the sensitivity d_i for Both was higher than the Not-learned and Neither conditions. As for the criterion-bias c_i, the evidence was also decisive supporting that the bias c_i for the Learned condition ($c_{Learned} = -0.32 \pm 0.38$) was lower than for the other three conditions ($c_{Not-learned} = -0.12 \pm 0.23$, $c_{Neither} = -0.15 \pm 0.34$, $c_{Both} = -0.39 \pm 0.28$), while the criterion-bias c_i for Both was lower than the Not-learned and Neither conditions. No strong evidence supported any differences between Not-learned and Neither conditions for both sensitivity d_i and bias c_i. (Table 4A).

For participants from group 2, this analysis revealed strong evidence that support differences in sensitivity d_i ($d_{Learned} = 0.290 \pm 0.048$, $d_{Not-learned} = 0.119 \pm 0.107$, $d_{Neither} = 0.126 \pm 0.084$, $d_{Both} = 0.339 \pm 0.083$) in almost all pairwise contrasts except Not-learned versus Neither. The same trend was also found in bias c_i ($c_{Learned} = -0.360 \pm 0.359$, $c_{Not-learned} = -0.073 \pm 0.262$, $c_{Neither} = -0.161 \pm 0.365$, and $c_{Both} = -0.543 \pm 0.191$). These results suggest that participants who mastered the learned features well in the learning stage were overall more sensitive to flowers with those features.

For participants from group 3, the sensitivity d_i of Learned condition ($d_{Learned} = 0.069 \pm 0.077$) was higher than those of Not-learned condition ($d_{Unlearned} = 0.003 \pm 0.080$) and lower than those of Both condition ($d_{Both} = 0.391 \pm 0.413$), but not different from those of Neither condition ($d_{Neither} = 0.096 \pm 0.019$). The sensitivity d_i of Both condition were higher than those of the other conditions, and the d_i of Not-learned condition were lower than those of Neither condition. As for biases c_i, the Bayesian paired t test did not show strong evidence supporting any differences between pairs of conditions ($c_{Learned} = -0.264 \pm 0.415$, $c_{Unlearned} = -0.183 \pm 0.155$, $c_{Neither} = -0.135 \pm 0.294$, and $c_{Both} = -0.132 \pm 0.176$), except moderate evidence suggesting differences in c_i between Learned and Neither conditions as well as Learned and Both conditions.

Figure 5 illustrates the joint posterior distributions of discriminability and bias for each condition. The main panel shows 15000 samples form the joint posterior of the mean μ^d and μ^c. The side panels show the marginal distribution for each of the group-level means. For all subjects, the group-level sensitivity d_i differed the most between Both and Not-learned conditions, and the group-level biases c_i were negative in Both and Learned conditions. That is, participants exhibited better sensitivity toward flowers with learned features and a tendency to overrespond "yes" in the recognition memory tasks (Figure 5A).

Table 3: Bayesian repeated measures ANOVA

Datasets	SDT parameters	Best models	BF_{Model}	BF_{10}
All subjects	d_i	Learned+Not-learned+Learned×Not-learned	5.39×10^{26}	1.43×10^{73}
	c_i	Learned	12.04	4.17×10^{13}
Experts	d_i	Learned+Not-learned+Learned× Not-learned	25.97	1.27×10^{51}
	c_i	Learned+Not-learned+Learned× Not-learned	884.46	1.27×10^{19}
Non-Experts	d_i	Learned+Not-learned+Learned× Not-learned	1.40×10^{8}	1.19×10^{13}
	c_i	Null model	4.26	1.00

d_i and c_i are individual sensitivity and biases estimated by the hierarchical Bayesian parameter estimation.

Table 4A: Bayesian paired sample t test for sensitivity and bias with all subjects. Numbers shown in the table indicate Bayes Factors.

Category comparison	Sensitivity d_i	Bias c_i
Learned vs. Not-learned	4.19×10^{12}	6.04×10^{4}
Learned vs. Neither	1.73×10^{23}	9.03×10^{2}
Learned vs. Both	8.77×10^{16}	0.773
Not-learned vs. Neither	3.24×10^{2}	0.183
Not-learned vs. Both	1.53×10^{27}	3.87×10^{10}
Neither vs. Both	8.72×10^{25}	2.03×10^{6}

Table 4B: Bayesian paired sample t test for sensitivity and bias with only subjects whose accuracy of the last twenty learning trials was above or equal to 80% (i.e., experts). Numbers shown in the table indicate Bayes Factors.

Category comparison	Sensitivity d_i	Bias c_i
Learned vs. Not-learned	2.37×10^{14}	1.75×10^{5}
Learned vs. Neither	7.29×10^{22}	1.48×10^{2}
Learned vs. Both	3.06×10^{2}	1.04×10^{3}
Not-learned vs. Neither	0.154	0.810
Not-learned vs. Both	8.56×10^{19}	3.25×10^{18}
Neither vs. Both	3.48×10^{19}	3.85×10^{8}

Table 4C: Bayesian paired sample t test for sensitivity and bias with only subjects whose accuracy of the last twenty learning trials was less than 80% (i.e., non-experts). Numbers shown in the table indicate Bayes Factors.

Category comparison	Sensitivity d_i	Bias c_i
Learned vs. Not-learned	1.15×10^{2}	0.411
Learned vs. Neither	1.35	1.63
Learned vs. Both	2.64×10^{3}	1.24
Not-learned vs. Neither	4.26×10^{6}	0.30
Not-learned vs. Both	4.92×10^{4}	0.41
Neither vs. Both	9.94×10^{2}	0.16

For subjects whose accuracy in the last twenty learning trials was greater than or equal to 80%, the difference in the group-level sensitivity d_i between Learned and Both conditions was less but the difference between Learned and Not-learned or Neither were greater. The group-level biases c_i in Learned and Both conditions were more negative than those in Not-learned and Neither conditions (Figure 5B). The results suggested that participants who learned category-relevant features well had better discriminability and stronger biases toward flowers with learned features. For subjects whose accuracy in the last twenty learning trials was less than 80%, the group-level sensitivity d_i differed the most between Both and Not-learned conditions, whereas the group-level biases c_i became closer to each other across conditions (Figure 5C). The results indicated that participants who did not learn the category-relevant features well had worse discriminability and little biases toward flowers with learned features.

Discussion

In this study we measured the extent to which learning novel categories influences recognition memory, and we focused on sensitivity and biases estimated in Bayesian SDT modeling. First, we corroborated previous findings that people exhibited biases toward stimuli within a learned category compared to stimuli not in the category, even when the relevant features are equally sampled during learning and study (De Brigard et al., 2017). That is, hit rates of stimuli with learned features (i.e., Learned and Both trials) were higher than stimuli with other values for that feature (i.e., Not-learned and Neither trials) (Figure 2). False alarm rates showed the same pattern. Going beyond this, we first fit full Bayesian SDT models and compared two measures of discriminability—sensitivity and criterion-bias—in four conditions. We observed that experts exhibited greater sensitivity and more negative criterion-bias than non-experts. We found greater discriminability for Learned and Both conditions than Not-learned and Neither conditions, which suggested people formed better memories of studied flowers with learned features. It is also clear that there was a response bias for Learned and Both conditions (Figure 4), indicating a tendency to overrespond "yes" (i.e., the flower was shown in the study stage) for these, in addition to the actual improved memory sensitivity. These results suggest that category learning affected recognition memory, improving discriminability as well as affecting response bias.

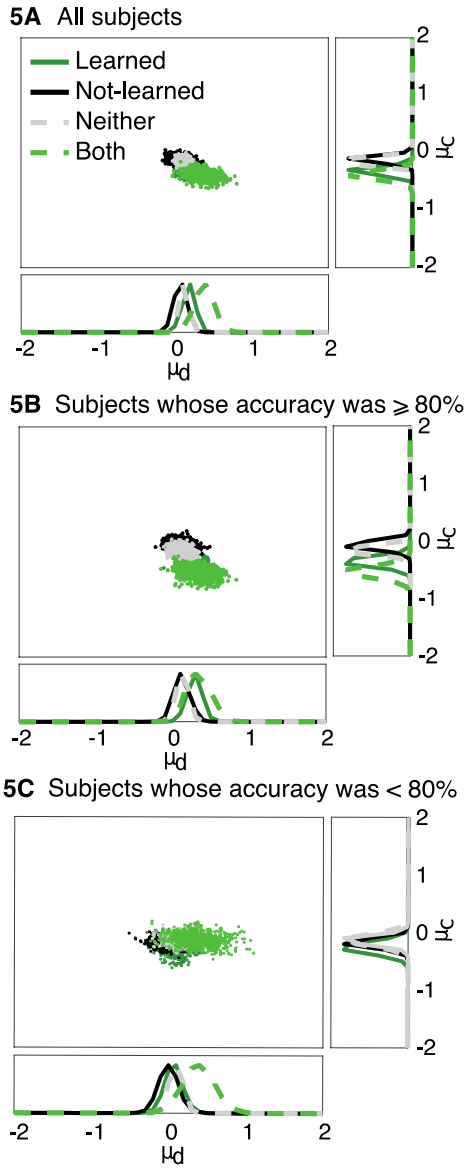

Figure 5: the joint distribution of mean discriminability d and mean bias c. The side panels show the corresponding marginal distribution. μ_d and μ_c are the group-level means of discriminability and criterion.

In the current study we employed a yes/no learning strategy to create new categories for novel stimuli and ask how they influence subsequent recognition memory. Our findings of the influence of category information on recognition memory are consistent with findings that show the influence of existing categories (Bae et al., 2015; Persaud & Hemmer, 2016) as well as newly learned episodic information about a category (Brady et al., 2018) on continuous recall measures. This suggests more insight into the influence of newly learned categories on memory looking at the effect of novel category learning on recognition memory employing

continuous measures. In addition, future studies may investigate whether different learning strategies may elicit the same biases. For example, supervised (i.e., with explicit guidance on category-inclusion criteria) and unsupervised (i.e., without explicit guidance), or active (i.e., trying to learn category-inclusion criteria with instant feedback) and passive (i.e., merely observing stimuli and their corresponding categories) learning processes may largely change biases toward stimuli with learned features.

It is worth noting that, in the current study, we used a somewhat arbitrary threshold to classify expert and non-expert learners. Future studies may apply Bayesian analyses to explore individual differences in learning and compare estimates of individual learning rates to individual recognition memory effects. This could provide a better characterization of the data rather than a binary division.

Previous studies have mainly focused on category learning and memory during the course of an experiment, but how these categories are acquired is also critical in this processing. In this study, we used a set of well controlled stimuli – computer simulated flowers – so that we can manipulate the degree of exposure of different features and reveal how the learning process affects recognition memory. In future work, it would be useful to adopt more naturalistic stimuli to examine the mechanisms of category learning in real world settings and how this varies as a function of context and with different age groups.

We applied SDT models to measure the effect of category learning on recognition memory. This effect may also be related to different learning procedures: for example, explicit reasoning and the nature and timing of feedback, which may or may not be directly associated with the learned feature only (Ashby & Maddox, 2005). Other categorization models such as the generalized context model (GCM, Nosofsky, 1986), the general recognition theory (GRT, Ashby & Townsend, 1986), or the deterministic exemplar model (DEM, Ashby & Maddox, 1993) will be worth exploring to make more refined quantitative accounts of the influence of category learning on recognition memory.

Finally, it is important to note that in the current study, participants were given binary choices in the testing stage (old/new). While this allowed us to apply signal detection models to probe the effect of category learning on recognition memory, to do so we needed to assume an equal variance signal detection model. Adopting a confidence scale and ROC analysis based on confidence rating data would provide a refined gauge of discriminability in the recognition memory task and allow us to measure the memory signal accurately, even in the case of unequal variance (as is common in recognition memory experiments). This would allow us to be more certain we had separately measured response bias and discriminability and address the nature of the memory signal more clearly (e.g., address whether unequal variance signal detection model, or a hybrid threshold and signal detection model is more applicable; Wixted, 2007). Broadly, however, our results show that participants discriminate more toward stimuli with learned features than those with not-learned features. These results contribute to our understanding of how prior category learning influences recognition memory.

Abstract

The present study investigated how younger and expert artists create artwork, paying special attention to the modification of conditions in the art-making process. Here, "process modification" is the means by which artists generate new artistic ideas/concepts by modifying elements of one's own previous artwork. To examine whether younger artists use such modifications in the same manner as experts, we interviewed 28 contemporary artists (including 14 experts). Results revealed that most of the younger artists modified their work unsystematically. Younger artists drastically changed the subject/motif, method, and concept for their new artwork. Experts, in contrast, actively used process modification to create a new technique and generated a new concept based on their creative vision.

Keywords: artistic creation; creative process; art-making process; process modification

Introduction

How do people create artwork and become experts in this domain? Are there differences in the cognitive processes underlying artistic creation between younger artists and experts? The present study investigated potential experienced-related differences in artistic creation by analyzing retrospective interviews with artists during the early and progressive stage of an artistic creation.

Artistic Creation as Problem-Solving

Artistic creation can be regarded as a creative problem-solving process (Simon, 1973). In such a process, people search for goals, tools, and ways to make art in ill-defined problem space(s). To do so, they need to explore new frames in a problem space or generate a new problem space itself (i.e., problem finding). In such cases, it is difficult to use algorism or well-known heuristics, because goals and methods are not known in advance. Therefore, exploration becomes an essential process in such an endeavor. This study tries to describe the detailed process of such explorations adopted by artists during their long-term artistic activities.

Cognitive Process of Art-Making

Several studies have been conducted on human creativity, especially within the artistic realm (e.g., Getzels & Csikszentmihalyi, 1976; Mace & Ward, 2002; Okada, Yokochi, Ishibashi, & Ueda, 2009; Patrick, 1937; Stokes, 2014). For instance, Getzels and Csikszentmihalyi (1976) and Mace and Ward (2002) emphasized the importance of the "problem-finding process" within artistic creativity. In particular, Getzels and Csikszentmihalyi (1976) studied art majors' constructions of still life drawings. Their results indicated that students whose drawings were evaluated as highly creative were more exploratory in their work both before and during their drawings (i.e., arranging still life objects or changing tools more frequently). The authors also observed that after graduating from art school, the students who participated more in problem-finding activities were more successful in their careers. Thus, problem-finding could be a key activity for quality artistic creation.

Mace and Ward (2002) conducted interviews with artists to identify how they generated ideas during creation process. The authors developed a process model of art-making with the following four steps: "Artwork conception," "Idea development," "Making artwork and idea development," and "Finishing the artwork." While the process model is helpful, Mace and Ward could only describe these four steps; they did not assess potential underlying mechanism for progressing through these steps.

Through the using of art historical biographies, Stokes (2014) analyzed the process of artistic creation as problem-solving activity, revealing that paired constraints play an important role. Constraints have been regarded as having the function of both promotion and inhibition (e.g., Simon, 1973). Applying this idea to the artistic creation process, Stokes argued that precluding a constraint on the creative process (e.g., realism) helps promote another aspect of the paired constraint (e.g., abstraction). Using this framework to describe the creation process of famous artists such as Mondrian, Klee, Monet, and Chuck Close, Stokes suggested that the creative process proceeds as a cascading cycle until a new artwork is created.

Recently, Okada and colleagues have conducted research on the medium-term or long-term creative process of art-making, including the process of making a series of artwork based on certain artistic styles or themes/concepts (Okada, Yokochi, Ishibashi, & Ueda, 2009; Takagi, Okada, & Yokochi, 2013, Takagi, Kawase, Yokochi, & Okada, 2015; Yokochi & Okada, 2006, 2007). Of specific focus is how an artistic theme/concept is formed in an artist's mind or how

sub-themes/sub-concepts are derived from the main theme/concept from a cognitive psychological perspective (Okada, Yokochi, Ishibashi, & Ueda, 2009; Yokochi & Okada, 2006, 2007).

Yokochi & Okada (2007) revealed that artists develop expertise through several phases over the years. For instance, artists often construct a main theme, "creative vision," after about 12 years of practice post-art school. Creative vision is a somewhat abstract theme/concept, such as "life and death," "viewing/seeing," and "relationship with others," and is formed through long-term practice. The authors claimed that creative vision guides the construction of an artwork series in a certain direction, giving the artwork the consistency as a common base. Based on this creative vision, an artist finds suitable motifs/subjects and generates new artistic methods and creative ideas.

Okada et al. (2009) investigated the creation process of art concepts focusing on "analogical modification," which refers to cognitive processes tasked with generating new artistic ideas/concepts by analogically modifying elements of the artists' previous artwork. The authors claimed that 1) patterns of art concept formation gradually change as artists accumulate experiences; 2) artists use their creative vision for analogical modification of their art-making process; and 3) analogical modification enables artists to generate various artwork series, which are mutually connected with each other under the same creative vision. Takagi et al. (2013) also discovered, through ten months of qualitative and quantitative analyses of interviews with an artist, that the artist generated a new art concept for a new series. Here, the artist modified his creative process in multiple ways, including the modification of perception and action. We refer to these modifications in art-making process, including analogical modification and modification of perception and action, as "process modification" throughout this paper.

For the present study, we investigated how artists form their goals, art concepts, and creative vision, as well as how they develop methods for creating artwork series, paying special attention to "process modification." In terms of the development of artistic creative expertise, a creative vision, which is formed through many years of creative activity and consists of long-term intentions or goals for creation, serves as a framework to guide the process of creation (Yokochi & Okada, 2007). Because of such a creative vision, experts' creative process would be substantially different from young ones. Therefore, we also examined similarities and differences between younger and expert artists in terms of this concept formation process.

Methods

Participants: We interviewed 28 Japanese contemporary artists, comprising 14 younger artists, "YNG" (including 7 art major graduate students; 7 women, age range = 20-30 years, mean age = 28.3 years, mean work experience = 8.64 years, *SD* = 4.19), and 14 expert artists, "EXP" (4 women, age range = 40-60 years, mean age = 44.9years, mean work experience = 23.14 years, *SD* = 7.84). These artists have created various art forms, including paintings, sculptures, installations, photographs, and so on. All artists have participated in solo or group exhibitions every year, especially the expert artists, who have exhibited their work worldwide (including the USA and Europe). Those who participated were recommended by their peers, and in the case of the graduate students, they were nominated by their advisers.

Procedure (Portfolio-interview): The present study was conducted from 2005 to 2018. Because each artist's whole body of work was large in size, we interviewed each artist individually several times, using a portfolio of his/her entire work, which we referred to as a "portfolio-interview." The average interview time was 8 hours for YNG and 10 hours for EXP. This difference in interview time was because experts had a longer career and created more artwork than did younger artists. The portfolio-interview was conducted in a quiet room, which was either an art studio, home, or our university office. All conversations were recorded with IC recorder and a video camera.

The portfolio-interview was conducted as follows; First, we asked artists to explain each of their artwork pieces (e.g., "when and how was the artworks made?" "What kind of materials was used?" and "What was the idea/concept for the artwork?"). Second, we asked artists to identify what aspects of their work were kept and which were changed from prior work (e.g., "What (element) was changed from previous work?" and "What was a new or additional idea of this artwork?"). Finally, after explaining all of their work by reflecting on their entire career, the artists were asked whether they had their main art concept/theme (i.e., creative vision); if so, they were asked to report when they had realized this vision (e.g., "What is your main art concept/theme?" "When did you recognize the theme?" and "When were the turning points in your own art career?"). Additionally, we conducted semi-structured interviews as follows to gather information on: 1) originality in making and evaluating artwork (e.g., "What do you think about originality in your artwork?" and "Do you think it is important to represent originality in your work?"), 2) general process of making art (e.g., "How long do you usually spend on making/thinking about your work each day?" and "When and how do new ideas come up?"), and 3) educational background and biography of the artists.

Analysis procedure (Analysis of the process modification type and developmental trajectory of creation):

We analyzed the words used by the artists during the portfolio-interview and the features of their artwork. The coding framework was both theory and data driven. The categories for process modification included the categories for analogical modification (Okada, et al., 2009), and were guided by related theories regarding creativity and education/expertise, such as exploration (Boden, 2004), and reflection (Schön, 1983; Zimmerman, 2006). Further, the categories were inductively derived from the transcripts of the portfolio interview data, using the KJ method, which consists of a set of systematic procedures that seek to derive

a common (affinity) feature of data and ideas (Kawakita, 1967).

First, we specified the "main art concept and related sub art concept," "method and related methodology," and "motif (subject)" of each of artwork, and identified how each was changed from previous artwork. Second, we refined the categories for analogical modification (Okada et al., 2009) reflected in the interview data and features of works. Finally, the categories for process modification included and defined eight codes reflected in the interview data (see Table 1).

The interview data and all photographs of artwork were organized and stored using the computer package, MAXQDA, which is designed to organize unstructured data in qualitative and quantitative analyses. We developed the categories of process modification, and coded the portfolio interview data with the help of MAXQDA.

Results and Discussion

Following analyses based on the process modification categories, we examined distinctions between YNG and EXP artists, particularly comparing *before* finding a creative vision, "EXP_before," and *after* finding a creative vision, "EXP_after." Besides, we assessed how the artists generated new art concepts and series after realizing their creative vision.

Group comparisons in process modification types

Table 2 shows the number of artists who used each type of process modification, and the mean number of times YNG and EXP used each type (before and after realizing their creative vision), and artists who had their creative vision, "AwCV" (before and after realizing their creative vision), respectively.

Table 2 shows that there is little difference between the number of types between YNG and EXP_before groups in terms of "Subject modification" (YNG 79% vs. EXP_before 93%), "Structure modification" (29% vs. 36%), and "Concept modification" (14% vs. 0%). Although there is a subtle difference in "Unsystematic change" (57% vs. 64%), which refers to changing the art subject/motif, methods, and concepts from prior work, YNG tended to use "Searching for suitable subjects and methods" (86% vs. 50%) and "Subject modification with reconsideration of artistic methods" (73% vs. 43%) more often than the EXP_before

Table 1. Types of process modifications and definitions

Reference Frame for Modification	Modification Type	Definition
None	Type 0 No modification	Reproducing a previous work
Idea	Type 1_1 Unsystematic change	Changing both a previous motif, method, and concept without any specific goal (or sub-goal) e.g., changing all based on a temporal (casual) idea
	Type 1_2 Searching for suitable subjects and methods based on prior artistic ideas	Changing both motifs/subjects and methods to make artwork more suitable for the prior idea e.g., searching motifs and methods based on the idea for prior work
Methodology	Type 2_1 Quantitative modification	Changing size or material of previous work without changing subjects and concepts (becoming bigger/smaller size than previous work) e.g., changing the size of Mobiles
	Type 2_2 Subject modification	Changing motifs/subjects to make a new artwork by using the same methodology as for prior artwork e.g., applying Mobiles to various motifs
	Type 2_3 Subject modification with reconsideration of methods	Reconsidering the methodology while making new artwork by changing subjects and realizing availability/possibility of the methodology e.g., reconsidering availability of Mobiles methodology
Sub or Main art concept	Type 3 Structure modification	Generating a new methodology, in line with a sub art concept or a main art concept of artwork series e.g., generating "Mobiles" as a new methodology of sculpture
Creative vision	Type 4 Concept modification	Forming a main art concept and generating sub-concept (artwork series) according to a creative vision e.g., generating "Constellations" series based on Calder's main theme "Universe"

artists. Moreover, artists using "Subject modification" ended up in a stalemate/dead-end (21% vs. 43%).

Comparing the YNG and EXP_after conditions, although both used "Subject modification" (YNG 79% vs. EXP_after 100%), YNG tended to use more "Unsystematic change" (57% vs. 27%), "Searching for suitable subjects and methods" (86% vs. 8%). In contrast, EXP_after tended to use more "Structure modification" (29% vs. 73%) and "Concept modification" (14% vs. 82%). Furthermore, the number of EXP_after artists who experienced dead-end was reduced (21% vs. 9%).

A two-way factorial analysis of variance (mixed plan, factor 1: artists (3 levels, YNG, EXP_before, and EXP_after) × factor 2: types of process modification (8 levels)) was conducted on the number of times each artist group used the various process modification types. First, Mauchly's test of sphericity revealed a sphericity violation ($p < .01$); hence, a Greenhouse-Geisser correction was used to adjust the p-values and degrees of freedom for interaction and main effects; p-values for simple main effects and multiple comparisons were determined based on Benjamini and Hochberg (1995).

The results revealed a significant interaction, F (6.48, 116.61) = 2.868, p = .0372, η^2 = .121, and a significant simple main effect of factor 1 at "Searching for suitable subjects and methods" and "Concept modification" (F (2, 36) = 6.384, p = .0169, η^2 = .262; F (2, 36) = 4.733, p = .0449, η^2 = .208, respectively). YNG used more "Searching for suitable subjects and methods" than EXP_after (p = .0032); in contrast EXP_after used more "Concept modification" than YNG and EXP_before (p = .0022, p = .0218, respectively).

The results indicate that artists in their early careers changed their artwork unsystematically and searched for suitable subjects and methods based on their previous ideas/concepts. Unsystematic refers to taking "a big jump" in creation, whereby it is difficult to identify commonality between new and previous artwork. Seeking suitable subjects and methods, however, is a means by which artists make more suitable artwork while keeping a prior art idea/concept. In fact, after enacting unsystematic changes, 36% (YGN 18%) of the artists searched for suitable subjects and methods. This suggests that the artists generated sub goals within their art-making process to find appropriate methods and motifs after taking "a big leap" in their creative activity.

Comparison in process modification types within AwCV group

To examine differences among usage types before and after

Table 2. - The number of artists using each type of process modification and the mean number of times each process was used

	YNG (n=14)		EXP _before vision (n=14)		EXP _after vision (n=11)		AwCV_before vision (n=14)		AwCV_after vision (n=14)

finding a creative vision, we focused on AwCV (artists with creative vision) and compared the number of artists using each type of process modification from before to after realizing this vision (see Table 3). McNemar's test was used for the matrix. The results indicate that the number of artists using "Concept modification" increased significantly after finding a creative vision (Holm's adjusted $p = .008$).

Next, we summed the number of times artists used each type of process modification before and after finding their creative vision and then conducted a two-way factorial analysis of variance (within-subjects, factor 1: types of process modification (8 levels) × factor 2: before and after finding creative vision (2 levels)). Mauchly's test of sphericity revealed a sphericity violation ($p < .01$). Therefore, the Greenhouse-Geisser correction and Benjamini-Hochberg adjustment were employed.

The results indicated a significant interaction, F (2.06, 26.77) = 3.902, $p = .0315$, $\eta^2 = .231$, and a significant simple main effect of types of process modification before and after finding a creative vision (respectively, F (2.58, 33.61)= 7.036, $p = .0014$, $\eta^2 = .351$; F (1.67, 21.73)= 5.048, $p = .0201$, $\eta^2 = .280$). AwCV before finding a creative vision used more "Unsystematic change" and "Searching for suitable subjects and methods" than after finding a vision. Conversely, AwCV after finding a vision used more "Concept modification" than before (respectively, F (1, 13)= 6.421, $p = .0249$, $\eta^2 = .331$; F (1, 13)= 4.924, $p = .0449$, $\eta^2 = .275$; F (1, 13)= 5.192, $p = .0402$, $\eta^2 = .285$). Additionally, "Subject modification" was used more frequently than all of other types of process modification before realizing a creative vision ($p < .05$), and more frequently than "Quantitative modification," "Unsystematic change," "Searching for suitable subjects and methods," and "Subject modification with reconsideration of artistic methods" after realizing a creative vision ($p < .05$).

These results suggest that artists who have not yet found their creative vision tended to change their artwork unsystematic or search for suitable subjects and methods to produce satisfactory work. After finding a creative vision, the artists typically generate new ideas/concepts and are productive based on this vision. For example, Figure 1 shows the developmental trajectory of EXP_SG, who is one of our expert artists. He realized his creative vision on "How to See" eight years after beginning his career as a contemporary artist. During his first artwork series, called "Inside Outside," the size of artwork became increasingly large; thus the series reached a deadlock. Because of his creative vision, he was able to generate new art concept, called "Institute of Intimate Museums (IIM)", which aims to encourage viewers/visitors of his work to create their own private museums in spaghetti boxes. This "IIM" concept has helped him develop many series, referred to as "museums in …" (e.g., windowed envelopes, garments, and toy boxes). Additionally, he generated new related ideas, including "Director in museum," "Viewer in museum," and so on. Other artists showed a similar pattern of development. We calculated z-scores on the mean number of artwork series before and after finding a creative vision (before: 14.69 vs. after: 23.39). This result suggests that the number of series increased after artists found their creative vision.

General Discussion

Several features of younger artists and experts (or artists before and after finding a creative vision) can be reviewed in terms of art-making process, specifically in terms of how artists engaged in process modification.

Overall, the results suggest that younger artists and artists *before* finding a creative vision create successful work through the following processes:

1) Using the same process modification, such as "Subject modification," as experts.

2) Using different types of process modification from experts, including "Unsystematic change" and "Searching

Table 3. Number of artists (AwCV) using each type of process modification before and after finding a creative vision

Type 0 No modification		After vision: Absence	After vision: Presence
Before vision	Absence	14	0
	Presence	0	0

Type 1_1 Unsystematic		Absence	Presence
Before vision	Absence	2	2
	Presence	9	1

for suitable subjects and methods."

Conversely, expert artists and artists *after* finding a creative vision create their work by:

3) Using "Concept modification" based on their creative vision.

4) Generating new art concepts and producing more artwork series than before finding a creative vision.

Half of the younger artists and artists in the early career stage tend to use Unsystematic change, which refers to changing the art subjects, methods, and concepts while creating artwork. As these artists are yet to clearly realize their superordinate concepts (or main theme/creative vision), they are unable to use Structure and Concept modification effectively. These younger artists, however, make new artwork while seeking suitable subjects and methods, which are based on concepts from prior work. This helps the younger artists form (or recognize) their own art-making theme.

After realizing a creative vision, artists create their work by implementing Structure and Concept modification. A creative vision, which is formed through many years of activity and consists of long-term intentions or goals for creation, plays a vital role in guiding the use of process modification. Thus, artists who have found their creative vision are able to work more productively and creatively.

Our results are consistent with the claim that artistic creation does not derive from "irrational and random thoughts/ideas" in creative writing (e.g., Oatley & Djikic, 2017), while several researchers claim that creativity depends on blind variation and random retention (e.g., Campbell, 1960). Creative writing studies indicate that writers continue to explore the same theme (or related themes) in their literary work (e.g., Patrick, 1937; Oatley & Djikic, 2017). Although previous studies described the exploration in the creation of poetry, literature, and fine art (e.g., Boden, 2010), they have not revealed how the exploration occurs or what kind of exploration contributes to longitudinal creative work.

Regarding these questions, using in-depth analysis of dancers' practice, Shimizu and Okada (2018) revealed that expert breakdancers engaged in "exploratory practice" to generate new and original skills. They claimed that "The dancers practiced with multiple goals, that is, not only to improve the quality of the skills but also to develop original and flexible skills that fit well into a performance by varying aspects of domain skills and by combining those domain skills with other domain skills" (Shimizu & Okada, 2018, p. 2392).

Artistic creation is also a process of exploring for a theme, concept, method, and motif to achieve one's goal as an artist. The present study reveals extensive explorations in artistic creation via process modification. A creative vision guides artists' creation and enables them to give consistency to their work. The formation of a creative vision seems to correlate with reconsiderations of the methods, subjects, and ideas for artwork series while reflecting on art-making processes and experiences. Thus, the process modification framework is useful when analyzing the details of the development of artwork series and creative expertise.

Preschool children's understanding of polite requests

Erica J. Yoon and **Michael C. Frank**
{ejyoon, mcfrank} @stanford.edu
Department of Psychology, Stanford University

Abstract

As adults, we use polite speech on a daily basis. What do children understand about polite speech? Looking at children's polite speech comprehension can help examine children's pragmatic understanding more generally, and can be informative for caregivers who want to teach children what it means to be polite. Even though children start to produce polite speech from early on, there is little known about whether they understand intentions behind polite language. Here we show that by 3 years, English-speaking preschool children understand that it is more polite and nicer (and less rude and mean) to use politeness markers such as "please" when making requests, and by 4 years, they understand that the use of these politeness markers indicates that the speaker is more socially likeable and is more likely to gain compliance from their conversational partners. This work can help lay the foundation for future work on children's understanding of polite speech and pragmatic development more generally.

Keywords: Politeness, pragmatic development, online experiment

Introduction

We use and hear polite speech on a daily basis: polite utterances range from simple words of apology ("sorry") or gratitude ("thanks") to compliments ("I love your dress!") and requests ("Can you please open the window?"). Yet polite utterances are seemingly inefficient and even misinformative: speakers say "Can you please ..." when it should suffice to say, "Open the window." These facts are a mystery for frameworks which describe communication in terms of efficient information transfer (e.g., Buhler, 1934; Goodman & Stuhlmuller, 2013; Shannon, 1948): If language is a tool for transferring information, speakers should be as efficient as possible in their communication to prioritize informativity. Nonetheless, everyday politeness is ubiquitous in everyday language use, and adults tend to use strategies to be polite even while arguing (Holtgraves, 1997).

So why do people speak politely? Linguistic theories assume that people's utterance choices are motivated by social concerns, framed as either maxims (Leech, 1983), social norms (Ide, 1989), or listener's and/or speaker's public identity (*face*; Brown & Levinson, 1987). For example, Brown & Levinson (1987)'s theory predicts that if a speaker's intended meaning contains a threat to the listener's face or self-image, the speaker's utterance will be less direct and less informative. For example, if a speaker considered that saying "Open the window" will give the impression that she is in a position to give orders to the listener, she could instead say "Can you please open the window?", using a more indirect form of request to give the other person a sense of autonomy or freedom from imposition (Clark & Schunk, 1980). Thus, while it may hinder the goal of efficient information transfer, using polite speech can help the speaker save the listener's face while simultaneously communicating her own positive social goals (Yoon, Tessler, Goodman, & Frank, 2017).

Do children speak politely, and if so, what do they understand about polite speech? Previous research shows that children begin producing polite speech early on; They produce "please" at 2.5 years (Read & Cherry, 1978), and request forms increase in their variety and frequency with age (Bates, 1976; Bates & Silvern, 1977; Bock & Hornsby, 1981; Ervin-Tripp, 1982; Nippold, Leonard, & Anastopoulos, 1982). Young children learn to produce different forms of requests depending on context: For example, by three years children are able to vary their utterances based on whether they are instructed to "tell" versus "ask" an addressee to given them a puzzle piece (Bock & Hornsby, 1981). And even at two years, children are able to modify their requests to make them more polite ("ask in the nicest way possible"; Bates & Silvern, 1977). Hence, children's production of polite speech seems to parallel adult speakers' desires to produce utterances with appropriate levels of face-saving.

While children appear to produce polite speech from an early age, less is known about whether they *understand* polite speech. Examining children's comprehension of polite speech is important for a number of reasons. First, children's polite speech understanding can reveal their inferential abilities underlying more general pragmatic understanding: going beyond what was literally said to infer what was intended. For example, children need to understand that, in saying "can you open the window?" the speaker does not literally question the listener's ability to open the window but rather wants to make a polite request. Thus, understanding what children comprehend about polite speech can help see how children are able to infer speaker's intentions behind utterances.

Second, understanding polite speech can have practical implications for education, as caregivers often care about teaching their children to be more polite. Indeed, from very early on, parents teach children to follow normative rituals to say "please", "thank you", "hello" and "good-bye" (Gleason, Perlmann, & Greif, 1984). It can be enlightening to know

whether and when children understand positive implications of following these norms.

Third, examining children's *comprehension* of polite speech as compared to their *production* is meaningful, in that children's comprehension can reveal more abstract representations and inferences about language than their productivity (e.g., Fisher, 2002): Children's ability to say "please" early on does not necessarily indicate that they understand saying "please" is more polite, nicer and socially apt, as children may simply obey or imitate what their caregivers tell them to say without understanding its meaning.

Research on children's comprehension of polite speech has received less focus than research on their production of polite speech. Moreover, the few studies that did examine children's understanding of polite speech have been largely inconclusive. Though there was some initial evidence to suggest that producing a request with "please" is judged to be polite by three years of age (Bates, 1976; Bates & Silvern, 1977), in a later study, the judgment of "please" as being polite was only replicated starting at five years of age, but not younger (Nippold et al., 1982). These initial studies also lacked statistical tests to assess each age group's performance, and did not systematically manipulate cues other than linguistic markers (e.g., prosody or facial expressions).

In addition to children's recognition of politeness markers, there are also many open questions about their abilities to recognize the intentions underlying polite speech. For example, do children know that the word "polite" should be associated with politeness rules people abide by (e.g., saying "please")? Relatedly, do children recognize polite speech as being positively valenced, such that they think it is better and nicer to say polite things? Do children understand the social implications of speaking politely? For example, polite people may be more likely to get their wishes granted ("I will pour him more water because he was nice") and may be better social play partners compared to those who are impolite. Finally, what cues to politeness do children recognize? Do they recognize linguistic politeness markers such as "please," or "can you," or both? Or do they rely on prosodic cues that make utterances sound more respectful, or on facial expressions that make a person look kind?

In this current work, we sought to answer these questions, and test what 2- to 4-year-old children understand about requests using politeness markers. Across three experiments, we presented stories about speakers who decided to speak politely (e.g., "Please pour me more water") or impolitely ("Pour me more water") and asked child participants to make judgments between the two speakers. We examined in each experiment whether: (1) children are able to reason about speakers using polite speech as being relatively more "polite" and "nice" and less "rude" or "mean" than speakers not using polite speech; (2) they can reason about social implications of using polite speech (e.g., politeness as a sign of a nice play partner, or greater likelihood of compliance from the addressee); and (3) they show improvement with age for these lines of reasoning. We also examined whether children need additional cues to politeness such as facial expressions (Expt 1) or prosodic cues (Expt 2), or they can make use of linguistic politeness markers alone (Expt 3) to make appropriate inferences about speakers.

Experiment 1

In Experiment 1, we tested whether 3- to 4-year-old children were able to understand the implications of using simple politeness markers, based on linguistic cues of interest (whether the speaker says "please," "can you") and other cues (facial expressions and prosodic cues) that make polite speech more salient and naturalistic.

Methods

Participants 3-year-old ($n = 20$; 12 F, M_{age} = 3.61 years, SD_{age} = 0.22) and 4-year-old children ($n = 18$; 6 F, M_{age} = 4.38 years, SD_{age} = 0.25) were recruited from a local preschool. An additional 3 children were tested but excluded due to failure on the practice questions ($n = 2$) or completion of fewer than half of the test trials ($n = 1$).

Stimuli and design We designed a picture book (see Figure 1) with twelve stories in which a protagonist is approached by two speakers, one of whom makes a request by producing an utterance with a politeness marker (e.g., "Please pour me more water"), and the other produces an utterance without ("Pour me more water"). There were three types of politeness marker that could be used: "please" (as in "Please pour me more water"), "can you" ("Can you pour me more water"), and "can you please" ("Can you please pour me more water").

We designed six question types to ask participants following the presentation of the stories: four *speaker attribute* questions (*polite*: "Which one was more polite?"; *rude*: "Which one was more rude?"; *nice*: "Which one was nicer?"; *mean*: "Which one was meaner?") and two *social implication* questions (*play partner*: "Which one would you rather play with?"; *compliance*: "Which one will [get what they want]?"). Each participant would be asked one of the four speaker attribute questions, followed by one of the two social implication questions.

In Experiment 1, all utterances were produced live by the experimeter, with appropriate proodic cues and facial expressions for each request: Utterances with politeness markers were produced by kind voice and facial expression, whereas utterances lacking politeness marker were produced with angry voice and facial cues.

Procedure The experimenter presented to the child a storybook with a total of thirteen stories about different characters. In the *practice* phase, the child heard a story with one clearly mean character (*Drew kicked Carol*) and one clearly nice character (*Graham gave Carol a gift*). After a reminder of what each character did, the experimenter asked the participant: *Which one was being meaner?* and *Which one was being nicer?* If the child answered the question wrong the first

Figure 1: Example story.

time, the experimenter read the story one more time, saying, "Let's think about the story one more time." Only children who correctly answered both questions in the first or second attempt were included in the analyses.

In the *test* phase, the child heard twelve stories, in each of which they saw one speaker who decided to speak politely (*Jean wanted more water in her cup. Jean said to Fred, "Please pour me more water"*) and another speaker who spoke impolitely (*Suzy also wanted more water in her cup. Suzy said to Fred, "Pour me more water."*). After a reminder about what each speaker said, the child was asked a total of two questions. For the first question, the experimenter asked one out of four possible questions for speaker attribute: "Which one was being more polite [more rude/nicer/meaner]?" For the second, social implication question, the experimenter either asked about play partner (*Which one would you rather play with?*) or likelihood of compliance (e.g., *Which one will Fred give water to?*). The order of story types and question types was counterbalanced.

Results and Discussion

We looked at the proportion of correct responses to various questions comparing speakers who used a politeness marker and spoke kindly, and speakers who did not use a politeness marker and spoke meanly (Figure 2, top row). A mixed-effects logistic regression predicting accuracy based on age, question type and politeness marker type[1] showed there was an improvement with age ($\beta = 0.2$, $p = .026$). The regression model also revealed that children seemed to find some question types easier than others: Responses to *nice* and *mean* questions were more accurate than to *polite* and *rude* questions ($\beta = 0.8$, $p = .002$), whereas social implication questions (*play partner* and *compliance*) were overall more difficult compared to speaker attribute questions (*polite*, *rude*, *nice*, and *mean*; $\beta = -0.33$, $p = .006$).

[1]for Experiments 1 and 2, we use this model structure with a maximal random effect structure that converges: `accuracy ~ age x question type x politeness marker type + (1 | item)`, where age is continuous, centered and scaled. All categorical variables were deviation coded, with specified contrasts of interest for the question type. Significance was calculated using the standard normal approximation to the t distribution (Barr, Levy, Scheepers, & Tily, 2013).

Looking more closely at responses for each of the question types, children from both age groups tended to accurately answer the *polite*, *nice*, *mean*, *rude*, and *play partner* questions overall (3-year-olds' mean accuracy range: 0.58 - 0.88; 4-year-olds' mean accuracy range: 0.68 - 0.9), indicating correctly that the speaker who used a politeness marker was more polite and nicer, and less mean and rude, and was likely a better play partner. For the *compliance* question, 4-year-olds overall answered correctly that the speaker who used politeness marker will likely get what they want from the listener ($M_{4y} = 0.75$, $p < .01$), but 3-year-olds did not perform above chance ($M_{3y} = 0.58$). As for the different politeness marker types, both age groups overall tended to give correct answers based on all three markers, but especially "can you please" (3-year-olds: $M_{please} = 0.66$, $M_{canyou} = 0.72$, $M_{canyouplease} = 0.74$; 4-year-olds: $M_{please} = 0.73$, $M_{canyou} = 0.77$, $M_{canyouplease} = 0.84$).

In sum, in this first experiment, we saw preliminary evidence that children pay attention to some cues to politeness and are able to use these cues to infer whether speakers are relatively polite, rude, nice or mean, and whether speakers are good play partners and are likely to get what they wanted from their addressees. 4-year-olds answered questions accurately more often compared to 3-year-olds, especially for the question about addressee's compliance with the speaker's request. In general, however, both age groups tended to be accurate when all the possible cues were used to signal that one speaker was polite (used "can you please", spoke with a kind tone and face) and the other speaker wasn't (did not use a politeness marker, spoke with an angry tone and face).

There were a number of remaining issues from Experiment 1. Children may not have used the linguistic politeness markers (e.g., "please") per se, and rather prosodic and facial cues that accompany these markers. That is, children may have relied on the speaker's kind voice and face rather than their use of "please" to evaluate their niceness or likeability as a play partner. Similarly, greater accuracy for some questions over others (e.g., *nice* > *polite*) may have been due to greater association between some of the words and prosodic and facial cues (e.g., a kind face may be seen to signal niceness more than politeness), not due to greater understanding for those words or concepts. Another concern is that the ex-

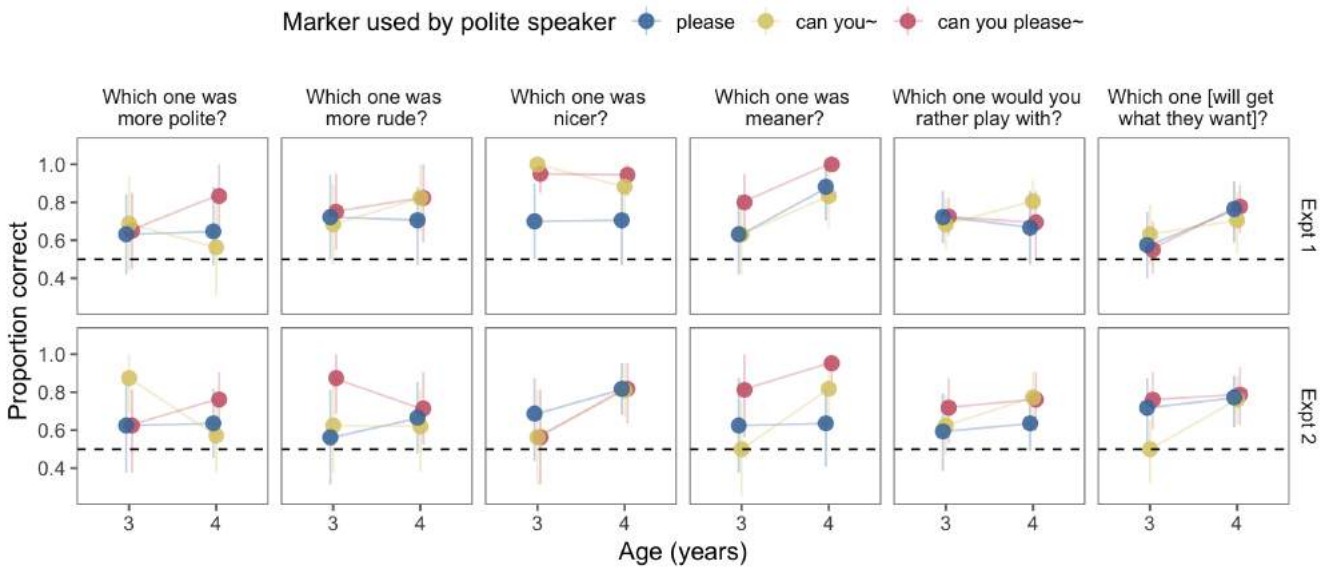

Figure 2: Experiment 1 and 2 results. Proportion of correct responses to questions comparing between a speaker who used a politeness marker (where blue indicates "please", yellow "can you", and red "can you please") versus a speaker who did not. Data are binned into one-year age groups. Each row represents data from a different Experiment. Columns represent different questions asked. Dashed line represents chance level at 50% (i.e., if participant were guessing at random).

perimenter was aware of the manipulations (i.e., they knew which speaker was supposed to be "polite") and thus could have affected the presentation of these speakers in ways that are not consistent across all participants. In our next two experiments, we sought to remove these potential confounds.

Experiment 2

In Experiment 1, we saw initial evidence that children can use some combinations of linguistic, prosodic, and facial cues to politeness. In Experiment 2, we examined whether children can make similar judgments using linguistic and prosodic cues only, without facial expressions. For this, we conducted a preregistered experiment where we used prerecorded voiceovers to present speaker utterances, so that (1) we could look at children's judgments based on linguistic markers and prosodic cues only, and (2) we could remove the role of the experimenter in presentation of these utterances.

Methods

Participants 3-year-old (n = 16; 8 F, M_{age} = 3.56 years, SD_{age} = 0.29) and 4-year-old children (n = 22; 13 F, M_{age} = 4.5 years, SD_{age} = 0.32) were recruited from a local preschool. An additional 5 children were tested but excluded due to failure on the practice questions.

Stimuli and design The design was identical to Experiment 1. Stimuli were the same as Experiment 1 except two changes: (1) Instead of a picture book, we presented the stories on a tablet; (2) the speakers' utterances were now presented as recorded voiceovers. The voiceovers were recorded by native English speakers, and contained prosodic cues that matched the presence/absence of a politeness marker (e.g., the speakers were instructed to record "Please pour me more water" with a "kind voice"" and "pour me more water" with an "angry voice").

Procedure The procedure was identical to Experiment 1, except for the following change: The participants now had to tap on a speaker on tablet in order either to hear them speak, or to choose an answer to the questions asked.

Results and Discussion

Overall we saw similar patterns of results in Experiment 2 (Figure 2, bottom row) compared to Exp. 1. A mixed-effects logistic regression predicting accuracy based on age, question type and politeness marker type showed that accuracy improved with age (β = 0.25, p = .002), and children made accurate judgments more often when the politeness marker was "can you please" than when the marker was "please" or "can you" (β = 0.33, p = .019). There was no main effect of question type, but there was an interaction between age and question type such that performance for *nice* and *mean* questions saw greater improvement with age than for *polite* and *rude* questions (β = 0.57, p = .011).

For children's responses to different question types, 3-year-olds' accuracy did not differ from chance level for *nice*, *mean*, and *play partner* questions, but their means numerically exceeded 50% for all question types, and 4-year-olds accurately answered questions of all types (3-year-olds' mean accuracy range: 0.6 - 0.88; 4-year-olds' mean accuracy range: 0.66 - 0.9). For politeness marker types, 3-year-olds' performance did not differ from chance for "please" and "can you", but

both age groups tended to answer questions about different politeness markers accurately overall (3-year-olds: M_{please} = 0.63, M_{canyou} = 0.61, $M_{canyouplease}$ = 0.72; 4-year-olds: M_{please} = 0.7, M_{canyou} = 0.72, $M_{canyouplease}$ = 0.8).

In sum, across Experiments 1 and 2, we saw that children tend to make accurate judgments about speakers given their use of politeness markers, especially "can you please," together with prosodic cues, and children get better with age in their use of politeness cues to respond to questions about speaker attributes and social implications.

Experiment 3

We conducted a third, preregistered experiment to see whether children are able to evaluate speakers based on linguistic markers only, without any other supporting cues such as prosodic cues or facial expressions.

Methods

Participants We recruited two samples of participants: one from the same local nursery school as Experiments 1 and 2, and the other from Lookit (`https://lookit.mit.edu/`), an online platform for child research participation, in which parents and their children can participate together. The nursery school sample consisted of 3-year-old ($n = 24$; 11 F, M_{age} = 3.65 years, SD_{age} = 0.26) and 4-year-old children ($n = 25$; 13 F, M_{age} = 4.48 years, SD_{age} = 0.28). An additional 3 children were tested but excluded due to failure on the practice questions. The online sample consisted of 2-year-old ($n = 23$; 12 F, M_{age} = 2.48 years, SD_{age} = 0.29), 3-year-old ($n = 31$; 15 F, M_{age} = 3.59 years, SD_{age} = 0.27) and 4-year-old children ($n = 27$; 12 F, M_{age} = 4.46 years, SD_{age} = 0.29). An additional 28 children were tested but excluded due to failure on the practice questions ($n = 19$) or completion of fewer than half of the test trials ($n = 9$).

Stimuli For the nursery school sample, stimuli were identical to Experiment 2 except that the voiceovers for all utterances had the same prosody: All utterances ended with a rising intonation. For the online sample, stimuli were identical to what the nursery school participants saw except that the story narrations (other than speaker utterances) were also pre-recorded such that parents did not need to read the stories aloud to their children.

Procedure For the nursery school sample, the procedure was identical to Experiment 2. For the online sample, the procedure was similar except that parents and children participated together at home and there was no experimenter present. Parents accessed the webpage for the study and gave their consent for participation, and then read instructions to proceed through the different stories, which specifically asked the parents to not tell their children correct answers for the questions.

Results and Discussion

Experiment 3 For Experiment 3, we were able to look at how children answered the *polite* and *rude* questions given the same three politeness marker types as in Experiments 1 and 2, with three age groups including 2-year-olds. (Fig. 3).

A mixed-effects logistic regression controlling for the effect of sample[2] showed improvement with age ($\beta = 0.19$, $p = .033$) as well as better performance for "can you please" than "please" and "can you" together ($\beta = 0.42$, $p = .002$), consistent with Experiment 2 results. Performance for "please" was also better than for "can you please" and "can you" together ($\beta = .3$, $p = .027$), which may be surprising given that we previously did not see the same effect in Experiments 1 and 2. One possible explanation is that controlling for prosodic cues in Experiment 3 actually made it *easier* to use "please" as a politeness cue. Because we had stripped all the other variations, it may have made the contrast between the presence and absence of the marker "please" *more* salient.

Additionally, children were better with the *polite* questions than *rude* overall (β = -0.19, $p = .04$), but especially given "please" (β = .42, $p = .002$). Finally, children showed a greater improvement with age for "can you please" compared to "please" and "can you" together ($\beta = 0.38$, $p = .004$).

All experiments Did children perform better given facial and/or prosodic cues, or were linguistic politeness markers sufficient? To see any potential effect of experiment on children's performance, we conducted an exploratory mixed-effects logistic regression on all three experiments together[3]. The regression model showed no significant main effect of experiment, suggesting that children did not perform more poorly when facial and prosodic cues were removed, and they were able to make accurate judgments based on linguistic cues alone. The model also showed that children improved with increasing age ($\beta = 0.33$, $p < .001$) and that children were more accurate with "can you please" than "please" and "can you" ($\beta = 0.25$, $p = .011$), confirming results from each individual experiment. Additionally, the model showed that children became better at judging the politeness marker "can you please" with age ($\beta = 0.73$, $p = .005$), and that children answered *polite* questions better than *rude* questions about the marker "please" ($\beta = 0.26$, $p = .006$)

General Discussion

What do young children understand about polite speech? In three experiments, we looked at how 2- to 4-year-old children reason about making requests with or without simple politeness markers such as "please", "can you" and "can you please." By 3 years, children pay attention to the use of politeness markers to accurately judge whether that speaker is relatively more polite, rude, nicer or meaner compared to another speaker. By 4 years, children reliably infer that a speaker who uses a politeness marker is a better play partner and more likely to get what they want. Across all three experiments, we saw a clear developmental trend such that children improved

[2]Model structure: `accuracy ~ sample + age x question type x politeness marker type + (1 | item)`

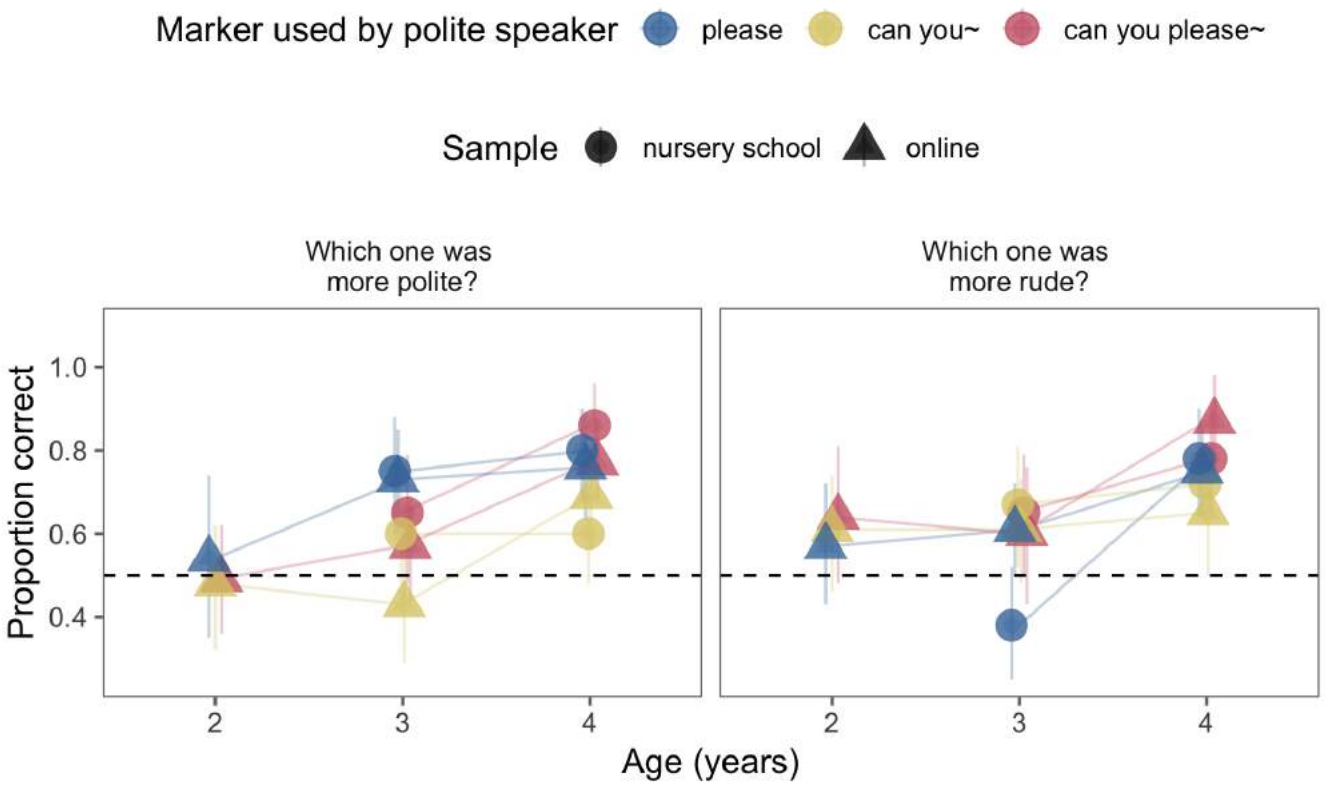

Figure 3: Experiment 3 results. Conventions are identical to Figure 2.

in their reasoning about polite speech with increasing age. We observed no large experiment effects as we eliminated facial and prosodic cues; instead, all these inferences appeared to be supported by linguistic markers alone.

Even though children have been shown to produce polite speech such as "please," evidence has been sparse and inconclusive for whether young children below 5 years comprehend speaker attributes and intentions based on polite speech. Here, we found that children are sensitive to the use of politeness markers in speech, and are able to use these markers to infer the speaker's attributes (e.g., niceness) by 3 years, and consequent social implications by 4 years. These ages are closer to the age of first reliable production of polite speech than have been suggested by earlier work.

Children in the US are often explicitly taught and prompted to use politeness markers such as "please" in their requests from early on (e.g., "What's the magic word?"; Gleason et al., 1984), thus they may quickly learn to use these markers as a rule in order to get what they want. They also might hear other remarks that pair politeness markers with positive words (e.g., "You should be *nice* and say *please*"), which may help them learn the association between polite speech and positive attributes. Gradually, children may recognize more subtle social processes that are related to polite speech production: Adults may praise and reward children who spoke politely, and children themselves may like peers who ask for permission to play with their toys rather than take the toys away without asking. Future work with corpus data analysis looking at these interactions between children and others may reveal important conversational patterns that help children acquire social meanings of polite speech.

There are limitations to the current work that present other opportunities for future research. Because this work looked only at the behaviors of English-speaking children with a relatively high socioeconomic status in the US, it is an open question how children with different language and cultural background may develop understanding of polite speech. Cross-cultural investigation of what markers are present in other languages, cultures and backgrounds, as well as how those markers are acquired, will be informative.

Also, we did not manipulate the social status of speakers or addressees. Though not explicitly stated, the visual depiction and narration used for the current work suggested that speakers were communicating with their peers only. However, one key prediction from politeness theory is that speakers will adjust their utterances based on the status of the addressees (Brown & Levinson, 1987). Indeed children adjust own their speech based on the listener status and age: Even at two years, children use a polite form of request ("Can I have…") to an adult but an imperative form ("Give me…") to a peer (Shatz & Gelman, 1973). Thus, future work should examine how children use cues to politeness to judge speaker

intentions in different contexts, including varied status differences between speakers and listeners.

In sum, the current work showed that young children understand implications of using simple politeness markers in requests. A broader understanding of the emergence of politeness may offer insights into how children become proficient users of language across the wide range of social situations that they encounter.

All experiments, data, and analysis code are available in the public repository for the project: (link will be available upon acceptance)

Modeling Number Sense Acquisition in A Number Board Game by Coordinating Verbal, Visual, and Grounded Action Components

Arianna Yuan (xfyuan@stanford.edu) **James L. McClelland (jlmcc@stanford.edu)**
Department of Psychology, Center for Mind, Brain, Computation and Technology, Stanford University, Stanford, CA

Abstract

Previous studies including Ramani and Siegler (2008) have shown that playing a number board game improved students performance on several numerical tasks, including numeral identification, magnitude comparison, counting and number line estimation. However, the computational mechanism underlying such number sense acquisition remains unclear. Here, we aim to fill this gap by building a model that simulates play of the game as well as the basic numerical tasks. We hypothesize that cognitive components that are used in the basic tasks are recruited to work together when children play the game, so that the learning induced by playing the game also manifests itself in those tasks. We reproduced the empirical findings with a neural network model implementing our hypothesis. This computational approach demonstrates how a single model that coordinates components of number processing in different modalities (visual, language and spatially-guided action) can explain the number sense acquisition in number board game playing.

Introduction

Mathematical concepts are notoriously hard to learn, perhaps because they often involve a range of distinct properties. Even the seemingly simple mathematical concepts, such as the natural numbers, may have diverse properties and multiple representations. For instance, the concept of "five" can be grounded as the *cardinality of a set*; as a *position on a line*; as a *distance in space*; or as a *number of events in a temporal sequence*. In fact, researchers have summarized these observations and proposed that humans use several grounding metaphors to understand numbers (Lakoff & Núñez, 2000), including *arithmetic as object collection*, *arithmetic as the use of a measuring stick* and *arithmetic as motion along a path*.

Given these diverse groundings, the perceptual variance of natural numbers may be much larger than that of many ordinary concepts. For example, "five dogs", "five houses", and the position in a row between 4 and 6 are perceptually very different, yet they can all instantiate the number "five". How do children learn to link different representations of numbers, particularly non-symbolic ones, such as cardinality and distance in space, to symbols such as verbal number words and written Arabic numerals? This problem is called the symbol grounding problem (Harnad, 1990), thought to be equivalent to the problem of determining how we assign a meaning to a symbol (in our case, a number word).

Many researchers have attempted to provide an answer to this problem. One popular account, the *approximate number system (ANS) mapping account*, assumes that a symbol acquires its numerical meaning by being mapped on a non-verbal and innate ANS. Evidence supporting this hypothesis includes longitudinal studies in developmental psychology. For instance, there is a large body of literature showing a correlation between non-symbolic number processing and symbolic math (Halberda, Mazzocco, & Feigenson, 2008; Libertus, Feigenson, & Halberda, 2011) and arguing for a causal link between the two (Park & Brannon, 2014).

Whatever the origin of non-symbolic number may be, the question remains, what is the process whereby the many diverse aspects of non-symbolic number and symbolic numbers are acquired, to support skills such as number-space mapping and numerical magnitude comparison? In the current paper, we begin to address this question. Particularly, we will focus on a number board game that has been used in several studies to provide a rich learning environment that grounds various aspects of numerical processing and links them to the printed and spoken symbols for numbers. In the seminal paper by Ramani and Siegler (2008), the authors showed that playing this number board game for roughly an hour spaced over several sessions increased low-income preschoolers' proficiency on four diverse numerical tasks: numerical magnitude comparison, number line estimation, counting (defined as reciting the count list from 1 to 10) and numeral identification. Below we describe the details of their intervention study.

In the board game, the board includes 10 horizontally arranged squares of the same size, with the word "Start" at the left end and "End" at the right end. There are two conditions in the study. In the experimental condition, the board the squares are numbered consecutively from 1 to 10 in order from left to right. In the control condition, the squares only have alternating colors. In addition, in the experimental condition, the game has an associated spinner with a "1" half and a "2" half, whereas in the color board version it has a spinner with colors that correspond to the colors of the squares on the board. Before playing the game, the participants were tested on 4 numerical tasks: numeral identification, magnitude comparison between two numbers, counting and number line estimation.

In the game, children chose an animal token and used it to mark their progress on the board. Children were instructed to take turns spinning the spinner and were told that the one who reaches the end first wins the game. Children in the experimental condition were told that on each turn, they would move their token the number of spaces indicated on the spinner. Also, they were required to say the number that they spun and the numbers on each of the squares they reached as they moved. For instance, if they were on 5 and they spun a "2", they would first say "two" then say "six", "seven" as they moved. In the control condition, children were told that

they would move their token to the next square with the color that matched the one they spun. Similar to the experimental group, they need to say the color they spun and the colors on the squares they reached as they moved.

After the participants played the game several times in each of four short sessions over the course of several weeks, they were tested a second time on the 4 numerical tasks mentioned previously. The experimental group demonstrated significant improvement, whereas the control group did not. The gains remained 9 weeks later in a follow-up session, in which the same tasks were tested a third time.

Here we propose a mechanistic account for the enhancement of numerical processing skills that was induced by playing the game. We hypothesize that multiple cognitive components (visual, language and spatially-guided action) are recruited and coordinated in the game environment. Particularly, the process of moving the token incrementally along the number board (motor) is coordinated with saying the next number word through the count list (verbal) as well as naming the printed numeral on each square tile on the board (visual). We suggest that the various components engaged in this process are also engaged in the basic numerical tasks, allowing learning occurring in the game to transfer to the basic tasks.

Another motivation for the current paper is that we want to address one of the common shortcomings of neural network models, which is their lack of flexibility in multi-task learning scenarios. In the current paper, we would like to show that as long as the model is composed of meaningful cognitive components that are also used in other tasks, it will be possible to demonstrate that training on one task could result in improvement on other tasks. The idea of constructing neural networks with multiple components that are responsible for different sub-tasks aligns with some recent advance in machine learning, e.g., neural networks composed of distinct modules have been used to solve language grounding problems (Andreas, Rohrbach, Darrell, & Klein, 2016; Johnson et al., 2017).

Below we first describe the architecture of our model, followed by the experiments we ran to simulate the learning in the number board game and the resulting learning effect. Finally, we present the implications of our results, some limitations of the current work and some future directions.

Model Architecture

There are three neural network modules in our model: the Visual component, the Language component (Figure 1) and the Action component (Figure 2).

Visual Component

The Visual component is composed of a pre-trained neural network named the ResNet (He, Zhang, Ren, & Sun, 2016) and two fully-connected readout layers. The ResNet is a deep neural network trained to recognize objects in ImageNet, a large image database of natural images with hand-annotated labels (Deng et al., 2009). The ResNet consists of stacked

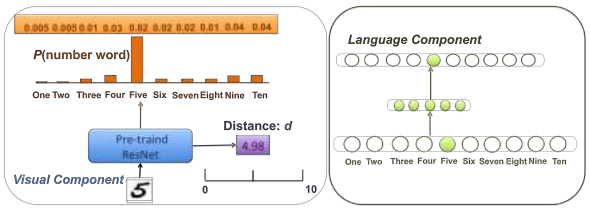

Figure 1: Illustration of the Visual component (left) and the Language component (right).

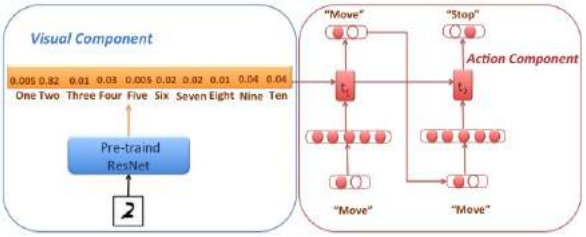

Figure 2: Illustration of the link between the number word output of the Visual component (left) and the Action component (right).

convolutional layers with non-linear activation functions and identity shortcut connections that skip one or more layers (see He et al. for details). We use the ResNet to process each image in our dataset and use the hidden activation of the last hidden layer as the feature vector of the image, i.e., as the image embedding. We then apply two fully-connected readout layers to the image embeddings, one *number word* readout layer and one *magnitude* readout layer. All of the images in our dataset are images of Arabic numerals ranging from 1 to 10 (see the Experiment Section for details). The *number word* readout layer is used to decode the numbers in the images. It outputs a probability distribution over the ten possible number words (one to ten). The *magnitude* layer is used to decode the magnitude of the number represented as a scalar, thought to be provided as a target for learning by the perceived distance of the number's location on the number line from zero. When simulating the number board game, we make the assumption that children attend to the board in two frames of reference, a global one and a local one: in the local frame of reference, they attend to and recognize the digit printed on the current square. In the global frame of reference, they keep track of how far their token has traveled from the "Start" point. These two processes are implemented by the *number word* readout layer and the *magnitude* readout layer, respectively. In the simulation of the number board game playing, these two layers were trained simultaneously. During the training we did not update the weights of the ResNet and only the connection weights of the two readout layers were updated. The equations of the Visual component can be written as follows:

$$
\begin{aligned}
e_i &= \text{ResNet}(I) \\
P(\text{number word}) &= \phi(W_{nw} e_i + b_{nw}) \\
m &= \text{ReLU}(W_m e_i + b_m)
\end{aligned} \tag{1}
$$

where $I \in \mathbb{R}^{28\times28\times3}$ is the raw pixels of the image, $e_i \in \mathbb{R}^{512}$ is the image embedding, $W_{nw} \in \mathbb{R}^{512\times10}$ ($W_m \in \mathbb{R}^{512\times1}$) are the connection weights from the embedding layer to the *number word* (*magnitude*) readout layer, $b_{nw} \in \mathbb{R}^{10}$ ($b_m \in \mathbb{R}^1$) are the biases of the *number word* (*magnitude*) readout layer. The softmax function $\phi(\boldsymbol{x})_i = \frac{e^{x_i}}{\sum_{j=1}^{n} e^{x_j}}$ is used to normalize the logits of the *number word* readout layer in order to get the probabilities over number classes. The prediction is thus the one with the highest probability. The ReLU activation function is used to restrict the magnitude output to be non-negative, i.e., $\text{ReLU}(x) = \max(0, x)$.

Language Component

This component learns the successor function in counting, i.e., it predicts the next number in a count list given the current number (Figure 1, right). Particularly, during training, we use (current-number, next-number) pairs as data, e.g., ("five", "six"), and the model takes the current-number as input and predict the next-number. During testing, we iterate from zero, and the score is coded as correct up to the point of the first error. The number words are represented as one-hot vectors and they are fed to a fully-connected layer with rectifier activation function (ReLU), which is followed by a fully connected output layer with the softmax activation function. The mathematical formula for this module can be written as:

$$
\begin{aligned}
h_l &= \text{ReLU}(W_l e_w + b_l) \\
P(\text{next word}) &= \phi(W_n h_l + b_n)
\end{aligned} \tag{2}
$$

where $e_w \in \mathbb{R}^{10}$ are the word embeddings for the stimuli (one-hot vector), $W_l \in \mathbb{R}^{10\times10}$ are the connection weights from the input embedding layer to the hidden layer. We use the softmax function $\phi(x)$ to normalize the logits to get the probabilities over the possible number words.

Action Component

The Action component is a recurrent network that learns to output a sequence of "MOVE" actions before it outputs a "STOP" action (Figure 2, right). We use the Visual component described above to read the spinner, which shows either "1" or "2", to generate a probability distribution over all possible number words. This serves as the initial hidden state of the Action recurrent network. The Action network then takes the initial hidden state h_0 and the initial action a_0 to predict the next action, which is either "MOVE" or "STOP"[1], and the new hidden state and the predicted action are used in the next time step t. The mathematical formulae can be written as:

$$
\begin{aligned}
h_t &= h_{t-1} + ReLU(W_a e_a) \\
O_t &= \phi(W_m h_t + b_m)
\end{aligned} \tag{3}
$$

[1]In this board game the first action is always "MOVE", so there's no need to make a prediction for the first action.

Figure 3: Digits stimuli used in the current task. 1 - 9 are randomly selected from the MNIST dataset and the 10s are generated by randomly selecting 1s and 0s from the dataset and combine them (LeCun et al., 2010).

where $e_a \in \mathbb{R}^5$ are the embedding of the action, $W_a \in \mathbb{R}^{5\times10}$ are the connection weights from the embedding layer to the hidden layer. We use the softmax function to normalize the logits of the output layer to get the probabilities over the two possible actions ("MOVE" or "STOP").

Experiments

We use digit images from the MNIST database (LeCun, Cortes, & Burges, 2010), a dataset of handwritten digits with labels. We use a randomly selected subset of the original training data to construct our training dataset, which contains 10,000 samples (Figure 3), and our test dataset contains 10,000 samples that do not overlap with our training data.

Our simulations have two conditions that correspond to the experimental condition and the control condition in Ramani and Siegler's empirical study. In the experimental condition, there are three phases: the pre-test training, the number board game training and the post-test training. For simplicity, and because no numbers were used in Ramani and Siegler's control condition, the simulation control condition included only the pre-test training and the post-test training. In the pre-test training phase, the *number word* readout layer of the Visual component is trained on the numeral identification task for 34 batches, the *magnitude* readout layer is trained on the number line estimation task for 46 batches and the Language component is trained on the counting task for 16 batches. The numbers of batches for each task are chosen to produce the pre-test accuracies that approximate the ones in Ramani and Siegler's original paper.

Each batch contained 100 trials. The numerals were equally distributed in trials of each task. In counting, each trial involved a single transition from a "current-number" to the "next-number". We used backpropogation to train the network. In the board game training phase the models were trained on board game trials corresponding to individual turns in the game for 50 batches. We next describe in detail how all the cognitive components work together in a single trial. Assuming that the agent's token is at square "3" and the spinner yields "2", the modules will perform the following sequence of computations:

1. The Visual component reads the spinner ("2") and feeds the computed P(number word) to the Action component as its initial hidden state.

2a. The agent moves one step forward. The Visual component takes the image of the square where the agent's token is currently located ("4") and recognizes the number

printed on it, i.e., "four".
2b. The *magnitude* readout layer of the Visual component predicts the distance between the token's current location to zero, i.e., 4.0, as the supervision signal is available in the game.
3. The Action component takes the initial hidden state and the embedding of the initial action "MOVE" to predict the next action "MOVE".
4a. The agent moves one step forward. The Visual component takes the image of the square where the agent's token is currently located ("5") and recognizes the number, i.e., "five".
4b. The *magnitude* readout layer of the Visual component predicts the distance between the token's current location and the "Start" point, i.e., 5.0.
4c. The Language module takes the number that the Visual module recognized in the last time step ("four") to predict the current number, i.e., "five".
5. The Action component takes the last hidden state and the last action "MOVE" to output the next action "STOP".

To summarize, in this single trial, the Visual component needs to map the image of "4" to ("four", 4.0) and "5" to ("five", 5.0); the Language component needs to map "four" to "five" and the Action component needs to map the image of "2" (the spinner's output) to the action sequence "MOVE (given), MOVE, STOP". On trials where the spinner's output is 1, then only the steps 1, 2, 5 will be performed.

Finally, in the post-test training phase, in both conditions the neural modules are trained on one batch to simulate the learning experience gained during the 9 weeks between the immediate post-test and the follow-up test. This is termed as the "1-batch post-test training" simulation. This amount of training yields changes in performance that are comparable to the change from the post-test to the follow-up test in the control condition of Ramani and Siegler's experiment. To get a comprehensive understanding of the advantage of the experimental group, we also simulate another scenario in which we train the neural modules with the same number of batches as in the pre-test training phase ("*n*-batch post-test training" simulation). This gives us a sense of how the model will continue evolving if we train it on more than one batch, although it is unlikely that participants actually got that much training during the 9-week period of time in Ramani and Siegler's experiment.

When measuring the model performance on each numerical processing task, the Visual component is used to perform the numeral identification task and the number line estimation task using randomly selected digit images not used in training, and the Language component is used to perform the counting task, starting from 0, until an error is made or the whole count list is completed. To measure the performance of the number line estimation, we report the linearity of the estimation (measured by the square of the coefficient of correlation R^2 between the models prediction and the target) and the slope of number line estimation. These are the same dependent variables as measured in (Ramani & Siegler, 2008). A perfect number line estimate should yield a R^2 equal to 1.0 and a slope equal to 1.0. For the magnitude comparison task, we randomly select images of two different numbers from 1 to 10 and feed them to the Visual component separately. We then use the output of its *magnitude* readout layer to determine a response, i.e., the one with larger magnitude output is determined to be the "bigger number". The training and the testing were simulated 20 times with different random initialization of the network parameters and random sampling of the data.

Results

Accuracies of the Cognitive Components across the Training

We find consistent patterns in results across all the tasks that were tested (numeral identification, number line estimation, counting and magnitude comparison). As expected, up to the point when number board game was introduced, accuracy did not differ between the experimental condition and the control condition were. However, after the number board game was introduced, across all tasks the experimental condition demonstrated better performance than the control condition. Figure 4 shows the learning curves of different tasks in the "*n*-batch post-test training" simulation.

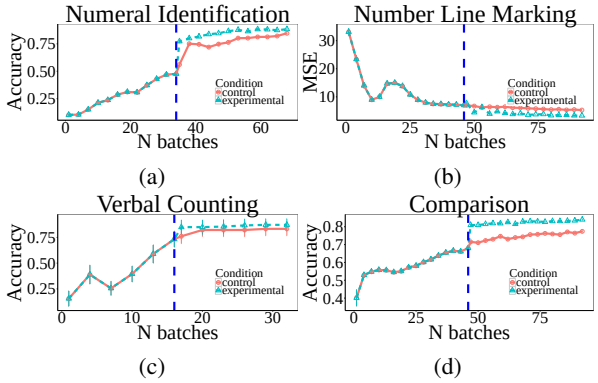

Figure 4: (a) Accuracy of the Visual component on the numeral identification task. (b) Mean Square Error of the Visual component on the number line estimation task. (c) Accuracy of the Language component on the counting task. (d) Accuracy of the magnitude comparison task. The vertical blue lines indicate the time points when number board game is introduced in the experimental condition.

Pre-test, Post-test and Follow-up Test

To compare our results with the results in Ramani and Siegler (2008), particularly their Figure 2, we also plot the pre-test scores, the post-test scores and the follow-up scores in the "1-batch post-test training" simulation. We run several paired *t*-tests to compare the pre-test scores and the post-test scores, as well as the pre-test scores and the follow-up test scores. In the control condition, as expected because

there is no training between the pre- and post-tests, the post-test scores are not significantly different than the pre-test scores. However, in the experimental condition, across all tasks the post-test scores are significantly higher than the pre-test scores (Table 1). The same results hold true for the comparison between the follow-up measures and the pre-test.

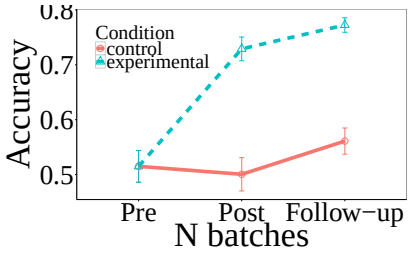

Figure 5: The model performance at the pre-test, the post-test, and the follow-up measures on the numeral identification task.

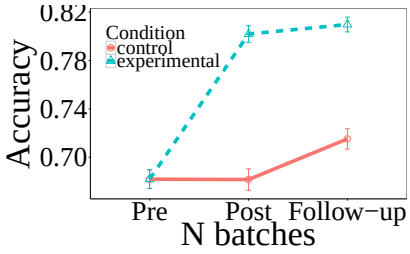

Figure 6: The model performance at the pre-test, the post-test, and the follow-up measures on the magnitude comparison task.

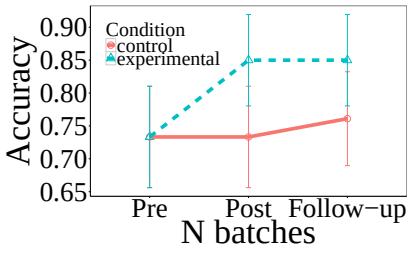

Figure 7: The performance of the Language component at the pre-test, the post-test, and the follow-up measures on the counting task.

As shown in Table 1, in the experimental condition, after the model is trained on the number board game, the numeral identification accuracy increases from 52% to 73%, the magnitude comparison accuracy increases from 68% to 80%, the counting performance increases from 73% to 85%, the square of the coefficient of correlation between the model's prediction and the target in number line estimation improves from 0.29 to 0.62, and the slope increases from 0.12 to 0.47. No improvement is observed in the control condition.

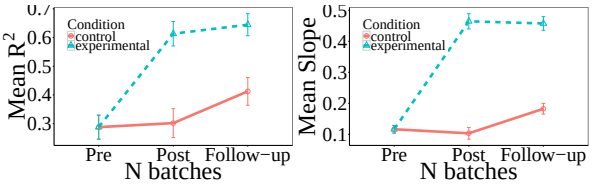
Linearity of the Number Line Estimation

One of the major motivations of Ramani and Siegler's work was to test whether playing the number board game could improve the linearity of children's number line estimation. As can be seen in Table 1 and Figure 8, in the experimental condition, both the linearity (measured by the square of the coefficient of correlation between the models prediction and the target) and the slope of number line estimation significantly increase after playing the number board game, and these learning outcomes are still significant at the follow-up test (Table 1).



(a) (b)

Figure 8: The linearity (a) and the slope (b) of the model performance in the number line estimation task evaluated at different stages.

Discussion

In the current study, we created a neural network model to provide a mechanistic account for the enhancement of numerical processing skills that was induced by playing a number board game (Ramani & Siegler, 2008; Ramani, Siegler, & Hitti, 2012). We hypothesized that various parts of the number board game actually train different components of the player that could later be used to perform other numerical tasks, such as numeral identification, magnitude comparison, counting and number line estimation. We reproduced the empirical learning effect in our computational model that implemented our hypothesis.

In our model, different cognitive components need to coordinate with each other to perform the task. For instance, as the Action component outputs the right actions, the agent constantly gets good teaching signals from the external environment which can be used by the Visual component and the Language component. As the Visual component recognizes the identities of the digits on the board, it further provides the language component with the proper inputs needed to predict the next number word. At the same time, as the agent's token moves along the board, the Visual component learns to associate the symbolic numeral with distance along the number line and the Visual and Language components jointly determine the number word to be uttered.

One limitation of the current paper is that we did not explicitly train the model's attention, e.g., we feed the Visual component with images of the current digits treating the "MOVE" action as simultaneously moving the player's token and shifting the focus of attention. We assume that the participants could allocate their attention to different parts of the environment and deploy their cognitive components in a synergistic way. Coordination of these processes to actually play the game requires executive control and working memory (Barnes et al., 2016). In future work we will explore how the selective attention and the executive control ability of the model can also be learned through training. This is a promising direction since recent advances in language grounding research in the artificial intelligence field have shown that neural network models can learn to attend different parts of an image in order to answer questions about the image (Yang, He, Gao, Deng, & Smola, 2016).

Another limitation is that we did not fully model the color board game control condition in Ramani and Siegler's work, i.e., we only modeled the aspect that participants did not receive any number-related training during the color board game playing, but we did not simulate the color-related training. In future work, we will fully model this color board game control condition. In addition to this control condition, in later studies researchers also compared the count-on procedure (reciting the number words for each new tile reached) used in Ramani and Siegler's study with the standard count-from-1 procedure (reciting the number words corresponding to the number of onward steps), and found that playing the same game using the standard procedure led to considerably less transfer to the other tasks (Laski & Siegler, 2014). This might occur because participants' attention was not directed either to the token position on the board or to the numerals on each square, as the task can be performed without this information. Also, the count-from-1 procedure provides no practice counting beyond the number two. It would be interesting to see whether modeling those control conditions within a network that learns to deploy its attention could provide a mechanistic account for why one of the interventions worked while the others did not.

In summary, the current work is a first step towards building a comprehensive computational model for numerical cognition that coordinates different modalities and integrates various training stimuli and paradigms. Our approach allows us to simulate the acquisition of number concepts as a process through which a set of component skills are assembled in different configurations in diverse task settings, promoting transfer across tasks that share components.

Abstract

Crossmodal correspondences are innate, language-based and statistically derived. They occur across all sensory systems and in different cultures. Despite their multiformity, they are exhibited analogously, mainly through robust congruency effects. One plausible explanation is that they rely on a common underlying mechanism, reflecting the fundamental ability to transfer relational patterns across different domains. We investigated the pitch-height correspondence in a bimodal sound-discrimination task, where the context of one relative sound pitch was changed online. The intermediate sound frequency was presented in successive blocks with lower *or* higher equidistant sounds and two squares at fixed up and down vertical positions. Congruency effects were transferred across sound contexts with ease. The results supported the assumption about the relational basis of the crossmodal associations. In addition, vertical congruency depended critically on the horizontal spatial representations of sound.

Keywords: crossmodal associations; relational mapping; pitch-height correspondence; SMARC effect

Introduction

Multidimensional information is integrated not only within the neural frame of one sensory system (e.g. Garner, 1974), but also across different modalities. Thus, certain features extracted from one perceptual realm interact with other, modality-specific attributes, and create coherent multimodal percepts, or intersensory Gestalts (for a review, see Spence, 2015). During the process of integration, particular aspects of the polysensory flow may modulate one another (like in McGurk & MacDonald, 1976, where visual stimuli modified auditory content, creating perceptual illusion), or bind together in bistable crossmodal entities with corresponding features. Examples of such corresponding features for pitch are shape (Melara & O'Brien, 1987; Walker et al., 2010); brightness (Marks, 1974; Martino &Marks, 1999; Melara, 1989); hue (Simpson, Quinn, Ausubel, 1956); smell (Belkin, Martin, Kemp, & Gilbert, 1997); size (Evans & Treisman, 2009; Mondloch & Maurer, 2004; Parise & Spence, 2012); height (Ben-Artzi & Marks, 1995; Chiou & Rich, 2012; Mudd, 1963; Patching & Quinlan, 2002; Rusconi, Kwan, Giordano, Umilta, & Butterworth, 2006) etc.

Apparently, invariable crossmodal associations might occur across all sensory systems. Examples of such associations are observed in different cultures (e.g. Bremner et al., 2013; Levitan et al., 2014; Parkinson, Kohler, Sievers, Wheatley, 2012; Wan et al., 2014) and are more or less implicit (Chen, Tanaka, Namatame, & Watanabe, 2016; Evans & Treisman, 2009; Parise & Spence, 2012). Given the broad scale and the diversity of the correspondence effect, at least three assumptions come to mind. First, these mappings should be nonrandom and in some way meaningful for perception. Second, they might comprise different processes and originate in different perceptual and cognitive networks. Third, they might be related to a common underlying mechanism, reflecting more general, inherent adaptive framework.

It was demonstrated that 4-month-olds are already sensitive to the associations between pitch and height, and pitch and sharpness (Walker et al., 2010). Lewkowicz and Turkewitz (1980) found evidence for mappings between brightness and loudness in infants 21 to 31 days of age. Along with that, crossmodal couplings are reported in nonhuman animals (see Ratcliffe, Taylor, & Reby, 2016, for a recent review). These findings are critical for the validity of the notion that multisensory associations are semantically mediated. It seems that they emerge on a lower, perceptual level and congruency effects are dependent on available attentional resources. More specifically, "attention is likely to play an important role in cross-modal perceptual organization" (Spence, 2015, p. 12). At the same time, it might be argued that even newborns have enough experience with environment, given the fact that they are

extremely sensitive to certain statistical frequencies. In fact, 6-month-olds were better than adults in extracting implicit crossmodal information from the context (Rohlf, Habets, von Frieling, & Röder, 2017). Additionally, it was suggested that human perceptual system might foster the development of language by auxiliary crossmodal mappings of speech sounds to other percepts, for example shapes (Ozturk, Krehm, & Vouloumanos, 2013). The opposite is also true – linguistic experience systematically promotes progressive coupling of nonlinguistic dimensions (Martino & Marks, 1999). In short, the importance of language in crossmodal perception is undeniable. However, not all data can be explained with semantics (consider the animal studies). By all appearances, perceptual constraints, environment and language contribute synchronously to the establishment of stable crossmodal links. According to Spence (2011) certain structural correspondences might be innate, while statistical and semantic ones are evidently learned, and all are a function of environment.

A basic tool for exploring the nature and the strength of crossmodal associations is the speeded discrimination task, developed by Garner (1974), where participants respond to one task-relevant dimension while ignoring another, task-irrelevant dimension. Corresponding dimensions are integrated and trigger congruency effects that influence selective attention and performance. Apart from that, particular dimensions might interact on different levels. There is evidence that certain crossmodal couplings might actually prompt perceptual change (e.g. Evans & Treisman, 2009; McGurk & MacDonald, 1976). Others communicate on decisional level (e.g. Melara, 1989; Rusconi et al., 2006) or result from semantic inconsistencies (e.g. Martino & Marks, 1999). Notably, they can be correlated directly – for instance, psychophysical dimensions, like pitch and height usually covary in magnitude. On the other hand, it is generally accepted that these mappings are relative – one level of the first dimension can be mapped on different levels of the second dimension, depending on the context (for a review, see Spence, 2011). However, the mechanisms behind these relative mappings remain unclear.

In short, crossmodal correspondences engage all sensory systems, they are universal, innate, automatic, can be learned and assist learning, and interact on lower, bottom-up and higher, top-down levels. Considering the relative nature of the mappings, it is plausible to assume that they recruit the mechanisms of another, major cognitive process, reflecting the ability to build and compare relations. What is more, "the ability to pick out patterns, to identify recurrences of these patterns despite variation in the elements that compose them, to form concepts that abstract and reify these patterns, and to express these concepts in language" is considered a fundamental core of cognition (Holyoak, Gentner, & Kokinov, 2001, p. 2). Besides, relational analyses can be performed online and automatically, with or without utilizing attentional resources. Evidence is piling up that relations can be retrieved unconsciously and transferred across corresponding sets of data (Hristova, 2017; Li, Li, Zhang, Shi, & He, 2018). That being said, the capacity to construct and compare associations across modalities is one possible explanation for the pervasiveness of crossmodal correspondences. Thus, perceptual dimensions are represented not in their absolute values but as correlated dyads. To check this hypothesis, we investigated the congruency effects between one sound frequency and two vertical spatial positions – higher and lower. In other words, we measured the interaction between pitch and height in a speeded sound-discrimination task. Crucially, the context of the sound was changed during the task – it was presented with either higher or lower pitch, so that it was perceived as relatively lower or higher than the other sound. Previous studies demonstrated that pitch and height were positively correlated – higher frequencies were consistently associated with higher vertical positions (e.g. Ben-Artzi & Marks, 1995; Evans & Treisman, 2009; Rusconi et al., 2006 etc.). If crossmodal correspondences are indeed represented as relations, are we should expect comparable congruency effects in both contexts – i.e., one and the same sound should be mapped to different vertical positions in accordance with its relative frequency. Importantly, this shift should be effortless and almost instantaneous.

Experiment: Sound-Discrimination Task

Method

Participants 24 students (7 males) with mean age 23.8 years (standard deviation SD=6.3) from the Psychology Department were recruited for the task, after approval from the Cognitive Science and Psychology Ethics Committee. All signed the informed consent form and reported no problems performing the task.

Stimuli and design The stimuli were three sinusoidal sound waves with different frequencies, and a black square presented at two vertical positions. The sounds were generated on *Audacity* at 600 Hz, 900Hz and 1200Hz; 16 bits, mono, on an amplitude level of -2.5 dBFS (decibels relative to full scale) and duration 1000 ms. The square was solid black, 100x100 pixels (px) JPEG image. Participants had to perform a sound-discrimination task with bimodal presentation of the stimuli – i.e. the values of the task-relevant (sound pitch) and task-irrelevant (square height) dimensions were coupled randomly for each trial and presented simultaneously in both visual and auditory modalities.

Procedure The experiment was conducted in the presence of the experimenter in one of the booths of the Experimental Psychology Laboratory. Presentation and timing were controlled by the E-prime software (Schneider, Eschman, & Zuccolotto, 2012) and the multifunctional USB-based stimuli and response device *Chronos* which recorded accuracy and response times (RTs) with 1 ms resolution

(*Chronos operator manual*, 2015). The sounds in the experiment were presented via *Chronos* accessory headset.

The experiment started with onscreen instruction about the task requirements. Participants were asked to keep their eyes on the screen (as cued by the fixation cross) and to respond by pressing one button for the *thick* sound and another button for the *squeaky* sound, with the index finger of their dominant hand. The buttons of the response box (the first and the third, with the finger resting on the middle one between trials) were counterbalanced across participants. The words *low* and *high* were avoided in the instruction because of possible semantic priming. The sounds were presented in pairs – 600/900 Hz or 900/1200 Hz, in two continuous blocks with a pair change in between. Crucially, participants were informed that at one point the sounds would be changed but they should continue performing the same task. The experimenter urged the participants to look at the screen and monitored the execution of the task.

Each trial started with 500 ms fixation cross (*Consolas*, 22 pt, black, on a white background). Then participants heard one of two sounds – lower or higher, presented pseudorandomly, no more than four of the same pitch successively (to avoid motor fluency). The sounds were randomly coupled with a black square, presented on a white background below or above fixation – at 20% or 80% along the vertical midline of a 24-inch monitor with 60 Hz refresh rate and resolution 1920x1080 px (at 7.5 cm below or above the center of the display). Each pitch was accompanied by an equal number of high and low squares. As the viewing distance was approximately 60 cm, the side of the square corresponded to 2.5°-3° horizontal visual angle. The sound and the square were presented simultaneously (bimodally) for 1000 ms or until response, and were followed by 1500 ms intertrial interval (white screen). The sequence of one trial is represented in Figure 1.

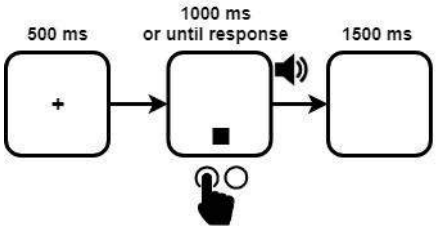

Figure 1: Schematic representation of one trial, not to scale.

For all participants the experiment started with one sound pair in the first block and ended with another sound pair in the second block, in counterbalanced order. There were 216 experimental trials. During the first 104 trials some participants responded to 600/900 Hz, and other – to 900/1200 Hz, and vice versa for the rest of the trials. The first 8 trials after the sound change were treated as practice and were analyzed separately. That way, the two blocks consisted of 104 trials each. Additionally, there were 8 practice trials before the experimental part, always with the sound pair of the following block. These trials were excluded from the analyses. Thus, there were 224 trials overall – 8 practice trials separated with a break from the experimental part, and 216 experimental trials (104 before the sound change, 8 practice trials after the sound change and 104 trials with the second sound pair) with no break. The experiment lasted about ten minutes.

Results

First, the overall accuracy was assessed (.94, range .83-1). No participant was excluded on that account. As 900 Hz was the pitch of interest, *only* responses to that pitch were considered in the subsequent analyses. Then, accuracy and RT were aggregated by trial in order to examine the nature of transition between the two contexts. The progress of the values over time is visualized on Figure 2.

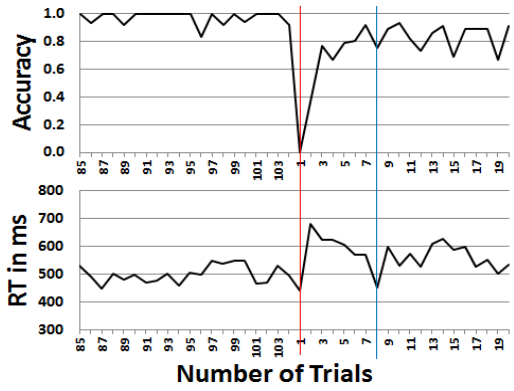

Figure 2: Accuracy and RT around context change, responses to relative pitch only (900 Hz), by trial. The red line indicates the point of change. The blue line marks the end of the online practice trials.

As participants had eight trials of practice before the experimental part, the first eight trials after the context change were also considered as practice and disregarded. Accuracy was analyzed as a function of experimental block and pitch-height congruency. There was no main effect of congruency – no difference in accuracy for congruent and incongruent responses ($F(1,23)=2.32$, $p=.142$; $\eta^2_p=.092$). However, there was main effect of experimental block ($F(1,23)=8.12$, $p=.009$; $\eta^2_p=.261$), i.e. more accurate responses in the first block; and an interaction between experimental block and congruency ($F(1,23)=5.24$, $p=.032$; $\eta^2_p=.185$). Newman-Keuls post-hoc revealed difference between the incongruent trials of the second block and the congruent and incongruent trials of the first block ($p<.001$), between the congruent trials of the first block and the second block ($p=.045$) and between the congruent and incongruent trials of the second block ($p=.008$). That is, participants made more mistakes in the second part of the experiment, especially in the incongruent trials.

There were a total of 5.6% errors in the experimental trials (.08% with no RT) which were also excluded. The data were then trimmed with 2.5 SDs from the subject means per condition (another 2.8%). Only trimmed data from the experimental blocks, concerning the correct responses to the relative pitch (900 Hz) were examined for differences in response times. The analyses were again performed with experimental block and pitch-height congruency as within factors. Means and standard deviations per condition are presented in Table 1.

Table 1: Descriptive statistics: mean RT (SD) per condition

First block		Second block	
Congruent	Incongruent	Congruent	Incongruent
512 (110)	529 (119)	497 (96)	522 (83)

There was no main effect of experimental block ($F(1,23)=.761$, $p=.392$; $\eta^2_p=.032$). At the same time, in accordance with the presumed crossmodal interaction between pitch and height, there was a substantial congruency effect ($F(1,23)=5.65$, $p=.026$; $\eta^2_p=.197$). Crucially for our hypothesis, there was *no* interaction between congruency and experimental block ($F(1,23)=.533$, $p=.473$; $\eta^2_p=.023$) – in other words, congruent responses were faster regardless of the relative sound context. Mind that only the context of the 900 Hz sound was changed between the blocks. And yet, in the presence of the higher pitch (1200 Hz) it was mapped to the lower vertical position, and subsequently to the higher vertical position in the presence of the lower pitch (600 Hz). Figure 3 illustrates the remapping of the sound across the two experimental blocks.

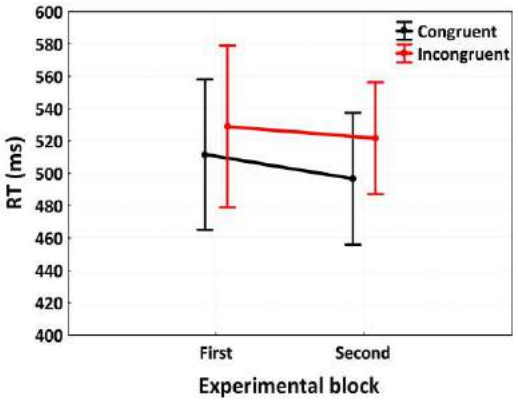

Figure 3: Transfer of vertical congruency effects across different sound contexts in the experimental blocks. Vertical bars denote .95 confidence intervals.

Due to the nature of the experiment, additional analyses were performed to account for alternative explanations. In the bimodal sound-discrimination task, sound pitch is coupled with visual stimuli presented along the vertical dimension. However, crossmodal correspondences were already demonstrated between pitch and the horizontal space (e.g. Rusconi et al., 2006). More specifically, lower pitch was mapped more readily to the left, and higher pitch was mapped more readily to the right. Our participants responded by pressing a left or a right button for the lower or higher pitch, in counterbalanced order. That is, for one half of the participants the sounds were horizontally congruent (they always pressed the left button for the lower pitch), while the other responded in horizontally incongruent manner.

To estimate the possible interaction between horizontal and vertical congruency, the mapping of the response was added as a categorical predictor in the above analyses. There was an interaction between horizontal and vertical congruency for accuracy ($F(1,22)=5.75$, $p=.025$; $\eta^2_p=.207$) and for RT ($F(1,22)=25.13$, $p<.001$; $\eta^2_p=.533$) (Figure 4).

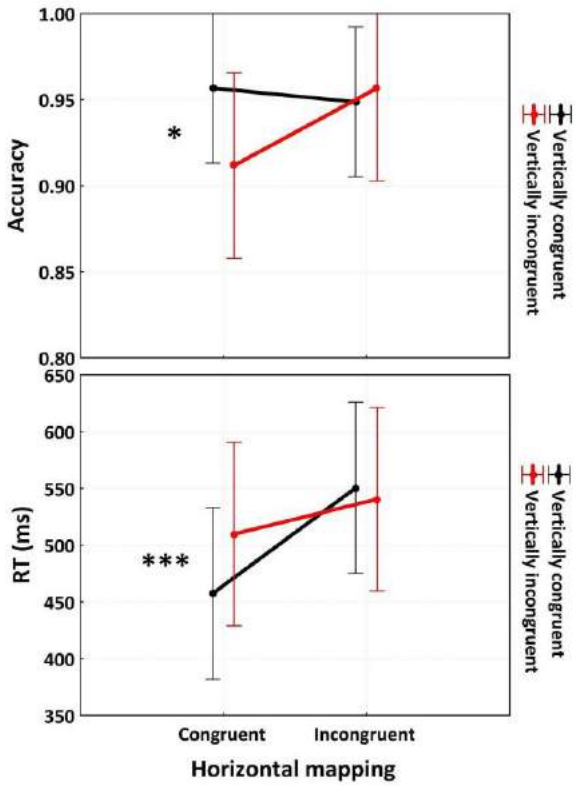

Figure 4: Interaction between horizontal and vertical congruency for accuracy (up) and RT (down). Vertical bars denote .95 confidence intervals.
* $p<.05$; *** $p<.001$

Newman-Keuls post-hoc revealed difference between the vertically congruent and incongruent trials ($p=.041$ for accuracy; and $p<.001$ for RT), but *only* when the responses were horizontally congruent. Remarkably, there was no difference when responses were mapped incongruently.

Discussion

On the whole, we did find the typical pitch-height congruency effects (Ben-Artzi & Marks, 1995; Chiou & Rich, 2012; Evans & Treisman, 2009; Patching & Quinlan, 2002; Rusconi et al., 2006 etc.). That way, we supported experimentally one of the major claims in the field – that the mappings between two dimensions are relative. For example, Gallace and Spence (2006) reported similar effects in a bimodal size-discrimination task with task-irrelevant sound frequencies, relatively mapped to the values of the visual stimuli. In another study, Smith, Grabowecky and Suzuki (2007) presented participants with the same visual stimuli (androgynous faces) accompanied by a sound in the male or female frequency speaking range, and found differences in perception of gender. Here, we demonstrated online remapping of one intermediate pitch to lower and higher vertical spatial positions in a speeded sound-discrimination task. Note that the intermediate pitch was presented throughout the whole experiment, but in a different context – with equidistant lower and subsequently higher pitch for one half of the participants, and the other way around for the other half of the participants. As follows, participants had to change their response as well – those who responded to the lower pitch with the *thick* button had to remap the same sound to the *squeaky* button, and vice versa. Moreover, in accordance with the expected congruency effects, responses to the same pitch were faster and more accurate when it was coupled with a square in the lower or higher visual field and perceived as *thick* or *squeaky*, respectively.

Crucially, the crossmodal correspondence between pitch and vertical space depended on the correspondence between pitch and horizontal space. Rusconi and colleagues (2006) provided conclusive evidence for explicit and implicit vertical and horizontal spatial mappings of pitch (but see Pitteri, Marchetti, Priftis, & Grassi, 2017). In their experiments responses were gathered vertically and horizontally, and participants performed the tasks with crossed and uncrossed hands. Higher pitch was mapped to upper and right buttons, and lower pitch was mapped to lower and left buttons (the so-called SMARC effect), even when responses did not require explicit processing of pitch, as in a wind vs. percussion sounds discrimination task. This implies that pitch-height correspondences are not solely semantically modulated, as horizontal mapping of sound is not linguistically promoted. Crossmodal correspondences depend mostly on failures in selective attention, especially within the speeded discrimination task (Spence 2011, 2015). When the task-irrelevant dimension is visuospatial, we might expect interaction between generated spatial and response codes (see Lu & Proctor, 1995, for a review of Simon and spatial Stroop effects). Interaction was reported also for mental representations and responses in horizontal space (Dehaene, Bossini, & Giraux, 1993). In our task, responses were gathered horizontally, while visual stimuli were presented along the vertical axis. And yet, we found substantial interaction between horizontal mental representation of sound and response side (unlike Pitteri et al., 2017, who reported the same effect for pitch and brightness, but only for musicians). It can be speculated that sound is represented both horizontally and vertically. That way, mentally generated horizontal and vertical spatial codes interact with stimuli-generated vertical spatial codes and modulate the crossmodal congruency effect. As a result, horizontal congruency emerged as an essential prerequisite for vertical congruency effects.

In addition, it seems that crossmodal mappings happen automatically and effortlessly. Our results are in line with previous findings, demonstrating that relations can be retrieved unconsciously and transferred across domains. (Hristova, 2017; Li, Li, Zhang, Shi, & He, 2018) Thus, as Holyoak, Gentner and Kokinov (2001) pointed out, the ability to manipulate relations might be basic for cognition.

That being said, the experiment is a beginning of a larger experimental work within the field of crossmodal correspondences. The hypothesis about the online relational analyses should be explored further. Additional experimental settings should investigate whether similar associations exist among isolated features, or are integrated in larger cognitive frameworks. Another major challenge would be to outline the dissimilarities between given crossmodal mappings and relating them to other forms of associations.

She Helped Even Though She Wanted to Play: Children Consider Psychological Cost in Social Evaluations

Xin Zhao & Tamar Kushnir
Cornell University

Abstract

Sometimes we incur a high psychological cost (for example, forgo something we really like) in order to fulfill social or moral obligations. How would the information of incurring psychological costs influence children's social evaluations? Prior work suggests that children do not recognize the virtue of resolving inner conflicts until age 8. In two studies, we de-confounded costs from inner conflicts and found that when the difficulty was not explicitly stated as having conflicting desires (a self-interested desire and a moral desire) at once, most 8- to 9-year-olds and some 6 to 7-year-olds gave adult-like favorable evaluations of the character who overcame psychological or physical difficulty to act morally. Moreover, neither adults nor children inferred conflicting moral and personal desires spontaneously. These together suggest that children's evaluation of moral virtue depends on understanding of cost rather than conflict: Physical cost is incorporated early in development, and psychological cost later.

Introduction

Suppose that you ask two of your friends to help you with a paper you have to finish tonight; at the same time there is a really good show on tv. One of your friends really likes this show. The other friend does not have any interest in the show at all. If each one of these friends offered to help you with your paper, would you evaluate their actions towards you differently? Even if both friends ended up helping you, the one who gave up watching her favorite show incurred a higher psychological cost to do so, and intuitively this might lead us to evaluate her as nicer, kinder, perhaps a better friend. The costliness of her choice to help seems to weigh heavily in our evaluation. We investigate children and adults' intuitions about psychological cost as it relates to moral status in the current studies.

The ability to make social evaluations about others develops early in childhood (Hamlin, Wynn, & Bloom, 2007; Hamlin, Wynn, Bloom, & Mahajan， 2011; Burns & Sommerville, 2014; Geraci & Surian, 2011; Sloane, Baillargeon, & Premack, 2012; Olson & Spelke, 2008). Even infants and young children prefer someone who helps another person fulfill a goal (e.g., climbing a mountain or opening a box) over someone who hinders another person from goal completion (e.g., Hamlin et al., 2007) and prefer someone who shares equally with others over someone who does not share equally (e.g., Olson & Spelke, 2008). This research has mainly focused on comparing actions that bring about different outcomes (usually a positive outcome vs. a negative outcome). By preschool age, children consistently consider the intention behind an action even when it is inconsistent with its outcome (e.g., attempted or innocent harm; see Baird & Astington, 2004; Cushman, Sheketoff, Wharton, & Carey, 2013; Killen, Mulvey, Richardson, Jampol, & Woodward, 2011). Prior work suggests a link between the development of intent-based social evaluation and theory of mind (Killen et al., 2011; Smetana et al., 2012).

Previous research has examined young children's consideration of costs in their inferences of individual's goals and preferences. For example, infants consider the cost that someone expends to achieve a goal when making inferences on how much the agent values the goal. After seeing someone achieve two goals one at a larger cost than the other (e.g. has to jump over a higher barrier), infants expect her to value the goal that incurs a larger cost more than the other goal (Liu, Ullman, Tenenbaum, & Spelke, 2017). Similarly, toddlers are more likely to exonerate a non-helper for whom helping would have been hard than someone for whom helping would have been easy (Jara-Ettinger, Tenenbaum, & Schulz, 2015). Preschoolers even consider the cost they themselves incur to share with others in interpreting if their own actions are prosocial (Chernyak & Kushnir, 2013, 2018).

To date, studies of young children's evaluation of agents' psychological or moral status based on cost have focused on tangible goods - physical obstacles such as distance or barriers or valuable resources such as toys or stickers. Our initial example of the friend who gives up her favorite tv show is both like and unlike these cases. It is like resource sharing because the tv show can be thought of as having value, like stickers or toys. However, it is unlike resource sharing in that the value is intangible rather than tangible, a mental state rather than an object. Less is known about how children's understanding of this, more psychological, type of cost plays a role in their social evaluations.

Several pieces of evidence suggest that understanding psychological cost may be challenging for young children. First, one recent study (Starmans & Bloom, 2016) looked at children's evaluation of inner moral conflicts. In this study, children of 3 to 8 years old and adults were asked to compare two characters who both ultimately acted morally, but one acted morally without experiencing inner conflict, while the other resolved an inner conflict between a self-interested desire and a moral desire in order to act morally. Starmans & Bloom (2016) found that although adults evaluated the conflicted character more favorably than the unconflicted character, children of 3 to 8 years old showed the opposite evaluation. This result shows that children do not recognize the moral virtue of resolving inner conflicts until after age 8. However, it leaves open the question of whether the conflict

itself was difficult for children to understand (having both a moral and selfish desire at once), or the psychological cost was difficult to understand (forgoing something one likes in order to act morally).

Second, much recent evidence has shown that during early and middle childhood children increasingly recognize the possibility and positivity of overcoming immediate self-interested desires. For example, between 4 and 7, children increasingly believe that one can choose to act contrary to personal desires (e.g., Kushnir et al., 2015). Children also increasingly predict that individuals will act against personal desires (e.g. play) to comply with moral rules (e.g. help brother) and would feel good about it (Lagattuta, 2005; Lagattuta, Nucci, & Bosacki, 2010). Similarly, they also increasingly predict that an individual will act towards higher-order goals (e.g. doing homework) rather than succumbing to immediate desires (e.g. watching cartoons) (Yang & Fyre, 2018) Therefore, it is likely that, during early and middle childhood, as children view forgoing immediate self-interested desires to be possible and positive, they may increasingly favorably evaluate someone who endures high psychological cost to do the right thing.

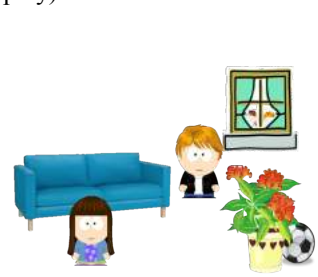
In two studies, we investigate how information about psychological costs affects children's social evaluations. Our first research question was, at what age can children evaluate someone who incurs higher psychological costs to fulfill social or moral obligations as more virtuous? In Study 1, we asked children and adults to compare two characters who ultimately did the right thing, but one incurred a larger psychological cost (i.e., forewent something she really likes) in order to do the right thing, while the other incurred a smaller psychological cost (i.e., forwent something she does not like). We closely followed the procedure of Starmans & Bloom (2016) but, importantly, we removed expressions of inner conflict from the procedure by mentioning moral actions without stating moral desires. We focused on children of 4 to 9 years old. Our second research question was how children make inferences on the agents' moral desires based on the information on psychological costs incurred to perform the moral action. Thus, after asking children to make evaluations, we also asked children to make inferences about the unstated moral desires of each character. Our final question was whether children's social evaluations may differ by the types of costs. Thus, in Study 2, we tested how children's evaluation of incurring psychological cost compare to their understanding of incurring physical cost.

Study 1

Method

Seventy-six 4- to 9-year-olds (4.02- 7.98, M = 5.80, SD = 1.06, 41 boys) from Ithaca, New York were recruited for this study. Mirroring the procedure in Starmans & Bloom (2016), we divided the children into three age groups: 4- to 5-year-olds, 6- to 7-year-olds, 8- to 9-year-olds. Specifically, 39 4- to 5-year-olds (4.02- 5.85, M = 4.99, SD = .52, 21 boys), 37 6- to 7-year-olds (6.00 - 7.98, M = 6.94, SD = .64, 17 boys) and 24 8- to 9-year-olds (8.03 – 9.65, M = 8.84, SD = .55, 11 boys) were included in the analyses. In addition, 92 adults were recruited from Amazon Mechanical Turk.

Each child was read four pairs of stories and shown accompanying pictures adapted from Starmans & Bloom (2016). See Figure 1 for an example of the stories. Each pair of stories described two characters who both performed a good action (e.g. helping her brother). One character (i.e., the "high psychological cost" character) incurred a higher psychological cost and forewent something she really liked in order to perform the good action. The other character (i.e., the "low psychological cost" character) incurred a lower psychological cost and forewent something she did not really like. Two story items (one Helping Story about helping siblings, one Honesty Story about telling truth to mom) were adapted from Starmans & Bloom (2017) and concerned moral obligations. We added two other pairs of stories about following rules (one Dishes Story about cleaning up dishes as mom asks, one Toys Story about playing the toy mom asks to play).



"High Psychological Cost" Character:
This is Ana, and this is Ana's brother. Ana's brother lost his favorite ball. He has been looking for it really hard, but he still hasn't found it. So he asked Ana to help him look for it. Helping people is the right thing to do. Ana's friends are playing right outside. Ana likes playing outside. She wants to go play outside right now.
But Ana helped her brother look for his ball. It was really hard for Ana to help her brother because she wanted to play outside. But Ana helped her brother anyway.

"Low Psychological Cost" Character:
This is Tiffany, and this is Tiffany's brother. Tiffany's brother lost his favorite ball. He has been looking really hard, but he still hasn't found it. So he asked Tiffany to help him look for it.
Helping people is the right thing to do. Tiffany's friends are playing right outside. But Tiffany doesn't like playing outside. She doesn't want to go play outside right now.
So Tiffany helped her brother look for his ball. It was really easy for Tiffany to help her brother because she didn't want to play outside. So Tiffany helped her brother.

Figure 1 Example of the images and scripts in Study 1.

All the characters were the same gender as the participants. The order of presenting the four stories was counterbalanced across participants. The order of presenting the high psychological cost character and the low psychological cost character was counterbalanced across story items for each participant. After hearing each pair of stories, the child was asked two remember check questions: "Who found it easy to do something good?" and "Who found it hard to do something good?" Children answered 95% of the trials correctly. We only included those trials where both remember check questions were answered correctly. Including those trials where the remember check questions were answered incorrectly did not change the pattern or significance of results reported here.

Following each story, we asked children two *social evaluation* questions. The first was (i.e., Prize question) "Which of the two characters would you give a prize to?" This was followed by a second question (i.e., Nicer question), "which one do you think is nicer?"

We then asked children a *moral desire rating* question for each character in each pair of stories: "How much do you think she (the "high cost" character) wants to do the right thing?" and "How much do you think she (the "low cost" character) wants to do the right thing?" For each question,

children were asked to use a 3-point rating scale ("a lot", "a little bit", "not at all") to infer the degree of moral desire.

The adults received identical stimuli and questions, but read through these materials themselves online, and the characters were not matched to adult participants' gender.

Results

Social Evaluation First, we examined our first research question that at what age can children evaluate someone who incurs higher psychological costs to fulfill social or moral obligations as more virtuous. See Figure 3.2 for results on children and adults' responses to the social evaluation questions. We conducted a binary logistic regression, with their responses ("low cost" character = 1, "high cost" character = 0) as the dependent variable and age group (4- to 5-year-olds, 6- to 7-year-olds, 8- to 9-year-olds, adults) as a between-subjects factor, and story item (helping, honesty, toys, dishes) and question (prize, nicer) as within-subjects factors. We found a significant main effect of age group (Wald $\chi^2(3, N = 192) = 71.08$, $p < .001$). Specifically, adults were more likely to choose the "high cost" character than either 6- to 7-year-olds Wald $\chi^2(1, N = 129) = 17.83$, $p < .001$, or the 4- to 5-year-olds, Wald $\chi^2(1, N = 131) = 62.65$, $p < .001$. The 8- to 9-year-olds were not significantly different from the adults, $p = .84$, and were more likely to choose "high cost" character than were either the 6- to 7-year-olds Wald $\chi^2(1, N = 61) = 8.79$, $p = .003$, or the 4- to 5-year-olds, Wald $\chi^2(1, N = 63) = 27.14$, $p < .001$. The 6- to 7-year-olds were also more likely to choose the character who incurred a higher psychological cost than the 4- to 5-year-olds, Wald $\chi^2(1, N = 76) = 6.94$, $p = .008$. No effects of questions or story item were found (p's > .06).

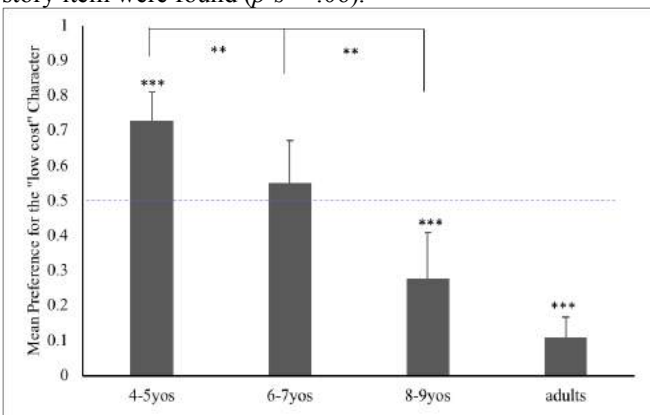


Figure 2. Children's and adults' mean preference for the "low cost" character in Study 1. Error bars represent 95% confidence intervals. Asterisks indicate significance of two-tailed t-tests. (**) $p < .01$, (***) $p < .001$.

Since no significant effects of question or story item were found, we averaged participants' responses in two dependent measure questions across four story items and ran two-tailed one-sample t-tests to compare to chance (0.5) for each age group. Adults significantly favored the "high cost" character ($M = .25$), $t(91) = -6.87$, $p < .001$, 95% $CI = [-.32, -.17]$. In contrast, the 4-to 5-year-olds significantly favored the "low cost" character ($M = .73$), $t(38) = 5.43$, $d =$, 95% $CI = [.14, .31]$. Responses of the 6- to 7-year-olds did not differ from chance ($M = .55$), $t(36) = .83$, $p = .41$, 95% $CI = [-.07, .18]$. The 8- to 9-year-olds significantly favored the "high cost" character ($M = .28$), $t(23) = -3.06$, $p = .006$, 95% $CI = [-.37, -.07]$.

Moral Desire Ratings We then examined participants' ratings of the characters' moral desires (see Figure 3). We ran an ordinal GEE with age group (4-to 5-year-olds, 6-to 7-year-olds, 8- to 9-year-olds, adults) as a between-subject factor, character ("low cost" character, "high cost" character) and story item as within-subject factors. We found a significant main effect of character (Wald $\chi2(1, N = 192) = 221.45$, $p < .001$) that participants' ratings of moral desire were higher for the "low cost" character than the "high cost" character. We also found a significant main effect of story item (Wald $\chi2(3, N = 192) = 47.18$, $p < .001$). Specifically, participants' ratings of moral desire were lower for the Dishes story than the three other stories (p's < .004). No significant differences were found among other stories. We found no significant main effect of age group ($p = .08$) but found a significant interaction between age group and character (Wald $\chi2(3, N = 192) = 24.57$, $p < .001$). To further investigate the interaction, for each age group, we ran an ordinal GEE with character ("low cost" character, "high cost" character) and story item as within-subject factors. We found that although participants in all age groups rated higher moral desire for the "low cost" character than the "high cost" character (4- to 5-year-olds: Wald $\chi2(1, N = 39) = 31.93$, $p < .001$; 6- to 7-year-olds: Wald $\chi2(1, N = 37) = 73.61$, $p < .001$; 8- to 9-year-olds: Wald $\chi2(1, N = 24) = 44.70$, $p < .001$; adults: Wald $\chi2(1, N = 92) = 58.03$, $p < .001$), the difference were strongest among the 6- to 7-year-olds.

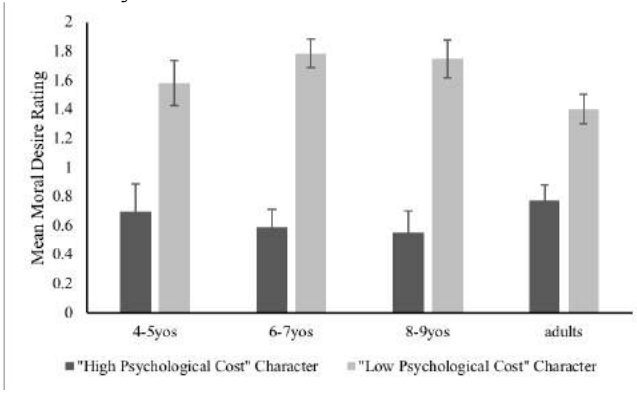

Figure 3. Mean moral desire ratings split by character and age group in Study 1. Error bars represent 95% confidence intervals.

Discussion

In Study 1, adults considered a person who incurred a higher psychological cost to do the right thing (e.g., help brother) more favorably than a person who incurred a lower psychological cost to do the same thing. We found a

developmental change in this evaluation among children. Four- to five-year-olds showed completely opposite evaluation from adults. With age, children increasingly showed a preference for the character who incurred a higher psychological cost to help.

Our results clarify age differences found in Starmans and Bloom (2016) in a few ways. First, in contrast to this prior study, when the difficulty was not explicitly stated as having conflicting desires (a self-interested desire and a moral desire) at once, 8- to 9-year old children gave adult-like favorable evaluations of the character who overcame the difficulty to act morally. Moreover, 6- and 7-year-olds were at chance, rather than favoring the easy action. The reversal from the adult pattern only appeared in the youngest group.

Both children and adults inferred that the person who incurred a lower psychological cost had stronger desire to do the right thing than the person who incurs a higher psychological cost. This suggests that neither children nor adults intuitively inferred coexistence of two conflicting desires (e.g., a self-interested desire and a moral desire).

Although ideally a direct replication and comparison to Starmans & Bloom (2016) would be more informative, we speculate that our results so far may together rule out moral conflict as the central understanding driving children's and adults' social evaluations. Instead, our findings suggest the importance of developing understanding the virtue of incurring costs to do the right thing in children's evaluations. To further investigate this developmental change, in Study 2, we look at how children's consideration of psychological costs may compare to their consideration of physical costs in social evaluations. We focused on the youngest children from study 1, 4- to 7-year-olds, since we found that their evaluations were significantly different from adults. We tested a group of adults as a reference group.

Study 2

Method

Data collection is still ongoing. We set our sample size as 36 children per age group (4- to 5-year-olds and 6- to 7-year-olds). So far, sixty-one 4- to 7-year-olds (4.00- 7.99, M = 5.32, SD = 1.17, 28 boys) from Ithaca, NY were recruited for this study. We divided the children into a younger group (4- to 5-year-olds) and an older group (6- to 7-year-olds). Specifically, 37 4- to 5-year-olds (4.00- 5.95, M = 4.89, SD = .58, 21 boys), 24 6- to 7-year-olds (M = 7.07, SD = .56, 6.03 - 7.99, 7 boys) were included in the preliminary analyses. addition, 101 adults took part in this study and were included in the analyses.

Participants were told four pairs of stories with accompanying pictures, each contrasting a "high cost" character (who incurred a high physical or psychological cost to do the right thing) with a "low cost" character (who incurred a low cost to do the right thing). Two pairs of the stories featured psychological costs and were the same as the Helping Story and the Dishes story in Study 1. The other two pairs of stories featured physical cost (see Figure 4). For example, in the Helping Story, the "high cost" character climbed up the stairs to picked up the ball for her brother, while the "low cost" character walked behind the sofa next to her and picked up the ball.

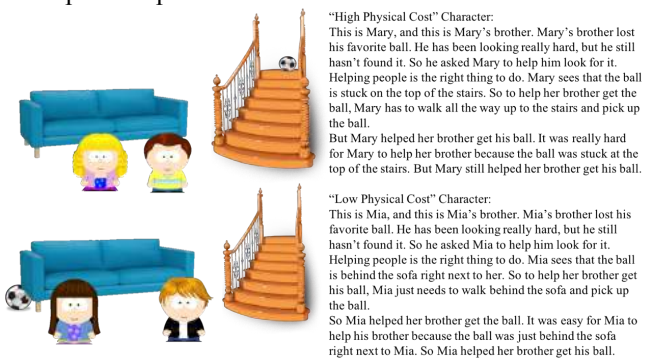

Figure 4 Example of the images and scripts featuring physical cost presented in Study 2.

All the characters were the same gender as the participants. The order of presenting the stories about psychological cost and stories about physical cost were counterbalanced across participants. The order of the high psychological cost character and the low psychological cost character were counterbalanced across stories for each participant. After hearing each pair of stories, the child was asked two remember check questions: "Who found it easy to do something good?" and "Who found it hard to do something good?" Children answered 93% of the trials correctly. We only included those trials where both remember check questions were answered correctly. Including those trials where the remember check questions were answered incorrectly did not change the pattern or significance of results reported here.

Following each story, children were asked the same two *social evaluation* questions (order counterbalanced) as in Study 1. One was (i.e., Prize question) "Which of the two characters would you give a prize to?" The other question (i.e., Nicer question) was "which one do you think is nicer?" We then asked children one *moral desire rating* question for each character using the same measures as Study 1.

The adults received identical stimuli and questions, but read through these materials themselves online, and the characters were not matched to adult participants' gender.

Results

Social Evaluations First, we examined participants' evaluation of the two characters (See Figure 5). We ran a binary logistic regression, with their responses ("low cost" character = 1, "high cost" character = 0) as the dependent variable and age group (4- to 5-year-olds, 6- to 7-year-olds, adults) as a between-subjects factor, and cost type (psychological vs. physical), story item (helping, dishes) and questions (prize, nicer) as within-subjects factors. We found a significant main effect of age group (Wald $\chi^2(2, N = 162) = 93.69$, $p < .001$). Specifically, adults were more likely to choose the "high cost" character than either the 6- to 7-year-

olds (Wald $\chi^2(1, N = 137) = 11.62$, $p = .001$), or the 4- to 5-year-olds (Wald $\chi^2(1, N = 125) = 83.69$, $p < .001$). The 6- to 7-year-olds were also more likely to choose the "high cost" character than the 4- to 5-year-olds (Wald $\chi^2(1, N = 61) = 25.06$, $p < .001$). We also found a significant main effect of cost type (Wald $\chi^2(1, N = 61) = 8.44$, $p = .004$). Specifically, participants were more likely to choose the "high cost" character in the physical stories than in the psychological stories. Interestingly, we also found a significant interaction between age group and cost type, Wald $\chi^2(2, N = 61) = 8.99$, $p = .011$. To further investigate the interaction, for each age group, we ran a binary logistic regression with responses ("low cost" character = 1, "high cost" character = 0) as the dependent variable and cost type (psychological vs. physical), story item (helping, dishes) and question (prize, nicer) as within-subjects factors. We found a marginal effect of cost type for 4- to 5-year-olds (Wald $\chi^2(1, N = 37) = 3.32$, $p = .068$), a significant main effect of cost type for 6- to 7-year-olds (Wald $\chi^2(1, N = 24) = 8.25$, $p = .004$), and no main effect of cost type for adults ($p = .66$). No significant effects question type or story item were found (p's > .25).

Since no significant effects of question type or story item were found, we averaged participants' responses in two dependent measure questions across two story items for each type of cost. We then ran one-sample t-tests to compare participants' responses in each type of story to chance (0.5) for each age group. Adults significantly favored the "high cost" character both for psychological stories ($M = .20$, $t(93) = -8.75$, $p < .001$, 95% $CI = [-.36, -.23]$) and physical stories ($M = .13$, $t(95) = -13.42$, $p < .001$, 95% $CI = [-.43, -.32]$). In contrast, the 4-to 5-year-olds significantly favored the "low cost" character both for physical costs ($M = .64$, $t(35) = 2.28$, $p = .029$, 95% $CI = [.02, .26]$) and psychological costs ($M = .75$, $t(36) = 5.16$, $p < .001$, 95% $CI = [.15, .35]$). The 6- to 7-year-olds significantly favored the "high cost" character for the physical stories ($M = .23$, $t(22) = -4.81$, $p < .001$, 95% $CI = [-.39, -.15]$) but their responses did not differ from chance for the psychological stories ($M = .40$, $t(22) = -1.18$, $p = .25$, 95% $CI = [-.27, .07]$).

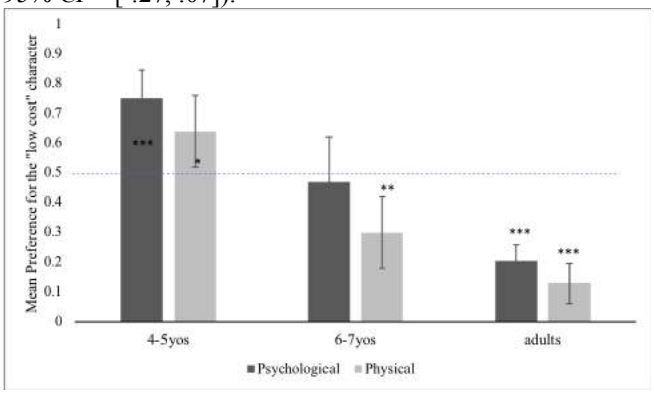

Figure 5. Children's and adults' mean preference for the "low cost" character in Study 2. Error bars represent 95% confidence intervals. Asterisks indicate significance of two-tailed t-tests. (**) $p < .01$, (***) $p < .001$.

Moral Desire Ratings We then examined participants' moral desire ratings for the characters (see Figure 6). We ran an ordinal GEE with age group (4-to 5-year-olds, 6-to 7-year-olds, adults) as a between-subject factor and character ("low cost" character, "high cost" character), cost type (psychological, physical) and story item (Helping, Dishes) as within-subject factors. We found a significant main effect of character (Wald $\chi^2(1, N = 158) = 88.03$, $p < .001$) that participants' moral desire ratings are higher for the "low cost" character than the "high cost" character. We also found a significant main effect of cost type (Wald $\chi^2(1, N = 158) = 4.98$, $p = .026$), that participants' moral desire ratings for the characters are higher in the psychological stories than the physical stories. We also found a significant main effect of story item (Wald $\chi^2(1, N = 158) = 32.74$, $p < .001$), that the moral desire ratings for the characters are higher in the Helping stories than the Dishes stories. Interestingly, we also found a significant interaction between character and cost type (Wald $\chi^2(1, N = 158) = 28.08$, $p < .001$). Follow-up analyses showed that participants rated stronger moral desire for the "low cost" character than the "high cost" character for both psychological cost (Wald $\chi^2(1, N = 158) = 78.21$, $p < .001$) and physical cost (Wald $\chi^2(1, N = 158) = 23.71$, $p < .001$), but the difference is stronger for psychological cost than for physical cost. We also found a significant interaction between age group and character (Wald $\chi^2(1, N = 158) = 28.08$, $p < .001$). Follow-up analyses showed that participants in all age groups rated stronger moral desire for the "low cost" character than the "high cost" character (4- to 5-year-olds: Wald $\chi^2(1, N = 37) = 33.25$, $p < .001$; 6- to 7-year-olds: Wald $\chi^2(1, N = 23) = 36.58$, $p < .001$; Wald $\chi^2(1, N = 98) = 15.67$, $p < .001$), but the difference is stronger among children than adults. Also, we found no significant main effect of age group ($p = .53$).

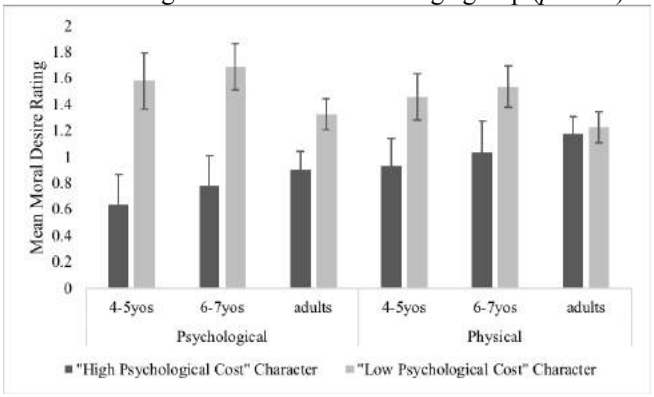

Figure 6. Mean moral desire ratings split by character, cost type and age group in Study 2. Error bars represent 95% confidence intervals.

Discussion

In Study 2, we looked at how children's considerations of psychological costs compare to their considerations of physical costs in social evaluations. Adults consistently demonstrated a favorable evaluation for someone who

incurred a high psychological or physical cost to do the right thing. Preschool-age children (4- to 5-year-olds) demonstrated an opposite evaluation from adults, favoring the person who incurred a lower psychological cost or physical cost. Most six- and seven-year-olds recognize the virtue of acting at a physical cost. Some of them also recognize the virtue of acting at a psychological cost. These results further support the idea that children's evaluation of moral virtue depends on their understanding of cost rather than conflict: Physical cost is incorporated early in development, and psychological cost later.

General Discussion

In this paper, we investigated children's consideration of costs in their social and moral evaluations. Prior studies have mostly focused on children's understanding of physical costs including physical obstacles or valuable resources. Across two studies, we show that young children may start out with an intuitive preference for individuals who find it easy to do something good, and that they gradually transition to an adult-like understanding that incurring costs to do something good is positive, praiseworthy and morally virtuous. Importantly, neither adults nor children inferred conflicting moral and personal desires spontaneously. This helps clear the findings in our study and findings in Starmans &Bloom (2016). It seems that children recognize the virtue of incurring costs before recognizing the virtue of resolving conflicting desires. Moreover, children's recognition of the positivity of incurring costs to do the right thing seems to develop in two stages: They first recognize the positivity of overcoming *physical* obstacles at around 6 to 7 years old, and then understanding the positivity of overcoming *psychological* obstacles at around 8 to 9 years old.

The difference we found between children's consideration of the psychological costs and physical costs add to prior work on children's understanding about costs. Understanding psychological costs is similar to understanding physical costs in that they both involve recognizing the possibility and positivity of making efforts and overcoming some kind of difficulty. However, they are also different in that understanding psychological costs relies on understanding that people may have different desires and that they need to make mental efforts to overcome the psychological obstacles, which may be part of higher-order theory-of-mind understanding (Lagattuta et al. 2015). Exploring interactions of understanding of costs and children's mental state understanding is an important direction for future work.

What underlies the development between ages 4 and 9? There are at least three possible explanations for this developmental change. First, it is possible that, as children age, they increasingly experience situations where they need to incur physical or psychological costs (for example, giving up something they really like) in order to achieve certain social or moral goals. Through such experience of they may gradually recognize the effort one needs to put in this process, and thus understand the virtue of incurring costs to do the right thing. Second, it is also possible that as children get older, they may be increasingly praised and encouraged for making efforts to overcome some physical or psychological difficulties to achieve certain goals by caregivers or teachers. The final possibility is that younger children may have a bias that someone who incurs a lower cost simply has higher competence, while only later they gradually understand that easiness is not necessarily the indicator for competence. This possibility is consistent with prior work in children's reasoning about ability showing that 4-year-olds judge someone who finds a task easy to be smarter than one who find the same task hard (Heyman, Gee, & Giles, 2003). These possibilities are certainly not mutually exclusive. It might be that children's first-person experience, the linguistic input they receive, and their increasingly mature understanding of competence together guide their development of an understanding of the virtue of incurring costs to do the right thing.

Acknowledgments

We gratefully thank the members of the Early Childhood Cognition Lab, and especially Jason Lin and Andrew Lee for assistance with recruitment and coding. We thank the staff of the Sciencenter and preschools, and the children and parents who participated in this research.

Abstract

We explored the impact of three types of decision granularity, problem level (Prob), step level (Step), and both problem and step levels (Both), on student learning. We first conducted an empirical study to directly compare the three conditions and then three subsequent studies to evaluate one or two of the three conditions. Overall our empirical results showed there was no significant difference among the three conditions. We further split students into different groups based on their performances on the single-principle and the multiple-principle problems in the pre-test. Solving the single-principle problems only involves one step while solving the multiple-principle ones involves generating multiple steps in a logic order. We define High students as those who were correct on *all* single-principle problems and *at least one* multiple-principle ones in the pre-test, Low students as those who were correct on *some or all* single-principle problems *but no* multiple-principle ones, and the rest are in the Medium group. Our empirical results showed that for Low students, Both can be better than Step. For the Medium and High students, no clear conclusions could be drawn because of small sample sizes. As a result, in a post-hoc analysis all students were combined by their assigned conditions. Overall, while no significant difference was found among the three conditions, we found that the impact of three types of granularity, Prob, Step, and Both differs significantly for High vs. Low students: $Both, Step > Prob$ for the High students and $Both, Prob > Step$ for the Low students. No clear conclusions could be drawn for the Medium group due to its small sample sizes. In short, while Prob could be effective for Low students but ineffective for High ones and Step could be effective for High students but ineffective for Low ones, Both seemed to be effective for both High and Low students.

Keywords: granularity, worked example, problem solving, student competence

Introduction

In STEM domains like math, probability and science, solving a *problem* often requires producing an argument, proof or derivation consisting of one or more inference steps, and each *step* is the result of applying a domain principle, operator or rule. For instance, an algebraic equation 2x+5=21 can be solved via two steps: 1) subtract the same term 5 from both sides of the equation; and 2) divide both sides by the non-zero term 2. As a result, tutoring in such domains is often structured as a two-loop procedure. An outer loop selects the *problem* or task the student should work on next, while the inner loop governs *step* level decisions such as whether or not to give a hint (Vanlehn, 2006).

In this paper, we directly explored the impact of three types of decision granularity on student learning by comparing three conditions: problem level (Prob), step level (Step), and both problem and step levels (Both). In the Prob condition, the tutor randomly decides whether the next problem is worked example (WE) or problem solving (PS). In WE, students observe how the tutor solves a problem, while in PS the students solve the problem themselves. In the Step condition, a random decision is made on whether the next *step* should be WE or PS. To differentiate it from the problem level PS and WE, we refer to such step level interleaving as *Faded Worked Example (FWE)*. Finally, the Both condition involves both levels of decisions: at the problem level, it randomly decides whether the next problem should be WE, PS or FWE; if FWE is selected, step level decisions will be randomly made.

A series of studies were conducted to evaluate the three types of decision granularity in the domain of probability using an Intelligent Tutoring System (ITS) named Pyrenees from 2014-2017. Pyrenees allowed us to rigorously control the content and vary only the types of decision granularity. In Fall 2014 (Fall'14), all three conditions were *empirically* compared; for the subsequent studies, only one or two conditions were examined.[1] In a post-hoc comparison, students from all studies were combined by their conditions because all conditions across different years went through the same standard 4-phase procedure: textbook, pre-test, training on ITS, and post-test, and all materials in each of the four phases were kept to be *identical* across different years. Overall, our results showed that there was no significant difference among the three conditions either in Fall'14 (Zhou, Price, Lynch, Barnes, & Chi, 2015) or in the post-hoc analysis.

On the other hand, the *aptitude-treatment interaction (ATI)* effect states that some instructional interventions can be more or less effective for particular students depending upon their specific abilities or knowledge (Cronbach & Snow, 1977; Snow, 1991). Here we argue that WE, PS, and FWE involve different *learning mechanisms*. More specifically, in WEs, students learn by *observing* how the tutor solves a problem; in PSs, students learn by *doing* – solving the problem with the tutor's assistance; in FWEs, students learn by *collaboratively constructing* the solution with the tutor. As a result, we argue that in the Prob condition students switched between learning by observing (WE) and learning by doing (PS); in the

[1] Please note that another purpose of the subsequent studies was to compare reinforcement learning induced policies with random policies. Due to participant limit, we were not able to compare the three conditions again.

Step condition, students learn by *collaboratively constructing* answers for (FWEs) with the tutor; in the Both condition, students experienced all three types of learning mechanisms. Therefore, we expect that Prob, Step, and Both can be more or less effective for different students.

To investigate whether there is indeed an ATI effect, we split students into High, Medium and Low groups based on their incoming competence measured by their performances on six single-principle and four multiple-principle problems in the pre-test. Solving the single-principle problems only involves one step while solving the multiple-principle ones involves generating multiple steps in a logic order. We define High students as those who were correct on *all six* single-principle problems and *at least one* multiple-principle ones in the pre-test, Low students as those who were correct on *some or all* single-principle problems *but no* multiple-principle ones, and the rest are in the Medium group. Our results from Fall'14 showed that for the Low students, both levels of the granularity (Both) is significantly more effective than the step level decisions (Step); for the Medium and High students, no clear conclusions could be drawn because of small sample sizes. In the post-hoc analysis, no clear conclusions could be drawn for the Medium group due to its small sample sizes and for the other two groups, we have: $Both, Step > Prob$ for the High students and $Both, Prob > Step$ for the Low students. In short, our post-hoc analysis suggested that the problem level decisions (Prob) could be effective for Low students but ineffective for High ones; on the other hand, the step level decisions (Step) could be effective for High students but ineffective for Low ones; finally, the both level decisions (Both) seemed to be effective for both High and Low students.

Background and Related Work

The Impact of Granularity Involving WE, PS, FWE

Much of prior research has investigated the effectiveness of WE, PS, FWE, and their various combinations (Sweller & Cooper, 1985; McLaren, Lim, & Koedinger, 2008; McLaren & Isotani, 2011; McLaren, van Gog, Ganoe, Yaron, & Karabinos, 2014; Van Gog, Kester, & Paas, 2011; Renkl, Atkinson, Maier, & Staley, 2002; Schwonke et al., 2009; Najar, Mitrovic, & McLaren, 2014; Salden, Aleven, Schwonke, & Renkl, 2010; Zhou et al., 2015; Zhou, Lynch, Price, Barnes, & Chi, 2016; Zhou & Chi, 2017; Zhou, Wang, Lynch, & Chi, 2017; Zhou, Azizsoltani, Ausin, Barnes, & Chi, 2019). Here we only include those that involved any of the three types of granularity. At the problem level granularity, for example, McLaren et al. (2008) found no significant difference in learning performance between Prob (WE-PS pairs) and PS-only, but the former spent significantly less time than the latter. In a subsequent study, McLaren and Isotani (2011) compared three conditions: WE-only, PS-only, and Prob (WE-PS pairs). Similarly, no significant differences were found among them in terms of learning gains, but the WE condition spent significantly less time than the other two; and no significant time on task difference was found between the PS and the Prob (WE-PS pairs) condition.

A series of studies compared the Step level and the Both level granularity with PS only (Schwonke et al., 2009; Salden et al., 2010). Results showed that the former two can be more effective than the latter. For example, Salden et al. compared three conditions: Both (WE-FWE-PS), Step (FWE), and PS-only (Salden et al., 2010). Their results showed that Step outperformed Both, which in turn outperformed PS-only, and no significant time on task difference was found among the three conditions. Note that in this study, the order of WE, FWE, and PS was fixed in Both; while in Step, the tutor used an adaptive pedagogical policy, expert rules combined with data-driven student models, to determine whether the next step should be WE or PS. Therefore, it is was not clear whether it was the adaption or the granularity that made the Step condition more effective than the other two conditions. In our studies, we factored out the impact of adaption by employing random policies.

While the studies described above mainly used PS-only as baselines, several studies directly compared different types of granularity. Overall, results suggested that the Both level granularity could be more effective than the Prob level (Renkl et al., 2002; Najar et al., 2014). For example, Renkl et al. (2002) compared Both (WE-FWE-PS) with Prob (WE-PS pairs) and the former significantly outperformed the latter on student learning performance while no significant difference was found between them on time on task. Similarly, Najar et al. (2014) compared Both (adaptive WE/FWE/PS) with Prob (WE-PS pairs). They found that the former significantly outperformed the latter in terms of learning outcomes and the former also spent significantly less time on task. Here, an adaptive pedagogical policy was also employed to make both the problem and step level decisions. Thus, it is quite possible that the superiority of Both over Prob stemmed from the adaption rather than from the granularity. In sum, while different decision granularities were involved in prior studies, the WEs and PSs were provided following some fixed or adaptive pedagogical policies. In this work, we factor out the impact of pedagogical policies by employing a random policy for all three types of granularity.

The ATI Effect of WE, PS, FWE

Some prior studies have also investigated the ATI effect of WE, PS, FWE, and their combinations (Kalyuga, Chandler, Tuovinen, & Sweller, 2001; Najar & Mitrovic, 2013; Najar, Mitrovic, & McLaren, 2016). For example, Najar and Mitrovic (2013) compared three conditions: 1) WE-only, 2) PS-only and 3) Prob (WE-PS pairs) in the domain of Structured Query Language and students were split into High vs. Low groups based on their pre-test scores. The results showed that for the High students: Prob, PS-only $>$ WE-only; while for their Low peers: Prob $>$ PS-only, WE-only. In a subsequent study, Najar et al. (2016) compared Both (adaptive WE/FWE/PS) with Prob (WE-PS pairs) and students were divided into High and Low groups by a median split on pre-test scores. Results showed that for the High students, Both

Table 1: Single-principle Problem vs. Multiple-principle Problem

Type	Single-principle Problem	Multiple-principle Problem
Question	If $p(A \cap B) = 0.2$ and $p(B) = 0.5$, find $P(A\|B)$.	If $p(B) = 0.06$, $p(\sim A \cap \sim B) = 0.87$ and $p(A \cap B) = 0.03$, find $p(A)$.
Answer	Apply the definition of conditional probability: $p(A\|B) = p(A \cap B)/p(B) = 0.2/0.5 = 0.4$	1) Apply the complement theorem: $p(\sim B \cap \sim A) + p(\sim (\sim B \cap \sim A)) = 1$ 2) Apply the de morgan's law: $p(A \cup B) = p(\sim (\sim B \cap \sim A)) = 1 - 0.87 = 0.13$ 3) Apply the addition theorem: $p(A \cup B) = p(A) + p(B) - p(A \cap B)$, $p(A) = 0.13 + 0.03 - 0.06 = 0.1$.

is more effective than Prob; while for the Low students, no significant difference was found.

In short, prior research investigating the ATI effect of WE, PS, FWE, and their combinations showed that for Low students, Prob could be more effective than doing WE and PS only; but for High students, Both can be more effective than Prob. While much of prior ATI research involved one or two types of granularity, to the best of our knowledge, no prior study has investigated the ATI effect when comparing the three types of granularity directly.

High, Medium, vs. Low Students

To investigate the ATI effect, we need to first distinguish students based on some specific abilities or knowledge. Learning in STEM domains such as math and science often involves acquiring two types of knowledge: declarative and procedural (Anderson, 1993). Declarative knowledge includes facts that we know and that can be described to others, for example, "the probability of TRUE is always 1". Procedural knowledge specifies how to retrieve and use declarative knowledge to solve problems. It is a type of knowledge that display with behaviors and often times cannot be explicitly described. Procedural knowledge often requires the interplay of many cognitive factors including but not limited to the following five ones in order of occurrence: 1) acquisition of declarative knowledge, 2) identification and retrieval of the proper declarative knowledge, 3) application of declarative knowledge, 4) organization and production of solution plans; 5) execution of solution plans and evaluation of answers.

Similar to previous research, we used pre-test to measure students' incoming competence. Our pre-test contains single-principle problems which involve applying one domain principle once and multiple-principle problems which involve applying multiple domain principles and for some principles more than once. Table 1 shows an example for each of them. The second column shows the question and answer for a single-principle problem. As we can see, the problem can be solved by directly applying a single-principle. The third column shows a multiple-principle problem. Solving the problem needs to not only apply three algebraic principles but also organize them in a logical order.

Based on the five cognitive factors described above, we argue that solving single-principle problems mainly involves factors 1-3, while solving multiple-principle ones involves all five of them. Thus, students must be able to solve single-principle problems before they can solve multiple-principle problems. Our data supported this point, showing that students who could solve multiple-principle problems always had the perfect score on all single-principle problems in the pre-test. Therefore, in the following we refer to students who could solve at least one multiple-principle problem correctly as High students, those who could only solve some or all of the six single-principle problems correctly as Low students, and the rest as the Medium students.

Methods

Participants

Four studies were conducted in each of the Fall semesters from 2014-2017 to evaluate the three conditions: Prob, Step, and Both using an ITS named Pyrenees in the undergraduate-level Discrete Mathematics course at North Carolina State University. They were assigned to students as one of their regular homework assignments and the completion of the tutor was required for full credit. Students were told that the assignment will be graded based on their demonstrated effort rather than performance. In different studies, different conditions were evaluated and in each study, students were randomly assigned to each condition. In Fall'14, all three conditions were *empirically* compared while for the subsequent three studies, only one or two conditions were examined and in the post-hoc analysis, students from all studies across the four years were combined by their conditions.

Table 2 shows an overview of participants in the four studies and the post-hoc analysis: the first two columns show the semester of the study and its corresponding conditions; columns 3 and 4 list the number of students initially assigned and finally completed in each condition. Overall, Pearsons Chi-squared test showed that there was no significant difference among the three conditions on their completion of study: $\chi^2(2) = 1.13, p = 0.57$ for Fall'14 and $\chi^2(2) = 0.65, p = 0.72$ for the post-hoc analysis. Here we only focus on Fall'14 and the post-hoc analysis because all three conditions are present.

Finally, students with perfect pre-test scores were excluded because we could not measure the improvement they made through training. The last column in Table 2 shows the number of students included in the following analysis.

Probability Tutor

Pyrenees is a web-based tutor that teaches students a general problem solving strategy and 10 major probability principles, such as the Complement Theorem and Bayes' Rule. It provides students with step-by-step instruction, immediate feedback, and on-demand help. Specifically, the help is provided via a sequence of increasingly specific hints. The last hint in

Table 2: Participants for E ach Study and Condition

Study	Cond	Distributed	Completed	Included
Fall'14	Prob	58	38	37
	Step	59	39	37
	Both	59	34	34
Fall'15	Prob	47	38	38
	Step	47	35	34
Fall'16	Prob	40	32	31
	Step	41	35	35
Fall'17	Both	70	57	56
Post-hoc	Prob	145	108	106
	Step	147	109	106
	Both	129	91	90

the sequence, i.e., the bottom-out hint, tells student exactly what to do. The ITS has three basic modes. In the WE mode, all the steps in a problem were solved by the tutor while in the PS mode, they were solved by the student. In the FWE mode, each step has a 50% chance to be solved by the tutor and 50% chance by the student. Except for the decision granularity, the remaining components of the tutor, including the GUI interface, the training problems and the tutorial support were identical for all students.

Procedure

All four studies include the four identical phases: 1) textbook, 2) pre-test, 3) training, and 4) post-test. The only difference among the three conditions was the decision granularity level, problem level for Prob; step level for Step; and both the problem and the step level for Both.

During textbook, all students studied the domain principles through a probability textbook. They read a general description of each principle, reviewed some examples of it, and solved some single- and multiple-principle problems. After solving each problem, the student's answer was marked in green if it was correct and red if incorrect. They were also shown an expert solution at the same time. If the students failed to solve a single-principle problem, then they were asked to solve an isomorphic one. This process was repeated until they either failed three times or succeeded once. The students had only one chance to solve each multiple-principle problem and were not asked to solve an isomorphic problem if their answer was incorrect.

The students then took a pre-test which contained 10 problems. They were not given feedback on their answers, nor were allowed to go back to earlier questions (this was also true for the post-test).

During training, students in all three conditions received the same 12 problems in the same order. Each main domain principle was applied at least twice. The minimal number of steps needed to solve each training problem ranged from 20 to 50. Such steps included variable definitions, principle applications, and equation solving. The number of domain principles required to solve each problem ranged from 3 to 11. The problems were given as WE, PS, or FWE, based upon the students' experimental condition. All students could access the textbook.

Finally, all students took the post-test which contained 16 problems in total. 10 of the problems were isomorphic to the pre-test problems given in phase 2. The remainder were non-isomorphic multiple-principle problems.

Grading criteria

The pre- and post-test problems required students to derive an answer by writing and solving one or more equations. We used three scoring rubrics: binary, partial credit, and one-point-per-principle. Under the binary rubric, a solution was worth 1 point if it was completely correct or 0 if not. Under the partial credit rubric, each problem score was defined by the proportion of correct principle applications evident in the solution. A student who correctly applied 4 of 5 possible principles would get a score of 0.8. The One-point-per-principle rubric in turn gave a point for each correct principle application. All of the tests were graded in a double-blind manner by a single experienced grader. The results presented below were based upon the partial-credit rubric but the same results hold for the other two. For comparison purposes, all test scores were normalized to the range of $[0,1]$.

Results

The three conditions were compared on test scores. For the Fall'14 study, a One-way ANOVA analysis on the pre-test score showed no significant difference among the three condition: $F(2,105) = 1.12$, $p = 0.33$, $\eta = 0.021$. A One-way ANCOVA analyses on the post-test score using the pre-test score as a covariate also showed no significant difference: $F(2,104) = 1.70$, $p = 0.19$, $\eta = 0.021$. Similar insignificant results were found in the host-hoc analysis: $F(2,299) = 0.68$, $p = 0.51$, $\eta = 0.005$ for the pre-test and $F(2,298) = 0.98$, $p = 0.38$, $\eta = 0.004$ for the post-test. In terms of time on task, contrast analysis revealed that Prob spent significantly less time than Step in both Fall'14: $t(105) = -2.62$, $p = 0.010$, $d = 0.61$ and post-hoc: $t(299) = -3.00$, $p = 0.003$, $d = 0.40$.

To evaluate the ATI effect, we split students based on their pre-test scores. Our pre-test included six single-principle and four multiple-principle problems. Following our splitting criteria discussed above, we refer to students who could solve at least one multiple-principle problem correctly (pre ≥ 0.7) as High students [2]; those who could only solve some or all of the six single-principle problems correctly (pre ≤ 0.6) as Low students, and the rest as Medium ones. As expected, in the pre-test the High group scored significantly higher than the Medium group: $t(105) = 6.94$, $p < 0.0001$, $d = 3.16$ in Fall'14 and $t(299) = 9.71$, $p < 0.0001$, $d = 2.37$ in post-hoc; the Medium group significantly outperformed the Low group: $t(105) = 8.41$, $p < 0.0001$, $d = 2.14$ in Fall'14 and $t(299) = 11.82$, $p < 0.0001$, $d = 2.08$ in post-hoc.

Incoming competence combined with three conditions partitioned the students into nine groups for both Fall'14 and

[2]Note that in our grading rubrics, all problems were weighted equally in both pre- and post-tests.

Table 3: Students Performance and Time (minutes) on Fall'14 Empirical Study and Post-hoc Analysis

Cond	Fall'14 Empirical Study					Post-hoc Analysis				
	N	Pre	Iso	Post	Time	N	Pre	Iso	Post	Time
Prob_H	12	.857(.065)	.817(.125)	.700(.169)	85.5(19.9)	56	.822(.086)	.844(.138)	.740(.178)	111.1(42.5)
Step_H	8	.800(.080)	.868(.156)	.769(.154)	125.2(40.0)	47	.827(.077)	.908(.089)	.819(.126)	128.2(29.4)
Both_H	13	.826(.064)	.863(.136)	.767(.160)	113.2(30.1)	46	.818(.073)	.902(.110)	.821(.156)	106.6(29.3)
Prob_M	5	.636(.017)	.728(.134)	.598(.168)	96.8(17.4)	10	.652(.021)	.813(.148)	.688(.173)	101.1(24.8)
Step_M	6	.647(.017)	.687(.187)	.559(.124)	124.1(22.2)	12	.649(.022)	.818(.190)	.715(.191)	125.7(28.5)
Both_M	6	.653(.028)	.740(.163)	.618(.189)	111.5(25.8)	11	.652(.025)	.736(.216)	.616(.216)	113.1(26.3)

Both_L	15	.414(.110)	.703(.170)	.550(.154)	105.1(37.4)	33	.415(.119)	.707(.208)	.565(.185)	110.3(36.3)

post-hoc. The number of students in each group is listed in the "N" column for Fall'14 in Table 3 (Left) and for post-hoc in Table 3 (Right). Fortunately, random assignment balanced the three conditions for ability, and this balance persisted even after the groups were subdivided into High, Medium, and Low. No significant difference was found on pre-test among the three High groups, the three Medium groups, or the three Low groups in both Fall'14 and post-hoc.

Empirical Fall'14 Study

In Table 3, the first column shows the condition-competence group and then followed by a section presenting the learning performance and time on task (in minutes) for Fall'14. Here it shows the number of students (N) and the mean and SD of pre-test score (Pre), isomorphic post-test score (Iso), overall post-test score (Post) and time on task (Time). A Chi-square test showed that there was no significant relation between condition and incoming competence $\chi^2(4) = 2.94, p = 0.57$.

To measure student learning improvement, we compared their isomorphic post-test scores with their pre-test scores. A repeated measures analysis using test type (pre-test vs. isomorphic post-test) as a factor and test score as the dependent measure showed that there is a main effect for test type: $F(1,107) = 50.82$, $p < 0.0001$, $\eta = 0.322$ in that they scored significantly higher on the isomorphic post-test problems than pre-test. Thus, our tutor is indeed effective on improving student learning. More specifically, all three conditions scored significantly higher in the isomorphic post-test than in the pre-test: $F(1,36) = 13.56$, $p = 0.0008$, $\eta = 0.274$ for Prob, $F(1,36) = 16.26$, $p = 0.0003$, $\eta = 0.311$ for Step, and $F(1,33) = 20.92$, $p < 0.0001$, $\eta = 0.388$ for Both respectively. This showed that the basic practices and problems, domain exposure, and interactivity of our ITS might be effective to help students acquire knowledge.

Finally, to obtain a comprehensive evaluation of students' final performance, analyses were performed on the overall post-test which contains six additional multiple-principles. A two-way ANCOVA analysis on the factors of granularity and incoming competence using the pre-test score as a covariate showed no significant interaction or main effect. A subsequent pairwise contrast analysis revealed that for Low students, the Both_L group scored significantly higher than the Step_L group: $t(98) = -2.01$, $p = 0.047$. The results suggested that the Both levels of decisions can be more effective than the step level decisions for the Low students.

In terms of time on task, a two-way ANOVA analysis on granularity and incoming competence showed a main effect on granularity: $F(2,99) = 3.97$, $p = 0.02$, $\eta = 0.071$ in that the Prob condition spent significantly less time than the Step condition $t(105) = -2.62$, $p = 0.01$, $d = 0.61$ and the Both condition $t(105) = -2.22$, $p = 0.029$, $d = 0.58$. Subsequent contrast analyses showed that such difference mainly came from the High students in that: Prob_H spent significantly less time than Step_H and Both_H: $t(99) = -2.72$, $p = 0.008$, $d = 1.35$ and $t(99) = -2.17$, $p = 0.03$, $d = 1.08$ respectively; no significant difference was found among the three Low groups.

Overall, Fall'14 results showed that on learning performance, Both was better than Step for the Low students; while on time on task, Prob spent less time than the other two for the High students. Note that since some of the groups are in small size, the absence of significant differences might be due to insufficient statistical power.

Post-hoc Analysis

The right section of Table 3 presents the post-hoc analysis results. Numbers in the "N" column revealed that the three High and the three Low groups are in reasonable size while the three Medium groups remain small. A Chi-square test showed no significant relation between condition and incoming competence: $\chi^2(4) = 2.11, p = 0.72$.

A repeated measures analysis using test type (pre-test vs. isomorphic post-test) as a factor and test score as the dependent measure showed that there was a main effect for test type $F(1,301) = 177.38$, $p < 0.0001$, $\eta = 0.371$ in that students scored significant higher in the isomorphic post-test than in the pre-test. Similarly, for each of the three conditions, students scored significantly higher in the isomorphic post-test than in the pre-test: $F(1,105) = 42.79, p < 0.0001, \eta = 0.290$ for Prob; $F(1,105) = 72.27$, $p < 0.0001$, $\eta = 0.408$ for Step and $F(1,89) = 67.46$, $p < 0.0001$, $\eta = 0.431$ for Both. The

results confirmed that our tutor is effective over the years.

For the overall post-test scores, a two-way ANCOVA analysis on the factors of granularity and incoming competence using the pre-test score as a covariate showed a significant interaction effect: $F(4,292) = 3.66$, $p = 0.006$, $\eta = 0.029$. Subsequent contrast analyses showed that for High students, the Step_H group and the Both_H group scored significantly higher than the Prob_H group: $t(292) = 2.25$, $p = 0.03$ and $t(292) = -2.50$, $p = 0.01$ respectively. For Low students, the Prob_L group and the Both_L group scored significantly higher than the Step_L group: $t(292) = 2.29$, $p = 0.02$ and $t(292) = 2.19$, $p = 0.03$ respectively. The results suggest that for High students, the Step level decisions and the Both level decisions are more effective than the Prob level while for Low students, the Prob level decisions and the Both level decisions are more effective than the Step level.

For time on task, a two-way ANOVA analysis on granularity and incoming competence showed a significant main effect on granularity: $F(2,293) = 4.98$, $p = 0.007$, $\eta = 0.032$ in that the Step condition spent more time than the Prob condition: $t(299) = 3.00$, $p = 0.003$, $d = 0.40$ and the Both condition: $t(299) = 2.22$, $p = 0.027$, $d = 0.34$. Subsequent contrast analysis revealed that for High students: the Step_H group spent longer time than the Prob_H group: $t(293) = 2.51$, $p = 0.01$, $d = 0.46$ and the Both_H group: $t(293) = 3.03$, $p = 0.003$, $d = 0.74$. No such significant difference was found among the three Low groups.

Overall, the results suggest that on learning performance, the problem level decisions can be effective for Low students but ineffective for High students, the step level decisions could be effective for High students but ineffective for Low students, while Both level decisions seem to be effective for both High and Low students. For time on task, the High students, the Step_H group can spend more time than the Prob_H and the Both_H groups while no significant difference was found among the three Low groups.

Conclusion & Discussion

In this paper, we explored the impact of three types of decision granularity on student learning by comparing three conditions: Prob involving WE and PS, Step involving FWE only, and Both involving all WE, PS and FWE. Overall, while no significant difference was found among the three conditions on learning performance, a significant difference was found among them on time on task in that Prob spent significantly less time than Step for both Fall'14 and the post-hoc.

We hypothesized that different learning mechanisms are involved in WE, PS and FWE and thus there may exist an ATI effect. Students were then split into High, Medium and Low groups based on their pre-test performance. Results from Fall'14 show that on learning performance, for Low students Both is more effective than Step; on time on task, for High students Prob would spend less time than Step. Overall because of small sample sizes, more general conclusions cannot be drawn here. Furthermore, our post-hoc results suggest that on learning performance, Prob can be effective for Low students but ineffective for High ones on the other hand, Step could be effective for High students but ineffective for Low ones; finally, Both seemed to be effective for both High and Low students; as for time on task, while no significant difference was found among the three Low groups either in Fall'14 or post-hoc, significant difference was found among the three High groups in that Prob_H spent significantly less time than Step_H in both Fall'14 and post-hoc.

Our results showed a difference between the Prob and Step granularity. In terms of time on task, students spent less time when learning with Prob than with Step. For learning performance, each of them can be effective for some students but ineffective for some other students, depending on students' knowledge level. This suggests that the granularity can have an impact on student learning. Additionally, results for the Both granularity suggest that mixing this two types of granularity together has the potential to get a more robust instructional intervention. The Prob granularity can be ineffective for the High students and the Step granularity can be ineffective for Low students, but our results suggest that Both can be effective for both High and Low students.

One possible explanation for our results is that different cognitive load were involved in the three conditions. At the problem level, students pay attention to either the tutor's solution in WE or their own solution in PS; while at the step level, they need to pay attention to both the tutor's solution and their own solution and integrate them. Compared with PSs, in FWEs the tutor may solve certain steps for students but on the other hand, students need to devote extra effort to understand and to integrate their answers with the tutor's answers. Thus, we hypothesized that in terms of cognitive load, WE <PS <FWE. This explains why the Step condition spent more time than the Prob condition (in both Fall'14 and post-hoc) despite that students in these two condition completed the same amount of work (as measured by the number of PS steps in our subsequent log analysis). Assuming that FWEs are more challenging than WEs or PSs, the results that Step benefits the High students more than Prob while Prob benefits the Low ones more than Step can be explained by the conjecture that High students have more prior knowledge and learning capacity than the Low ones. However, this is only our hypothesis and much more research is needed to fully understand it. More importantly, more research is needed to explain why the Both levels of granularity benefits both High and Low students.

Lots of prior research has shown that studying WEs help students learn. However, questions about how and when WEs should be presented remain open. Our findings inform researchers that the granularity can have an impact on student learning and the impact of granularity can differ for students at distinct knowledge levels. Thus, it urges researchers to consider the impact of granularity when designing instructions and adapt the instruction based on students' knowledge level.

Abstract

Most objects in the visual world are partially occluded, but humans can recognize them without difficulty. However, it remains unknown whether object recognition models like convolutional neural networks (CNNs) can handle real-world occlusion. It is also a question whether efforts to make these models robust to constant mask occlusion are effective for real-world occlusion. We test both humans and the above-mentioned computational models in a challenging task of object recognition under extreme occlusion, where target objects are heavily occluded by irrelevant real objects in real backgrounds. Our results show that human vision is very robust to extreme occlusion while CNNs are not, even with modifications to handle constant mask occlusion. This implies that the ability to handle constant mask occlusion does not entail robustness to real-world occlusion. As a comparison, we propose another computational model that utilizes object parts/subparts in a compositional manner to build robustness to occlusion. This performs significantly better than CNN-based models on our task with error patterns similar to humans. These findings suggest that testing under extreme occlusion can better reveal the robustness of visual recognition, and that the principle of composition can encourage such robustness.

Keywords: visual recognition; occlusion; computational model; neural network; psychophysics

Introduction

Objects in the visual world are occluded much more than objects in typical visual science experiments. The ability to handle occlusion is essential for survival and everyday activities. For instance, in order to safely drive on the road, one must be able to swiftly detect other vehicles and pedestrians in advance even when they are only partially visible. However, both humans and object recognition models are rarely tested on the level of occlusion we encounter in the real world. Several studies have addressed this important issue by investigating real-world object recognition under occlusion (Tang et al., 2018; Rajaei, Mohsenzadeh, Ebrahimpour, & Khalligh-Razavi, 2018). These authors successfully developed models that could handle constant mask occlusion as shown in Figure 1 (a), and produced results consistent with human performance. In this paper, we take a step further and propose a more challenging task of object recognition under extreme occlusion to test humans and object recognition models.

We designed our task using a public occlusion image dataset from the computer vision community (Wang et al., 2017). In the proposed task, target objects are heavily occluded by several superimposed irrelevant real-world objects (occluders) with an average target occlusion ratio above 0.6, see Figure 1 (b). The biggest difference from previous studies is that both targets and occluders are real objects in real backgrounds. This task provides new insights in two ways. First, compared to testing in an occlusion-free domain, it challenges both humans and object recognition models and better tests the robustness of visual recognition. Second, it provides a way to check whether the ability to handle constant mask occlusion can entail robustness to real-world occlusion.

To begin with, we experimentally measured human performance on our task. Figure 1 (c) provides an example stimulus used in the behavioral experiments. Humans were very good at recognizing such extremely occluded objects and showed great robustness to occlusion. The results also suggest that our task is feasible and that an ideal object recognition model should be able to accomplish it.

Therefore, we subsequently tested several recent object recognition models on our task. The first model tested is the hierarchically feed-forward model, represented by convolutional neural networks (CNNs) (LeCun, Bengio, & Hinton, 2015). These models mimic the feed-forward process in biological vision. They achieve impressive performance and can explain some human data in several non-challenging visual tasks (DiCarlo & Cox, 2007; Yamins et al., 2014). However, there is still considerable variability in human neural and behavioral data at the individual image level that CNNs cannot explain (Rajalingham et al., 2018; Schrimpf et al., 2018). Our experiments show that CNNs perform very well without occlusion but their performance is not very good under extreme occlusion, suggesting that they lack robustness to occlusion.

The second model is a hybrid model that combines CNNs with models of recurrent computations. In biological vision, recurrent computations are essential for recognition under occlusion (Lamme & Roelfsema, 2000; Lamme, Zipser, & Spekreijse, 2002; Tang et al., 2018; Rajaei et al., 2018; Wyatte, Curran, & O'Reilly, 2012). Tang et al. (2018) modelled recurrent computations as lateral connections realized by a Hopfield network, which acted as a content addressable memory (Hopfield, 1982). They used Hopfield networks to store CNN activations of occlusion-free objects and later recover activations of occluded objects. This model improved CNN performance for recognition under constant mask occlusion, but we did not observe improvements under extreme occlusion, implying that the ability to handle constant mask occlusion does not entail robustness to real-world occlusion.

(a) (b) (c)

Figure 1: Examples of different types of occlusion (on car images). (a) An image of constant mask occlusion used in (Tang et al., 2018). (b) An image of extreme occlusion used to test computational models in our paper. (c) An image of extreme occlusion used in our behavioral experiments.

As a comparison to the models above, we propose a third model designed with the principle of composition. Throughout this paper, we use the term "composition" in its traditional sense meaning the process where smaller parts are composed together to form larger parts. This principle is not inherently addressed by CNNs (Stone et al., 2017), but it is supported by biological evidence showing that populations of neurons in macaque V4 and IT areas represent complete shapes with aggregates of shape fragments (Brincat & Connor, 2006; Pasupathy & Connor, 2002; Yamane, Carlson, Bowman, Wang, & Connor, 2008). Our model uses two stages to recognize objects from parts/subparts in a compositional manner. In the first stage, we consider spatial relations among subparts and detect parts. In the second stage, we consider spatial relations among detected parts and compose them into objects. Both stages are designed to be robust to occlusion. This two-stage model can handle missing parts under occlusion as long as the visible parts conform to reasonable spatial constraints. Our model performed better than the other two models under extreme occlusion with similar error patterns to humans, demonstrating a way to build robustness to occlusion by exploiting object compositional structures.

Task and Dataset

Recognition Under Extreme Occlusion Task

Object recognition under occlusion involves recognizing targets occluded by other entities (called occluders). Depending on task specifics, targets could be as simple as letters, digits, and symbols, or as complex as objects in real scenes. Occluders can also vary substantially. There are simple occluders like constant masks and also complex ones like real objects.

Simple occlusion by constant masks and complex occlusion by real objects are actually treated differently during recognition. For instance, in CNNs, neurons tuned to fur textures may fire on the presence of cats as occluders and distort the CNN activation of the target. However, fewer misguiding neurons are likely to fire on constant masks without textures. Thus, real objects as occluders are more likely to distort target object recognition by providing irrelevant context.

To test the robustness of visual recognition to real-world occlusion, we propose a difficult task of object recognition under extreme occlusion. Specifically, it involves recognizing vehicles occluded by other irrelevant real occluders, including animals, furniture and other objects, in real backgrounds (see Figure 1 (b)). This task is challenging because occluders are irrelevant real objects and the occlusion ratio is high, which discourages the use of context during recognition.

Training and Testing Dataset

For the purpose of training computational models to perform our task, we propose that only occlusion-free images should be used. A single object can be occluded in an exponential number of ways and it is unlikely for a limited training set to cover all occluder appearances, positions and so on. Therefore, we used 4049 occlusion-free training images covering five types of vehicles, including *aeroplane*, *bicycle*, *bus*, *car* and *motorbike* from VehicleSemanticPart dataset (Wang et al., 2017). 113 different types of object parts, such as car wheels, bicycle pedals and jet engines, are annotated with part identities and bounding box positions.

For testing purposes, we built an occlusion testing set using another 500 images from VehicleOcclusion dataset (Wang et al., 2017). To our knowledge, this is the only public occlusion dataset with accurate occlusion annotations of parts and objects. In each image, 2-4 randomly-positioned real occluders are placed onto the single target object (see Figure 1 (b)). The target occlusion ratio is constrained. 77% of the images have an occlusion ratio of 0.6-0.8; 18.4% of the images have an occlusion ratio of 0.4-0.6; 4.6% of the images have an occlusion ratio of 0.2-0.4. Furthermore, we also created an occlusion-free testing set by collecting the corresponding 500 clean images before occluders were placed. Neither these clean images nor superimposed occluders are met in the training set.

For evaluation metrics, we evaluated human and model performance both quantitatively by recognition accuracy and qualitatively by confusion matrices and representational dissimilarity matrices (Kriegeskorte, Mur, & Bandettini, 2008).

Behavior Experiments

Participants

We designed a survey on Amazon Mechanical Turk to collect human responses for the task of object recognition under extreme occlusion. 25 human subjects completed our survey.

Procedure

We had 1,250 human intelligence tasks (HITs) with 20 stimuli in each, so that there were 50 repetitions of the occlusion testing set (500 stimuli). In each HIT, subjects were given unlimited time to observe and respond to 20 stimuli one at a time. The stimuli had red bounding boxes around the targets (see Figure 1 (c)). Subjects were asked to type the names of the objects in the bounding boxes without knowing that they should belong to the aforementioned five categories.

Data Processing and Exclusions

We collected 25,000 typed strings as subject responses. There were 785 different strings from the responses and we manually assigned them to the five vehicle categories. We first

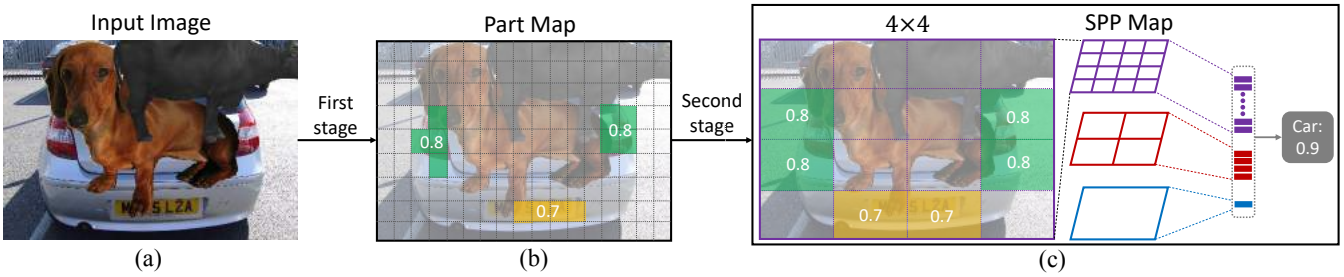

Figure 2: The overall framework of our two-stage model. The input image (a) contains a car whose back trunk is occluded. In the first stage, we detect several parts, including tail lights (green) and the license plate (yellow), and output part maps (b). In the second stage, we apply spatial pyramid pooling (SPP) to part maps and obtain SPP maps (c) (4×4 scale shown here). We consider spatial constraints over parts and aggregate part confidence scores at different scales to determine the object identity.

excluded 300 responses whose corresponding images were oversized for computational models. We further excluded 5,359 responses assigned to either none or more than one category. The rest of 19,341 responses with valid reported and ground-truth category labels were used for data analysis.

Computational Models

CNNs: AlexNet, ResNet and VGG16

Recently, CNNs achieved impressive performance in object recognition. They use stacked convolutional layers and pooling layers to extract image features for classification. We used AlexNet (Krizhevsky, Sutskever, & Hinton, 2012), ResNet (He, Zhang, Ren, & Sun, 2016) and VGG16 (Simonyan & Zisserman, 2014) as three representative CNN-based object recognition models and modified them to get the best possible performance. In AlexNet, we substituted fully-connected layers fc6 and fc7 with two equivalent convolutional layers with kernel size 6×6 and 1×1, followed by a global average pooling layer. In VGG16, we also made similar modifications to the fully-connected layers. In ResNet, we used ResNet-18 and substituted the last average pooling layer with a global average pooling layer. These modifications enable the networks to handle inputs of variable sizes. The classification layers were also changed to fit our five object categories.

Training and Testing The training and testing images were resized so that the short object edge had 224 pixels. During the training phase, we froze weights in earlier layers and fine-tuned ImageNet pre-trained models. In AlexNet, we froze weights in the first two convolutional layers. In ResNet, we froze weights in the first two residual stages. In VGG16, we froze weights in the first two convolutional stages. The training inputs were randomly cropped image patches of size 224×224 containing at least part of the target objects. During the testing phase, inputs were full-sized images.

Hybrid Model: AlexNet+Hopfield Network

Tang et al. (2018) proposed a hybrid model of CNNs with Hopfield networks that improved object recognition under constant mask occlusion and produced results consistent with human performance. Concretely, they adopted a fully-connected Hopfield network with binary threshold nodes. It can store patterns as local minima and later recover incomplete patterns by iteratively processing them until convergence. The capacity of a Hopfield network with N nodes is only about 0.15N memories. When the number of patterns to store increases, local minima are more likely to be spurious minima. We followed the experimental settings from Tang et al. (2018) and used 4096-dimensional features from the fc7 layer in ImageNet-trained AlexNet as patterns to store and recover in the Hopfield network.

Training and Testing During the training phase, we fed a random subset of 500 resized images (224×224) to ImageNet-trained AlexNet. Following Tang et al. (2018), we extracted fc7 features, binarized them with a threshold of 0 and used them to train a Hopfield network with 4096 nodes (implemented in MATLAB's newhop function) and a linear multiclass Support Vector Machine (SVM). We used a small training set due to the limited capacity of the Hopfield network. During the testing phase, we fed images to AlexNet, binarized fc7 features and used them to initialize the Hopfield network. Each node in the network receives weighted inputs from connected nodes and updates its binary state accordingly and synchronously. Converged outputs (timestep=256) are classified using the SVM.

Ours: Two-stage Voting Model

Motivation Object appearance and context can change drastically under occlusion yet spatial constraints over objects and parts are largely preserved. With a few parts missing, an occluded object can be recognized as long as the positions of visible parts make sense, that is, if they conform to reasonable spatial constraints. This motivates us to exploit object compositional structures for object recognition under occlusion. We developed a two-stage object recognition model that could utilize these spatial constraints (Figure 2). Specifically, in the first stage, we detected different object parts in the images. In the second stage, we considered spatial constraints over objects and parts and used those detected parts to determine object identities. In both stages, we utilized deep networks

to capture these spatial constraints via spatial voting mechanisms. The core idea of spatial voting is to detect larger parts by considering spatial relations of smaller parts and gathering their votes, which are confidence scores for their presence. We now elaborate our two stages in more details.

Stage 1: Part Detection In the first stage, we want to robustly detect object parts. Zhang, Xie, Wang, Xie, and Yuille (2018) developed a robust voting model to detect semantic parts under occlusion. We adopted their method and produced part maps as shown in Figure 2 (b), which contained confidence scores for the presence of different object parts at different locations. Following Zhang et al. (2018), we first obtained subparts by clustering corresponding CNN intermediate activations at the *pool-4* layer from a VGG network (Simonyan & Zisserman, 2014). We subsequently implemented the spatial voting mechanism as a convolutional layer with kernel size 15×15 on top of the subparts to capture spatial constraints over subparts and parts in a larger spatial region. The intuition for this voting stage is that a partially occluded object part could be robustly detected as long as it gathered enough votes from a set of subparts which conformed to certain spatial constraints in a spatial region.

Stage 2: Object Recognition In this stage, we used part maps as inputs and designed another voting method to aggregate parts to form objects. There are two challenges for our voting method. First, it needs to capture spatial constraints over parts and produce fixed-length vectors for classification. Second, it needs to tolerate within-category variation so that the learned spatial constraints are generalized for most objects in a category. To this end, we applied spatial pyramid pooling (SPP) (Lazebnik, Schmid, & Ponce, 2006) at three different scales (4×4, 2×2, 1×1) to the normalized part maps and obtained three SPP maps as shown in Figure 2 (c). This method maintained some spatial information and was different from the sliding window pooling of deep networks. Concretely, we evenly divided part maps into $n \times n$ local spatial bins ($n = 4, 2, 1$) and applied max pooling to each bin. SPP maps contained maximum confidence scores for the presence of parts in each spatial bin. Later, we concatenated SPP maps and appended a dropout layer (dropout ratio 0.1) and a fully-connected layer. The dropout layer randomly dropped a subset of part votes during training and improved the robustness of our model under occlusion. The fully-connected layer aggregated part votes and learned spatial constraints over parts at different scales to determine the object identities. The learned weights of this layer are referred to as object-part spatial heatmaps (visualized in Figure 3). Both stages in our model were robust to occlusion due to the use of spatial voting and dropout mechanisms, which allowed larger parts to be detected using only a subset of smaller parts under certain spatial constraints.

Training and Testing Training and testing images were resized so that the short object edge had 224 pixels. Two stages were trained separately. When training the first stage, inputs were randomly cropped image patches of size 224×224 containing at least part of target objects. More details are available in (Zhang et al., 2018). When training the second stage, inputs were parts maps obtained by feeding training images to the first stage. During testing, inputs were full-sized images.

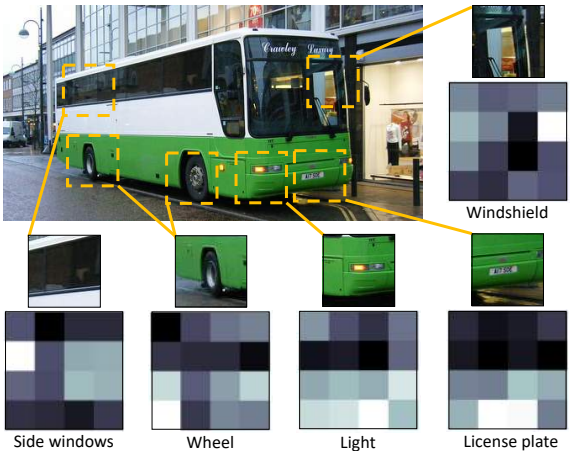

Figure 3: Visualization of object-part spatial heatmaps at the 4×4 scale for the bus category. Each heatmap shows the learned spatial constraints between the bus and the part. Brighter regions indicate higher voting weights. For instance, a license plate in the lower region of a image often casts a highly weighted vote in favor of the presence of a bus.

Results and Discussions

Testing without Occlusion

First, we test three computational models on the task of recognizing occlusion-free vehicles. Human subjects are not tested for this task because it is very easy for humans when they are given unlimited time to recognize vehicles without occlusion.

Both CNNs and our model perform reasonably well on this task (Table 1). Our model has a comparable accuracy (92.9%), showing that spatial constraints over parts/subparts are useful information for the recognition of occlusion-free objects. However, these results tell little about the robustness of different models given their similar performances.

The hybrid model of AlexNet and Hopfield networks gets a relatively lower accuracy without occlusion. When we use SVM to directly classify binarized fc7 features without using the Hopfield network, the accuracy increases from 77.7% to 85.4%. This implies that the relatively lower accuracy may be caused by the Hopfield network. In order to check whether the Hopfield network setting was implemented correctly, we followed Tang et al. (2018) and tested the hybrid model on mask occlusion images from five categories with an average occlusion ratio above 0.7; see Figure 1 (a) for an example testing image. The use of the Hopfield network increased the accuracy from 40.9% to 46.8%, which was qualitatively similar to the improvement reported in Tang et al. (2018). This shows that the Hopfield network was implemented correctly and improved object recognition performance under constant

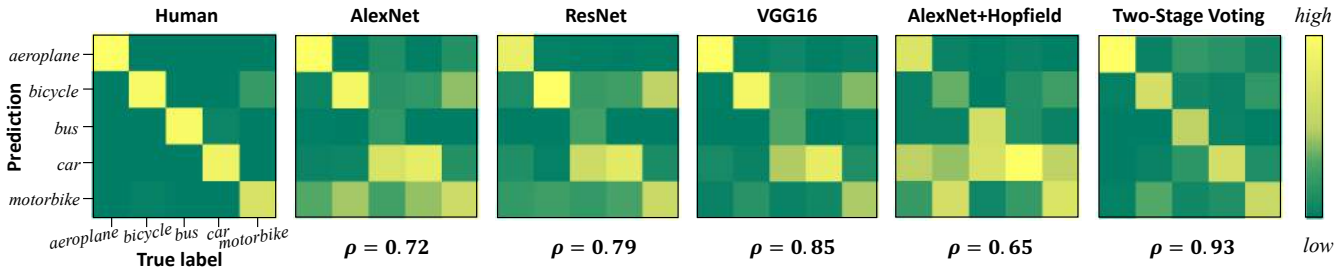

Figure 4: Category-level confusion matrices under extreme occlusion. The Pearson correlation coefficients between the human confusion matrix and each model confusion matrix are listed below the matrices.

Table 1: Testing Accuracy under No/Extreme Occlusion.

Humans/Models	w/o occlusion	w/ occlusion
Humans	-	**93.3%**
AlexNet	89.8%	50.0%
ResNet	90.1%	54.0%
VGG16	**94.7%**	62.6%
AlexNet+Hopfield	77.7%	46.0%
Two-stage Voting (Ours)	92.9%	**67.0%**
Ablation 1	91.2%	47.5%
Ablation 2	89.9%	58.9%

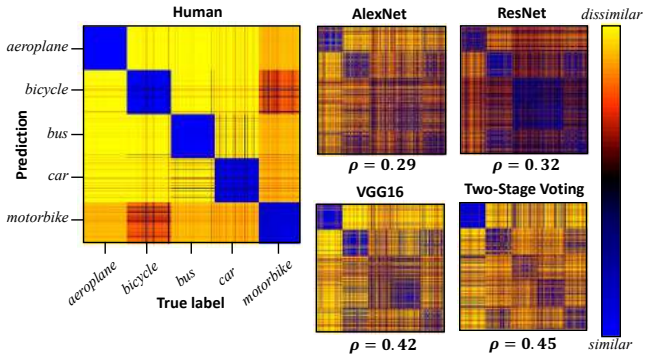

Figure 5: Image-level representational dissimilarity matrices (RDMs) under extreme occlusion. Each testing image is characterized by a 5-dimensional categorical distribution obtained from either human response frequencies for five vehicle categories on that image or the Softmax output in the final layer of each model. The dissimilarity between two images is measured as the Euclidean distance between two vectors representing the associated categorical distributions. The Pearson correlation coefficients between the human RDM and each model RDM are listed below the matrices.

mask occlusion. We will further discuss the possible causes of the relatively low accuracy of the hybrid model on our task later with testing results under extreme occlusion.

Testing under Extreme Occlusion

We further test humans and these models on recognizing objects under extreme occlusion with our occlusion testing set.

Table 1 shows that humans have very high accuracy at recognizing occluded vehicles and are robust to extreme occlusion. It also confirms that our task of object recognition under extreme occlusion is feasible and the information in these occlusion images is sufficient to determine object identities.

For CNNs, the accuracy is relatively low (Table 1). Despite their good performance without occlusion, CNNs do not manifest robustness under extreme occlusion as humans do. Our results support previous findings that CNN activation is not inherently compositional and cannot explicitly address contextual and non-contextual information (Stone et al., 2017).

For the hybrid model, we do not observe performance gains compared to CNNs under extreme occlusion. If we use SVM to classify binarized fc7 features without using Hopfield networks, the accuracy rises from 46.0% to 48.6%. This result together with previous ones shows that the Hopfield network did not improve performance on our task, either without occlusion or under extreme occlusion, although it improved performance under constant mask occlusion. There are two possible reasons. First, it may require more representative training features because our dataset is more complex than the one from Tang et al. (2018). However, given the limited capacity of Hopfield networks, too many training features may result in more spurious minima. Second, mask occlusion may only suppress some neurons in CNNs while real occluders can activate additional misguiding neurons, making it hard for pattern recovery. Thus, the ability to handle constant mask occlusion does not entail robustness to real-world occlusion.

Our model outperforms other models under extreme occlusion in terms of accuracy. We further compare the performance of humans and different models by analyzing their category-level confusion matrices (Figure 4) and image-level representational dissimilarity matrices (RDMs) (Figure 5). These provide a better way to qualitatively compare the robustness of human vision and these computational models. Although the accuracy of our model is still lower than humans, it shows greater robustness than other models and produces the most similar results to humans. Figure 6 also shows some representative improvements and errors from our model. The performance of our model suggests that spatial constraints over parts are important cues for object recogni-

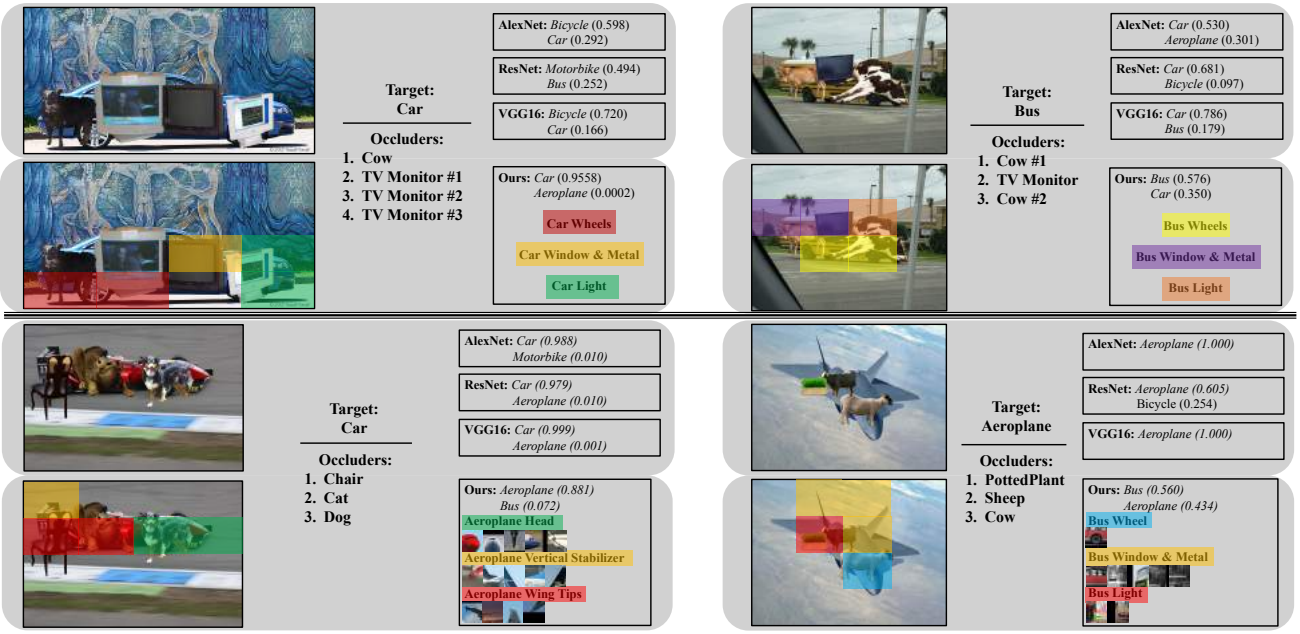

Figure 6: Representative improvements (top two) and errors (bottom two) from our model. In the top two cases, our model produced correct object labels by exploiting spatial relations among detected object parts. In the bottom left case, our model misclassified the race car as an aeroplane partly because they are similar in the aerodynamic design. In the bottom right case, our model incorrectly detected bus parts and was subsequently misled by these false part detection results.

tion under occlusion, and that the principle of composition is a promising solution for bridging the gap between the robustness of human vision and these computational models.

Ablation Experiments

Finally, we show the effectiveness of each voting stage in our model. We substituted each stage respectively with alternative models to do the same task with the same supervision.

In the first experiment (Ablation 1 in Table 1), we substituted the first voting stage with Faster-RCNN (Ren, He, Girshick, & Sun, 2015), a state-of-the-art object detection model. We trained Faster-RCNN to detect parts and obtained SPP maps. Later, we trained our second stage and tested the whole model. The accuracy changed little without occlusion but dropped from 67.0% to 47.5% under extreme occlusion. As Zhang et al. (2018) pointed out, it is difficult for proposal-based detection methods including Faster-RCNN to extract good proposals under occlusion and even with correct proposals, the classifier may still go wrong due to the presence of occluders. This result further confirmed the robustness of the first stage model on detecting parts under occlusion.

In the second experiment (Ablation 2 in Table 1), we substituted the second stage with a bag-of-words module where all spatial relations were discarded by a global max pooling layer. We concatenated the highest confidence score in each part map into a vector and appended a dropout layer and a fully-connected layer. We trained the bag-of-words module and tested the whole model. The accuracy changed little without occlusion but dropped from 67.0% to 58.9% under extreme occlusion, implying the effectiveness of spatial voting under occlusion. Figure 3 also shows that the learned spatial constraints are meaningful. Wheels and windshields often appear in lower and higher regions of bus images respectively.

Together, the results suggest that the higher accuracy of our model is not purely a result of additional part-level supervision but also due to the use of object compositional structures.

Conclusion

Occlusion is often present in everyday visual tasks yet humans and models are rarely tested under real-world occlusion. We proposed a task of object recognition under extreme occlusion and tested humans and models, including CNNs, a hybrid model of CNNs with Hopfield networks and our two-stage voting model. Our findings lead us to three conclusions.

First, testing under extreme occlusion can better reveal the robustness of visual recognition than testing without occlusion. Object recognition models that can compete with humans in the occlusion-free domain may not show the same robustness under extreme occlusion as humans do.

Second, the ability to handle constant mask occlusion does not entail robustness to real-world occlusion. Different types of occlusion may alter context differently yet object inherent structures could still be exploited for recognition purposes.

Third, the performance of our model is better and more correlated with human results under occlusion, suggesting that the principle of composition is a possible solution for building robustness to occlusion as demonstrated by human vision.

Abstract

The judgments that people make are not independent – initial decisions can bias later perception. This has been shown in tasks in which participants first decide whether the direction of moving dots is to one side or the other of a reference line: their subsequent estimates are biased away from this reference line. This interesting bias has been explained in past work as either a consequence of weighting sensory neurons, or as a consequence of participants adjusting their estimate to match their decision. We propose a new explanation: that people sequentially sample evidence to make their decision, and reuse these samples to make their estimate (i.e., amortised inference). Because optimal stopping leads to samples that strongly favor one or another decision alternative, the subsequent estimates are also biased away from the reference line. We introduce a sequential sampling model for posterior samples that does not assume constant thresholds, and provide evidence for our explanation in a new experiment that generalizes the perceptual bias to a new domain.

Keywords: decision biases, adaptive sampling, amortised inference.

Introduction

Experiments in motion perception show that making a perceptual decision biases subsequent perception. As illustrated in Figure 1A, participants in these random-dot-motion experiments are first asked whether the motion was clockwise (CW) or counter-clockwise (CCW) of a decision boundary. After making this decision, participants are then asked to estimate the direction of motion. While participants' estimates are unsurprisingly consistent with their decision, these estimates also show a surprising perceptual bias: estimates are biased *away from* the decision boundary (Jazayeri & Movshon, 2007; Luu & Stocker, 2018; Zamboni, Ledgeway, McGraw, & Schluppeck, 2016).

Two main theories have been proposed to explain this perceptual bias: (a) the optimal weighting of outputs of orientation-tuned neurons used in the decision task is also used in the estimation task (Jazayeri & Movshon, 2007), or (b) people employ self-consistent reasoning by only considering hypotheses consistent with their initial decision when making an estimate (Luu & Stocker, 2018). Existing comparisons favor the self-consistency account (Luu & Stocker, 2018; Zamboni et al., 2016).

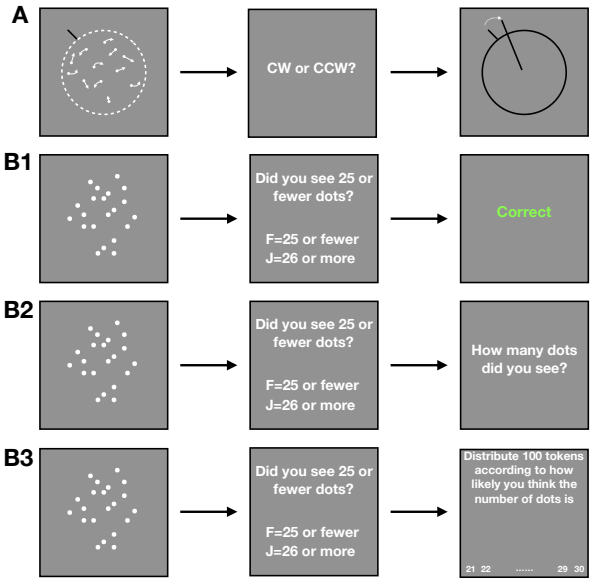

Figure 1: Illustration of experimental tasks. **(A)** Decision-estimation (D-E) task for random-dot-motion. **(B)** Numerosity experiment. **(B1)** Decision with feedback (D-F) task. **(B2)** D-E task. **(B3)** Decision-histogram (D-H) task.

However, it may be that self-consistency is unnecessary to explain the perceptual bias. We take a sequential sampling approach to modelling this task, following a long history of models in human decision making that sequentially draw perceptual or posterior samples and optimally accumulate evidence (Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006; Vul, Goodman, Griffiths, & Tenenbaum, 2014). We introduce a sequential sampling model that optimally accumulates posterior samples, and then demonstrate that the perceptual bias in estimation is produced by simply averaging samples that were optimally accumulated for the initial decision. The intuition for why the bias is produced is simple: because sequential sampling models stop when the samples favor one of the alternatives, the estimate (i.e., the average) also favors one of the alternative. Interestingly, similar Bayesian analysis have arisen in a different experimental domain: the studies of probability estimation from sequential samples, where

optimal stopping has shown to predict a distorting effects on subsequent judgments (Coenen & Gureckis, 2016). However, when the sampling process is external, such distortion did not receive empirical supports (Coenen & Gureckis, 2016).

To discriminate between these accounts, we first show that weighted decoding, self-consistency, and sequential sampling make qualitatively different predictions about the perceptual beliefs that people will have about individual stimuli. We then test these predictions in a new experiment which generalizes the perceptual bias from a simple random-dot-motion task to a perceptually more complex numerosity task (see Figure 1B), finding that the perceptual bias is best explained by sequential sampling.

Computational Models

In this section, we introduce and compare computational models of the perceptual bias.

Weighted Decoding

The Weighted Decoding (WD) model argues that post-decision bias is a result of optimally tuning the sensory representation to boost responses for the initial decision (Jazayeri & Movshon, 2007; Zamboni et al., 2016). For example, to discriminate whether a random-dot-motion stimulus is coherently moving clock-wise or counter-clockwise of a reference line, the neurons that respond maximally to motion directions that are slightly different from the reference line are the most informative. This leads to a optimal weighting profile that is bimodal: emphasizing directions that are slightly away from the reference line.

WD assumes this weighting profile is also used in the estimation task, and that the mode of the weighted sensory distribution is taken as the estimate. As a result, a post-decision bias naturally emerges (Figure 2A).

Self-Consistency

To predict the post-decision bias, WD must assume that the selective read-out of sensory information in the decision task is carried over to the subsequent estimation task. However, more recent work has demonstrated that the perceptual bias is actually a late decision-related bias, rather than a sensory bias (Luu & Stocker, 2018; Zamboni et al., 2016).

The Self-Consistency (SC) model is a Bayesian model that makes the initial decision according to which option has highest posterior probability, given noisy sensory evidence. However, because the estimate is made after the decision, this model assumes that the quality of the sensory evidence has decayed by the time participants are asked to make an estimate. Instead of relying on the low-quality sensory evidence alone, SC assumes that the participant treats their initial decision (which was made with high-quality sensory evidence) as information as well (cf. Fleming & Daw, 2017), only considering hypotheses that are consistent with the initial decision. SC's estimate is then the mean of the posterior distribution over hypotheses consistent with the initial choice. As shown in Figure $2B_1$, SC also produces estimates that are biased away from the decision boundary.

Our implementation of SC also predicts a bias toward the decision boundary for true stimuli that are far away from the boundary. This is for an uninteresting reason: in the task we will describe below the response range was restricted, and so we also truncated the posterior at the edges of the allowable response range – this leads presentations of extreme values to be biased toward the center of the range.

Simple Amortised Sampling

Because perfectly storing and representing probability distributions can easily become computationally daunting, sample-based approximations have been proposed as a way for the brain to approximate Bayesian inference (Sanborn & Chater, 2016; Zhu, Sanborn, & Chater, 2018). On each trial, the Simple Amortised Sampling (SAS) model generates a set of N samples from the posterior distribution:

$$x_i \overset{\text{i.i.d}}{\sim} P(X|S), \quad i = 1, 2, ..., N \tag{1}$$

where $P(X|S)$ is the posterior sensory representation of number of dots given the stimulus. For the decision task, SAS chooses the alternative that attracts the larger number of samples, which introduces a natural stochasticity into the decision.

In the later estimation task, it makes little sense to draw a new set of samples, as an average of the samples drawn to make the decision can serve as the estimate. This effort-saving strategy is a form of *amortised inference* (Gershman & Goodman, 2014). Reusing samples in this way ensures a high degree of consistency between the decision and the estimate SAS make. However, SAS will not produce a perceptual bias away from the decision boundary – the average of a fixed number of samples is unbiased (Figure $2C_3$), and it only shows a bias toward the center for extreme stimuli. Thus, this model is not actually a candidate for explaining the perceptual bias, but instead serves to illustrate why the following model does.

Bayesian Amortised Sequential Sampling

If samples are drawn sequentially and require effort to generate, it often makes no sense to continue sampling until a fixed number are obtained. Instead, it is more efficient to stop sampling when it is no longer worthwhile.

Many different kinds of sequential sampling models have been proposed, including those that accumulate sensory information (Bogacz et al., 2006), and those that accumulate the kind of posterior samples similar to SAS (Vul et al., 2014). We take as a starting point the sequential model introduced in Vul et al. (2014), which accumulates samples until there are a threshold T more in favor of one alternative than the other. This scheme has the advantages of producing a fixed probability of choosing the better alternative regardless of the number of samples, and it is possible to find the optimal threshold for maximizing utility.

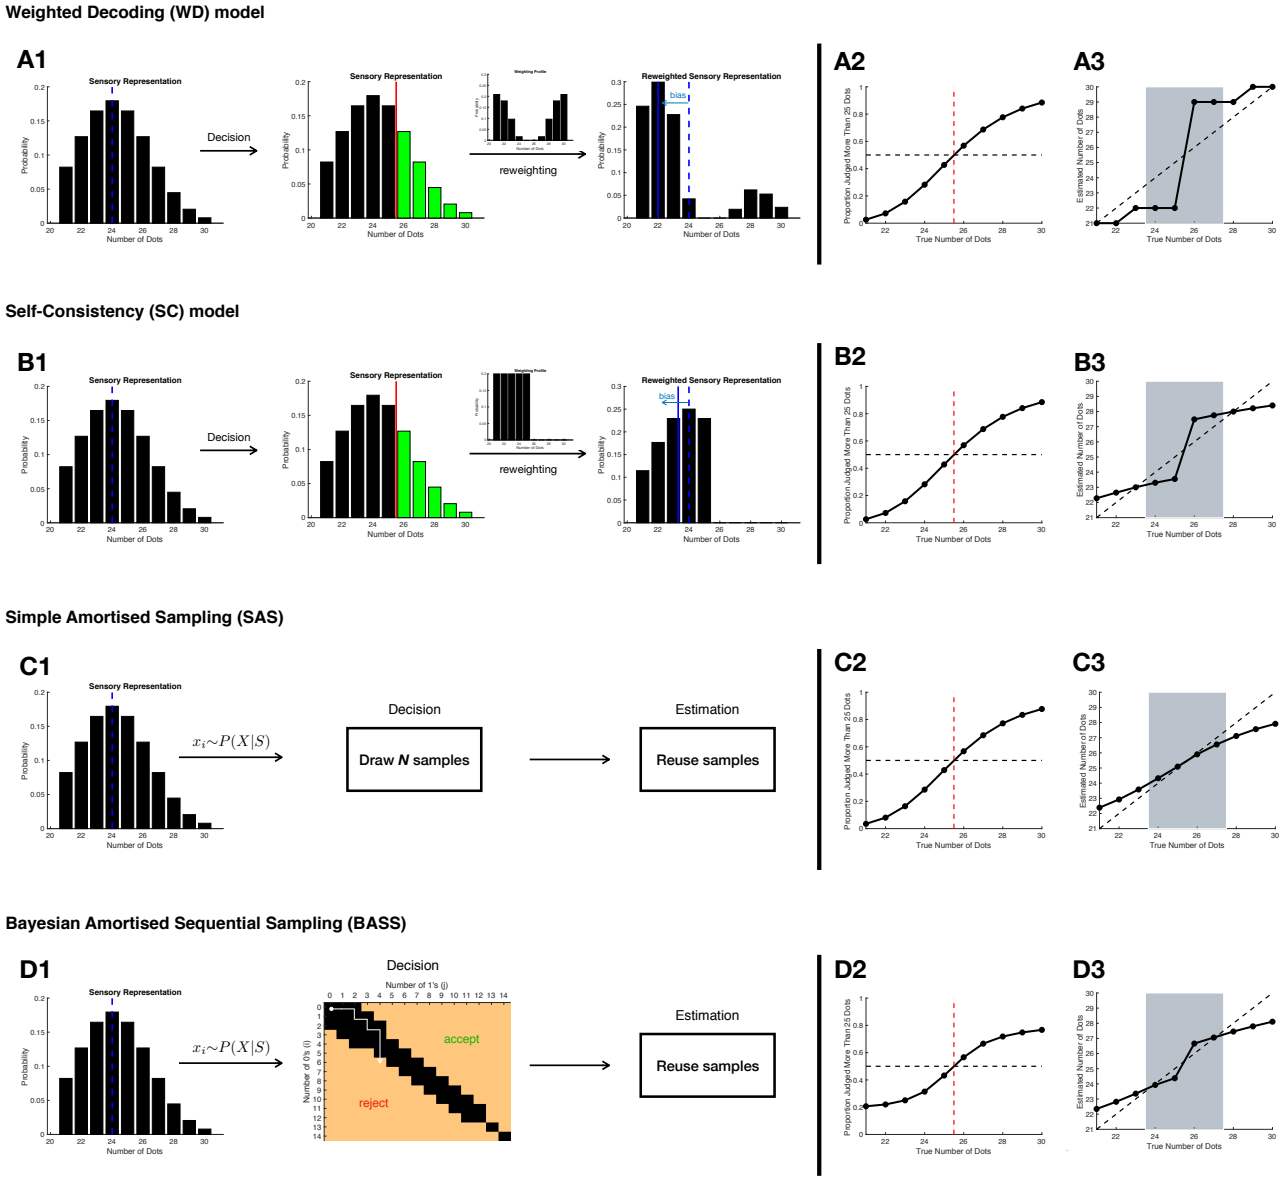

Figure 2: A comparison of model mechanisms and predictions for the numerosity task. For illustrative purposes, we assume a Gaussian likelihood of dot numbers. Then, the posterior distribution combines this likelihood with the prior (i.e., a uniform distribution from 21 to 30). A posterior distribution with its mean at 24 dots (dashed blue line) is shown for each model. **(A)** Schematic illustration of the WD model (Jazayeri & Movshon, 2007). The sensory representation is reweighted according to the optimal bimodal weighting profile. The initial decision is based on the relative probability above and below the decision boundary. The estimate is then the mode of this same reweighted sensory representation. **(B)** Schematic illustration of the SC model (Luu & Stocker, 2018). The initial decision is based on whether there is more probability above or below the decision boundary. The estimate is the mean of the portion of the posterior distribution that is consistent with the initial decision. **(C)** Schematic illustration of the SAS model. A fixed number of posterior samples are drawn and the alternative that attracts the larger number of samples is chosen in the initial decision. The average of these samples is the estimate. **(D)** Schematic illustration of the BASS model. Samples are sequentially drawn from the posterior distribution until it is no longer worthwhile to continue. The alternative that attracts the larger number of samples is chosen in the initial decision. The average of these samples is the estimate.

However, it is possible to sequentially draw samples from a posterior distribution even more efficiently by allowing a non-constant threshold and determining before every sample whether it is better to continue or stop sampling. We term this

scheme Bayesian Amortised Sequential Sampling (BASS). The problem of finding for the optimal changing threshold was solved by Wald (1950) for deciding when to stop drawing binomial samples from an external source, and a similar approach to external samples was investigated empirically by Coenen and Gureckis (2016). We simply adopt Walds approach to optimally drawing internal posterior samples.

The posterior probability p that one decision alternative is true is assumed to be unknown, but we assume that binomial samples can be sequentially drawn with probability p. We perform Bayesian inference using the obtained samples, by first placing a prior distribution over p and assume a fixed cost c of drawing a sample, reflecting the time and effort of doing so. After drawing j samples in favor of a decision alternative and i against, we denote p_{ij} as the posterior probability of a decision alternative given those samples, with p_{00} being the prior probability. The binary decision task essentially becomes a sequential test on whether $p_{ij} < 1/2$ and the optimal stopping rule for this test can then be derived from the following using dynamic programming:

$$F(i,j) = \min \begin{cases} F_0(i,j), \\ c + p_{ij}F(i,j+1) + (1 \pm p_{ij})F(i+1,j). \end{cases} \tag{2}$$

where $F(i,j)$ and $F_0(i,j)$ are respectively the expected cost of sampling and expected cost of termination after i samples against and j in favor have been observed. The sampling process should terminate whenever $F(i,j) \geq F_0(i,j)$.

Because $F_0(i,j)$ represents the expected cost of stopping the sampling process when the posterior probability of an alternative is p_{ij}, if the punishment for an incorrect decision is one unit of utility and thus,

$$F_0(i,j) = \min \begin{cases} i/(i+j), \\ j/(i+j). \end{cases} \tag{3}$$

This is the expected cost of incorrectly choosing an alternative when the posterior probability of that alternative is $p_{ij} = \text{Beta}(i,j)$.

The expected cost of drawing another sample is the sum of (a) the cost of generating one sample c, (b) the expected cost if the new sample turns out to be in favor $p_{ij}F(i,j+1)$, and (c) the expected cost if the new sample turns out to be against $(1 \pm p_{ij})F(i+1,j)$.

While the exact solution of the Bayesian optimal stopping problem is difficult to obtain, once computed it can also be reused across different cognitive tasks. For illustrative purpose, we set cost of collecting one sample $c = 0.006$ and prior probability to $\text{Beta}(1,1)$. This leads to the termination conditions for sequential sampling in Figure $2D_1$, which shows a collapsing threshold.

We assume that BASS is performing amortised inference, and because the decision and estimation tasks are so similar, the samples drawn for decision are simply averaged to produce the estimate. Like SAS, BASS produces a high degree of consistency between decision and estimate and a biased toward the decision boundary for extreme stimuli. However, unlike SAS, BASS produces estimates that are biased away from the decision boundary for central stimuli (Figure $2D_3$). The reason for the model's behavior can be seen in the termination conditions shown in Figure $2D_1$. The sampling process is very unlikely to stop when there are an equal number of samples in favor of the two alternatives, instead waiting until there are more samples in favor of one of the alternatives. Then, after averaging the resulting samples to produce an estimate, these estimates are unlikely to be close to the decision boundary.

Table 1: Summary of model predictions on empirical effects

Effects	WD	SC
Decision bias	yes	yes
Self consistency	low	high
Belief distribution	bimodal	one-sided
	SAS	BASS
Decision bias	no	yes
Self consistency	high	high
Belief distribution	undistorted	favors one side

Note. WD=Weighted Decoding, SC=Self-Consistency, SAS=Simple Amortised Sampling, BASS=Bayesian Amortised Sequential Sampling.

Comparing the Models

As seen across Figure 2, qualitatively similar patterns of decision and estimation bias are predicted by the WD, SC, and BASS models. What distinguishes the models are the beliefs about the probability of each possible response in the estimation task. WD predicts that the optimal weighting will result in a bimodal belief distribution. SC predicts a one-sided belief distribution: that only estimates consistent with the decision will be considered. In contrast, BASS predicts that people will believe that several estimates are possible, including a low probability of those that are not consistent with the decision (see Table 1 for a summary).

We now test these predictions in a new experiment that includes a new type of trial that is used to elicit participants' belief distributions over possible estimates. We use a numerosity task in this experiment both to generalize the results, and because the discrete responses required in a numerosity experiment make it easier to elicit a belief distribution.

Experiment

Participants

Twenty-four participants (12 Males, ages between 18 and 35) were recruited through SONA system, University of Warwick. They received £4 for completing the experiment.

Materials

Participants were shown a briefly appearing number of dots (0.5 sec) on computer screen in a series of trials. The true number of dots was uniformly distributed between 21 and 30, and participants were explicitly told this at the beginning of the experiment. To generate a stimulus, dots were randomly positioned within a circular field subject to a minimum spacing between any two dots of four times the dot size. To encourage reliance on numerosity, rather than low-level visual features, the dot sizes varied uniformly between 3 and 9 pixels, and the radius of the dot field also varies uniformly between 150 and 450 pixels.

There were three different trial types (Figure 1B). For all trial types, participants made an initial decision as to whether there were 25 or fewer or 26 or more dots, so that the trials were identical until after this point. Following the decision, participants either immediately received feedback (D-F trials), were immediately asked to estimate the number of dots (D-E trials), or were immediately asked to state their beliefs about the number of dots using a histogram (D-H trials). When given a histogram, participants were asked to distribute 100 tokens among all of the possible numbers of dots according to how likely they believed these numbers were on that particular trial.

Procedure

Before the main experiment, participants received one practice example for each of the D-F, D-E, and D-H trials (Figure 1B). Participants additionally received feedback during practice, to introduce them to the point system used in the experiment that was used to encourage them to engage with the more demanding histogram trials. Correct decisions and estimates were both worth one point, while the number of points assigned to a histograms was $R = 100 \times [(1 \pm T_i/100)^2]$, where T_i was the number of tokens placed on the correct response. This formula is based on the Brier score, which incentivizes accurately reporting a belief distribution. Participants were also told, "If you had placed all the tokens on the correct number of dots, you would have scored 100 points. But if you had placed no tokens on the correct number of dots, you would have scored 0 points." Points were tallied throughout the experiment, but were only displayed to participants at the end of the experiment.

Results and Discussion

Decisions As shown in Figure 3A, participants were more likely than not to pick the correct answer for each true number of dots, but were never perfect.

Estimates Figure 3B shows the results of the estimates from the D-E trials for each true number of dots. True numbers that were close to the edge of the range showed an average bias towards the decision boundary, as participants tended not to respond outside the allowable range, and these responses outside the allowable range were excluded from further analysis (7.32%).

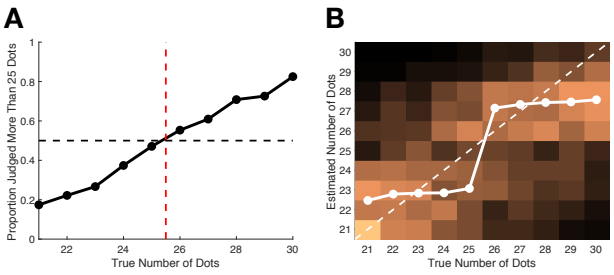

Figure 3: Behavioural data from the decision-estimation trials. **(A)** The psychometric curve describing the relationship between the true number of dots displayed and the average proportions of times participants judged the number of dots to be 26 or more. **(B)** The estimated number of dots (solid white line) systematically deviates from the true number of dots (dashed white line), constituting a perceptual bias.

For true numbers of dots near the decision boundary, particularly for numbers 25 and 26, participants were biased away from the decision boundary, in line with past work on the perceptual bias. When true number of dots was 25, estimates were on average smaller than 25, $t(23) = \pm 14.97, p < .001$. When true number of dots was 26, estimates were on average larger than 26, $t(23) = 6.37, p < .001$. This estimation bias is, as expected, further qualitative evidence against the SAS model.

Histograms Figure 4A shows the average belief histogram following a decision of 25 or fewer, and the average belief histogram following a decision of 26 or more. These average histograms show greater mass on the side of the boundary consistent with the decision, indicating that overall participants engaged with these trials. They also show no evidence of bimodality as WD predicts, nor is the mass completely on one side of the boundary as SC predicts. Instead qualitatively these average histograms are most consistent with BASS.

To quantitatively test for whether there were the kind of bimodal histograms that WD predicts, we computed the average proportions, for each participant, that the mean token mass on the boundary numbers (i.e., 25 and 26) would be lower than either the mean token mass on 21-24 or the mean token mass on 27-30 (Figure 4B). If responses were random, we expect a $1/3$ chance that the mean token mass on 25 and 26 would be smallest. However, there were very few histograms that were bimodal, fewer than would be predicted by random responding, $t(23) = \pm 7.68, p < .001$.

We then quantitatively tested whether all of the belief mass was on one side of the boundary, as SC predicts. We first estimated how much true responding there was, by calculating the proportion of trials on which a participant's histogram was consistent with their decision. Per participant, we calculated the proportion of trials on which the majority of token mass matched the decision. Next, we calculated,

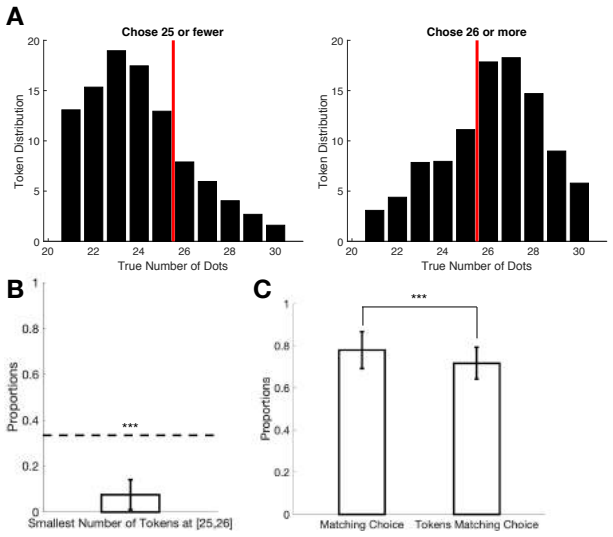

Figure 4: Results from the belief distributions reported in decision-histogram trials. **(A)** Average histograms when people chose "25 or fewer" (*left*) and when people chose "26 or more" (*right*). **(B)** The proportion of times when the token mass on central boundary numbers (25 and 26) is smallest. Error bar indicates 95% confidence interval across participants. **(C)** The proportion of times when preponderance of tokens matches the choice (*left*) and the percentages of token mass consistent with the choice (*right*). Error bars indicate 95% confidence interval across participants.

per participant, the proportion of tokens on the same side of boundary as the decision, as a measure of whether inconsistent estimates were considered. These two quantities, shown in Figure 4C, were different, $t(23) = 3.46, p = .002$, showing that tokens were certainly placed on numbers that disagreed with the decision, a number that exceeded what was expected from our estimate of noisy responding.

The results of the histogram trials are in line with the predictions of BASS, in which samples from both sides of the boundary are expected to be reused for the estimate. According to BASS, the amount of tokens placed on the opposite side of choice is a consequence of stochastic samples from the posterior distribution. Due to the termination conditions, there are always more samples that match the decision than those that mismatch the decision, but there are often samples on both sides of the boundary.

Conclusions

We proposed a new explanation for the decision bias in perception. To make a decision, we assume that participants sequentially sample hypotheses about the true nature of the environment, and stop when they have strong enough evidence in favor of one alternative over the other. As an application of amortised inference, we assumed that participants then reuse the samples to save cognitive effort, averaging them to produce their estimate. The bias in the estimate occurs because the samples that were sequentially obtained are never balanced between the options, and so estimates tend to be biased away from the decision boundary.

We generalized the bias from orientation tasks to a numerosity task, showing that it also occurs when participants give discrete responses to these perceptually complex stimuli. Using a novel type of trial in which we elicited participants' beliefs about which numbers were likely on a single trial, we found evidence for sequential sampling over other explanations of the decision bias in perception.

The sequential sampling model we evaluated here, BASS, is a novel application of the work of Wald (1950) for optimally deciding when to stop sampling from a binomial distribution with unknown probability. Of course it is almost certain that other sequential sampling approaches, such as those by Vul et al. (2014) and Bogacz et al. (2006), would predict the same qualitative results. Discriminating between these sequential sampling approaches will likely require quantitative comparisons, which is an interesting avenue for future work.

Additionally, a soft version of the self-consistency model, which relaxes the assumption that self-consistent estimates are made by every participant on every trial, could reproduce the qualitative results here. To distinguish the BASS model from a soft self-consistency account, we could test whether the belief distributions are a mixture of self-consistent sensory representations and unmodified sensory representations. However, to properly answer this question, we will need a further experiment that characterizes unmodified sensory representations for comparison.

Another avenue for future work is to explore the extent to which amortised inference and sequential sampling can explain other psychological biases. One interesting possibility is the anchoring bias (Tversky & Kahneman, 1974). In anchoring, participants are first asked to make a decision about whether a number, such as the percentage African countries in the UN, is smaller or larger than an often transparently irrelevant number, such as a number that results from the spin of wheel of fortune. Then participants are asked to make their estimate. While the task participants engage in is almost identical to the one that we used here, the effect that is found is the opposite: participants estimates are biased *toward* the anchor (Tversky & Kahneman, 1974). A unified explanation of these similar perceptual and cognitive biases will need to account for both the push and pull that decisions can exert on subsequent estimates.

Abstract

We quantitatively modeled and compared two types of errors in numerical estimation for naturalistic judgment targets: *mapping errors* and *knowledge errors*. *Mapping errors* occur when people make mistakes reporting their beliefs about a particular numerical quantity (e.g. by inflating small numbers), whereas *knowledge errors* occur when people make mistakes using their knowledge about the judgment target to form their beliefs (e.g. by overweighting or underweighting cues). In two studies, involving estimates of the calories of common food items and estimates of infant mortality rates in various countries, we found that knowledge error models predicted participant estimates with very high out-of-sample accuracy rates, significantly outperforming the predictions of mapping error models. The knowledge error models were also able to identify the objects and concepts most associated with incorrect estimates, shedding light on the psychological underpinnings of numerical judgment.

Keywords: judgment errors; numerical estimation; word embeddings; word vectors; knowledge representation; cognitive model

Introduction

Decades of research on judgment and decision making has established that people make systematic errors when estimating numerical quantities, such as the frequencies of lethal events, proportions of demographic groups, or the calories of food items (Chernev & Chandon, 2011; Landy, Guay, & Marghetis, 2017; Lichtenstein et al., 1978). Researchers studying these judgment errors have identified a number of factors responsible for numerical mis-estimation, such as the use of non-linear weighting functions (e.g. Gonzalez & Wu, 1999; Hollands & Dyre, 2000; Landy et al., 2017; Tversky & Kahneman, 1992) or the use of heuristic cue-aggregation rules (Brown & Siegler, 1993; von Helversen & Rieskamp, 2008).

These factors can be understood in terms of two types of errors – *mapping errors* and *knowledge errors*. *Mapping errors* occur when people make mistakes reporting their beliefs about a particular numerical quantity. In other words, people may have the correct belief about the numerical quantity but incorrectly map this belief into a response. For example, prior literature on numerical estimation has found an inverse-S-shape pattern when plotting participant estimations against objective statistics, with overestimation of small values and underestimation of large values (e.g. Erlick, 1964; Hollands & Dyre, 2000; Landy et al., 2017; Varey, Mellers, & Birnbaum, 1990). Such patterns have typically been modeled using non-linear functions, e.g. power functions and their variants (Curtis, Attmeave, & Harrington, 1968; Hollands & Dyre, 2000), log-odds transformations (Shepard, 1981; Zhang & Maloney, 2012), and probability weighting functions (Fennell & Baddeley, 2012; Tversky & Kahneman, 1992). These models all assume that a systematic distortion takes place when transforming correct internal beliefs into an explicit numerical response.

In contrast, *knowledge errors* occur when people make mistakes using their knowledge about the judgment target to form their beliefs. These can lead to the formation of incorrect beliefs (e.g. through the biased use of memory cues), though people may still be able to accurately report these beliefs. For example, Chernev and Chandon (2011) have documented halo biases in food calorie estimation, according to which health-related cues are given an incorrectly high weight, which can then lead to the underestimation of food calories. Media coverage or word frequency has also been shown to be used as a cue in probability estimation (Dougherty, Franco-Watkins, & Thomas, 2008; Tversky & Kahneman, 1974) and frequency estimation (Hertwig, Pachur, & Kurzenhäuser, 2005; Lichtenstein et al., 1978), which can lead to the overestimation of the size of minority groups (Gallagher, 2003; Herda, 2013). More generally, many researchers in cognitive psychology have proposed that people use heuristics to weigh and aggregate judgment cues, which can, at times, lead to systematic errors in numerical estimation. These heuristics simplify the decision process by ignoring certain cues (and thus assigning them incorrectly low weights), or by using equal weights for all cues (and thus over-weighting irrelevant cues and under-weighting relevant cues) (see Hertwig, Hoffrage, & Martignon, 1999; Juslin, Olsson, & Olsson, 2003; von Helversen & Rieskamp, 2008). Our division of numerical judgment errors into mapping and knowledge errors has precedent. For example, Lichtenstein et al. (1978) suggested that there are two types of biases in frequency estimation – a primary bias (i.e. overestimation of small numbers and underestimation of large numbers) and a secondary bias (which may due to media bias, disproportionate exposure, imaginability, etc.). Likewise, Brown and Siegler (1993) argued that there are two types of knowledge that come into play in quantitative estimation – metric knowledge (e.g. statistical induction) and mapping knowledge (e.g.

heuristics). Von Helversen and Rieskamp (2008) extended this work by showing that people are likely to sample objects that are similar to the judgment target (where *knowledge errors* may occur) and make estimation based on some transformation of the sampled objects' values (where *mapping errors* may occur). Finally, Landy et al. (2017) showed the presence of two features that lead to errors in demographic estimation – domain-general bias (i.e. a log-odds mental representation of proportion) and domain-specific bias (e.g. media bias and xenophobia).

Although this work has greatly expanded our understanding of numerical estimation, most of it pertains to estimates of simple frequencies, rather than more general (and complex) numerical quantities. Additionally, experiments that do examine such complex numerical estimates, typically use artificial experimental stimuli – such as toxicity of fictional bugs (Juslin et al., 2003), percentage of dots in a mixture of black and white dots (Varey et al., 1990) and proportion of letters (e.g. "A") in a random letter string (Erlick, 1964) – and/or experimenter-generated cues that provide only an abstract representations of the rich knowledge present in the human mind (Brown, 2002; Juslin et al., 2003; von Helversen & Rieskamp, 2008). Although artificial stimuli and simplified knowledge representations help establish theoretical foundations, it is also necessary to model how people make quantitative estimates in the real world where they usually possess rich and complex knowledge and apply it at their discretion.

Our goal in this paper is to address these issues by formalizing, fitting, and comparing mapping and knowledge error models of numerical estimation with policy-relevant consequences. We consider two domains: estimates of food calories and estimates of infant mortality rates in countries. For the mapping error model, we drew insights from prior work and fit various non-linear functions to predict participant estimates from correct answers. For the knowledge error model, we used word embeddings – models trained on large text corpora that preserve semantic knowledge of words and phrases in high-dimensional vectors – to obtain rich quantitative representations for food items and countries, and then attempted to predict participant estimates from these representations by implicitly learning cue weights on semantic knowledge. Word embeddings have been shown to mimic representations at play in human cognition, such as associative judgment (Bhatia, 2017; Caliskan, Bryson, & Narayanan, 2017), free recall in memory (Manning & Kahana, 2012; Steyvers, Shiffrin, & Nelson, 2004), priming (Günther, Dudschig, & Kaup, 2016), and stereotypes (Garg, Schiebinger, Jurafsky, & Zou, 2018). Thus these representations are likely to capture common knowledge about the judgment targets that may hinder or facilitate numerical estimation. More importantly, these representations will offer insights into the psychological qualities and cues that most contribute to over- and underestimation.

Experimental Methods

Participants

We recruited a total of 101 participants – 50 participants (mean age = 30 years, 52% were female) in Study 1 and 51 participants (mean age = 31.4 years, 60.78% were female) in Study 2 from Prolific Academic, an online experiment platform. All participants were from the U.S. and had an approval rate of 80% or above. They were paid at a rate of approximately $6.50 per hour.

Stimuli

For Study 1, we obtained 200 food items and their true calorie amounts from a United States Department of Agriculture (USDA) database. Sample items include lamb, butter, mint, etc. For Study 2, we obtained the infant mortality rates of 200 countries from the Central Intelligence Agency (CIA)[1]. These countries include Denmark, Nepal, Estonia, etc.

Procedure

In Study 1, participants were asked to estimate how many calories (in kcal) there are in 100 grams of a particular food item; in Study 2, they were asked to estimate the infant (child under 1 year old) mortality rate in number of deaths per 1,000 live births in a particular country. Each participant estimated all 200 stimuli and saw only one item on each screen. The order of the 200 stimuli was randomized and there was a 30-second break after every 50 stimuli. After completing all questions, participants were asked for their age and gender.

Predicting Estimates

Computational Methods

For each target i (e.g. peanuts), we obtained both the average participant estimate y_i (e.g. estimated calories in peanuts) and the correct answer z_i (e.g. actual calories in peanuts). To quantitatively study mapping explanations for these errors, we fit three different mapping models that transformed correct answers into participant responses. Formally, our mapping error models predicted y_i as some function (linear or nonlinear) of z_i. The first function we used was a simple linear function (Eq.1); the second function was a third-degree polynomial (Eq.2); and the third function was a power function with a constant term (Eq.3)[2]. Parameters were estimated by minimizing the residual sum of squares.

$$y_i = \beta_0 + \beta_1 z_i \tag{1}$$

$$y_i = a z_i^3 + b z_i^2 + c z_i + d \tag{2}$$

[1] There are 224 countries and regions in CIA database. We excluded the ones that do not have a vector representation in our word embedding model (see the computational methods in the next section) and those whose public data are limited (e.g. no electricity usage data, no literacy rates, etc.)

[2] Although linear pattern was rarely found in previous literature, we included the linear model here as a baseline. A third-degree polynomial served to model any potential S-shape or inverse-S-shape pattern. We incorporated a power function due to its prevalence in prior work.

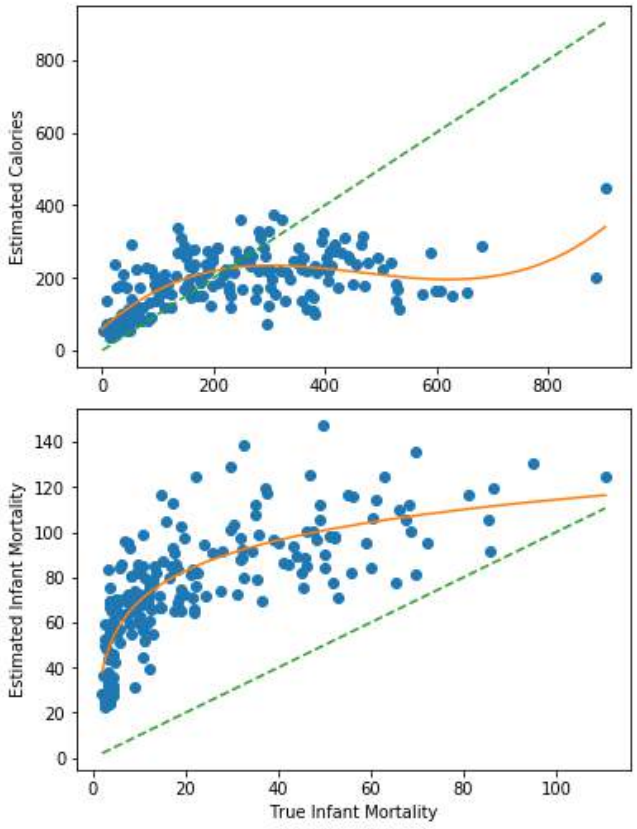

Figure 1: Scatterplots of average participant estimates vs. correct answers for Study 1 (top) and Study 2 (bottom). The green dotted lines indicate perfect calibration where participant estimates are equal to the correct answers. The red curves represent the best fitting mapping error models – third-degree polynomial (Eq.2) for Study 1 and power function (Eq.3) for Study 2.

$$y_i = \lambda z_i^{\delta} + \gamma \tag{3}$$

To examine knowledge errors, we used pretrained Word2Vec word embeddings (Mikolov et al., 2013) to obtain rich quantitative representations for food items and countries. These gave us a 300-dimensional vector x_i for each target i. Our knowledge error model involved fitting a (regularized) linear function with a 300-dimensional weight vector w (w_1 for Study 1 and w_2 for Study 2), to predict y_i using $w * x_i$[3]. The weight vectors (300-dimensional) transform semantic knowledge represented in a 300-dimensional space to an one-dimensional numerical estimation line. Intuitively, each dimension of x_i can be seen as a semantic cue that participants might rely on to facilitate estimation and these weight vectors can be seen as capturing cue weights on semantic knowledge. We compared mapping and knowledge error models through leave-one-out cross-validation (LOOCV)[4], on both the aggregate and the individual level.

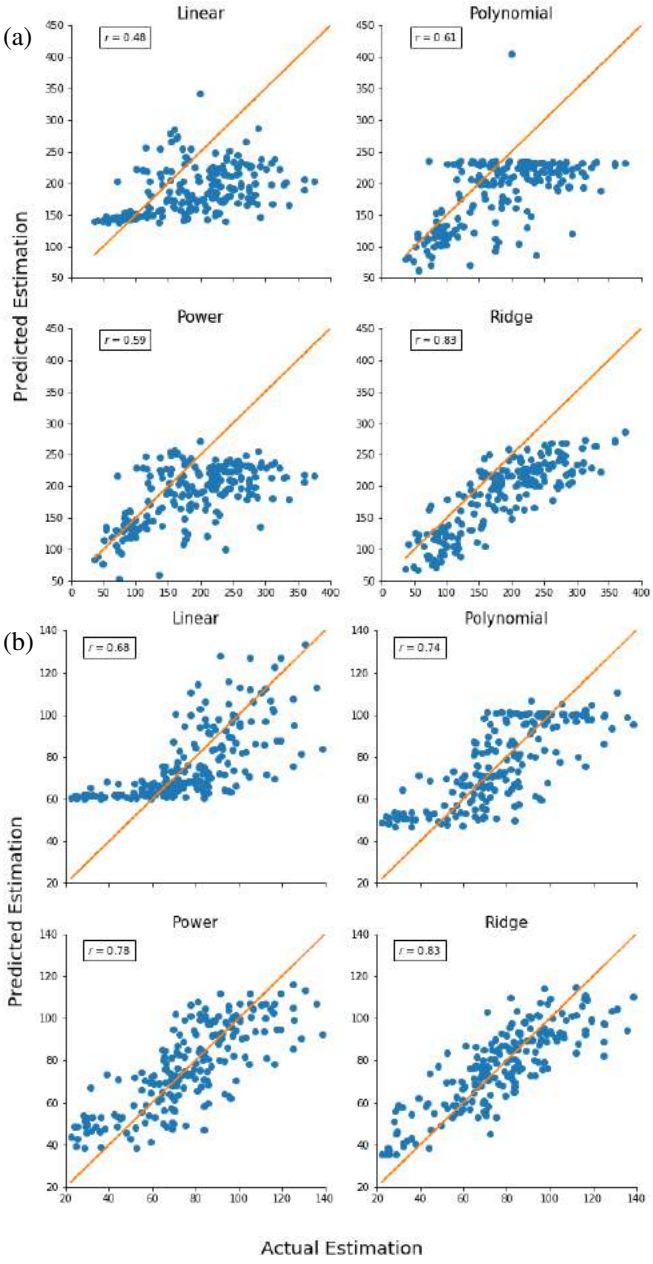

Figure 2: Scatterplots of predicted estimates using leave-one-out cross-validation (LOOCV) vs. actual participant estimates for (a) Study 1 and (b) Study 2, along with Pearson correlations.

Results

Study 1 and 2 elicited a total of 40,400 participant estimates for 400 distinct naturalistic entities in two domains calories

[3]Specifically, we implemented a ridge regression in the Scikit-Learn Python machine learning library (Pedregosa et al., 2011). There was a set of hyperparameters in this library. To avoid manipulating the hyperparameters to improve model performance, we took the default values of all these hyperparameters. We focused on ridge regression because previous results (e.g. Bhatia, 2019; Richie, Zou, & Bhatia, 2018, Dec) suggested that compared to other models such as lasso and support vector regression, ridge regression often works best in predicting human judgments from word embeddings.

[4]For each domain, we trained our models on 199 judgment targets and then used the trained model to predict participant estimates of the left-out target. This procedure was repeated for each judgment target to get LOOCV predictions

Table 1: Aggregate level predictive accuracy of the three mapping error models – linear (Eq.1), polynomial (Eq.2), power (Eq.3), and knowledge error model (ridge) using leave-one-out cross-validation (LOOCV) for Study 1 and Study 2.

	Study 1			Study 2		
	Correlation	R^2	RMSE	Correlation	R^2	RMSE
Linear	0.48	0.23	4609.04	0.68	0.46	348.72
Polynomial	0.61	0.37	3772.07	0.74	0.55	291.82
Power	0.59	0.35	3902.78	0.78	0.60	258.64
Ridge	0.83	0.68	1924.11	0.83	0.68	208.10

of 200 common food items and infant mortality rates of 200 countries. Consistent with prior work, we found that participants made substantial errors. The average absolute differences between the average participant estimate, y_i, and the correct answer, z_i, for food calories and infant mortality rates were -45.28kcal per 100g ($se = 10.8$) and 53.44 deaths per 1,000 live births ($se = 3.78$) respectively, indicating an overall underestimation of food calories and overestimation of infant mortality rates. Figure 1 reflects some overestimation of low calories, significant underestimation of high calories, and overall overestimation of infant mortality rates.

Table 1 summarizes the aggregate level performance of the three mapping error models and one knowledge error model. We evaluated model performance using the Pearson correlation between observed y_i and predicted y_i, R^2, and root mean square error (RMSE), in the out-of-sample tests. Figure 2 shows scatterplots of predicted estimates using LOOCV and average participant estimates, along with Pearson correlations. We found that the knowledge error model was able to predict average participant estimates fairly accurately, with out-of-sample correlation rates of .83 for both domains on the aggregate level. In contrast, the best mapping error models were only able to achieve aggregate-level out-of-sample correlation rates of .61 for foods and .78 for countries (all $p < 10^{-22}$). We obtained similar results on the individual level. The best mapping error model achieved average individual-level out-of-sample correlation rates of .37 for foods and .43 for countries, while the knowledge error model achieved .51 for food and 0.47 for countries. Our results showed statistically significant improvements in predictive accuracy when using the knowledge error model compared to the mapping error models on both the aggregate and the individual level.

Traces of Judgment Errors

Computational Methods

In the previous section, we showed that the word-embedding-based vector representations could be used to predict estimates of food calories and infant mortality rates by multiplying x_i (the vector representations for the foods and countries) with different weight vectors w_1 (Study 1) and w_2 (Study 2). As mentioned in computational methods of last section, these weight vectors can be seen as capturing cue weights on semantic knowledge. In this section, we hope to better understand the psychological substrates of the judgment errors that these weights generate. What are the features that lead to the overestimation or underestimation of food calories and infant mortality rates?

To address this, we took the 5,000 most frequent words from the corpus of contemporary American English (`http://corpus.byu.edu/coca/`) that were not judgment targets and for each word j, we also obtained a 300-dimensional vector, s_j, from the Word2Vec model. Intuitively, the weight vector w in the previous section could be seen as a function that projects the semantic knowledge represented by x_i onto a numerical estimation line y_i. By multiplying s_j by the weight vector w, we got a vector representation e_j for these 5,000 words in the numerical estimation line. Similarly, we also trained a weight vector w' to predict the correct answer, z_i, using $w' * x_i$. Multiplying s_j by this new weight vector w' would give us a vector t_j that pinpoints the location of the 5000 words in a line of correct answers. The difference between e_j and t_j then informs us of what words and concepts might be overweighted (or underweighted) in the estimation process. In other words, this difference would offer a quantitative measure of how much any given word contributes to overestimation (or underestimation).

Results

Figure 3 has word clouds of 50 words[5] that greatly contribute to over- and under- estimation for both domains. These words reveal potential conceptual underpinnings of judgment biases that match our intuition. For example, words related to dining out (e.g. restaurant, menu, chef, wine) bias toward overestimation of calories; words appearing to be small in portion (e.g. flour, candy, powder, dust) bias toward underestimation of calories; developing-country-related words (e.g. Iraqi, Cuban, Palestinian, Arab) contribute to overestimation of infant mortality rates; and European-country-related words (e.g. Dutch, German, French, European) contribute to underestimation of infant mortality rates.

[5]We included 50 words because that was the maximum number of legible words that could be fit into the graphs.

Figure 3: Word clouds of words that greatly contribute to overestimation and underestimation of (a) food calories and (b) infant mortality rates. Font reflects the magnitude of over- and under-estimation. Color has no meanings.

Discussion

We built computational models to compare two types of errors in numerical estimation: *mapping errors* and *knowledge errors*. We applied these models to study naturalistic numerical estimates in two studies involving judgments of calories of food items and judgments of infant mortality rates of countries. Consistent with previous findings, the best fitting mapping error models in both studies were not linear and drastically outperformed simple linear regression (baseline). We found the common inverse-S-shape pattern in food calorie estimation but not in the infant mortality domain. Although almost all countries' infant mortality rates were overestimated, the magnitude of overestimation appeared to be larger for countries with low infant mortality than for countries with high infant mortality.

Although our mapping error models were able to provide a good account of our data, we obtained even higher predictive accuracy rates from our knowledge error models. This indicates that we can predict participant estimates better if we assume some flexible (potentially incorrect) use of memory cues instead of some flexible (potentially incorrect) use of correct beliefs, and that judgment errors appear to stem primarily from the incorrect use of knowledge, rather than the incorrect mapping of the true quantities. Here it is also useful to note that our knowledge error models, unlike our mapping error models, did not know the correct responses. Rather they were able to predict participant estimates merely by proxying the rich semantic knowledge that participants used in their own judgments. This showcases both the descriptive power of the models as well as their domain-general applications: We can use these models to predict participant estimates even when we (the researchers) do not know the correct answers.

So far, we've only studied *mapping errors* and *knowledge errors* separately. It is likely that these two types of errors take place simultaneously as suggested by prior work (e.g. Brown & Siegler, 1993; von Helversen & Rieskamp, 2008). Future work should investigate the interaction between the two types of errors and also the interplay between error type and judgment domain – how do people balance between these two types of errors to minimize overall errors and in which domains are people more likely to make one type of errors than the other?

For our knowledge error model, we used semantic knowledge which was captured by word embeddings to predict participant estimates. Building upon recent successful applications of such models in naturalistic judgments (e.g. Bhatia, 2019; Richie et al., 2018, Dec), we showed how a single knowledge representation derived from natural language data was able to predict participant numerical estimation with high out-of-sample accuracy. We acknowledge that due to its high dimensionality, word-embedding-based representations are likely to contain more knowledge about judgment targets than what people actually use to estimate numerical quantities, and due to its generality, they also don't account for individual differences, such as personal experience and level of expertise. One way to address this may involve training different word embeddings for different populations, which is a potential topic for future work.

Although our mapping error models and knowledge error models lack some interpretability in terms of cognitive process underlying numerical estimation, the different non-linear mapping error models for food calories and infant mortality rates suggest different transformations from internal beliefs to external responses. Likewise, the words generated from the knowledge error models reveal intuitive conceptual bases of judgment errors, e.g. a misuse of food size associations in food judgment and a misuse of poverty associations in infant mortality judgment. These results show that our knowledge

error model has explanatory value, and can shed light on the types of associations that contribute to judgment errors across different domains.

Finally, we would like to emphasize the naturalism of the two domains examined in this paper. Our approach is unique in that it can be applied to numerical estimates for arbitrary natural entities, such as food items and countries. This opens up new avenues for applying cognitive science theory to policy-relevant applications, such as those pertaining to health-related and humanitarian issues. We look forward to future work that extends our approach to model the types of errors at play in the many important judgments that people make on a day-to-day basis.

Abstract

People use speech and gesture together when describing an event or action, where both modalities have different expressive opportunities (Kendon, 2004). One question is how the two modalities are semantically coordinated, i.e. how meaning is distributed across speech and accompanying gestures. While this has been studied only for adult speakers so far, here, we present a study on how young children (4 years of age) semantically coordinate speech and gesture, and how this relates to their cognitive and (indirectly) their verbal skills. Results indicate significant positive correlations between cognitive skills of the children and gesture-speech coordination. In addition, high cognitive skills correlate with the number of semantically relevant child descriptions revealing a link between verbal and cognitive skills.

Visuo-Motor Control Using Body Representation of a Robotic Arm with Gated Auto-Encoders

Abstract

We present an auto-encoder version of gated networks for learning visuomotor transformations for reaching targets and representating the location of the robot arm. Gated networks use multiplicative neurons to bind correlated images from each others and to learn their relative changes. Using the encoder network, motor neurons categorize the induced visual displacements of the robot arm when applying their corresponding motor commands.Using the decoder network, it is possible to infer back the visual motion and location of the robot arm from the activity of the motor units, aka body image.Using both networks at the same time, near targets can simulate a fictious visual displacement of the robot arm and induce the activation of the most probable motor command for tracking it. Results show the effectiveness of our approach for 2 degree of freedom and 3 degree of freedom robot arms. We discuss then about the network and its use for reaching task and body representation, future works and its relevance for modeling the so-called gain-field neurons in the parieto-motor cortices for learning visuomotor transformation.

Culture as ground for cross modality unidimensional timelines

Abstract

Current evidence supports the idea that time is mentally represented by unidimensional spaces. One main question is whether the language modality grounds differences on using these spaces when signers and speakers share the cultural framing of time (e.g., by clocks, calendars, etc.). We tested whether past and future events are represented along a Left-Past Right-Future and a Behind-Past Ahead-Future mental timeline in two language modalities. In Experiments 1 and 2 deaf signers of Uruguayan Sign Language (LSU) categorized the temporal reference of LSU sentences by pressing a directional key. The congruency effect was registered for the Left-Past Right-Future trials and for hand setting counterbalanced Behind-Past Ahead-Future trials. Experiments 3 and 4 replicated the congruency effect for Spanish speakers. The findings answered the research question in line with the suggestion that when signers and speakers share the cultural framing of time the tested space-time mappings activates on the same fashion.

Information Theory Meets Expected Utility: The Entropic Roots of Probability Weighting Functions

Mikaela Akrenius
Indiana University Bloomington, Bloomington, Indiana, United States

Abstract

This paper proposes that the shape and parameter fits of existing probability weighting functions can be explained with sensitivity to uncertainty (as measured by information entropy) and the utility carried by reductions in uncertainty. Building on applications of information theoretic principles to models of perceptual and inferential processes, I suggest that probabilities are evaluated relative to the distribution of maximum entropy (the uniform distribution) and that the perceived distance between a probability and uniformity is influenced by the shape (relative entropy) of the distribution that the probability is embedded in. These intuitions are formalized in a novel probability weighting function, VWD(p), which is simpler and has less free parameters than existing probability weighting functions. VWD(p) captures characteristic features of existing probability weighting functions, introduces novel predictions, and provides a parsimonious account of findings in probability and frequency estimation related tasks.

The Effect of Chronic Regulatory Focus on Sampling Behavior and Risky Decisions

Lujain Al Alamy
Columbia University, New York, New York, United States

James E. Corter
Columbia University, New York, New York, United States

Abstract

Prior research on a possible role of regulatory focus orientation (Higgins, 1998) in financial decision-making has focused on description-based tasks in which people receive explicit information about the characteristics of a decision problem a priori. However, relatively few real-world decisions resemble this type of laboratory task. Here, we examine how regulatory focus orientation influences peoples decision behavior in an experience-based sampling paradigm (Hertwig et al., 2004), where people learn about the characteristics of a decision problem only through experience. We investigated if individuals chronic regulatory focus orientation (promotion-focus or prevention-focus) predicts process (sampling) and outcomes (risky versus sure-thing choices) in a sampling paradigm task. Regulatory focus did not predict sampling behavior, nor the number of risky choices in the gain domain, but promotion focus orientation was correlated with the prevalence of risky choices in the loss domain. Also, the big-5 personality trait of Openness was found to be related to number of sampled outcomes for losses and to risky choices for gains.

Showing without telling: Indirect identification of psychosocial risks during and after pregnancy

Kristen Allen
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Alex Davis
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Tamar Krishnamurti
University of Pittsburgh, PITTSBURGH, Pennsylvania, United States

Abstract

During the perinatal period, psychosocial health risks, including depression and intimate partner violence, are associated with serious adverse health outcomes for both parent and child. To appropriately intervene, healthcare professionals must first identify those at risk, yet stigma often prevents people from disclosing the information needed to prompt an assessment. We use techniques from natural language processing to indirectly identify psychosocial risks in the perinatal period. We apply latent Dirichlet allocation (LDA) and latent semantic indexing (LSI) to categorize themes from brief diary entries by pregnant and postpartum women and apply sentiment analysis to characterize affect, then perform regularized regression to predict diagnostic measures of depression and emotional intimate partner violence. Journal text entries quantified through sentiment analysis and topic models show promise for improved identification of depression and intimate partner violence, both stigmatized risks. Such methods may serve as an initial or complementary screening approach.

Modeling Gaze Distribution in Cross-situational Learning

Andrei Amatuni
Indiana University, Bloomington, Indiana, United States

Chen Yu
Indiana University, Bloomington, Bloomington, Indiana, United States

Abstract

Here we investigate the performance of two models in predicting human gaze behavior in cross situational word learning. Previous work has developed two diverging accounts of potential mechanisms that might serve this learning ability. The first, associative learning, relies on the integration of contextual statistics across time. The second, hypothesis testing of the "propose-but-verify" sort, suggests that learners do not track co-occurrence statistics, instead only tracking a single label-object mapping at a time. To adjudicate between these two mechanisms, we examine real time selective attention behavior as a window into learning processes. We demonstrate systematic biasing in gaze allocation as a function of the associative evidence accumulated for a label-object pairing over time, favoring the associative learning account. Moreover, we predict learning outcomes with model parameters controlling sensitivity and noise in memory encoding. This is novel evidence supporting associative learning and highlights the unique role of memory in cross-situational learning.

Learning by doing: Supporting experimentation in inquiry-based modeling

Abstract

Inquiry-based modeling plays an important role in science; Science makes progress through formulating and evaluating questions, hypothesis, and arguments. The inquiry-based modeling approach also enhances learning about science. However, engaging in modeling requires domain knowledge as well as quantitative skills. The Virtual Ecological Research Assistant (VERA) is an interactive learning environment that supports inquiry-based modeling for citizen and student scientists. VERA provides a visual language for conceptual modeling in the domain of ecology and an AI compiler for automatic generation of agent-based simulations in the process of constructing, evaluating, and revising the models. We conducted a pilot study with college-level biology students (N=15) using VERA for modeling ecological phenomena. The 2-hour pre- and post-test study demonstrates gains in the learning of ecological content knowledge. We also found that the use of the Encyclopedia of Life as a source of domain knowledge helped students create more complex models.

Composing Indeterminate Event Information In Context: Evidence from an Eye-Tracking Memory Paradigm

Caitlyn Antal
Yale University, New Haven, Connecticut, United States

Roberto de Almeida
Concordia University, Montreal, Quebec, Canada

Abstract

A sentence such as ”We finished the paper” is indeterminate regarding what we finished doing with the paper. These sentences constitute a test case for two major issues regarding the nature of language comprehension: (1) whether or not semantic composition is simple (classical) or enriched with intended or implicit constituents; and (2) the nature of the linguistic and cognitive resources that help us interpret the event the sentence conveys. We conducted an eye-tracking study to investigate whether indeterminate sentences embedded within biasing contexts would trigger event interpretations, using a long-term memory paradigm. In each trial, participants were presented with one of three recognition probe types for reading while having their eyes monitored. Recognition probes were presented 0 seconds (s) after having read the indeterminate sentence, or following an additional 25s of neutral discourse. Results suggest that abductive processes, relying on the propositional content of supporting context, drive indeterminate sentence interpretation.

Linguistic Distributional Information and Sensorimotor Similarity Both Contribute to Semantic Category Production

Briony Banks
Lancaster University, Lancaster, United Kingdom

Cai Wingfield
University of Lancaster, Lancaster, United Kingdom

Louise Connell
University of Lancaster, Lancaster, United Kingdom

Abstract

We investigated the contribution of sensorimotor and linguistic distributional information in a semantic category production task, hypothesizing that the task would rely on both but particularly on linguistic distributional information, which may provide a shortcut for conceptual processing. In a pre-registered study, we asked participants to name members of semantic categories and tested whether responses were predicted by a novel measure of sensorimotor proximity (based on an 11-dimension representation of sensorimotor experience) and linguistic proximity (based on word co-occurrence derived from a large subtitle corpus). Both proximity measures predicted the order and frequency of responses and, critically, linguistic proximity had an effect above and beyond sensorimotor proximity. Our findings support linguistic-sensorimotor accounts of the conceptual system and suggest that category production is based on both the similarity of sensorimotor experience between the category and member concepts, and on the linguistic distributional relationship between the category and member labels.

Listeners use descriptive contrast to disambiguate novel referents

Claire Bergey
The University of Chicago, Chicago, Illinois, United States

Dan Yurovsky
University of Chicago, Chicago, Illinois, United States

Abstract

People often face referential ambiguity; one cue to resolve it is adjectival description. Beyond narrowing potential referents to those that match a descriptor, listeners may infer that a described object is one that contrasts with other present objects of the same type (tall cup contrasts with another, shorter cup). This contrastive inference guides the visual identification of a familiar referent as an utterance progresses (Sedivy et al., 1999). We extend this work, asking whether listeners use this type of inference to guide explicit referent choice when reference is ambiguous, and whether this varies with adjective type. We find that participants consistently use size adjectives contrastively, but not color adjectives (Experiment 1)even when color is described with more relative language (Experiment 2) or emphasized with prosodic stress (Experiment 3). Listeners can use adjective contrast to disambiguate a novel words referent, but do not treat all adjective types as equally contrastive.

Emulating Human Developmental Stages with Bayesian Neural Networks

Marcel Binz
Philipps-Universitt Marburg, Marburg, Germany

Dominik Endres
Philipps-Universitaet, Marburg, Hesse, Germany

Abstract

In this work we compare the acquisition of knowledge in humans and machines. Research from the area of developmental psychology indicates, that human-employed hypothesis are initially guided by simple rules, before evolving into more complex theories. This observation is shared across many tasks and domains. We investigate whether the stages of development in artificial learning systems are based on similar characteristics. We operationalize developmental stages as the size of the data-set on which the artificial system is trained. For our analysis we look at the developmental progress of Bayesian Neural Networks on three different data-sets, including occlusion, support and quantity comparison tasks. We compare the results with prior research from the developmental psychology literature and find agreement between the family of optimized models and pattern of development observed in infants and children on all three tasks, indicating common principles for the acquisition of knowledge.

An asymmetry between distance estimates made to and from a target

David Bosch
New York University, New York, New York, United States

Yaacov Trope
New York University, New York, New York, United States

Abstract

In three experiments, we demonstrated that the self can act as a cognitive reference point, producing an egocentric asymmetry effect on distance judgments such that targets are judged as closer to the viewer than the viewer is to the target. Egocentric asymmetry was observed even when there was a fixed reference object that people could use to anchor distance estimates across trials (Experiment 2). Further, egocentric asymmetry was greater to a non-human artifact than to a human avatar (Experiment 3). In addition, distances from a mailbox to a human avatar were estimated as shorter than distances from an avatar to a mailbox, suggesting that the special status of the self may extend to other people when compared to non-human objects even in allocentric distance judgments (Experiment 2).

Neither the time nor the place: Omissive causes yield temporal inferences

Gordon Briggs
U.S. Naval Research Laboratory, Washington, District of Columbia, United States

Hillary Harner
US Naval Research Laboratory, Washington, District of Columbia, United States

Christina Wasylyshyn
U.S. Naval Research Laboratory, Washington, District of Columbia, United States

Paul Bello
U.S. Naval Research Laboratory, Washington, District of Columbia, United States

Sangeet Khemlani
Naval Research Laboratory, WASHINGTON, District of Columbia, United States

Abstract

Is it reasonable to draw temporal conclusions from omissive causal assertions? For example, if you learn that not charging your phone caused it to die, is it sensible to infer that your failure to charge your phone occurred before it died? The conclusion seems intuitive, but no theory of causal reasoning explains how reasoners make the inference other than a recent proposal by Khemlani and colleagues (2018a). We present that theory and describe its consequences. If people conceive of omissions as non-events, i.e., events unmoored in space and time, they might refrain from drawing conclusions when asked whether an omissive cause precedes its effect. Two experiments speak against these predictions of the non-event view and in favor of a view that omissive causation imposes temporal constraints on events and their effects. We conclude by considering whether drawing a temporal conclusion from an omissive cause constitutes a reasoning error.

Modeling Long-Distance Cue Integration Strategies in Phonetic Categorization

Wednesday Bushong
University of Rochester, Rochester, New York, United States

T. Florian Jaeger
University of Rochester, Rochester, New York, United States

Abstract

Language temporally unfolds, with relevant cues arriving at different moments in time. For comprehension to be optimal, listeners must maintain gradient representations of cues in order to integrate with later-arriving cues. Several studies have established during speech perception listeners integrate cues that occur far apart in time. There are several proposals about how restricted this is, but there's little rigorous work establishing and testing models of long-distance cue integration strategies. We take a first step at addressing this gap by formalizing four different models of how listeners use cue information during real-time processing, testing them on two perception experiments. In one experiment, we find support for optimal integration of cues. In another, more attention-taxing experiment, we find evidence in favor of a strategy that avoids maintaining detailed representations of cues in memory. These results represent a first step toward understanding how listeners change their cue integration strategies across contexts.

Simplicity preferences in young childrens decision-making

Rebecca Canale
University of Rochester, Rochester, New York, United States

George Loewenstein
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Celeste Kidd
University of California, Berkeley, Berkeley, California, United States

Abstract

Classic theories of multi-attribute choice typically assume that preferences are an additive function of attribute values. However recent work (Evers et al.) demonstrates a preference for simplicity that can violate the most basic assumptions and predictions of conventional models. For example, a set of 7 colored pencils that are all unique colors are preferred over a set of 8 colored pencils with one redundant color. This preferential choice, however, cannot be explained by the utility of consumption itself. Does this preference emerge as a result of adults substantial experience with such sets in the world (e.g., through shopping or organizing ones possessions), or is this preference present much earlier? Does the preference for simplicity, in fact, facilitate cognitive encoding? We investigate these questions through a series of experiments conducted with children in an effort to understand the emergence of this simplicity bias, and its connection to the development of working memory.

Exploring the Role of Social Priming in Alcohol Attentional Bias

Stephen Cantarutti
City, University of London, London, United Kingdom

Emmanuel Pothos
City, University of London, London, United Kingdom

Abstract

Recent studies have linked the Stroop Effect with social priming, suggesting that social concept priming tends to trigger automatic behaviour aligned with the primed concept (Augustinova & Ferrand, 2014; Goldfarb, Aisenberg, & Henik, 2011). This study attempts to test the efficacy of social priming on alcohol attentional bias, integrating a social priming interference task into an alcohol-Stroop test to measure Stroop interference before and after participants have been socially primed. Results show no significant interaction between stimulus category (alcohol and neutral), experiment block, and social priming condition (alcohol addiction, alcohol preoccupation and control) to indicate that social priming had triggered expedited, automatic behaviour. Our results do show a significant interaction between experiment block and social priming condition ($F(6, 426) = 2.166$, $p = .045$), suggesting the alcohol social priming tasks may have induced a greater general interference for participants in those conditions, than for participants receiving the neutral interference task.

Visual Spatial Attention Skills and Holistic Processing in High School Students With and Without Dyslexia

Ronald Chan
The Education University of Hong Kong, Hong Kong, Hong Kong

Chin-wai Kwok
The Education University of Hong Kong, Hong Kong, Hong Kong

Duo Liu
The Education University of Hong Kong, Hong Kong, Hong Kong

Ricky Van-yip Tso
The Education University of Hong Kong, Taipo, N.T., Hong Kong

Abstract

Visual-spatial attention has been shown to influence literacy development, yet studies investigating its influence on reading in non-alphabetic scripts such as Chinese are scarce, despite recent studies demonstrating orthographic and visuo-spatial skills to be key deficits in people with dyslexia in Chinese. Here, we investigate visual-spatial processing skills in Chinese adolescents by measuring their 1) exogenous and endogenous attentional orienting, and 2) holistic processinga phenomenon typically demonstrated in face perceptionin Chinese character recognition. Compared with typically developing students, Chinese high-school students with dyslexia showed deficits in both endogenous and exogenous visual-spatial attention. Dyslexics also perceived characters more holistically than the controls, suggesting that they selectively attended to individual components within Chinese characters less readily. These results demonstrated irregularities in visual-spatial processing skills in students in dyslexia. This study provides implications for reading intervention programs in order to facilitate selective attention to character components to enhance literacy.

Elucidating the Cognitive Anatomy of Representation Systems

Peter Cheng
University of Sussex, Brighton, United Kingdom

Grecia Garcia Garcia
University of Sussex, Brighton, United Kingdom

Holly Sutherland
University of Sussex, Falmer, United Kingdom

Daniel Raggi
University of Cambridge, Cambridge, United Kingdom

Aaron Stockdill
University of Cambridge, Cambridge, United Kingdom

Mateja Jamnik
University of Cambridge, Cambridge, United Kingdom

Abstract

We present a framework to assess the relative cognitive cost of alternative representational systems for problem solving. The framework consists of 19 cognitive properties of representational systems, which are distributed across 4 dimensions (registration, semantic encoding, inference, and solution) and three scales of granularity (symbol, expression, and sub-representations). It examines components and processes spanning the internal mental representation and external physical display, and also addresses heterogenous representations of problems. We provide functions to evaluate the cost of each cognitive property by examining, for example, types of matches between display symbols and concepts, the arity of relations, or the depth of solution trees. The cognitive costs for each property are combined to estimate the overall cognitive cost, and hence the relative effectiveness, of a representation. The frameworks development is motivated by our goal of engineering an automated system that will select representations suited to specific classes of problems for individual users.

Why Some Events Are More (or Less) Random: The Role of Alternation Rate and Number of Occurrence

Karen H. H. Chu
University of Macau, Macau SAR, China

Sophia Deng
University of Macau, Macau SAR, Macao

Abstract

How do people tell the difference between random and nonrandom events? What affects peoples understanding of randomness? In two experiments, we investigated the role of two characteristics of a sequencealternation rate and number of occurrencein peoples perception of randomness. We presented participants with a pair of binary sequences of length 6 (e.g., OXOXXO vs. XOXXXX) and asked them to evaluate which of the two was more likely to occur. In Experiment 1, we examined how participants randomness perception changed as the difference in alternation rate and the difference in the number of occurrence changed. In Experiment 2, we further examined whether participants exhibited differential reliance on alternation rate and number of outcomes. Results suggest that people exhibit differential reliance on alternation rate and number of occurrence. When the two characteristics are in conflict, people tend to rely more on the alternation rate in their randomness judgement.

Integrating Methods to Improve Model-based Performance Prediction

Michael Collins
Air Force Research Laboratory, Dayton, Ohio, United States

Kevin Gluck
Air Force Research Laboratory, Wright-Patterson AFB, Ohio, United States

Abstract

The initial performance of individuals is often difficult for models of learning and retention to predict. One such model is the predictive performance equation (PPE) a mathematical model of learning and retention that uses regularities seen in human learning to predict future performance.To generate predictions, PPEs free parameters must be calibrated to a minimum amount of historical performance data, preventing valid predictions for initial learning events.Prior research (Collins, Gluck, Walsh, Krusmark & Gunzelmann, 2016; Collins, Gluck, & Walsh, 2017), has shown that the generalization of best fitting parameters from prior data can improve initial performance predictions.Here we build on that research, using Bayesian hierarchical modeling to estimate free parameters from various sources of prior data. Bayesian hierarchal modeling allows an opportunity to improve and add structure to the parameters used by PPE, improving its application to cognitive technology in education and training.

Compositional subgoal representations

Carlos Correa
Princeton University, Princeton, New Jersey, United States

Frederick Callaway
Princeton University, Princeton, New Jersey, United States

Mark Ho
UC Berkeley, Berkeley, California, United States

Tom Griffiths
University of California, Berkeley, Berkeley, California, United States

Abstract

When faced with a complex problem, people naturally break it up into several simpler problems. This hierarchical decomposition of an ultimate goal into sub-goals facilitates planning by reducing the number of factors that must be considered at one time. However, it can also lead to suboptimal decision-making, obscuring opportunities to make progress towards multiple subgoals with a single action. Is it possible to take advantage of the hierarchical structure of problems without sacrificing opportunities to kill two birds with one stone? We propose that people are able to do this by representing and pursuing multiple subgoals at once. We present a formal model of planning with compositional goals, and show that it explains human behavior better than the standard "one-at-a-time" subgoal model as well as non-hierarchical limited-depth search models. Our results suggest that people are capable of representing and pursuing multiple subgoals at once; however, there are limitations on how many subgoals one can pursue concurrently. We find that these limitations vary by individual.

Rule-following, Lexical Competence and Categorization Processes

Marco Cruciani
University of Trento, Trento, Italy

Francesco Gagliardi
ORCID:0000-0002-4270-1636, Naples, Italy

Abstract

The article addresses the issues of extending a category and updating a lexical concept, and determining its reference. We try to answer the questions: how can an object seen for the first time extend a category or update a concept? How is it possible to determine the reference of a concept that represents a behaviour? Firstly, we discuss the learning of inferential linguistic competence used to update a concept through an approach based on prototype theory. Secondly, we discuss the learning of referential linguistic competence used to determine the reference of a concept through an approach based on embodied cognition. Finally, on the basis of the dual dimension of the praxis of rule-following, we show how it is possible to combine the two approaches into a single model that deals with both the extension of a category and the updating of a concept, and the determination of the reference.

Magnitude Comparisons of Improper Fractions

Lucy Cui
UCLA, Los Angeles, California, United States

Zili Liu
UCLA, Los Angeles, California, United States

Abstract

Previous studies examining the mental representations of fractions have focused on fractions with magnitudes less than one (e.g., 2/3). In the current study, we examine the mental representations of fractions with magnitudes greater than one, specifically those of improper fractions. Participants were asked to make magnitude comparisons of these improper fractions to a reference that was in an improper fraction, a mixed fraction, or a decimal format. Results show that magnitudes of improper fractions were more accurately accessed when they were compared to mixed fractions and decimals. This suggests that the reinterpretation of these improper fractions benefited magnitude processing. Distance effects on error rate and response time were observed for all three reference formats and more consistently took the form of a Welford function, which predicts worse performance above rather than below the reference. Possible explanations of these results are discussed.

Magnitude Comparisons of Discounted Prices: Are They Similar to Fractions?

Lucy Cui
UCLA, Los Angeles, California, United States

Zili Liu
UCLA, Los Angeles, California, United States

Abstract

The present study examines whether peoples mental representation of discounted prices, which have a part-whole relationship of the current price to the original price, is similar to that of fractions. Participants performed a fraction comparison task and a deal comparison task on the same set of fractional magnitudes. In two experiments, we observed worse performance (error rate, RT of correct trials) on the deal comparison task. The distance effect, where magnitude comparisons are made more slowly and less accurately the closer two magnitudes are, observed in the two tasks was best modeled using logarithmic distance between the fractional magnitudes as a predictor of performance.

Magnitude Processing of Improper Fractions When Comparing Bundle Deals

Lucy Cui
UCLA, Los Angeles, California, United States

Zili Liu
UCLA, Los Angeles, California, United States

Abstract

People encounter improper fractions in real life contexts on a regular basis. One such example is with bundling at the grocery store (2/$4 or two for $4). The present study seeks to understand how people process these bundle prices compared to improper fractions. Participants completed a magnitude comparison task with different bundling formats (2/$4 vs. $4/2) and their fractional equivalents. We found a reliable difference between the bundle format (2/$4) seen in grocery stores and the most visually similar fraction (2/4). This difference shows that participants are not using a heuristic (larger fraction means cheaper per item) when comparing these bundle deals and instead do need to process them like improper fractions. Overall, we found that participants were better at comparing fractional magnitudes in a math context than in a financial context and that this effect of context also depended on format (2/4 vs. 4/2).

Category-Specific Verb-Semantic Naming Deficit in Alzheimers Disease: Evidence from a Dynamic Action Naming Task

Roberto de Almeida

George Schwartz
Douglas Mental Health University Institute, Montreal, Quebec, Canada

Abstract

Numerous studies have found category-specific semantic deficits in Alzheimers disease (AD). Thus far, however, only a small number of studies have investigated how semantic categories lexicalized by verbs are represented, and how these categories might be impaired in AD. We investigated the representation and breakdown of verb knowledge employing different syntactic and semantic classes of verbs in a group of probable AD patients (N=10) and matched controls. In our main task, we employed movies of events and states depicting verbs belonging to three different classes: causatives, perception/psychological, and movement verbs. These verbs differ with regards to their argument structure, the thematic roles they assign, and their hypothetical semantic templates. Patients had more difficult employing verbs of the perception/psychological class. We suggest that thematic roles play the most important role in verb semantic representations. We further suggest that verbs are not represented by decompositional semantic templates.

A Reservoir Model for Intra-Sentential Code Switching Comprehension in French and English

Pauline Detraz
Inria, Bordeaux, France

Xavier Hinaut
Inria, Bordeaux, France

Abstract

Some people can mix two languages within the same sentence: this is known as intra-sentential code-switching. The majority of computational models on language comprehension are dedicated to one language. Some bilingual models have also been developed, but very few have explored the code-switching case. We collected data from human subjects that were required to mix pairs of given sentences in French and English. Truly bilingual subjects produced more switches within the same sentence. The corpus obtained have some very complex mixed sentences: there can be until eleven language switches within the same sentence. Then, we trained ResPars, a Reservoir-based sentence Parsing model, with the collected corpus. This Recurrent Neural Network model processes sentences incrementally, word by word, and outputs the sentence meaning (i.e. thematic roles). Surprisingly the model is able to learn and generalize on the mixed corpus with performances nearly as good as the unmixed French-English corpus.

Assessment of Cognitive Load in the Context of Neurosurgery

Daniel Di Giovanni
McGill University, Montreal, Quebec, Canada

Simon Drouin
Montreal Neurological Institute (McGill University), Montreal, Quebec, Canada

Marta Kersten-Oertel
Concordia University, Montreal, Quebec, Canada

Louis Collins
McGill University, Montreal, Quebec, Canada

Abstract

The work presented in this paper explores the amount of effort, defined by cognitive load, needed to understand depth visualization while navigating a virtual space in the context of planning for image guided surgery. In this context, cognitive load is evaluated by measuring brain activity through event-related electroencephalography (EEG). We found a significant difference between dynamic depth cue renders versus statically rendered cues. The work presented here demonstrates the usefulness of EEG as an acceptable and efficient method to inspect brain activity for future user studies in the operating room, and that cognitive load can serve as an objective measure of visualization effectiveness.

Skill Acquisition in a Dynamic Collaborative Task

Cvetomir Dimov
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

John R. Anderson
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Shawn Betts
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Dan Bothell
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Abstract

Skill acquisition studies have generally focused on individual tasks, such as language learning, learning how to use a text editor or how to play video games. Here we present a study that investigates how subjects learn to work in a team in a dynamic collaborative task. The task - Coop Space Fortress - is a modification of a computer game used extensively in research, in which subjects fly space ships in a frictionless environment and coordinate to destroy a space fortress. When learning to play this computer game, subjects not only master the game controls, but also typically settle on team roles to more efficiently achieve their goal, despite not being allowed to communicate.

Liars Intent: A Multidimensional Recurrence Quantification Analysis Approach to Deception Detection

Hannah Douglas
Macquarie University, Macquarie Park, NSW, Australia

Adriana Rossi
Macquarie University , Sydney, NSW, Australia

Rachel W. Kallen
Macquarie University, Macquarie Park, NSW, Australia

Michael J Richardson
Macquarie University, Sydney, NSW, Australia

Abstract

The current study utilizes dynamical systems and embodiment theory to better understand how movement dynamics impact deception detection. While research has consistently revealed humans are often no better than chance at discriminating a truth from a lie, individuals may reveal more than they know through the dynamic movement of the face and the body beyond discrete gestures traditionally examined in deception detection research (e.g., rise of a brow). As expected, the present study found that the dynamic stabilities of facial and body movements were significantly influenced by deceptive intent such that untruthful statements elicited less stability in both the face and upper body. Moreover, despite detection levels no greater than chance, the accuracy of observers to detect deceptive intent covaried with these dynamic stabilities. The research presented provides another piece to the illusive puzzle of deception detection, affording researchers and practitioners a possible tool to tap into deceptive intent.

Human-level but not human-like: Deep Reinforcement Learning in the dark

Rachit Dubey
Princeton University, PRINCETON, New Jersey, United States

Pulkit Agrawal
UC Berkeley, Berkeley, California, United States

Deepak Pathak
UC Berkeley, Berkeley, California, United States

Alyosha Efros
UC-Berkeley, Berkeley, California, United States

Tom Griffiths
University of California, Berkeley, Berkeley, California, United States

Abstract

Deep reinforcement learning (RL) algorithms have recently achieved impressive results on a range of video games, learning to play them at or beyond a human level just from raw pixel inputs. However, do they leverage visual information in the same manner as humans do? Our investigations suggest that they do not: given a static game, we find that a state-of-the-art deep RL algorithm solves that game faster without visual input (only the agent location was provided to the algorithm). We posit that this is because deep RL attacks each problem tabula rasa, i.e. without any prior knowledge, as also suggested by other recent work. We further propose that in certain settings, an agent is better off having no visual input compared to having no visual priors. To demonstrate this, we conduct an experiment with human participants and find that people solve a game that hid all visual input (except agent location) much faster than a game that prevented the use of various visual priors. These results highlight the importance of prior knowledge and provide a compelling demonstration of how the lack of prior knowledge leads to deep RL algorithms approaching a problem very differently from humans.

Exergame Training of Executive Function in Preschool Children: Generalizability and Long-term Effects

Cassondra Eng
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Melissa Pocsai
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Dominic Calkosz
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Nathan Williams
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Erik Thiessen
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Anna Fisher
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Abstract

Studies with older children and adults have found that physically engaging video games (i.e., Exergames) that promote both cognitive control and physical activity improve executive function (EF) skills; yet, children below school age remain understudied with regard to the impact of Exergames on EF. Additionally, research on the extent of the impact of Exergames resulting in prolonged changes, and whether training generalizes to EF-related behaviors in a real-world context remains scarce. This study examined the short- and long-term changes in EF of 4- to 5-year-olds after participation in two 20-minute Exergame sessions. Results indicate that Exergame training improved performance on EF tasks and resulted in higher teacher ratings of EF in the classroom compared to a sex-/classroom-/age-matched control group. The improvements in EF persisted over a one-month period. This study provides novel insights into the short-term and long-term effects of Exergame training on executive function in preschool-aged children.

Using Known Words to Learn More Words: A Distributional Analysis of Child Vocabulary Development

Andrew Flores
University of Illinois Urbana-Champaign, Champaign, Illinois, United States

Jessica Montag
University of Illinois, Champaign-Urbana, Champaign, Illinois, United States

Jon Willits
University of Illinois at Urbana-Champaign, Champaign, Illinois, United States

Abstract

Why do children learn some words before others? Understanding individual variability across children and also variability across words, may be informative of the learning processes that underlie language learning. We investigated item-based variability in vocabulary development using lexical properties of distributional statistics derived from a large corpus of child-directed speech. Unlike previous analyses, we predicted word trajectories cross-sectionally, shedding light on trends in vocabulary development that may not have been evident at a single time point. We also show that whether one looks at a single age group or across ages as a whole, the best distributional predictor is whether a child knows a word is the number of other known words with which that that word tends to co-occur.

Agent framing moderates concerns about moral contagion

Stephen Flusberg
Purchase College, SUNY, Purchase, New York, United States

Carly LaPlace
Purchase College, SUNY, Purchase, New York, United States

Abstract

Concerns about moral contamination shape peoples attitudes towards the objects they encounter in daily life. For example, money seems less desirable when it comes from a robbery (Tasimi & Gelman, 2017). Drawing on the theory of dyadic morality, we hypothesized that increasing an individuals sense of agency would reduce the salience of moral contagion and make people feel less vulnerable to moral contamination. Across two experiments, we adapted the study design of Tasimi and Gelman (2017), asking participants how much they desired a $1 (Experiment 1) or $100 (Experiment 2) bill associated with different negative moral histories. We modified the stimulus language so that participants were framed as either the moral agent or patient for all scenarios. As predicted, participants in the agent language condition expressed nearly the same level of desire regardless of the bills moral history, highlighting the role that feelings of agency play in moral decision-making.

The Impact of Speech Complexity on Preschooler Attention, Speaker Preference, and Learning

Ruthe Foushee
University of California, Berkeley, Berkeley, California, United States

Mahesh Srinivasan
UC Berkeley, Berkeley, California, United States

Fei Xu
UC Berkeley, Berkeley, California, United States

Abstract

How do children decide what speech to tune into and learn from? We extend the idea that learners preferentially attend to stimuli at an intermediate level of complexity to the domain of spoken language. Preschoolers (2.5-6.5 years in Exp.1 and 3.5-5.5 years in Exp. 2) watched two speakers alternate narrating pages of a textless picture book, before selecting who they wanted to hear finish the story. We manipulated the complexity of the narrators speech, such that the SIMPLE speaker used earlier-acquired words than the COMPLEX speaker. In Experiment 1, both speakers introduced rare target words that children were later tested on. While children learned an impressive number of them, the inclusion of these rare words may have made both speech streams too complex for children to show a systematic preference for one over the other. In Experiment 2, we narrowed our age range, and amplified the contrast in complexity between the two speech streams. Preliminary results suggest that children discriminated between the two levels of complexity, systematically selecting the simpler speaker to finish the story. These results suggest that preschoolers can track the relative complexity of different linguistic inputs, opening the possibility that they may actively direct their attention toward linguistic input that is more appropriate for them.

Experimental Investigation on Top-down and Bottom-up Processing in Comprehension of Graphs to Justify Decisions

Misa Fukuoka
Nagoya University, Nagoya Aichi, Japan

Kazuhisa Miwa
Nagoya University, Nagoya-shi, Aichi-ken, Japan

Abstract

Authors (2017) examined decision-making processes together with graph comprehension and in particular the influence of bottom-up and top-down processing on them. Using an altered procedure, this study examined bottom-up and top-down processing relative to graph comprehension where a decision is made first, followed by graph comprehension. We compared the results of the two studies. Some of the results observed in the previous study were not observed in this study, suggesting that the influence of impressions provisionally formed on graph comprehension was mitigated to justify the declared decision in advance. Attitude s that individuals have in a daily life were observed to have an influence in the decision in both the previous and current studies, showing that it strongly influences decision making regardless of the degree to which the graph is comprehended.

A New Class Of Proximity Data Obtained From Dictionary Networks

Camilo Garrido
Universidad de Chile, Santiago, Chile

Claudio Gutierrez
Universidad de Chile, Santiago, Chile

Guillermo Soto
Universidad de Chile, Santiago, Chile

Abstract

Background. Proximity data is a notion that indicates the degree of psychological closeness of concepts. It includes, among others, judgments of similarity, relatedness and cause-effect. Obtaining proximity data is challenging because it involves experts, corpora and people. On the other hand, dictionaries are fair representations made by experts (and thus, good proxies) of the lexicon and linguistic heritage of people.

Methods. We present a method to automatically obtain proximity data from dictionaries. We construct a network representation of a dictionary; exploit classical techniques on networks to build a similarity matrix; extract parameterized clouds of lexical proximity; test them with native speakers.

Results. Preliminary evaluations show that the method captures word associations significant to humans. Although the research was done in Spanish, the methods are easily reproducible in other languages.

Conclusions. Dictionaries are good sources of proximity data. We conjecture that dictionary networks are good proxies to human mind semantic associations.

Human Visual Object Similarity Judgments are Viewpoint-Invariant and Part-Based as Revealed via Metric Learning

Joseph German
University of Rochester, Rochester, New York, United States

Robert Jacobs
University of Rochester, Rochester, New York, United States

Abstract

We describe and analyze the performance of metric learning systems, including deep neural networks (DNNs), on a new dataset of human similarity judgments of Fribbles, naturalistic, part-based objects. Metrics trained using pixel-based or DNN-based representations fail to explain our experimental data, but a metric trained with a viewpoint-invariant, part-based representation produces a good fit. We also find that although neural networks can learn to extract the part-based representation—and therefore should be capable of learning to model our data—networks trained with a triplet loss function based on similarity judgments do not perform well. We analyze this failure, providing a mathematical description of the relationship between the metric learning objective function and the triplet loss function. The comparatively poor performance of neural networks appears to be due to the nonconvexity of the optimization problem in network weight space. We discuss the implications for neural network research as a whole.

Reinstatement of Old Memories and Integration with New Memories

Pierre Gianferrara
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Marlieke van Kesteren
Vrije Universiteit, Amsterdam, Netherlands

Martijn Meeter
Vrije Universiteit, Amsterdam, Netherlands

Abstract

The acquisition of new knowledge relies on our ability to connect old information to new information using semantic networks. This process can be referred to as memory integration. In this study, we investigated how such integration may aid memory reactivation, defined as the retrieval of previously encoded information. In addition, we were interested in whether congruency (or semantic similarity) between two separately learned associations (AB-AC) enhances memory integration. University students learned congruent and incongruent AB-AC associations in an fMRI scanner and reported subjective reactivation. In addition to a behavioral score, we measured the degree of neural activity in the PPA to test for potential effects of reinstatement (neural reactivation) using the multivoxel pattern analysis (MVPA) technique. Our analyses revealed a robust effect of memory reactivation (behaviorally) and reinstatement (neurally). An effect of congruency was also found behaviorally, but was not evident in the PPA.

Why Are Some Online Educational Programs Successful?: A Cognitive Science Perspective

Marissa Gonzales
Georgia Institute of Technology, Atlanta, Georgia, United States

Ashok Goel
Georgia Institute of Technology, Atlanta, Georgia, United States

Abstract

Massive Open Online Courses (MOOCs) once offered the promise of accessibility and affordability. However, MOOCs typically lack expert feedback and social interaction, and have low student engagement and retention. Thus, alternative programs for online education have emerged including an online graduate program in computer science at a major public university in USA. This program is considered a success with over 9000 students now enrolled in the program. We adopt the perspective of cognitive science to answer the question why do only some online educational courses succeed? We measure learner motivation and self-regulation in one course in the program, specifically a course on artificial intelligence (AI). Surveys of students indicate that students self-reported assessments of self-efficacy, cognitive strategy use, and intrinsic value of the course are not only fairly high, but also generally increase over the course of learning. This data suggests that the online AI course might be a success because the students have high self-efficacy and the class fosters self-regulated learning.

A Convolutional Self-organizing Map for Visual Category Learning

Chris Gorman
University of Otago, Dunedin, New Zealand

Lech Szymanski
University of Otago, Dunedin, New Zealand

Anthony Robins
University of Otago, Dunedin, New Zealand

Alistair Knott
University of Otago, Dunedin, New Zealand

Abstract

In this paper we present a novel neural network architecture that aims to combine the highly popular and successful convolutional neural network architecture with the learning mechanism of an unsupervised self-organizing map. The convolutional self-organizing map (ConvSOM) is a hierarchical network consisting of several independent self-organizing maps. It incorporates features associated with convolutional networks, such as weight sharing, spatial pooling, and hierarchical abstraction, with the unsupervised, topographically organized self-organizing map. We will show that the resulting architecture performs poorly on the MNIST data set, but offers interesting avenues for further research.

Boundaries of Creativity: Thick or Thin Organization?

Jean-Christophe Goulet-Pelletier
University of Ottawa, Ottawa, Ontario, Canada

Denis Cousineau
University of Ottawa, Ottawa, Ontario, Canada

Abstract

Semantic organization of knowledge has a long history in theories of creativity. Flexibility of thinking and distant connections are indispensable elements of a creative network. Simultaneously, convergence of thoughts and evaluation of ideas are essential at many stages of the creative process. The current study evaluates these complementary aspects through the lens of an exploratory concept known as mental boundaries. Correlation analyses are used to compare flexible and rigid tendencies of organizing the world, the concepts of intellect, schizotypy, perfectionism, divergent thinking and self-perceived creativity. Results (n = 316) reveal an interesting contrasting pattern where divergent thinking is significantly related to flexible internal and external organizations, whereas self-perceived creativity is significantly related to rigid external and non-significantly related to rigid internal organizations. The present findings have implications for the measurement of creativity and the identification of factors that facilitate the creative process.

Failing to see what you are a part of: Wisdom among crowd members

Ulrike Hahn
Birkbeck, University of London, London, London, United Kingdom

Toby Pilditch
University College London, London, United Kingdom

Nicole Cruz
Birkbeck, University of London, London, United Kingdom

Abstract

One of the key features that make human cognition so successful is its social basis. The fact that we can exchange information with others is integral to the knowledge humans have collectively built up over centuries. One place where this can readily be seen is in the aggregation of judgments. As is well documented, aggregates of individual judgments are often considerably more accurate than the individual judgments themselves, giving rise to so-called wisdom of the crowd effects. A key determinant of the benefits of aggregation is the degree of dependency between judgments. Here, we probed experimentally lay peoples understanding both of the value of aggregation and informational dependency, using a numerical prediction task. We found only an equivocal trend in people's understanding of the value of aggregation, and no clear evidence of people's understanding of the accuracy benefit of diversity.

Demonstrating the Impact of Prior Knowledge in Risky Choice

Mathew Hardy
Princeton University, Princeton, New Jersey, United States

Tom Griffiths
University of California, Berkeley, Berkeley, California, United States

Abstract

Bayesian models that optimally integrate prior probabilities with observations have successfully explained many aspects of human cognition. Research on decision-making under risk, however, is usually done through laboratory tasks that attempt to remove the effect of prior knowledge on choice. To test the effects of manipulating prior probabilities on participants' choices, we ran a large online experiment in which risky options paid out according to the distribution of Democratic and Republican voters in unknown congressional districts in known US states. This setup allows us to directly manipulate prior probabilities while holding observations constant and to compare people's choices with the options' true posterior values. We find that people's choices are appropriately influenced by prior probabilities, and discuss how the study of risky choice can be integrated into the Bayesian approach to studying cognition.

The role of AMPA receptor exchange in systems memory reconsolidation: A computational model

Peter Helfer
Dept. of Psychology, Montreal, Quebec, Canada

Thomas Shultz
McGill University, Montreal, Quebec, Canada

Abstract

In the mammalian brain, a newly acquired memory depends on the hippocampus for maintenance and recall, but over time the neocortex takes over these functions, rendering the memory hippocampus-independent. The process responsible for this transformation is called systems memory consolidation. Interestingly, retrieval of a well-consolidated memory can trigger a temporary return to a hippocampus-dependent state, a phenomenon known as systems memory reconsolidation. The neural mechanisms underlying systems memory consolidation and reconsolidation are not well understood. Here, we propose a neural model based on well-documented mechanisms of synaptic plasticity and stability and describe a computational implementation that demonstrates the models ability to account for a range of findings from the systems consolidation and reconsolidation literature. Based on the computational model, we derive a number of predictions and suggest experiments that may put them to the test.

Statistical Learning Ability as a Measure of Cognitive Function

Steffen Herff
Agency for Science, Technology and Research (A*STAR), Singapore, Singapore

Nur Amirah Abdul Rashid
Institute of Mental Health, Singapore, Singapore

Jimmy Lee
Institute of Mental Health, Singapore, Singapore

Tih Shih Lee
Duke-NUS Medical School, Singapore, Singapore

Kat Agres
Institute of High Performance Computing, A*STAR, Singapore, – Select State/Province –, Singapore

Abstract

Statistical Learning (SL), the ability to extract probabilistic information from the environment, is a subject of much debate. It appears intuitive that such a profound mechanism of learning should carry predictive power towards general cognitive ability. Yet, previous attempts have struggled to link SL ability to measures of general cognitive function, suffering from low correlations and mediocre test-retest reliability. Here, we deploy a new continuous auditory SL task that achieves high test-retest reliability (r = .8) and shows that SL ability does significantly correlate with general cognitive function (up to r =. 56). Results are discussed in light of i) the theoretical implications of the high test-retest reliability of our novel SL task, ii) SL ability as a marker of general cognitive function, and iii) future methodological considerations.

Prepare to Swear: Considering Phonological Preparation of Taboo Words

Kathryn Hodges
Muhlenberg College, Allentown, Pennsylvania, United States

Alyce Huot
Muhlenberg College, Allentown, Pennsylvania, United States

Alexandra Frazer
Muhlenberg College, Allentown, Pennsylvania, United States

Hazem Abdelaal
Muhlenberg College, Allentown, Pennsylvania, United States

Jessica Oxer
Muhlenberg College, Allentown, Pennsylvania, United States

Abstract

The current studies investigated whether speakers can prepare to swear the same way they prepare non-taboo words. Swearing, when produced reflexively, has greater right hemisphere activation than normal production suggesting that swearing is a different linguistic process. We used a form preparation paradigm to consider phonological preparation for non-reflexive swearing. Participants were given two types of lists; homogeneous - all words shared phonological onset (e.g. /f/ - feet, fork, film, fuck), and heterogeneous nothing shared (e.g. film, shit, dock, poll). Results indicated the taboo words did not contravene preparation for homogeneous sets, and taboo words were facilitated similarly to non-taboo words. Next, we tested variable homogeneous sets (taboo item was inconsistent with majority onset, e.g. shit, film, fork, feet) to understand whether increased attention to taboo items would disable preparation. Results showed reduced preparation for items sharing the majority onset in variable sets, but preparation was still significant.

The Phenomenological Mind: Foregrounding Experience Through Cognitive Anti-realism and Quantum Cognition

Pamela Hoyte
Queensland University of Technology, Brisbane, Qld, Australia

Peter Bruza
Queensland University of Technology, Brisbane, QLD, Australia

Greg Thompson
Queensland University of Technology , Brisbane, Qld, Australia

Abstract

Two perspectives on human cognition are contrasted: the computational mind and the phenomenological mind. The computational mind derives from the cognitivist hypothesis and is based on representation, computation and realism. While useful for cognitive modelling, it is limited as it cannot cater for a cognitive agents experience. The phenomenological mind foregrounds experience by drawing on the concept of the enactive mind. The phenomenological mind refers to a view of cognition that is not predicated on the pre-existing mental representation of an objective world, and so is cognitively anti-realist and non-representational. Quantum cognition offers the prospect for cognitive modelers to step out of the computational mind but still have tools to rigorously and formally explore the anti-realism inherent to the phenomenological mind. The concept of contextuality from quantum cognition is proposed as a signature of experience in the phenomenological mind.

Understanding Individual Differences in Eye Movement Pattern During Scene Perception through Co-Clustering of Hidden Markov Models

Janet Hsiao
University of Hong Kong, Hong Kong, Hong Kong

Kin Yan Chan
University of Hong Kong, Hong Kong, Hong Kong

Yuefeng Du
City University of Hong Kong, Hong Kong, Hong Kong

Antoni Chan
City University of Hong Kong, Hong Kong, China

Abstract

Here we combined the Eye Movement analysis with Hidden Markov Models (EMHMM) method with the data mining technique co-clustering to discover participant groups with consistent eye movement patterns across stimuli during scene perception. We discovered explorative (switching between foreground and background information) and focused (mainly on foreground) eye movement strategy groups among Asian participants. In contrast to previous research suggesting a cultural difference where Asians adopted explorative and Caucasians used focused eye movement strategies, we found that explorative patterns were associated with better foreground object recognition performance whereas focused patterns were associated with better feature integration in the flanker task and higher preference rating of the scenes. In addition, images with a salient foreground object relative to the background induced larger individual differences in eye movements. Thus, eye movements in scene perception not only contribute to scene recognition performance, but also reflects individual differences in cognitive ability and scene preference.

The Effect of Semantic Diversity on Serial Recall for Words

Yaling Hsiao
University of Oxford, Oxford, Oxfordshire, United Kingdom

Matthew H.C. Mak
University of Oxford, Oxford, United Kingdom

Kate Nation
University of Oxford, Oxford, United Kingdom

Abstract

We investigated whether semantic diversity (SemD) influences immediate serial recall for words. SemD was calculated using LSA to quantify semantic similarity across contexts in large corpus. We examined the effects of SemD and imageability, a classic semantic variable. Participants saw and recalled the 6-word list by typing out the words in correct serial order. Experiment 1 was conducted in the laboratory (N=40). There was no main effect of SemD or imageability but exploratory analyses showed that SemD was modulated by list position and imageability. Among high-imageability words, low-SemD words were better recalled in latter positions (4 & 5) of the list. Experiment 2 conducted online (N=44) replicated the results, showing better recall of low-SemD words in the high-imageability condition at Position 5. These findings suggest that the availability of more semantic connections induces more competition between items, which impacts on performance later on in serial recall.

Examining the association between elementary students lexcio-syntactic writing features and cognitive-motivational profiles using Natural Language Processing

Melissa Hunte
University of Toronto (OISE), Toronto, Ontario, Canada

Christine Barron
University of Toronto, Toronto, Ontario, Canada

Jeanne Sinclair
University of Toronto (OISE), Toronto, Ontario, Canada

Hyunah Kim

Samantha McCormick McCormick
University of Toronto (OISE), Toronto, Ontario, Canada

Megan Vincett Vincett
University of Toronto (OISE), Toronto, Ontario, Canada

Eunhee Eunice Jang
University of Toronto, Toronto, Ontario, Canada

Abstract

Natural language processing (NLP) provides an innovative avenue to understand and explore human language content, yet minimal research has utilized it to classify students literacy, cognition, or motivation. This study investigated the association between grade 4-6 students (n = 143) writing and their cognitive-motivational profiles (CMPs) based on their self-regulated learning, locus of control, writing self-efficacy, and goal-orientation. LPA (Mplus 7.4) results indicated a two-class CMP solution with predominantly positive or negative CMPs. Using NLP, 404 lexico-syntactic writing features were extracted from students writing. Random forest with 10-fold cross-validation was implemented in Weka 3.8 (with SMOTE to equate class instances) to accurately (93%) classify students CMPs (class 1 True Positive Rate (TPR) = .942; class 2 TPR = .925) based on the NLP-processed lexico-syntactic writing features. These results highlight the potential for machine learning to analyze students writing and accurately classify learner profiles to provide formative feedback and customized interventions.

How does art appreciation promote artistic inspiration?

Chiaki Ishiguro
Kanazawa Institute of Technology, Kanazawa, Japan

Takeshi Okada
The University of Tokyo, Tokyo, Japan

Abstract

Through art appreciation, viewers are sometimes inspired to express or implement creative ideas. Such an experience is thought to be important for art learning. In this study, we conduct a questionnaire to examine how art appreciation promotes creative inspiration in non-experts. We hypothesize that: (a) individual experience of art-related activities and self-evaluation of artistic expression affect creative inspiration, mediated by the method of appreciation of artworks; and (b) the type of artworks affects creative inspiration, mediated by the method of appreciation of artworks. The participants were 373 adults, who were not art professionals (179 women, age: M = 45.02, SD = 13.45, range: 20-69 years). The data are analyzed using structured equation modeling for the two hypotheses. The two hypotheses are mostly supported, suggesting that self-evaluation of artistic expression and the type of artworks (especially classic works of art) influence creative inspiration, mediated by the method of appreciation of artworks. However, experience of art-related activities has no significant direct effect on inspiration for artistic creation.

Learning to control the others body facilitates the embodied perspective taking

Ryota Ishikawa
University of Tsukuba, Tsukuba, Ibaraki, Japan

Kyohei Sasaki
University of Tsukuba, Tsukuba, Japan

Saho Ayabe-Kanamura
University of Tsukuba, Tsukuba, Ibaraki, Japan

Jun Izawa
University of Tsukua, Tsukuba, Japan

Abstract

Perspective taking, a cognitive process of understanding information from the others viewpoint, is essential for forming communication skills. Whereas this process is considered to involve detachment of the reference frame from the own eye and attachment of it to the others eye, we instead hypothesized here that it is mediated by representing the others intrinsic (i.e., proprioceptive) coordinate frame, since our cognitive abilities often rely on the physical presence. To examine this possibility, we asked the participants to learn to control avatars motion in the virtual reality space from the third-person perspective and sought interaction between the ability to represent avatars intrinsic coordinate systems via motor adaptation and the ability to take avatars spatial perspective. We found significant facilitation of perspective taking ability by the motor adaptation experience, which supports our hypothesis that the perspective taking encompasses a process of representing the others intrinsic coordinate frame. We suggest that the perspective taking is an embodied cognitive process which underpins theory of mind and empathy.

Spatial Updating Based on Visually Signaled Self-motion in Virtual Reality

Georg Jahn
Chemnitz University of Technology, Chemnitz, Germany

Manuel Dudczig
Institute for Machine Tools and Production Processes (IWP), Chemnitz, Saxony, Germany

Philipp Klimant
Institute for Machine Tools and Production Processes, Chemnitz, Saxony, Germany

Abstract

Spatial updating during self-motion can be effortless, however, in virtual reality if there are inconsistent cues about self-motion, spatial updating of egocentric representations of object locations usually relies on perceived scene motion or imagery of a spatial situation model. Strong presence and illusory self-motion with a quick onset are presumed necessary for effortless spatial updating if self-motion is signaled visually only. In the reported experiment, participants performed spatial updating compensating for visually signaled forward self-motion in a virtual scene presented in a head-mounted display. Higher visual detail in the scene improved performance only slightly. Overall, the result pattern suggests that participants did not experience illusory self-motion that could support effortless updating despite more favorable conditions than in a previous study. Several modifications to the experiment are discussed as further tests of conditions fostering effortless updating in virtual reality.

Emergence: A Proposal for a Foundational Revolution in Cognitive Science

Jay Jennings
Institute of Cognitive Science, Ottawa, Ontario, Canada

Abstract

Emergence has been a fundamental part of physics, chemistry, and biology since the turn of the century. The sub-disciplines of cognitive science have all adopted emergentist approaches in many areas within their field, yet cognitive science as a whole lacks an overarching theory between the sub-disciplines. Therefore, I propose that emergence is a valuable conceptual tool for unifying the sub-disciplines of cognitive science, as it will facilitate communication via a shared emergentist framework. Although there are several definitions of emergence, cognitive science can benefit from an overarching view that regardless of discipline, reductionistic approaches are unable to describe cognition from the macro to the micro without invoking emergent stages of explanation. The reluctance to adopt an emergent paradigm surrounds the issue that emergent phenomena cannot be predicted from their component parts, which challenges the way experiments in cognitive science are designed and conducted, and how cognition is modeled computationally.

Do Deep Neural Networks Model Nonlinear Compositionality in the Neural Representation of Human-Object Interactions?

Aditi Jha
IIT Delhi, New Delhi, India

Sumeet Agarwal
IIT Delhi, New Delhi, India

Abstract

Visual scene understanding often requires the processing of human-object interactions. Here we seek to explore if and how well Deep Neural Network (DNN) models capture features similar to the brain's representation of humans, objects, and their interactions. We investigate brain regions which process human-, object-, or interaction-specific information, and establish correspondences between them and DNN features. Our results suggest that we can infer the selectivity of these regions to particular visual stimuli using DNN representations. We also map features from the DNN to the regions, thus linking the DNN representations to those found in specific parts of the visual cortex. In particular, our results suggest that a typical DNN representation contains encoding of compositional information for human-object interactions which goes beyond a linear combination of the encodings for the two components, thus suggesting that DNNs may be able to model this important property of biological vision.

Single Template vs. Multiple Templates: Examining the Effects of Problem Format on Performance

Yang Jiang

Peter Scupelli
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Abstract

Classroom and lab-based research have shown the advantages of exposing students to a variety of problems with format differences between them, compared to giving students problem sets with a single problem format. The rapid development of technologies such as intelligent tutoring systems (ITS) in education affords the opportunity to automatically generate and adapt problem content for practice and assessment purposes. In this paper, we investigate whether this approach can be effectively deployed to an ITS, conducting a randomized controlled trial to compare students who practiced problems based on a single template and those who were exposed to problems based on multiple templates, both in the same ITS. Results show no statistically significant difference in the two conditions on students post-test performance and hint request behavior. However, students who saw multiple templates spent more time to answer the practice items compared to students who solved problems of a single structure.

Assessing Integrative Complexity as a Measure of Morphological Learning

Tamar Johnson
University of Edinburgh, Edinburgh, United Kingdom

Jennifer Culbertson
University of Edinburgh, Edinburgh, United Kingdom

Hugh Rabagliati
University of Edinburgh, Edinburgh, United Kingdom

Kenny Smith
University of Edinburgh, Edinburgh, United Kingdom

Abstract

Morphological paradigms differ widely across languages in their size and number of contrasts they mark. Recent work on morphological complexity has argued that certain features of even very large paradigms make them easy to learn and use. Specifically, Ackerman & Malouf, 2013 propose an information-theoretic measure, i-complexity, which captures the extent to which forms in the paradigm predict each other, and show that languages which differ widely in surface complexity exhibit similar i-complexity; in other words, paradigms with many contrasts reduce the learnability challenge for learners by having predictive relationships between inflections. We present three artificial language learning experiments testing whether i-complexity in fact predicts learnability of nominal paradigms where nouns inflect for class and number. Our results reveal only weak evidence that paradigms with low i-complexity are easier to learn than paradigms with high i-complexity. We suggest that alternative aspects of complexity may have a larger impact on learning.

Elicitation and Assessment of Emotion in Computational Rationality

Jussi Jokinen
Aalto University, Helsinki, Finland

Viet Ba Hirvola
Aalto University, Espoo, Finland

Abstract

Computational modelling of human emotion has a promising outlook within the approach of computational rationality, which formalises adaptive behaviour as a bounded optimisation problem. However, testing different hypothetical emotion models under this approach is hindered by lack of structured data, that have been collected in experimentation coherent with the underlying formal assumptions. Here, we design an interactive task that is used to elicit and assess emotion, and aligns with the problem solving formalism of a partially observable Markov decision problem. From the literature on emotion modelling, we derive hypotheses about what affects emotional responses, and use the collected data to test the hypotheses. We demonstrate how emotion can be assessed in a semi-continuous manner throughout the trials of the experiment, and in a way that can be used to test computational rationality models of emotion.

How the Organization of Autobiographical Memories Changes Over Time

Yoed Kenett
University og Pennsylvania, Philadelphia, Pennsylvania, United States

Alexa Tompary
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Sharon Thompson-Schill
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Abstract

Cognitive scientists have discovered much about the acquisition, consolidation, and retrieval of episodic memories; however, much less is known about how memories of our daily experiences are organized, nor how this organization may change as memories become consolidated. Here, we apply computational network science methodologies to quantify the organization of recent (within the past year) and remote (5 10 years ago) autobiographical memories and quantitatively examine how these networks change over time. We found that remote memories exhibited higher global connectivity relative to recent memories, and that this increased connectivity is coupled with lower subjective ratings of vividness. Our results demonstrate how such cognitive features of episodic memory can be quantitatively examined and shed novel light on the organization and reconfiguration of episodic memories over time.

Learning to Recognize Uncertainty: Effects of Disconfirming Evidence on Confidence Scale Use in Preschoolers

Isabella Killeen
University of California- San Diego, La Jolla, California, United States

Caren Walker
University of California San Diego, La Jolla, California, United States

Abstract

Although young learners often express overconfidence, research has demonstrated that 3- to 4-year-old children may be able to use a confidence scale to discriminate between their correct and incorrect responses. The current research introduces a novel paradigm to facilitate childrens reflection and reporting of confidence, based on the presentation of disconfirming evidence. This paradigm presents 3-, 4- and 5-year-olds with windows of varying occlusion (none, partial, and full). Children used a 3-point scale to assess their confidence that a target shape was behind each window. In four conditions, we varied when and whether children received disconfirming evidence. Results suggest that violating childrens expectations about the presence of the target shape on the first trial results in improves confidence calibration on future trials. Results also suggest that baseline confidence scale use improves with age. We discuss theoretical implications for development of uncertainty monitoring and potential applications of this novel paradigm.

Measuring Selective Sustained Attention in Children with TrackIt and Eyetracking

Jaeah Kim
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Shashank Singh
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Emily Keebler
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Erik Thiessen
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Anna Fisher
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Abstract

Measuring selective sustained attention (SSA) development in preschool-aged children has been difficult due to challenges in designing age-appropriate measurement paradigms. The TrackIt task, together with eye-tracking and a recently proposed Bayesian-model based eye-tracking analysis method, creates opportunity for fine-grained measurement of SSA in young children. The current study 1) provides the first rigorous validation of this method by comparing model judgments with human video-coding of the data, and 2) further explores potential uses of this method for providing nuanced measures of SSA. More specifically, we use the analysis method to explore different ways of characterizing SSA based on eye-gaze data obtained during TrackIt with 3- to 6-year old children. We look at patterns of in-trial eye-gazing across age and across time.

Information Distribution Depends on Language-Specific Features

Josef Klafka
University of Chicago, Chicago, Illinois, United States

Dan Yurovsky
University of Chicago, Chicago, Illinois, United States

Abstract

Language can be thought of as a code: A system for packaging a speakers thoughts into a signal that a listener must decode to recover some intended meaning. If language is a near-optimal code, then speakers should structure information in their utterances to minimizes the impact of errors in production or comprehension. To examine the distribution of information within utterances, we apply information-theoretic methods to a diverse set of languages in various spoken and written corpora. We find reliably non-uniform and cross-linguistically variable information distributions across languages. These distributions are consistent across contexts, and are predictable from typological features, most notably canonical word order. However, when we include even a small amount of predictive context (bigrams or trigrams), the language-specific shapes disappear, and all languages are characterized by uniform information distribution. Despite cross-linguistic variability in communicative codes, speakers structure their utterances to preserve uniform information distribution and support successful communication.

Exploring Monaural Auditory Displays that Convey Positional Information to Users

Takanori Komatsu
Meiji University, Tokyo, Japan

Masahiro Yamada
Meiji University, Tokyo, Japan

Seiji Yamada
National Institute of Informatics, Tokyo, Japan

Abstract

The purpose of this study is to confirm whether monaural auditory displays that indicate leftward and rightward directions to users can be used together with speech sounds in order to convey positional information to users. We conducted two experiments; experiment 1 was for investigating how a speech sound followed by auditory displays can convey three positions, right, center, and left, to participants, and experiment 2 was for exploring the effects of the durations of these auditory displays on how users interpreted these pieces of positional information. As a result of experiment 1, a speech sound followed by monaural auditory displays with durations of 0.25, 0.50, and 0.75 sec succeeded in conveying the three pieces of positional information to users. As a result of experiment 2, the speech sound followed by monaural auditory displays with durations of 0.25, 0.50, 0.75 or 1.00 sec was interpreted by users correctly.

How to find axioms for finite domains: A computational exploration of mathematical discovery

Gordon Krieger
McGill University, Montral, Quebec, Canada

Dirk Schlimm
McGill University, Montral, Quebec, Canada

Abstract

Axioms are pervasive in mathematics and formulating the axioms for a particular discipline has often been an important step in the development of mathematics. One way mathematicians arrive at axioms is by characterizing a given domain that consists of objects (e.g., numbers or points and lines) and relations between them. We present a software system that, given a set of objects and relations as input, determines, first, a set of first-order formulas that are satisfied in that domain, and, second, a set of axioms from which all of these formulas can be derived. Several domains are used to illustrate our program. By comparing the axioms for different domains, analogies between these domains can be expressed, such as structural and invariance properties. From the complexities of the implementation and the discussion of various examples, conclusions are drawn about the process of axiomatization in mathematical practice.

Choosing the unimaginable: Social psychological factors in seeking transformative experiences

Marta Kryven
MIT, Cambridge, Massachusetts, United States

Laura Niemi
University of Toronto, Toronto, Ontario, Canada

Laurie Paul
Yale University, New Haven, Connecticut, United States

Josh Tenenbaum
MIT, Cambridge, Massachusetts, United States

Abstract

How do people make transformative decisions (the outcomes of which are hard to imagine, and which might change one's self in lasting ways)? We investigate social psychological factors that contribute to making transformative decisions in contrast to ordinary decisions (with easily imaginable outcomes). We show that transformative decisions are uniquely predicted by a desire for self-improvement and forming new social bonds. However, contrary to our expectations, epistemic curiosity did not play a role in making transformative decisions. In contrast, ordinary decisions are uniquely predicted by the preferences of the community, and younger age. We identify important differences that point to separate cognitive mechanisms used to evaluate transformative decisions.

Various sources of distraction in analogical reasoning

Hanna Kucwaj
Jagiellonian University, Krakow, Poland

Jan Jastrzebski
Jagiellonian University, Krakw, Poland

Micha Ociepka
Jagiellonian University, Krakw, Poland

Adam Chuderski
Jagiellonian University, Krakow, Poland

Abstract

Two leading analogical reasoning paradigms: A:B::C:D task and scene analogies, to date studied in isolation, were applied to the same 61 participants. The former task included 3 types of distracting response options (relational, semantic, and perceptual); the latter task imposed cross-mapping (response options that suggested a wrong structure to be mapped). First, relational and semantic, but not perceptual, distractors were similarly frequently selected, but their choices were weakly correlated. These choices were unrelated to cross-mapping in the other task, either. So, various sources of distraction can play a role in the analogical reasoning process.

Temporal Structure in Reaction Time Data is sensitive to exercised control

Devpriya Kumar
Indian Institute of Technology, Kanpur, Uttar Pradesh, India

Narayanan Srinivasan
University of Allahabad, Allahabad, India

Akanksha Malik
Indian Institute of Technology, Kanpur, India

Abstract

Hierarchical control theories of perception-action conceptualize action as control of input, occurring simultaneously at multiple levels. These levels differ in terms spatio-temporal proximity of the perception controlled. However, it is not clear how this interaction between different levels in a control hierarchy can be measured from the behavior of the organism. We propose that Long Range Temporal Correlations (LRTC) in RT data can be used as a measure of coupling between different control levels within such complex system. Participants perform the task of controlling a hierarchical stimulus either at global level or at local level in a noisy presentation, while the level of control and noise are manipulated. The results suggest that LRTC in control task is higher for global level of control compared to local level of control in the no noise condition. We discuss implications of the results for understanding of perception-action interactions as a complex dynamic system.

Rudimentary modeling of acceptability judgement from a large scale, unbiased data

Kow Kuroda

Yuichiro Kobayashi
Nihon University, Tokyo, Japan

Toshiyuki Kanamaru
Kyoto University, Kyoto, Japan

Takumi Tagawa
University of Tsukuba, Tsukuba, Japan

Abstract

Acceptability Rating Data for Japanese (ARDJ) is a project that explores the true nature of acceptability judgement based on a large-scale survey using theoretically unbiased stimuli. Its main survey was carried out in 2018 in two phases with carefully constructed 300 stimulus sentences: Phrase 1 was a smaller scale experiment with roughly 300 college students; Phase 2 was a large scale web survey with over 1,600 participants.

This paper reports on phase 2 and provides two results: Analysis 1 brought us a good typology of 300 sentences; Analysis 2 implements explicit modeling of acceptability judgement using Semi-supervised local Fisher discriminant analysis.

The results, if combined, suggest that i) acceptability is not a simple dichotomous partitioning of stimuli; ii) acceptability is a complex property that emerges through an interplay among the three factors: 1) degree or strength of deviance, 2) syntactic and/or semantic complexity of stimulus, and 3) localizability of deviance.

How the Brain Learns Language: an Exploration of The Brain Areas Involved in Statistical Language Learning

Imme Lammertink
University of Amsterdam, Amsterdam Center for Language and Communication (ACLC), Amsterdam, Netherlands

Gillian Clark
Deakin University, School of Psychology, Cognitive Neuroscience Unit, Melbourne, Australia

Judith Rispens
University of Amsterdam, Amsterdam Center for Language and Communication (ACLC), Amsterdam, Netherlands

Jarrad Lum
Deakin University, School of Psychology, Cognitive Neuroscience Unit, Melbourne, Australia

Abstract

It has been suggested that the detection of statistical regularities in language a skill fundamental to language acquisition is supported by brain areas that are also involved in implicit motor skill learning. The present study is one of the first to explore this claim in an artificial language learning experiment. We used continuous theta-burst transcranial magnetic stimulation (cTBS) to temporarily inhibit functioning of the left dorsolateral prefrontal cortex (DLPFC) or the primary motor cortex (M1) in healthy adults. We hypothesized that the left DLPFC plays a role in adults detection of nonadjacent dependencies (NADs) and therefore that learning should be disrupted in the group of adults receiving cTBS to this area. Our results provide no evidence for (or against) this claim, however. An interesting exploratory result is that learning of NADs may be enhanced in adults who received cTBS to the M1 as compared to participants who received sham cTBS.

Expertise and Anchoring Bias in Medical Decision Making

Aron Liaw
UC San Francisco, San Francisco, California, United States

Matthew Welsh
University of Adelaide, Adelaide, South Australia, Australia

Hillary Copp
UC San Francisco, San Francisco, California, United States

Benjamin Breyer
UC San Francisco, San Francisco, California, United States

Abstract

Anchoring bias describes the tendency to base an estimate around a previously given value, the anchor. Herein, a cohort of 124 medical providers and trainees, from medical students to practicing physicians, were shown to display anchoring bias when faced with medical scenarios including an anchoring value in the form of a prior assessment. Anchoring bias did not vary significantly with participants level of training although tolerance to risk did. However, they showed increased reliance on the anchor when its source had greater expertise. Analyses showed no correlation between anchoring susceptibility and participants preference for Rationality or Intuition as measured by the Decision Styles Scale. The results suggest that medical decisions can be vulnerable to anchoring effects, particularly when the anchor is sourced from an authoritative source. Given that authoritative sources should be more knowledgeable, this is reasonable, but will hold true regardless of the accuracy of the anchoring value.

Selecting and evaluating evidence: The garden of forking information paths

Alice Liefgreen
University College London, London, United Kingdom

Toby Pilditch
University College London, London, United Kingdom

David Lagnado
University College London, London, United Kingdom

Abstract

In order to make accurate inferences and judgments, one needs to not only be able to aptly evaluate and integrate information, but be able to seek and acquire the right information in the first place. The present work explored human information acquisition and evaluation in a novel probability context and utilising a more naturalistic criminal investigation scenario. Focus was placed on exploring the relationship between searching for information, evaluating it and integrating it within ones belief model in order to make a causal judgement. Results indicated that although participants search choices approximated those of informed Bayesian OED models, belief updating accuracy systematically decreased throughout the task. Findings suggested a dichotomy between information evaluation and belief integration, questioning the descriptive abilities of OED principles to account for these processes. The implications of these finding in relation to the psychological literature of human inquiry are discussed.

Different Frames of Players and their Empathy as Motive of Prosocial Behavior in Digital Games

Ji Soo Lim
Dokkyo University, Soka, Saitama, Japan

Abstract

Advanced technologies used in games allow players to behave freely in the game world. Like in the real world, there may be complex motives for a behavior. Although how a player behaves in a game is afforded by the games rules, motives may differ depending on the type of player. For example, a player who regards the game as mere rule-based play may behave differently as compared to a player who perceives the game as another reality with its own rules and sociality. This study focuses on understanding players prosocial behavior in games and empathy as their motive. A survey was conducted to look at the relationships between prosocial behavior, empathy, and different types of players (depending on their interpretation of gameplay). The results showed that the type of player did not affect their levels of empathy, but it moderated the effect of empathy on prosocial behavior toward other characters.

Comparison of Chinese and Western Categorization: Based on Bayesian Model

Junyao Liu

Fei Xu
UC Berkeley, Berkeley, California, United States

Abstract

Xu and Tenenbaum (2007a, 2007b) applied the Bayesian model to explain the impact of differences in exemplification on words learning, and they achieved milestones. It remains unexplored if there are differences when native language and culture are changed. Taking the same method as the original research, we added test after a long time interval, and use between-subject design to eliminate the practice effect. The results of Chinese adults and children show that: (1) The Bayesian model has stability over time and culture. (2) When the objects in the same category differ greatly from each other, the Bayesian model's predictive power on children's results is significantly reduced. (3) Since the low-level words in Chinese vocabulary are often composed of high-level words and adjectives, Chinese easier to generalize. (4) Results of Chinese subjects reflect more instinct rather than logical reasoning stylewhich is differ from westerners.

Gestures for Self Help Learning by Creating Models

Yang Liu
Teachers College, Columbia University, New York, New York, United States

Melissa Zrada
Teachers College, Columbia University, New York, New York, United States

Barbara Tversky
Columbia Teachers College/Stanford, New York, New York, United States

Abstract

People spontaneously gesture when studying spatial descriptions. Doing so improves comprehension and learning. Their gestures create spatial models of the described environments. Here, we address two questions in two experiments: will people gesture to study descriptions that are not inherently spatial, and will people gesture when information is presented visually rather than text. The answers to both questions are yes. Together, the results suggest that gestures facilitate comprehension and learning by creating spatial-motor representations that directly reflect meaning.

Inferring the social meaning of objects with intuitive physics and Theory of Mind

Michael Lopez-Brau
Yale University, New Haven, Connecticut, United States

Julian Jara-Ettinger
Yale University, New Haven, Connecticut, United States

Abstract

Humans primarily communicate through words and gestures. In some cases, however, humans also communicate indirectly through objects, such as trafc cones or stanchion ropes. How does the human mind generate and interpret the social meaning of objects? Here we show that a computational model that uses commonsense physics and Theory of Mind spontaneously gives rise to the ability to communicate through objects. As predicted by our model, we show that people can infer the communicative meaning of novel objects by reasoning about the costs they impose, even in the absence of a pre-existing convention. Moreover, we show that people store the meaning of an object after a single exposure and recognize it in subsequent encounters. Our model sheds light on how humans bootstrap cognitive capacities that we share with other animals to give rise to uniquely-human cognition.

Integration of gaze information during online language comprehension and learning

Kyle MacDonald
University of California Los Angeles, Los Angeles, California, United States

Elizabeth Swanson
Stanford University, Stanford, California, United States

Michael Frank
Stanford University, Stanford, California, United States

Abstract

Face-to-face communication provides access to visual information that can support language processing. But do listeners automatically seek social information without regard to the language processing task? Here, we present two eye-tracking studies that ask whether listeners' knowledge of word-object links changes how they actively gather a social cue to reference (eye gaze) during real-time language processing. First, when processing familiar words, children and adults did not delay their gaze shifts to seek a disambiguating gaze cue. When processing novel words, however, children and adults fixated longer on a speaker who provided a gaze cue, which led to an increase in looking to the named object and less looking to the other objects in the scene. These results suggest that listeners use their knowledge of object labels when deciding how to allocate visual attention to social partners, which in turn changes the visual input to language processing mechanisms.

Comparing cognitive models in dynamic agent-based models: A methodological case study

Jens Madsen
University of Oxford, Oxford, United Kingdom

Richard Bailey
University of Oxford, Oxford, United Kingdom

Ernesto Carrella
University of Oxford, Oxford, United Kingdom

Nicolas Payette
University of Oxford, Oxford, United Kingdom

Abstract

Dynamic models, such as agent-based models (ABMs), are becoming an increasingly common modelling tool in cognitive sciences. They enable cognitive scientists to explore how computational, analytic models scale up when placed in complex, interactive, and dynamic environments where agents can sequentially interact over time and in space. Frequently, ABMs are built to yield a particular behaviour (riots, echo chamber emergence, etc.). As such, some models may bake in the desired behaviour. However, many models may yield this behaviour, making it difficult to discriminate between the adequacies of each computational model. The paper directly addresses this methodological challenge. We explore a case study (fisheries). Agents make decisions in this dynamic and complex environment. Given a rich data set against which to calibrate and validate model predictions, we compare and contrast statistical, adaptive, and perfect agents. We show that adaptive computational agents equal statistical agents in calibration and outperform them for validation. In addition, we show that perfect and random agents fare poorly. This provides a method for using dynamic, agent-based models to choose between computational models

Spatial Representations of Symbolic Fractions and Nonsymbolic Ratios: SNARC Effect and Number Line Estimation

Rui Meng
University of Wisconsin Madison, Madison, Wisconsin, United States

Percival Matthews
University of Wisconsin - Madison, Madison, Wisconsin, United States

Abstract

Recent research on numerical cognition has begun to systematically detail the ability to perceive the magnitudes of symbolic fractions and non-symbolic ratios. The current study extended this line of research by investigating spatial representations of symbolic fractions and nonsymbolic ratios with two behavioral measures: the Spatial-Numerical Association of Response Codes (SNARC) effect and number line estimation. The two research questions were: 1) what are the similarities and differences of spatial representations between symbolic fractions and nonsymbolic ratios? 2) do mechanisms driving the SNARC effect and performance on number line estimation rely on a shared cognitive mechanism? Participants completed four tasks: magnitude comparison with symbolic fractions, magnitude comparison with nonsymbolic ratios, number line estimation with symbolic fractions, and number line estimation with nonsymbolic ratios. Results suggested the existence of both shared and specific spatial representations of symbolic fractions and nonsymbolic ratios. Moreover, individual participants SNARC effects and number line estimation performances were not correlated with each other. Findings further elucidate the relations between different spatial representations for symbolic fractions and nonsymbolic ratios and cast doubt on the prospect of their sharing common cognitive mechanisms.

An experiment in the neuroscience of learning interactions: The effect of agency on emotional processing in dyads learning physics with a serious computer game

Julien Mercier
UQAM, Montreal, Quebec, Canada

Ariane Paradis Ph.D. Student
Universit du Qubec Montral , Montral, Quebec, Canada

Kathleen Whissell-Turner
UQAM, Montreal, Quebec, Canada

Ivan Avaca
UQAM, Montreal, Quebec, Canada

Abstract

Many educational approaches assume that making the learner active leads to better learning although this improvement in learning has not be firmly quantified experimentally. The goal of this paper is to articulate a model of agency in cooperative learning based on a predictive cognitive architecture and to explore methodological strategies as well as theoretical and applied implications of agency in the study of cooperative learning, in this case with data on emotional processing. Results from 27 dyads (1 player and 1 watcher) who played a serious game for learning physics for 120 minutes show that agency has no effect on the overall quantity of emotional processing, but that the emotional processing of a watcher and player is synchronized. A watchers emotional processing may precede or be delayed from the players. The cornerstone of this framework is the notion of predictions, which unites top-down and bottom-up influences as modulated by the possibility for action (agency). The model presented is the foundation for process-oriented studies of cooperative learning from an educational neuroscience perspective.

Interlocutors preserve complexity in language

Madeline Meyers
University of Chicago, Chicago, Illinois, United States

Dan Yurovsky
University of Chicago, Chicago, Illinois, United States

Abstract

Why do languages change? One possibility is they evolve in response to two competing pressures: (1) to be easily learned, and (2) to be effective for communication. In a number of domains, variation in the worlds natural languages appears to be accounted for by different but near-optimal tradeoffs between these pressures. Models of these evolutionary processes have used transmission chain paradigms in which errors of learning by one agent become the input for the subsequent generation. However, a critical feature of human language is that children do not learn in isolation. Rather, they learn in communicative interactions with caregivers who draw inferences from their errorful productions to their intended interests. In a set of iterated reproduction experiments, we show that this supportive context can have a powerful stabilizing role in the development of artificial patterned systems, allowing them to achieve higher levels of complexity than they would by vertical transmission alone while retaining equivalent transmission accuracies.

The Role of Sketch Quality and Visuo-Spatial Working Memory in Science Accuracy

Dana Miller-Cotto
University of Pittsburgh, Pittsburgh, Pennsylvania, United States

Nicole Hallinen
Temple University, Philadelphia, Pennsylvania, United States

Julie Booth Ph.D.
Temple University, Philadelphia, Pennsylvania, United States

Abstract

Sketching is often a helpful strategy for solving science problems. We examined the role of visuo-spatial working memory and sketching in predicting science problem solving accuracy. Sketches were coded for quality based on whether they included elements and relationships in the sketches. Regression analyses were done regressing working memory on to science problem solving. A mediation analysis was also conducted to determine whether sketch quality mediated the relationship between working memory and science accuracy. Findings are discussed in terms off implications for education and classroom instruction.

The Cognitive Process of Reinterpreting Non-art Objects in an Art Context

Koto Minami
The University of Tokyo, Graduate School of Interdisciplinary Information Studies, Tokyo, Japan

Daichi Shimizu
Graduate shool of education, Bunkyo-ku, Tokyo, Japan

Takeshi Okada
The University of Tokyo, Tokyo, Japan

Abstract

In this study, we investigated the reinterpretation process of a non-art object. It is often said that a unique perspective different from daily life arises in the cognitive process of an art activity. We assumed that such a unique viewpoint can also be applied to non-art objects and people will discover new aspects of objects and/or their own viewpoints through the reinterpretation of non-art objects. We conducted a between-subjects experiment to investigate the process in detail. We expected the artistic context of the participant to influence the interpretation. We conducted two types of interventions to manipulate participants artistic context. The result of the experiment suggests that the artistic context influenced the interpretation process of non-art objects.

L1 Influence on Content Word errors in Learner English Corpora: Insights from Distributed Representation of Words.

Kanishka Misra
Purdue University, West Lafayette, Indiana, United States

Hemanth Devarapalli
Purdue University, West Lafayette, Indiana, United States

Julia Rayz
Purdue University, West Lafayette, Indiana, United States

Abstract

The first language of a person has been shown to influence the processing of words when they learn a new language. This has been previously researched in behavioral studies, as well as by using lexical distributions or co-occurrence counts between word combinations to detect errors. In this paper we follow the findings of two recent studies and test their hypotheses within the framework of two different word embedding models, based on their representation of the erroneous usage of concent words. Using an error-annotated corpus of essays written by learnings bellowing to 16 different first languages, we compare incorrect words and their correct replacements as vectors in English and the learners first language. The results are consistent with previous findings that the first language has an influence on errors in the second language. The relationships between typologically similar languages differed between the models of embedding, suggesting an avenue for future explorations.

Planning failures induced by budgetary overruns cause intertemporal impulsivity

Arjun Mitra
University of Allahabad, Allahabad, Uttar Pradesh, India

Narayanan Srinivasan
University of Allahabad, Allahabad, India

Nisheeth Srivastava
Indian Institute of Technology, Kanpur, UP, India

Abstract

Recent research has identified intertemporal impulsivity as a critical cognitive variable for explaining the autocatalytic nature of socioeconomic status (SES). But how exactly this relationship transpires has not been clearly identified. We present results from a novel experimental study, demonstrating that decision-makers' time preference becomes more present-focused when they experience budgetary overruns in a sequential decision-making task. On the basis of these results, we hypothesize that steep intertemporal discounting in low SES individuals may arise as a rational metacognitive adaptation to persistently experiencing planning and control failures in long-term plans. Consilient evidence in support of this hypothesis and downstream policy implications are briefly discussed.

Evaluation of Methods for Tracking Strategies in Complex Tasks

Jarrod Moss
Mississippi State University, Mississippi State, Mississippi, United States

Aaron Wong
Mississippi State University, Mississippi State, Mississippi, United States

Kevin Barnes
Mississippi State University, Mississippi State, Mississippi, United States

Jaymes Durriseau
Mississippi State University, Mississippi State, Mississippi, United States

Gary Bradshaw
Mississippi State University, Mississippi State, Mississippi, United States

Abstract

In complex tasks, high performers often have better strategies than low performers even with similar practice. Relatively little research has examined how people form and modify strategies in tasks that permit a large set of possible strategies. One challenge with such research is determining strategies based on behavior. Three algorithms were developed to track the task features people employ in their strategies while performing a complex task. An ACT-R model that performs the task was created to collect simulated data with a range of known strategies. The performance of the three algorithms is compared, and a decision tree classification algorithm yielded the best performance across the test cases. Summary data from applying the algorithms to human data on the tasks is also presented and highlights potential challenges for future work. However, this approach to tracking strategy exploration may enable further development of theories about how people search for good strategies.

”Give me a break”: Can brief bouts of physical activity reduce elementary children’s attentional failures and improve learning?

Grace Murray
Kent State University, Kent, Ohio, United States

Karrie Godwin
Kent State University, Kent, Ohio, United States

Abstract

In classroom settings, young children are frequently off-task, which may be due in part to childrens still-maturing attentional system. Lapses in attention may impede academic success by reducing the amount of time spent engaged in instructional activities. One popular strategy to increase on-task behavior is to provide brief physical activity (PA) breaks in between instructional tasks. Though PA breaks are hypothesized to increase on-task behavior, much is unknown regarding the effectiveness of breaks and their underlying mechanism(s). The present study systematically investigated the effectiveness of PA breaks, using direct measures of attention and learning. Break type (PA vs. Sedentary control) was manipulated within-subjects. Preliminary results indicate PA breaks benefit learning compared to the sedentary control (p=.03, Cohens d=.389). A marginally significant increase in on-task behavior was also found following the PA break. These results provide tentative support for the benefit of PA breaks for childrens attention and learning.

Gradations in task engagement emerge from metacognitive priority control

Dominic Mussack
University of Luxembourg, Belval, Luxembourg

Paul Schrater
University of Minnesota, Twin Cities, Minneapolis, Minnesota, United States

Abstract

Engagement is a critical motivational factor that has broad effects on learning, productivity, performance, and even satisfaction and happiness. However, it can also be impacted by a myriad of factors which have made it difficult to model and design interventions. Here we address this problem by developing an integrated metacognitive framework for understanding task engagement. We treat engagement as resulting from a unified metacognitive decision process where the gradient of engagement results from a common priority calculation. Priority signals are computed relative to a set of available tasks and updated across time and environmental changes. We propose a metacognitive controller makes decisions about both task switching (when to quit, next task) and cognitive resourcing (working memory, attention, etc) using the graded priority signals. By simultaneously choosing the task and allocating resources using the same graded signals, we capture the complex dependencies of engagement with task errors, performance, and time allocation.

The impact of sequences on the learning of contingencies at UK traffic lights

William G. Nicholson
University of Exeter, Exeter, United Kingdom

Ciro Civile
University of Exeter, Exeter, United Kingdom

IPL McLaren
University of Exeter, Exeter, Devon, United Kingdom

Abstract

Previous work has found that the contingencies experienced at UK traffic lights can affect drivers behavior potentially leading to risky driving. However, these studies did not account for the sequences experienced at traffic lights. This experiment seeks to rectify this. As with previous research we used an incidental go/no-go task in which colored shapes were stochastically predictive of whether a response was required. The stimuli encoded the contingencies of traffic lights and their appropriate response, for example, stimuli G was a go cue, mimicking the response to a green light. Crucially, cues were displayed in the sequences experienced at traffic lights. Supporting earlier work, the 50/50 cue that mimicked amber traffic lights was experienced as a go cue, and the stop cue that represented red lights was responded to as a neutral cue. The sequences seemed to enhance this pattern of learning with much larger effect sizes than previously found.

Investigating the Role of Future-orientated Feedback in Self-Monitoring Devices

Milena Nikolic
Queen Mary University London, London, United Kingdom

Magda Osman
Queen Mary University, London, United Kingdom

Abstract

Standard self-monitoring devices provide real-time daily feedback. This may not help users learn the long-term future cumulative effects of their behaviour because it orientates attention on the now. We test the hypothesis that future oriented feedback is more effective than real-time feedback in increasing users propensity to exercise. We asked 54 female treadmill users in a gym to report the feedback they got from the machine (calories burnt, time spent running and distance covered) upon finishing their workout and were then provided with additional feedback which varied in format across three between-subject conditions: day only feedback (no additional feedback), monthly feedback (additional projection of the future cumulative effect of the activity repeated daily after one month), and all times feedback (additional projection of the future cumulative effect of the activity repeated daily after one month and after one year). All participants were then asked about the extent to which they felt their own running workout affected their weight loss, as well the extent to which running leads to weight loss in general. They also all answered two questions aimed at measuring their time perspective after being exposed to the various feedbacks. In comparison to participants who had been exposed to the standard real time feedback, participants who had been exposed to the future oriented feedbacks perceived the causal connection between their own running workout and their weight loss as significantly higher, and reported a significantly more future oriented time perspective. The results highlight the need to consider time orientation as an important dimension to aid decisions through technologies.

On Language and Thought: How Bilingualism Affects Conceptual Associations

Siqi Ning
Northwestern University, Evanston, Illinois, United States

James Bartolotti
Northwestern University, Evanston, Illinois, United States

Viorica Marian
Northwestern University, Evanston, Illinois, United States

Abstract

Language experience influences cognition. Using behavioral and ERP measures, the present study examines whether experience with multiple languages can change how we form associations between concepts. Four experiments comparing bilingual and monolingual groups on semantic relatedness judgments indicate that highly proficient bilinguals perceive concepts as more related to one another than monolinguals. Results suggest that bilinguals denser lexical and phonological connections across their two languages may shorten semantic distances between concepts. This finding is consistent with connectionist models of language and suggests that the structure of the lexical and phonological systems may influence conceptual level associations. We conclude that bilingualism has consequences for the structure of the language system at the level of lexical-semantic connections.

Bringing Order to the Cognitive Fallacy Zoo

Ardavan S. Nobandegani
McGill University, Montreal, Quebec, Canada

William Campoli
McGill University, Montreal, Quebec, Canada

Thomas Shultz
McGill University, Montreal, Quebec, Canada

Abstract

Investigations into human decision-making have led to the discovery of numerous cognitive biases and fallacies, with new ones continually emerging, leading to a state of affairs which can fairly be characterized as the cognitive fallacy zoo! In this work, we formally present a principled way to bring order to this zoo. We introduce the idea of establishing implication relationships (IRs) between cognitive fallacies, formally characterizing how one fallacy implies another. IR is analogous to, and partly inspired by, the concept of reduction in computational complexity theory. We present several examples of IRs involving experimentally well-documented fallacies: base-rate neglect, availability bias, conjunction fallacy, decoy effect, framing effect, and Allais paradox. We conclude by discussing how our work: (i) allows for identifying those pivotal cognitive fallacies whose investigation would be the most rewarding research agenda, and (ii) permits a systematized, guided research program on cognitive fallacies, motivating influential theoretical as well as experimental avenues of future research.

On Robustness: An Undervalued Dimension of Human Rationality

Ardavan S. Nobandegani
McGill University, Montreal, Quebec, Canada

Kevin da Silva-Castanheira
McGill University, Montreal, Quebec, Canada

Timothy ODonnell
McGill University, Montreal, Quebec, Canada

Thomas Shultz
McGill University, Montreal, Quebec, Canada

Abstract

Human rationality is predominantly evaluated by the extent to which the mind respects the tenets of normative formalisms like logic and probability theory, and is often invoked by appealing to the notion of optimality. Drawing on bounded rationality, there has been a surge in the understanding of human rationality with respect to the mind's limited computational and cognitive resources. In this work, we focus on a fairly underappreciated, yet crucial, facet of rationality, robustness: insensitivity of a model's performance to miscalculations of its parameters. We argue that an integrative pursuit of three facets (optimality, efficient use of limited resources, and robustness) would be a fruitful approach to understanding human rationality. We present several novel formalizations of robustness and discuss a recently proposed metacognitively-rational model of risky choice (Nobandegani et al., 2018) which is surprisingly robust to under- and over-estimation of its focal parameter, nicely accounting for well-known framing effects in human decision-making under risk.

Decoy Effect and Violation of Betweenness in Risky Decision Making: A Resource-Rational Mechanistic Account

Ardavan S. Nobandegani
McGill University, Montreal, Quebec, Canada

Kevin da Silva-Castanheira
McGill University, Montreal, Quebec, Canada

Thomas Shultz
McGill University, Montreal, Quebec, Canada

A. Ross Otto
McGill University, Montral, Quebec, Canada

Abstract

A wealth of experimental evidence shows that, contrary to normative models of choice, people's preferences are markedly swayed by the context in which options are presented. In this work, we present the first resource-rational, mechanistic account of the decoy effect—a major contextual effect in risky decision making. Our model additionally explains a related, well-known behavioral departure from expected utility theory: violation of betweenness. We demonstrate that, contrary to widely held views, these effects can be accounted for by a variant of normative expected-utility maximization—sample-based expected utility model (SbEU; Nobandegani et al., 2018)—which acknowledges cognitive limitations. Our work is consistent with two empirically well-supported hypotheses: (i) In probabilistic reasoning and judgment, a cognitive system accumulates information through sampling, and (ii) People engage in pairwise comparisons when choosing between multiple alternatives.

1.9 Million Hits and Counting: An Investigation of the Cognitive Alignment of Hundred Boards for Subtraction Thinking

Julie Nurnberger-Haag
Kent State University, Kent, Ohio, United States

Karrie Godwin
Kent State University, Kent, Ohio, United States

Rachael Todaro
Kent State University, Kent, Ohio, United States

Abstract

The primary numerical activities in kindergarten through third grade are aimed at developing an understanding of the structure of base-ten numbers and learning to add and subtract with increasingly larger numbers. Many students in the U.S. continue to find this difficult. Thus, the most common instructional tools intended to support childrens learning of these ideas should be analyzed for their cognitive alignment and, if needed, redesigned for optimal learning. This study reports the findings from a study examining the cognitive alignment of a standard hundred board for the more difficult subtraction operation. Additionally, we investigate whether redesigning the hundred board such that addition goes up and subtraction goes down is more optimal for subtraction.

Verb arguments in Japanese picture books

Naho Orita
Tokyo University of Science, Tokyo, Japan

Asumi Suzuki
Tohoku University, Sendai, Japan

Yuichiro Matsubayashi
Tohoku University, Sendai, Japan

Abstract

Previous experiments have demonstrated that Japanese children can use the number of arguments and the case markers to learn novel verbs. However, these cues are mostly omitted in child-directed speech. We revisit this gap between the ability of children to use syntactic cues and the deficiency of such input by examining a different mode of input in the form of picture books. We built a Japanese picture book predicate-argument structure corpus containing annotations of predicate-argument structure and non-linguistic information. The analyses show that Japanese picture books contain more overt arguments and accusative case markers, and that these cues have significant influence on the prediction of verb transitivity. In addition, this study demonstrates that non-linguistic information (animacy and the numbers of potential referents) could help predict transitivity if learners are able to use these cues to infer the presence of null arguments.

How Different Metaphor Styles Impact on Creativity of the Poetry Receivers?

Magorzata Osowiecka
SWPS University of Social Sciences and Humanities, Sopot, Poland

Alina Kolaczyk
SWPS University of Social Sciences and Humanities, Sopot, Poland

Abstract

Poetry is one of the most creative uses of language. Yet the influence of poetry on creativity has received little attention. The present research aimed to determine how the reception of different types of poetry affect creativity levels. In two experimental studies, participants were assigned to two conditions: poetry reading and non-poetic text reading. Participants read poems (Study 1 = narrative/open metaphors; Study 2 = descriptive/conventional metaphors) or control pieces of non-poetic text. Before and after the reading manipulation, participants were given a test to determine levels of divergent thinking. In Study 1 (N = 107), participants showed increased fluency and flexibility after reading a narrative poem. In Study 2 (N = 131) reception of conventional, closed metaphorization significantly lowered fluency and flexibility (compared to reading non-poetic text). The most critical finding was that poetry exposure could either increase or decrease creativity level depending on the type of poetic metaphors.

Does Expressive Writing About Negative Emotions Influence Divergent Thinking?

Magorzata Osowiecka
SWPS University of Social Sciences and Humanities, Sopot, Poland

Radosaw Sterczyski
SWPS University of Social Sciences and Humanities, Sopot, Poland

Abstract

Many researchers claim that negative emotions inhibit creativity. However, describing emotions in a safe environment has beneficial effects: it allows for the restructuring of difficult experiences, as a result, we discover the world again, which can influence creativity. The classic method of writing about emotions is long-term one. The hereby study was an attempt to verify, if one session of expressive writing improves creative thinking. This hypothesis was tested in an experimental study by exposing participants (N = 60) to emotionally laden content. Participants viewed unpleasant images. The first group wrote about their emotions in connection with the images. The second described their typical day. At the end all participants solved creativity measure (Alternative Uses Task). After each stage, emotions of respondents were measured. The conducted analyses had shown that, performance was better in the unpleasant emotions describing condition. At the same time, negative emotions persistence has been observed.

Testing Accuracy, Additivity, and Sufficiency of Human Use of Probability Density Information in a Visuo-Cognitive Task

Keiji Ota
New York University, New York, New York, United States

Jakob Phillips
New York University, New York, New York, United States

Laurence Maloney
New York University, New York, New York, United States

Abstract

We tested three fundamental properties of Bayesian Decision Theoryaccuracy, additivity, and sufficiency. In Experiment 1, observers were shown a sample of dots from a bivariate Gaussian and estimate the probability that an additional sample would fall into specified regions. There were three types of regions: symmetric around the mean (S), the upper and lower halves of the symmetric region (SU and SL). In Experiment 2, the same observers were asked to maximize the expected rewards based on jointly sufficient statistics for given the sample (herein, mean and covariance of a Gaussian). In Experiment 1, We found that the observers estimates of symmetric region P[S] were close to accurate. However, they showed a highly patterned super-additivity: the sum of P[SU] + P[SL] ¿ P[S]. In Experiment 2, the observers violated sufficiency by assigning too much weight to a feature of the sample rather than jointly sufficient statistics.

Domestic Dogs Sensitivity to the Accuracy of Human Informants

Madeline Pelgrim
University of Toronto, Toronto, Ontario, Canada

Emma Tecwyn
Birmingham City University, Birmingham, United Kingdom

Julia Espinosa
University of Toronto, Toronto, Ontario, Canada

Angie Johnston
Yale University, New Haven, Connecticut, United States

Sarah MacKay Marton
University of Toronto, Toronto, Ontario, Canada

Daphna Buchsbaum
University of Toronto, Toronto, Ontario, Canada

Abstract

Domestic dogs excel at understanding human social-communicative gestures. The present study explores whether dogs can use peoples past accuracy when deciding who to trust. In Experiment 1, dogs watched an informant hide a treat under one of two containers and then point at one of them. Dogs were more likely to follow an accurate (pointed correctly) vs. the inaccurate (pointed incorrectly) informants point. In Experiment 2, dogs interacted separately with an accurate and inaccurate informant and again were more likely to follow an accurate point. In test trials, dogs did not witness hiding of the treat and saw the same two informants simultaneously point at different locations. Here, they chose between the locations at chance-level. Dogs inability to selectively follow a previously accurate informant when presented with conflicting information suggests that, unlike children, they may not be able to use past informant accuracy when choosing whose information to use.

The inverse operation modulates confidence

Gabriel Penagos
Pontificia Universidad Javeriana, Bogota, Colombia

Santiago Alonso Diaz
Universidad Javeriana, Bogota, Colombia

Abstract

Inversion is an essential operation, for instance in math (negatives) and action (to move in an opposite direction). Even though humans can invert is unclear how is implemented. There are two alternative hypotheses. The first possibility (H1) is that only positives are represented and negatives (inverses) are implemented as either a response (e.g. left to right) or task demand flip (e.g. ¿ to ¡). The second possibility (H2) is that both positives and negatives (inverses) are encoded. To disambiguate them, we ran two experiments where participants had to apply the inverse while implicitly reporting confidence. If inverting modifies encoding of otherwise identical stimulation then confidence should differ. We found that confidence was lower in inverse trials than direct/positive trials. This suggests that the inverse is not a simple response strategy or modification of task demands (H1), rather inverting modulates how cognitive information is encoded and used in the brain (H2).

Phonological and semantic processing in short-term memory

Theresa Pham
The University of Western Ontario, London, Ontario, Canada

Lisa Archibald
The University of Western Ontario, London, Ontario, Canada

Abstract

Much research has focused on phonological representation in verbal short-term memory (STM), with less attention paid to semantic representations despite evidence of linguistic long-term memory (LTM) effects. We investigate when phonological and semantic representations are activated in verbal STM: does it occur during retrieval (redintegration account) or there is direct access to language knowledge stored in LTM (language-based account). A probe recognition paradigm was used to test phonological and semantic encoding in verbal STM. Participants studied a list of words and then judged whether a probe word presented after the list rhymed or was synonymous to any item in the word list. Probe recognition was better was semantically processed words than the phonological task, suggesting that semantic encoding was evident at first exposure during encoding rather than a redintegration effect. It appears that semantic knowledge, in addition to and separate from phonological knowledge, is actively maintained in verbal STM.

Linguist Alignment in Collaborative and Conversational Contexts

Ramon Pieternella
Tilburg University, Tilburg, Noord-Brabant, Netherlands

Travis Wiltshire
Tilburg University, Tilburg, North Brabant, Netherlands

Abstract

Effective communication is a crucial factor contributing to successful collaborative problem solving (CPS) teams. Research in cognitive science has long shown evidence of linguistic alignment, or convergence in ways of speaking, but its functional role, if any, during CPS is unknown. Based on recent theorizing, we expected that both goal-oriented dialogue and non-goal-oriented dialogue should exhibit alignment. However, if linguistic alignment contributes to effective CPS, then conversations in this context should exhibit higher levels of alignment. In this study, we compared levels of syntactic and lexical alignment between a corpus of CPS dialogue and a corpus of spontaneous dialogue. Contrary to our prediction, we observed that the mean lexical alignment level was lower in the CPS corpus than in the Switchboard corpus. Implications for future research into linguistic alignment in CPS are discussed.

A round Bouba is easier to remember than a curved Kiki: Sound-symbolism can support associative memory

Marie Poirier

Abstract

Past research has shown that prior knowledge can support our episodic memory for recently encountered associations (Chalfonte & St-Giles, 1996; Naveh-Benjamin, 2000). Badham, Estes and Maylor (2012) for example, showed that integrative relationships between words help associative memory, even if the relationships are highly unfamiliar. A pair of words is integrative if the words make sense when considered together (e.g. monkey-foot). We extend this phenomenon to sound-symbolism associations; here, the latter refer to relationships between phonemes and object characteristics– relationships that participants readily find natural, even without prior knowledge of the items. For instance, the non-word maluma is much more readily associated with a random shape with rounded contours than with a shape that has sharp angles (Khler, 1929, 1947). In our study, 70 participants completed paired-associate memory tests after studying lists of three shape / non-word pairs. The sound-shape pairs that relied on known sound-symbolism links facilitated associative memory.

How much harder are hard garden-path sentences than easy ones?

Grusha Prasad
Johns Hopkins University, Baltimore, Maryland, United States

Tal Linzen
Johns Hopkins University, Baltimore, Maryland, United States

Abstract

The advent of broad-coverage computational models of human sentence processing has made it possible to derive quantitative predictions for empirical phenomena of longstanding interest in psycholinguistics; one such case is the disambiguation difficulty in temporarily ambiguous sentences (garden-path sentences). Adequate evaluation of the accuracy of such quantitative predictions requires going beyond the classic binary distinction between ”hard” and ”easy” garden path sentences and obtaining precise quantitative measurements of processing difficulty. We report on a self-paced reading study designed to estimate the magnitude of the disambiguation difficulty in two temporarily ambiguous sentence types (NP/Z and NP/S ambiguities). Disambiguation was more than twice as hard in NP/Z sentences as in NP/S sentences. This contrasts with the predictions of surprisal estimates derived from current broad-coverage language models, which lead us to expect a smaller difference between the two.

Proposing a Cognitive System for Universal Mental Spatial Transformations

Kai Preuss
Technical University Berlin, Berlin, Germany

Nele Russwinkel
Technische Universitt Berlin, Berlin, Germany

Abstract

Mental spatial transformation processes are often modeled by assuming imaginal processes, highly task-specific assumptions, or both. We propose the existence of a dedicated, unified cognitive system for the simulation of spatial processes, and show ways to model this system, including an ACT-R implementation that is currently in development. Results of spatial cognition and brain-imaging research support this proposal. Operations of this system are proposed to be influenced by their complexity, which we assume to be a product of the extent and amount of necessary transformation steps. This complexity is further assumed to be limited in its extent, possibly explaining decision time effects between task difficulties in a mental folding task as being caused by cognitive re-encoding processes. A model for the mental folding task lacking such a spatial system is presented, serving as a baseline to demonstrate the need of a system dedicated to mental transformations.

SpotLight on Dynamics of Individual Learning

Roussel Rahman
Rensselaer Polytechnic Institute, Troy, New York, United States

Wayne Gray
Rensselaer Polytechnic Institute, Troy, New York, United States

Abstract

How do individuals learn a complex task? Averaging performance over a group of individuals implicitly assumes that only one set of methods exists for accomplishing the task and that all learners acquire those methods in the same sequence. Rather than profiling a mythical "average subject", we focus on individuals using SpotLight – a tool for analyzing changes in individual performance as a complex task is learned. Specifically, we investigate 9 individuals who spent 31 hours learning the task of Space Fortress (SF). The SpotLight enables us to uncover the evolution of strategies and the iterative efforts of individuals to explore and devise new ways to improve performance. To our surprise, these players seem to have followed a common 'design for the weakest link' rule, in which after the current weakest link of performance is strengthened, an individual's attention turns to the next weakest link.

Cue Validity, Feature Salience, and the Development of Inductive Inference

Robert Ralston
The Ohio State University, Columbus, Ohio, United States

Vladimir Sloutsky
The Ohio State University, Columbus, Ohio, United States

Abstract

Young children can generalize properties to novel stimuli, but the mechanism underlying these early inductions is still debated. Some researchers argue that from an early age induction relies on category information and undergoes little development, while others believe that early induction is similarity-based, and the use of categories emerges over time. This present study brings new evidence to the debate by exploring the kinds of features 4-year-old children and adults (N = 123) rely on in their induction. Our results indicate that induction undergoes dramatic development: young children tend to rely on salient features when performing induction, whereas adults rely primarily on category information. We argue that the reported findings present evidence challenging category-based accounts of early induction, while supporting similarity-based accounts.

I Never Even Considered That!: Investigating explanations for adults failures to learn conjunctive causal rules

Alexandra Rett
UC San Diego, La Jolla, California, United States

Elizabeth Bonawitz
Rutgers University - Newark, Newark, New Jersey, United States

Koeun Choi
Virginia Tech, Blacksburg, Virginia, United States

Caren Walker
University of California San Diego, La Jolla, California, United States

Abstract

Despite having sophisticated causal reasoning skills, there are a variety of cases in which adult learners consistently ignore the available evidence and make an incorrect inference. Here, we focus on a specific case in which adults fail to infer and apply a conjunctive causal rule (Lucas et al., 2014), and examine two explanations for this failure. In Experiment 1, we manipulate information about the probabilistic nature of the events to test whether adults failure results from an endorsement of noisy relations. In Experiment 2, we manipulate the physical design of the causal system to test an alternative account: that this phenomenon is due to a failure to consider the correct, conjunctive hypothesis. Taken together, our results suggest that failures to learn the conjunctive rule may not be entirely due to a noisy prior that affords discounting of the evidence, but instead results from a failure to generate the relevant hypothesis.

Distinguishing the Phenomenal from the Cognitive: An Empirical Investigation into the Folk Concepts of Emotions

Kevin Reuter
University of Bern, Bern, Switzerland

Rodrigo Daz
University of Bern, Bern, Switzerland

Abstract

The two dominant theories on the nature of emotions are feeling theories (e.g., Prinz 2004) and cognitive theories (e.g., Lazarus 1991). The former take feelings to be the essential core aspect of emotions. The latter argue that emotions are based on judgements or some other conceptual states in order to account for the datum that emotions always seem to be directed towards events or objects. In this paper we argue that the controversy between feeling theories and cognitive theories rests on the false assumption that people do not distinguish emotional feelings from emotional judgements, i.e., that expressions of the form I feel x and I am x are largely intersubstitutable (Bennett & Hacker 2003). We present new empirical evidence from both corpus studies and a vignette study showing that feeling happy (sad/angry) and being happy (sad/angry) are two separate states that people are able to conceptually and linguistically distinguish.

You must know something I dont: risky behavior implies privileged information

Emory Richardson
Yale University, New Haven, Connecticut, United States

Julian Jara-Ettinger
Yale University, New Haven, Connecticut, United States

Abstract

People make sense of each others behavior by assuming that beliefs and desires vary across agents. We propose that people are more conservative when it comes to risk: when an agent takes an extreme risk, we assume they have privileged information rather than high risk tolerance. Participants watched an agent choose either to obtain three guaranteed tokens, or guess which box from a set had four tokens. After watching the agents choice, participants played the game themselves. In Study 1, participants were quicker to imitate an agent who immediately made extremely risky bets than one who started out making low-risk bets that became progressively riskier, suggesting that they inferred that risk-seeking agents were knowledgeable. In Study 2, participants ceased taking risky bets when the anonymous agent did, suggesting that participants choices depend on mental state inferences rather than contagious but mind-blind risk-seeking behavior.

Preparing not to Forget: Actions Take to Plan for Memory Error

Lorena Rosales
California Lutheran University, Thousand Oaks, California, United States

AndreaJ. Sell
California Lutheran University, Thousand Oaks, California, United States

Abstract

The present study was designed to examine actions people take in everyday life to prevent potential memory errors. Many past studies focus on the nature of forgetting, and additional studies have assessed cognitive interventions for those with varying degrees of impairment from aging or injury. However, there are a limited number of studies examining everyday remembering for healthy, functioning adults. In this study, across two experiments (n1=136; n2=85), participants completed a self-reported questionnaire regarding various types of daily prospective memory actions. We hypothesized that people would report using external memory aids (ex. technology) rather than internal aids (ex. mnemonics) and participants would report lower forget scores when using external aids. Results showed that participants overwhelmingly used external memory aids to prevent future memory errors for all tasks analyzed. Results also showed that levels of self-reported forgetting were not associated with particular types of preventative actions. Thus, the results imply that people tend to use what they perceive to work.

(A)symmetry (Non)monotonicity: Towards a Deeper Understanding of Key Cognitive Di/Trichotomies and the Common Model of Cognition

Paul Rosenbloom
University of Southern California, Los Angeles, California, United States

Abstract

Many dichotomies from across the cognitive sciences can be reduced to one of two fundamental distinctions (a)symmetry and (non)monotonicity of processing simplifying greatly the space of dichotomies needed to structure this broad interdisciplinary discipline. Taking the cross-product of these two dichotomies then yields a 2x2 structure of cells that in its turn yields a deeper understanding of two key trichotomies based on control and content hierarchies with each mapping to three out of the four cells. This cross-product and its four cells further provide a deeper understanding of the structure of the Common Model of Cognition an attempt to develop a community consensus concerning the processes and structures implicated in human-like minds as well as cognitive architectures that map onto it, such as ACT-R, Sigma and Soar and even AlphaZero with results that bear on the structure of integrative architectures, models and systems; and on their commonalities, differences and gaps.

Learning a novel rule-based conceptual system

Joshua Rule
MIT, Cambridge, Massachusetts, United States

Josh Tenenbaum
MIT, Cambridge, Massachusetts, United States

Steven Piantadosi
University of California, Berkeley, Berkeley, California, United States

Abstract

Humans have developed complex rule-based systems to explain and exploit the world around them. When a learner has already mastered a system's core dynamicsidentifying its primitives and their interrelationsfurther learning can be effectively modeled as discovering useful compositions of these primitives. It nevertheless remains unclear how the dynamics themselves might initially be acquired. Composing primitives is no longer a viable strategy, as the primitives themselves are what must be explained. To explore this problem, we introduce and assess a novel concept learning paradigm in which participants use a two-alternative forced-choice task to learn an unfamiliar rule-based conceptual system: the MUI system (Hofstadter, 1980). We show that participants reliably learn this system given a few dozen examples of the systems rules, leaving open the mechanism by which novel conceptual systems are acquired but providing a useful paradigm for further study.

Modeling Axonal Plasticity in Artificial Neural Networks

james ryland
University of Texas at Dallas, Richardson, Texas, United States

Abstract

Axonal growth and pruning is the brains primary method of controlling the structured sparsity of its neural circuits, as without long distance axon branches connecting distal neurons no direct communication is possible. Further, artificial neural networks have almost entirely ignored axonal growth and pruning instead relying on implicit assumptions that prioritize dendritic/synaptic learning above all other concerns. This project proposes a new model called the Axon Game, which allows the incorporation of biologically inspired axonal plasticity dynamics into most artificial neural network models with computational efficiency. We will explore the qualities of receptive windows grown under this methodology and discuss how they can integrate with neural network simulations.

How Productivity and Compositionality May Emerge from a Neural Dynamics of Perceptual Grounding

Daniel Sabinasz
Ruhr-Universitt Bochum, Bochum, Germany

Mathis Richter
Ruhr-Universitt Bochum, Bochum, Germany

Jonas Lins
Ruhr-Universitt Bochum, Bochum, North Rhine-Westphalia, Germany

Gregor Schner
Ruhr-Universitt Bochum, Bochum, Germany

Abstract

The productivity and compositionality of language and thought have often been taken as evidence that higher cognition is a form of information processing on systems of symbols with combinatorial syntax and semantics. We present a non-symbolic neural dynamic architecture that can ground combinatorial concepts in perception, i.e., establish a link between a combinatorial concept and an object in the perceptual array. The components of a combinatorial concept tree are sequentially grounded from the leaves to the root, while the output of each grounding step is passed on to the next grounding step by means of a mental map. This way, compositionality is an emergent property of the neural dynamics and does not require any form of symbolic information processing. We discuss how this process account contrasts with other neural accounts of compositionality and conclude with implications for the modeling of higher cognition.

Assessing the role of matching bias in reasoning with disjunctions

Mathias Sabl-Meyer
NeuroSpin center, CEA DRF/I2BM, INSERM, Universit Paris-Sud, Universit Paris-Saclay, 91191 Gif-Sur-Yvette, France

Salvador Mascarenhas
Ecole Normale Suprieure, Paris, France

Abstract

On mental models theories, reasoners create mental representations of information which they manipulate in order to derive new conclusions. These theories have been uniquely successful at explaining a class of attractive fallacies involving disjunctions. The original theories have appealed to low-level matching mechanisms (Walsh & Johnson-Laird, 2004; Koralus & Mascarenhas, 2013) to compare the models of the premises and the models of the conclusion and predict an answer. In three experiments, we show that the check for overlap in content involved in these accounts must take place at a high level of cognition in order to incorporate complex world knowledge. We introduce variants of illusory inferences from disjunction whose acceptance is accurately predicted by independant measures of confidence in causal connections. We conclude that the Revised Mental Model Theory of Khemlani et al. (2018) holds promise, but cannot account for our data out of the box.

On the purpose of ambiguous utterances

Gregory Scontras
UC Irvine, Irvine, California, United States

Asya Achimova
University of Tbingen, Tbingen, Germany

Christian Stegemann
University of Tbingen, Tbingen, Germany

Martin Butz
University of Tuebingen, Tuebingen, Germany

Abstract

Traditionally, linguists have treated ambiguity as a bug in the communication system, something to be avoided or explained away. More recent research has taken notice of the efficiency ambiguity affords us. The current work identifies an additional benefit of using ambiguous language: the extra information we gain from observing how our listeners resolve ambiguity. We propose that language users learn about each others private knowledge by observing how they resolve ambiguity. If language does not do the job of specifying the information necessary for full interpretation, then listeners are left to draw on their private knowledgeopinions, beliefs, and preferencesto fill in the gaps; by observing how listeners fill those gaps in, speakers learn about the private knowledge of their listeners. We implement this hypothesis as a computational model within the Rational Speech Act framework. We then test our hypothesis by using the model to predict behavioral data from naive participants.

A Smile Goes a Long Way: Exploring the Effect of Culture, Weather, and Connectedness on Smile Diffusion with an Agent-based Modell

Victoria Scotney
University of British Columbia, Kelowna, British Columbia, Canada

Fabian Cid Yanez
University of British Columbia, Kelowna, British Columbia, Canada

Joshua Cooper
University of British Columbia, Kelowna, British Columbia, Canada

Liane Gabora
University of British Columbia, Kelowna, British Columbia, Canada

Abstract

This paper first synthesizes research showing that (a) people reciprocate smiles, (b) smiling and being smiled at elevates mood, and (c) elevated mood is associated with proclivity to smile. Collectively, these findings suggest that smiling is contagious, i.e., smiles diffuse through a social network. The paper then presents experiments carried out to investigate how various factors affect the contagiousness of smiling using an agent-based model in which smiling affects a mood variable, which in turn affected proclivity to smile. The society consistently stabilized on a proportion of smilers, the magnitude of which was a function of social connectivity. Using previous data on the effect of weather and cultural differences on smile reciprocity, we simulated how these factors affect smile diffusion. Smile diffusion was greater in the sunny condition than the cloudy condition, and in the American condition than the Japanese condition, and both effects were magnified by increased social connectivity.

Learning and Production in the Explanation of Regularization Behaviour: a Computational Model

Chiara Semenzin
University of Edinburgh, Edinburgh, United Kingdom

Vanessa Ferdinand
University of Melbourne, Melbourne, VIC, Australia

Simon Kirby
The University of Edinburgh, Edinburgh, United Kingdom

Abstract

We propose a computational model to account for the regularization behaviour that characterizes language learning and that has emerged from experimental studies, specifically from concurrent multiple frequency learning tasks (Ferdinand, 2015). These experiments show that learners regularize the input frequencies they observe, suggesting that domain-general factors might underlie regularization behaviour. Standard models have failed to capture this pattern, so we explore the consequences of adding a production bias that follows the learning stage in a probabilistic model of frequency learning. We simulate and fit to experimental data a beta-binomial Bayesian sampler model, which allows an explicit quantification of both the learning and the production bias. Our results reveal that adding a production component to the model leads to a better fit to data. Given our results, we hypothesize that linguistic regularization may result from general-domain constraints on learning combined to biases in production, which need not to be considered innate.

An Associative Theory of Semantic Representation

Kevin Shabahang
University of Melbourne, Melbourne, VIC, Australia

Hyungwook Yim
The University of Melbourne, Melbourne, Australia

Simon Dennis
The University of Melbourne, Melbourne, VIC, Australia

Abstract

We present a new version of the Syntagmatic-Paradigmatic model (SP; Dennis, 2005) as a representational substrate for encoding meaning from textual input. We depart from the earlier SP model in three ways. Instead of two multi-trace memory stores, we adopt an auto-associative network. Instead of treating a sentence as the unit of representation, we go down a scale to the level of words. Finally, we specify all stages of processing within a single architecture. We show how the model is capable of forming representations of words that are independent of the surface-form through some question-answering examples. We end with a discussion of how the current model can provide a mechanistic account of elaborative and inferential processes during comprehension.

Associations versus Propositions in Memory for Sentences

Kevin Shabahang
University of Melbourne, Melbourne, VIC, Australia

Hyungwook Yim
The University of Melbourne, Melbourne, Australia

Simon Dennis
The University of Melbourne, Melbourne, VIC, Australia

Abstract

Propositional accounts of organization in memory have dominated theory in compositional semantics, but it is an open question whether their adoption has been necessitated by the data. We present data from a narrative comprehension experiment, designed to distinguish between a propositional account of semantic representation and an associative account based on the Syntagmatic-Paradigmatic (Dennis, 2005; SP) model. We manipulated expected propositional-interference by including distractor sentences that shared a verb with a target sentence. We manipulated paradigmatic-interference by including two distractor sentences, one of which contained a name from a target sentence. That is, we increased the second-order co-occurrence between a name in a target sentence and a distractor. Contrary to the propositional assumption, our results show that subjects are sensitive to second-order co-occurrence, hence favouring the associative account.

One-Object Decision-Making model: Fast and Frugal Heuristic for Human Activity Classification

karan sharma
Keysight Technologies, Atlanta, Georgia, United States

Suchendra Bhandarkar
The University of Georgia, Athens, Georgia, United States

Abstract

Consider an uncertain situation where an artificial intelligence (AI) system is called upon to determine a human action or activity in an image or scene. The AI system has not been previously trained to recognize any human action or activity, and has no prior information on pose, parts, spatial layout of the object in an image. In such a situation, what is the AI system supposed to do? Its options are limited, and it must determine the action or activity with the aid of the most probable inanimate object (other than the human actor) that it can detect in the image. The AI system needs to formulate two hypotheses to infer the action or activity in a zero-shot manner; first, that the most probable inanimate object detected in the image is one that is involved in the action or activity, and second, that the most likely action or activity associated with this object in the real world is the one actually occurring in the image. To what extent are these hypotheses valid? We propose that correct detection of the highly probable object and use of natural language word embeddings obtained via training on a general text corpus such as Wikipedia could enable the AI system to determine the underlying human action or activity in an image with reasonable classification accuracy. We conducted studies on the HICO dataset, which is a challenging dataset containing many rare human action/activity categories. Our experimental results show that if the AI system can reliably detect the most probable inanimate object in the image and then infer the corresponding verb in a zero-shot manner using language models trained on general text corpora, then it has a reasonable chance of correctly guessing the underlying action/activity in an image.

A CTA-DCD Model to Determine Design Requirements for Technology to Support People with Mild Cognitive Impairment / Dementia at Work

Karan Shastri
University of Waterloo, Waterloo, Ontario, Canada

Jennifer Boger
University of Waterloo, Waterloo, Ontario, Canada

Parminder Flora

Katja Karjalainen
University of Eastern Finland, Joensuu, Finland

Anna Mki-Petj-Leinonen
University of Eastern Finland, Joensuu, Finland

Louise Nygrd
Karolinska institutet, Huddinge, Sweden

Abstract

Work is an integral and meaningful part of many peoples lives. Research has shown that the consequences of MCI and dementia (MCI/dem) before the age of sixty-five can profoundly affect a persons vocational situation. Technology plays a significant role in supporting different abilities for people with MCI/dem at communities and home; however, there is little research to investigate the role of technology and address the technological requirements of people with MCI/dem at work who are employed. We propose a new systematic human factors model to study peoples tasks, activities, and requirements derived from in-depth interviews with six people living with MCI/dem and one caregiver. By characterizing the barriers or problems faced by people with MCI/dem in the context of cognitive work, we organized individual barriers of the participants in terms of macrocognitive activities and cognitive support requirements.

An Empirical investigation of JointSeparate Effect on Preference of Causal Explanation

Asaya SHIMOJO
Nagoya University, Nagoya city, Japan

Kazuhisa Miwa
Nagoya University, Nagoya-shi, Aichi-ken, Japan

Hitoshi Terai
Kindai University, Iizuka-shi, Fukuoka, Japan

Abstract

What makes an explanation better than another explanation? Previous studies have suspected that explanatory virtues, such as Simplicity and Scope, affect individuals' evaluation of the explanatory goodness. Although almost all of these studies have focused on the situation that some explanations are presented simultaneously, we do not always obtain some explanations in daily life. In this research, we conducted an experiment to investigate the preference change in causal explanation between Joint and Separate Evaluations. The results showed that Latent scope has a large effect as a criterion for evaluating explanatory goodness regardless of Joint and Separate Evaluation. Furthermore, Simplicity affects the evaluation of explanatory goodness differently between these situations of evaluation; however, the effect of comparison was observed only by online reflection in which evaluation is performed for two explanations simultaneously and not by offline reflection in which evaluation is re-performed after ending all evaluations.

Recombinant building: the ability to generate and recombine navigation structures is difficult to acquire through just reinforcement learning

Ganesh Shinde
Centre for Modeling and Simulation,Savitribai Phule Pune University , Pune, Maharashtra, India

Harshit Agrawal
Homi Bhabha Centre for Science Education, TIFR, Mumbai, Maharashtra, India

Sanjay Chandrasekharan
Homi Bhabha Centre for Science Education, TIFR, Mumbai, India

Abstract

Humans build novel tools, external knowledge structures (markers, maps etc.), and internal structures (analogies, mental models etc.) to facilitate cognition. Humans also recombine these building strategies to suit any task. Other organisms generate such structures as well, but they use them to optimize single tasks. This suggests that the human species' cognitive advantage stems from the capability to recombine built structures, and the resulting extended mind. Chandrasekharan & Stewart (2007) hypothesized that this capacity could emerge from reinforcement learning. We tested this proposal, by studying three foraging models, which examined whether novel recombinations of building (external and internal navigation structures) emerged in reactive agents, from just reinforcement learning. Results showed that recombination does not emerge with just reinforcement. This was because the building of external structures provided a very high reward profile, including free riding, thus acting as an attractor, blocking the recombination strategy. We discuss the implications of these results.

Can a forward posture enhance willingness to change ones own attitude in decision making? Nudging with embodied cognition approach

Masaru Shirasuna
The University of Tokyo, Tokyo, Japan

Hidehito Honda
Yasuda Womens University, Hiroshima, Japan

Kazuhiro Ueda
The University of Tokyo, Tokyo, Japan

Abstract

Recently, nudging approaches wherein peoples decisions are altered in a predictable direction have attracted attention. Conversely, many embodied cognition approaches that relate peoples mind with their body have been studied in cognitive science. Based on these approaches, we investigated whether a forward posture (defined by leaning forward in a chair) generated by the environment can enhance a particular decision. We also evaluated the types of decisions that are likely to be enhanced by the forward posture. Behavioral experiments via a forward or normal chair where the seat allows little or no lean revealed that a forward posture can affect the decision making, particularly participants willingness to change their own attitude. We discuss the possible applications of leading predictable decisions from the environment and setting the decision environment in the real world.

Real-time inference of physical properties in dynamic scenes

Kevin Smith

MIT, Cambridge, Massachusetts, United States

Ilker Yildirim
Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Jiajun Wu
MIT, Cambridge, Massachusetts, United States

Josh Tenenbaum
MIT, Cambridge, Massachusetts, United States

Abstract

Human scene understanding involves not just localizing objects, but also inferring the latent causal properties that give rise to the scene for instance, how heavy those objects are. These properties can be guessed based on visual features (e.g., material texture), but we can also infer them from how they impact the dynamics of the scene. Furthermore, these inferences are performed rapidly in response to dynamic, ongoing information. Here we propose a computational framework for understanding these inferences, and three models that instantiate this framework. We compare these models to the evolution of human beliefs about object masses. We find that while peoples judgments are generally consistent with Bayesian inference over these latent parameters, the models that best explain human judgments are approximations to this inference that hold and dynamically update beliefs. An earlier version of this work was published in the proceedings of CCN 2018 at https://ccneuro.org/2018/proceedings/1091.pdf.

Cognitively-Inspired Salience Computation for Intelligent Agents

Sterling Somers
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Konstantinos Mitsopoulos
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Christian Lebiere
Carnegie Mellong University, Pittsburgh, Pennsylvania, United States

Robert Thomson
United States Military Academy , West Point, New York, United States

Abstract

We describe a method for determining feature salience of action decisions in intelligent agents based on cognitively-inspired salience. Salience is defined as the degree of influence that a factor has on a given decision. This is generated by having a cognitive model using instance-based learning theory to mirror the actions of an intelligent agent, and then determining which features most uniquely contributed to the actions of the agent. We present three examples of this salience techniques, including reinforcement learning agents based in the StarCraft II and autonomous drone domains, as well as part of a risk assessment model. A benefit of our method is that it does not rely on a specific implementation of an agent, it only requires the underlying decision feature-space. It is also capable of utilizing features at different levels of abstraction

An Attractor Neural-network Simulation of Decision Making

Ashley Stendel
McGill University, Montreal, Quebec, Canada

Thomas Shultz
McGill University, Montreal, Quebec, Canada

Abstract

We apply an attractor neural-network model to experiments on monkeys who decided which direction tokens are moving, while firing rates of large numbers of neurons in premotor cortex are being recorded. Using pools of artificial excitatory and inhibitory neurons, our network model accurately simulates the neural activity and decision behavior of the monkeys. Among the simulated phenomena are decision time and accuracy, commitment, patterns of neural activity in trials of varying difficulty, and an urgency signal that builds over time and resets at the moment of decision. Predictive simulations of decision change are also presented, suggesting gradual passing through an uncertain region on the way to a new decision. The model shows that committed decisions need not involve any explicit threshold detection mechanism. Instead, competition, suppression, decision, and commitment naturally emerge from the dynamics of the system.

A Cognitive Modeling Approach for Predicting Behavioral and Physiological Workload Indicators

Christopher Stevens
Air Force Research Laboratory , Dayton, Ohio, United States

Megan Morris
Ball Aerospace, Fairborn, Ohio, United States

Christopher Fisher
Air Force Research Laboratory, Dayton, Ohio, United States

Christopher Myers
Air Force Research Laboratory, WPAFB, Ohio, United States

Abstract

Measuring cognitive workload is a persistent challenge in cog-nitive science. Cognitive architectures may offer a principledway to measure, define, and understand workload and its be-havioral and physiological consequences in terms of under-lying cognitive dynamics. Previous research has shown thatmodel-based workload relates to subjective workload judg-ments in simple tasks. Our goal was to further validate model-based workload measurement with known physiological work-load indicators in a complex task characterized by varying de-grees of workload levels. Participants completed an unmannedvehicle management task while their physiology was recorded.Correlations between model-based workload and physiologi-cal metrics generally trended in the predicted direction, andthe engagement index showed the strongest and most consis-tent relationship to model workload. The results provide pre-liminary validation for model-based workload measurement.

A Geometric Interpretation of Feedback Alignment

Andreas Stckel
University of Waterloo, Waterloo, Ontario, Canada

Terrence Stewart
University of Waterloo, Waterloo, Ontario, Canada

Chris Eliasmith
University of Waterloo, Waterloo, Ontario, Canada

Abstract

Feedback alignment has been proposed as a biologically plausible alternative to error backpropagation in multi-layer perceptrons. However, feedback alignment currently has not been demonstrated to scale beyond relatively shallow network topologies, or to solve cognitively interesting tasks such as high-resolution image classification. In this paper, we provide an overview of feedback alignment and review suggested mappings of feedback alignment onto biological neural networks. We then discuss a novel geometric interpretation of the feedback alignment algorithm that can be used to analyze its limitations. Finally, we discuss a series of experiments in which we compare the performance of backpropagation and feedback alignment. We hope that these insights can be used to systematically improve feedback alignment under biological constraints, which may allow us to build better models of learning in cognitive systems.

A case study of formation of an art concept by a contemporary artist: Analysis of the utilization of drawing in the early phase

Kikuko Takagi
The University of Tokyo, Tokyo, Japan

Takeshi Okada
The University of Tokyo, Tokyo, Japan

Sawako Yokochi
Tokyo Future University, Tokyo, Japan

Abstract

When producing a new series of artworks, an artist may engage in a variety of activities in the formation of an art concept. In a specific instance, a contemporary artist was demonstrated first to draw his ideas on paper, as an initial phase of developing his art concept. This paper utilizes data from a previous study to analyze the drawings and interviews conducted during this drawing phase. The results show that the artist used various types of modification of his art-making process. By changing his own creative activity, the artist often reflected upon his creative process, asking himself what he really wanted to do, and explored new images in response to unexpected findings and the feeling of confusion at his own drawings.

What Factors of Background Music Disrupt Task Performance? Influence of Types of Sound, Tasks, and Working Memory Capacity on Irrelevant Sound/Speech Effect

Maiko Takahashi
University of Tokyo, Tokyo, Japan

Mika Ishikawa
Nagoya University, Nagoya, Japan

Sachiko Kiyokawa
Nagoya University, Nagoya, Japan

Abstract

Task-irrelevant background speech or sounds are known to have detrimental effects on task performance which are called irrelevant-speech/sound effects (ISEs). In this study, we have investigated the contributing factor responsible for magnitude of ISE focusing on the meaningfulness of the background noise and working memory capacity (WMC). Participants were asked to perform reading comprehension task (Exp. 1), serial recall task (Exp 2), and match-to-sample task (Exp.3) with or without task-irrelevant instrumental music and lyrics, and their WMC was measured with the Reading Span Test. The results revealed that the irrelevant sounds with lyrics, but not instrumental music disrupted the performance of the participants in both the reading comprehension and serial recall tasks , while that in match-to-sample task was not interfered by either sound types. The moderating effect of WMC was not observed in any experiments. The results implied that ISEs were observed when phonological loop was used to conduct these tasks. Based on these results, the function of a learners WMC in the ISE is discussed.

What strategies do adults use to solve fraction arithmetic problems?

Shawn Tan
Carleton University, Ottawa, Ontario, Canada

Jo-Anne LeFevre
Carleton University, Ottawa, Ontario, Canada

Abstract

When children perform fraction arithmetic, they generate a variety of solutions. In this study, we extended this research to adults. We report that adults performance is best for addition and subtraction, worse for division, and is susceptible to the same kinds of strategy errors observed in 6th grade children. Specifically, solvers common strategy errors involved maintaining the values of fractions with common denominators even when that strategy was not appropriate. We also present two other findings that were not observed in children. First, adults applied an incorrect division algorithm; they incorrectly inverted the first, rather than the second operand in fraction division problems. Second, adults applied reduction procedures for fraction multiplication and division in order to simplify numerator-denominator pairs during fraction arithmetic. Our results suggest that strategy selection was cued by identifying common fraction components within problems.

Cognitive Complexity of Logical Reasoning in Games: Automated Theorem Proving Perspective

Katrine Thoft
Technical University of Denmark, Lyngby, Denmark

Nina Gierasimczuk
Technical University of Denmark, Lyngby, Denmark

Abstract

We use formal proof techniques from artificial intelligence and mathematical logic to analyse human reasoning in problem solving. We focus on the Deductive Mastermind game, as implemented in the Dutch massive online learning system for children, Math Garden. The game is formalised in propositional logic and the game-playing procedure is given a form of a logical proof. We use Resolution and Natural Deduction proof methods (implemented in JAVA). The difficulty of a particular logical reasoning step is associated with the computationally obtained parameters of the proofs, which are compared with each other, and against the empirical difficulty of the game. We show, among others, that the complexity parameters derived from Natural Deduction agree with the Analytical Tableaux parameters, and with the empirical difficulty as experienced by human subjects.

Estimating Average Body Size of Sets of Bodies

Michelle To
Lancaster University, Lancaster, Lancashire, United Kingdom

James Brand
University of Canterbury, Christchurch, New Zealand

Georgia Hampton
Lancaster University, Lancaster, United Kingdom

Martin Tovee
Lincoln University, Lincoln, Lincolnshire, United Kingdom

Abstract

In two behavioral experiments, we demonstrated that human observers can extract average body size from a group of individuals. In Experiment 1, we asked 38 participants to estimate the average body size from a group of 5, 10 or 15 bodies that were presented in various angles of view (Profile, Three-Quarter, Frontal, and Mixed). Participants were able to extract the average body size, but they systematically overestimated thinner body groups, and underestimated larger body groups. Biases were generally reduced for smaller sets sizes and when bodies were shown in profile view, but the trend was reversed for sets with larger bodies. In Experiment 2, we tested 37 participants and showed that the accuracy of their estimates was modulated by presentation time: Accuracy was poorest when groups were presented for 1s, but significantly improved for 3s and 5s presentations. Implications of these finding are discussed.

Be timely: when gaps are more than symptoms

John Tomlinson Jr
Leibniz Centre for General Linguistics, Berlin, Germany

Abstract

Recently, turn-taking gaps, or unfilled pauses, have been viewed as a symptom or by-product of predictive planning mechanisms in speech production (Levinson & Torreria, 2015). Other works has shown that gaps can take signaling functions and that this is governed by politeness (Bgels, Kendrick, & Levinson, 2015). Two mouse-tracking experiments examined when gaps are interpreted as a symptom of processing or as a signal. This was tested by examining how gaps are interpreted in tandem to scalar implicatures (Bonneferon, Dahl, & Holtgraves, 2015). Experiment 1 found that longer gaps slightly reduce implicature rates at longer gaps and these longer gaps do not lead to faster implicature responses. Experiment 2 found that filled and unfilled pauses (gaps) both signal hesitation, though filled pauses signaled hesitation at short gaps. Overall, these experiments show that gaps lengths can have signaling functions beyond politeness and question bias.

Sub-morphemic form-meaning systematicity: the impact of onset phones on word concreteness

Sean Trott
UC San Diego, San Diego, California, United States

Arturs Semenuks
University of California, San Diego, San Diego, California, United States

Benjamin Bergen
UC San Diego, La Jolla, California, United States

Abstract

Do individual sounds carry meaning? The relationship between sound and meaning in human languages is typically assumed to be arbitrary, though recent research provides evidence for the existence of both iconicity and systematicity between word forms and their meaning. However, this research has not asked whether individual sounds in a language covary in systematic ways with aspects of meaning. In two analyses, we find evidence for more systematicity between the initial phones of words and those words concreteness ratings than one would expect in a truly arbitrary lexicon. This suggests that initial phones may act as cues to aspects of word meaning, and raises questions about whether language learners detect and exploit these cues.

The Scaffolding of Inferential Reasoning: Intuitive Analysis of Variance

David Trumpower
University of Ottawa, Ottawa, Ontario, Canada

Nicolas Robinson
University of Ottawa, Ottawa, Ontario, Canada

Abstract

In the present study, we explored the effect of a scaffolding exercise designed to make salient the importance of within-group variance on participants informal reasoning during a subsequent intuitive analysis of variance task. Participants were first presented with several datasets that varied with respect to within-group differences and were asked to provide examples of extraneous factors that could be the source of the variance. Afterwards, participants were given additional datasets that differed with respect to both within and/or between-group variability, and were asked to rate the strength of evidence provided by the dataset in support of a hypothetical theory. Consistent with prior research, the majority of participants tended to place a strong emphasis on between-group variability while minimizing the importance of within-group variation. However, the results indicate that for a subset of participants (n=6), the scaffolding exercise was effective in highlighting the significance of within-group variation. We found that all participants who reasoned normatively on the scaffolding exercise were able to successfully complete the analysis of variance task in a normative manner.

Group Discussion Clarifies the Difference between Maximin and Equality Principles in Social Distribution for Others

Atsushi Ueshima
The University of Tokyo, Bunkyo, Tokyo, Japan

Tatsuya Kameda
The University of Tokyo, Bunkyo, Tokyo, Japan

Abstract

The allocation of scarce resources is a ubiquitous process in human societies, yet it is challenging to aggregate peoples diverse distributive viewpoints into group consensus. We investigate whether such heterogeneity in preferences may be reduced when people participate in group discussion in a distribution task. In two interactive experiments, we found that after group discussion, participants became less inequity-averse and preferred the maximin allocation. Analyses of participants conversations and information-search behaviors showed that such shifts toward the maximin allocation were facilitated by a strong concern for the worst-off recipient during group discussion. These results suggest that a maximin concern exhibited in discussion helped participants to understand the difference between the inequity-aversion principle and the maximin principle, which are often confounded in individual judgments. These results provide empirical insight into how social interaction can help to aggregate peoples diverse distributive preference into a social consensus.

The Role of Sensorimotor and Linguistic Information in the Basic-Level advantage

Rens van Hoef
Lancaster University, Lancaster, United Kingdom

Louise Connell
University of Lancaster, Lancaster, United Kingdom

Dermot Lynott
Lancaster University, Lancaster, United Kingdom

Abstract

The basic-level advantage is one of the best-known effects in human categorisation. Traditional accounts argue that basic-level categories present a maximally informative or entry-level into a taxonomic organisation of concepts in semantic memory. However, these explanations are not fully compatible with most recent views on the structure of the conceptual system, which emphasise the role of sensorimotor (i.e., perception-action experience of the world) and linguistic information (i.e., statistical distribution of words in language) in conceptual processing. In a pre-registered wordpicture categorisation study, we hypothesised that our novel measures of sensorimotor and linguistic distance would contribute to categorical decision making, and would outperform traditional taxonomic levels (i.e., subordinate, basic, superordinate) in predicting the basic-level advantage. Results showed that, overall, our measures predicted the basic-level advantage at least as well as taxonomic level. Sensorimotor information best explained processing speed, whereas taxonomic level best explained participants choices.

Analyzing Performance Differences in Artists and Engineers- An RPM Study

sravya vatsavayi
International Institute of Information and Technology, Hyderabad, Telengana, India

Priyanka Srivastava
International Institute of Information Technology, Hyd, Hyderabad, Telangana, India

Kavita Vemuri
International Institute of Information Technology - Hyderabad, Hyderabad, Telangana, India

Abstract

Analytic reasoning differences, as gauged from intelligence metrics, in students engaged in streams requiring a predominantly divergent (arts) or convergent thinking (science and engineering) is a topic of interest. In this paper we have examined this difference by a modified sequence of two sections (D & E) of the Standard Ravens Progressive matrices (RPM). The scan path gaze behavior was analyzed with an eye tracker. The 30 engineering students (half of them are also trained in fine arts) scored higher than the 15 fine arts students. In the former cohort, the artistic and the non-artistic set show no difference in performance but the scan path, fixation count and time taken indicate possible differences in visual strategies for pattern identification. From the detailed analysis, we argue that intelligence as measured by RPM is enhanced by training in reasoning and logic as in engineering streams and might not reflect an innate ability.

Understanding the design neurocognition of industrial designers when designing and problem-solving.

Sonia Vieira
Faculty of Engineering University of Porto, Porto, Porto, Portugal

Marco Parente
University of Porto, Porto, Portugal

Antnio Fernandes
University of Porto, Porto, Portugal

Abstract

This paper presents results from an experiment to determine brain activation differences between problem-solving and designing of industrial designers. The study adopted and extended the tasks described in a previous fMRI study of design cognition and measured brain activation using EEG. The experiment consists of 4 tasks: problem-solving, basic design and open design tasks using a tangible interface and sketching. By taking advantage of EEG's temporal resolution we focus on time-related neural responses during problem-solving compared to design tasks. Statistical analyses indicate increased activation when designing compared to problem-solving. Results of time-related neural responses connected to Brodmann areas cognitive functions, contribute to a better understanding of industrial designers' cognition. The study is part of a research project whose goal is to correlate design cognition with brain behavior across design domains. Bringing neuroscience methods to design research is contributing to a better understanding of the emergent field of design neurocognition.

Social Learning and Decisional Constraints in Uncertain Environments

Marius Vollberg
Harvard University, Cambridge, Massachusetts, United States

Matthias Hofer
MIT, Cambridge, Massachusetts, United States

Mina Cikara
Harvard University, Cambridge, Massachusetts, United States

Abstract

The ability to learn from others is central to our species. At the same time, we are more than able to independently learn from our own experience. Investigating how these pathways function in concert, past research has looked at how we integrate what can be learned from others with our own observations. To do so, social information is typically operationalized as observed behavior. However, social information often comes in the form of normative advice. Humans have been shown to value decisional freedom and reject constraints to it. Some forms of social information, such as normative advice, plausibly comprise potential for both social learning and perceived constraint. Past research on decisional constraints posed by social information has been of limited granularity. We present an experimental framework to study behavior in the face of normative social information and explore data from two experiments using computational modeling.

The Temporal Dynamics of Belief-based Updating of Epistemic Trust: Light at the End of the Tunnel?

Momme von Sydow
LMU Munich, Munich, Bavaria, Germany

Christoph Merdes
Universitt Erlangen, Erlangen, Bavaria, Germany

Ulrike Hahn
Birkbeck, University of London, London, London, United Kingdom

Abstract

We start with the distinction of outcome- and belief-based Bayesian models of the sequential update of agents beliefs and subjective reliability of sources (trust). We then focus on discussing the influential Bayesian model of belief-based trust update by Eric Olsson, which models dichotomic events and explicitly represents anti-reliability. After sketching some disastrous recent results for this perhaps most promising model of belief update, we show new simulation results for the temporal dynamics of learning belief with and without trust update and with and without communication. The results seem to shed at least a somewhat more positive light on the communicating-and-trust-updating agents. This may be a light at the end of the tunnel of belief-based models of trust updating, but the interpretation of the clear findings is much less clear.

Foundations of search behavior, beyond the exploration-exploitation trade-off

oana vuculescu
Aarhus University, Aarhus, Denmark

Carsten Bergenholtz
Aarhus University, Aarhus, Denmark

Ali Amidi
Aarhus University, Aarhus, Denmark

Abstract

We investigate the cognitive micro-foundations of individual search. The aim of this study is to identify important cognitive antecedents of the heterogeneity of individual level search behavior. We introduce a problem-solving task that not only requires a binary trade-off between either exploration or exploitation, but solicits the individual to understand the underlying problem structure in order to be able to optimize the search. Combining data collected from individuals solving this experimental task (N = 407) with a quantitative survey of cognitive styles as well as a neuropsychological test of cognitive ability (g-factor) we explain how different cognitive micro-foundations translate into substantial variation in search behaviors.

Successes of the Intuitive Psychologist: Observers make reasonable judgments in the role conferred advantage paradigm

Drew Walker
UCSD, San Diego, California, United States

Nicholas Christenfeld
University of California, San Diego, La Jolla, California, United States

Ed Vul
University of California, San Diego, La Jolla, California, United States

Abstract

In a now classic experiment Ross, Amabile & Steinmetz (1977) showed that observers think that a participant who is randomly assigned to invent questions has more general knowledge than a participant assigned to answer these questions. This is taken to be an error arising from a reasoning process in which observers ignore social roles, and instead rely on surface behavior to make social judgments. Here we test two potential explanations for this observation: (1) observers are using a flawed reasoning process in which they do not consider the advantages and disadvantages that different social roles may confer, or (2) observers are using an unbiased reasoning process in which they do consider the influence of social role, but they are simply operating with an imperfect estimate of the advantage afforded the questioner. In a series of five studies, we show that not only is reasoning in this task consistent with an unbiased inference account, but, that observers are also surprisingly well calibrated to the influence of the social roles used in this paradigm.

Evidence for constructive influences from simple evaluations

Lee White
City, University of London, London, London, United Kingdom

Emmanuel Pothos
City, University of London, London, United Kingdom

Michael Jarrett
INSEAD, Singapore, Singapore

Abstract

There have been several demonstrations of constructive influences from choice paradigms, for example, when a decision maker has to commit to one of the available options and abandon the rest. In such cases, an expectation of constructive influences, whereby the preference for the chosen option increases, while the preference for the abandoned ones decreases, is perhaps reasonable (e.g., as a way to reduce cognitive dissonance). However, this reasoning is harder to translate to situations such that there is a simple evaluation. We employ an organizational questionnaire to show that a simple evaluation of an earlier statement can lead to systematic influences on a later one. Our results generalize our understanding for when constructive influences may occur. We outline a technical framework for predicting this bias (which we label evaluation bias), based on quantum theory. Quantum theory is an appropriate framework for modelling constructive influences, because the theory involves a fundamental process of state change when a measurement (evaluation) is made.

Testing Gender Markedness of Nouns with Self a Paced Reading Study

Ethan Wilcox
Harvard University, Cambridge, Massachusetts, United States

Abstract

Some English nouns occur in gender-marked pairs, which fall into two classes: In the Superordinate class, the unmarked (masculine) form is available to refer to female referents ("Allison Janey is a good actor"), whereas in the specific class it is not (*"Diana is a good prince"). Two theories account for this alternation: The Featural Theory proposes that the unmarked are unspecified for gender features. The second, Frequency Theory proposes relative frequency of the marked vs. unmarked forms are responsible (Haspelmath, 2006). This work provides evidence against the frequency theory by employing a self-paced reading study that tests relative processing times of anaphoric pronouns referring to gendered nouns. If noun pairs are split along Specific/Superordinate class lines, a processing slowdown is found for processing processing pronoun gender mismatches, except for nouns like 'actor', as expected. However, when the noun pairs are split by relative frequency the effect disappears.

Do typically and atypically developing children learn and generalize novel names similarly: the role of conceptual distance during learning and at test

Arnaud Witt
University of Bourgogne Franche-Comt, Dijon, France

Annick Comblain
University of Liege, Liege, Belgium

Jean-Pierre Thibaut
University of Bourgogne Franche-Comt, Dijon, Bourgogne, France

Abstract

There is a large body of evidence showing that comparison leads to better conceptualization and generalization of novel names than no-comparison settings in typically developing (TD) children (e.g., Gentner, 2010). So far, comparison situations have not been studied with children with intellectual disabilities (ID) (Chapman & Kay-Raining Bird, 2012). In the present research children with ID and TD children matched on mental age with the Ravens coloured progressive matrices RCPM (Raven, 1965) were tested in several comparison conditions. We manipulated the conceptual distance between stimuli in the learning phase and between the learning phase stimuli and the generalization phase stimuli for object and relational nouns. Results showed that overall both populations had rather similar performance profile when matched on their cognitive skills (low vs. high functioning). Unexpectedly, ID childrens performance was equivalent or better than their TD peers. We discuss our results in terms of the role of conceptual distance on participants conceptual generalization as a function of their intellectual abilities and cognitive functioning.

Surprisingly unsurprising! Infants looks to probable vs. improbable events is modulated by others expressions of surprise

Yang Wu
Stanford University, Stanford, California, United States

Hyowon Gweon
Stanford University, Stanford, California, United States

Abstract

Research in diverse disciplines suggests that agents own prediction errors enhance their learning. Yet, human learners also possess powerful capacities to learn from others. Here we ask whether infants can use others expressions of surprise as vicarious prediction error signals to infer hidden states of the world. First, we conceptually replicated Xu & Garcia (2008), showing that infants (12.0-17.9 months) looked longer at improbable than probable sampling outcomes (Experiment 1). Then we added emotional cues to the design (Experiment 2). Before revealing an outcome to an infant, the experimenter looked at the outcome and expressed either happiness or surprise. While infants still looked longer at the improbable than the probable outcome following the experimenters happy expression, this trend was reversed when the experimenter had expressed surprise at the outcome. Such early-emerging ability to use others surprise as vicarious prediction error may guide infants own learning about the world. Preprint:https://psyarxiv.com/8whuv

Revealing Long-term Language Change with Subword-incorporated Word Embedding Models

Yang Xu
San Diego State University, San Diego, California, United States

Jiasheng Zhang
The Pennsylvania State University, State College, Pennsylvania, United States

David Reitter
Penn State, University Park, Pennsylvania, United States

Abstract

We propose an augmented word embedding model that better incorporates subword information with additional parameters that characterize the semantic weights of characters in composing words. Our model can reveal some interesting patterns of long-term change in Chinese language, which provides novel evidence and methodology that enriches existing theories in evolutionary linguistics. The resulting word vectors also has decent performance in NLP-related tasks.

Demonstrative This and Hand Pointing Can Promote Socio-Centric Interpretations About Invisible Objects

Tetsuya Yasuda
Tokyo Denki University, Saitama prefecture, Japan

Kei Kashiwadate
Graduate school of TokyoDenki University, Saitama prefecture, Japan

Harumi Kobayashi
Tokyo Denki University, Saitama prefecture, Japan

Abstract

Conveying referential intention is essentially important to cooperate with others. It is reported that even adults sometimes take ego-centric perspective (i.e., perspective that is based on one's own perspective ignoring other's perspective) in comprehending others utterances. In the present study we used a modified version of Keysars paradigm of 4x4 grid, and examined whether the interpretation of the instruction by the addressee was affected by the directors use of two social-pragmatics aspects; demonstratives and gestures. Results showed if the director did not use a demonstrative and hand pointing, the addressees interpreted the object from ego-centric perspective. In contrast, if the director used a demonstrative and hand pointing, the addressees correctly interpreted the referred object showing their use of the directors perspective. The result suggested that demonstratives and hand pointing may promote the addressees interpretation based on the directors perspectives.

Can Paradigmatic Relations be Learned Implicitly?

Hyungwook Yim

Olivera Savic
The Ohio State University, Columbus, Ohio, United States

Layla Unger
Ohio State University, Columbus, Ohio, United States

Vladimir Sloutsky
The Ohio State University, Columbus, Ohio, United States

Simon Dennis
The University of Melbourne, Melbourne, VIC, Australia

Abstract

A wealth of statistical learning research has provided evidence that regularities in which items co-occur (referred to here as syntagmatic) can be learned implicitly. However, it is not known whether higher-order relations can also be learned implicitly. Here we present two experiments that investigate whether regularities, where items do not co-occur but instead share co-occurrence with each other (referred to here as paradigmatic), can be learned implicitly. In Experiment 1, we used a traditional auditory statistical learning paradigm where participants passively listened to an auditory stream containing syntagmatic and paradigmatic regularities and found evidence only of syntagmatic learning. In Experiment 2, we instructed participants to attend to items during the training session and found evidence of learning paradigmatic relations in participants who demonstrated high-level of syntagmatic learning. The results are discussed in terms of the limits of implicit learning and the role of attentional mechanisms in learning higher-order statistical regularities.

Understanding Human Memory for Where Using Experience Sampling Data

Hyungwook Yim
The University of Melbourne, Melbourne, Australia

Bree Wan Rong Ong
The University of Melbourne, Melbourne, VIC, Australia

Benjamin Stone
The University of Melbourne, Melbourne, VIC, Australia

Simon Dennis
The University of Melbourne, Melbourne, VIC, Australia

Abstract

We examined how people remember 'where' a certain event happened given the time and date of the event (i.e., memory for where). We especially focused on the kinds of information people use when trying to retrieve their memory for where. In order to increase ecological validity, we used experience sampling technology. In the task, participants watched a video that depicted a 3rd person's life for a month period, which was generated by using the 3rd person's experience sampling data. Then, participants were cued with a certain time and were asked where the person was at that time as well as how confident they were with their response. Using a conditional logit model, we found that, temporal and spatial distances were the main predictors of participants' choice. We also found that generic knowledge about one's life and repeating events (or locations) also affect participants retrieval of memory for where.

Exploring How People Use Star Rating Distributions

Jingqi Yu
Indiana University Bloomington, Bloomington, Indiana, United States

David Landy
Indiana University, Bloomington, Bloomington, Indiana, United States

Abstract

When purchasing products online, often two products may have similar mean ratings and numbers of reviews, but such apparent similarities may hide important differences. Sometimes, the distribution of star ratings is also available to decision makers in addition to these two attributes. Will the decision still be as undifferentiated as before or will the distributions of stars engender a preference towards one of the products? To answer this question, the current study manipulated the displayed variability of ratings for choices with the same average rating. The behavioral studies showed that participants exhibited distinctive choice patterns when the distribution of ratings was provided even when the average rating and total number of reviews were the same between two compared products. A utility-based cognitive model was therefore developed to identify the underlying mechanism as to why people chose the way they did.

Neural Network Modeling of Learning to Actively Learn

Lie Yu
McGill University, Montreal, Quebec, Canada

Ardavan S. Nobandegani
McGill University, Montreal, Quebec, Canada

Thomas Shultz
McGill University, Montreal, Quebec, Canada

Abstract

Humans are not mere observers, passively receiving the information provided by their environment; they deliberately engage with their environment, actively participating in the information acquisition stage to improve their learning performance. Despite being a hallmark of human cognition, the computational underpinnings of this active (or self-directed) mode of learning have remained largely unexplored. Drawing on recent advances in machine learning, we present a neural-network model simulating the process of learning how to actively learn. To our knowledge, our work is the first neural-network model of learning to actively learn. Extensive simulations demonstrate the efficacy of our model, particularly in handling high dimensional domains. Notably, our work serves as the first computational account of the recent experimental finding by MacDonald and Frank (2016) showing that prior passive learning improves subsequent active learning. Our work exemplifies how a synergistic interaction between machine learning and cognitive science helps develop effective, human-like artificial intelligence.

Lexical diversity and language development

Yawen Yu
University of California, Los Angeles, LOS ANGELES, California, United States

Dan Yurovsky
University of Chicago, Chicago, Illinois, United States

Abstract

Previous research has demonstrated a relationship between quantity of language input and childrens rate of language development: Children who hear more words learn faster. This work takes on two mutually-constraining questions: (1) How should we define quality, and (2) what is the relationship between input quality and language development? We analyzed a longitudinal corpus of interactions between 50 children and their parents using four measures of lexical diversity: Type Token Ratio (TTR), Moving Average TTR, and two more recent measuresvocd-D and MTLD. We found that only MTLD gave a prima-facie correct characterization of childrens development, and parents MTLD was correlated with childrens over development. Results of simulations showed that MTLD was distinct from the other measures in its sensitivity to both lexical diversity and word order, suggesting that quality should be defined not just by diversity of words, but also by the variability of sentence structures in which they occur.

Chinese Children Learning Higher-Order Generalizations through Free Play: The Influence of Parenting Style

Li Zhao
Department of Psychology, Beijing Forestry University, Beijing, Beijing, China

Zi L. Sim
Department of Psychology, University of California, Berkeley, Berkeley, California, United States

Mingyi Wang
Department of Psychology, Beijing Forestry University, Beijing, Beijing, China

Fei Xu
Department of Psychology, University of California, Berkeley, Berkeley, California, United States

Abstract

Rational constructivism believes children are active learners, they are able to learn causal rules through free play. Empirical evidence has demonstrated that 2- and 3-year-old children successfully identified causality and acquired higher-order generalizations using self-generated evidence during free play, and their performances were same as in didactic learning(Sim & Xu, 2017). However, if this conclusion is true across cultures? In the current study, we used the same methods and found that 2.5- to 4-year-old Chinese children could also acquire higher-order generalizations under two different learning conditions, but their performances were better in the didactic condition than that in the free play condition. One of the reasons affected childrens learning is parenting styles, but only in the free play condition: children with authoritative parents performed significantly better than children with authoritarian parents.

Key words: free play, active learning, higher-order generalization, parents cultural belief systems, parenting style

The Role of Causal Information and Perceived Knowledge in Decision-Making

Min Zheng
Stevens Institute of Technology, Hoboken, New Jersey, United States

Jessecae Marsh
Lehigh University, Bethlehem, Pennsylvania, United States

Samantha Kleinberg
Stevens Institute of Technology, Hoboken, New Jersey, United States

Abstract

Causal knowledge is key to making effective decisions, yet little is known about how we combine new causal information with what we already know. This scenario, with a mix of prior beliefs and new information is common to many settings, and is pervasive in health decisions. We specifically examine how decision-making with causal models differs in abstract decisions versus those more reminiscent of daily life, and how new information interacts with people's perceived knowledge about the decision-making domains. We found that while people can successfully use causal models to answer abstract questions, causal models can lead to worse choices in everyday decisions, especially when people believe they know a lot about the domain (Experiment 1). We then used an IOED task to determine if showing people how little they actually understand about a domain may improve the use of causal models in decision-making (Experiment 2).

Change and social distribution of figurative language

on Uruguayan female population

Roberto Aguirre. Center of Basic Research in Psychology. Uruguay

Manuel García-Ruiz. University Institute of de Lisbon. CIES-IUL. Portugal

Yliana Rodríguez. Foreign Languages Center. Uruguay

Mauricio Castillo. Center of Basic Research in Psychology. Uruguay

María Noel Macedo. Center of Basic Research in Psychology. Uruguay

Metaphors change through time in different cultures, languages and across generations. This research aimed to test the change and social distribution of some metaphors in Uruguayan Spanish. This study tested figurative expressions for the metaphors BEING IN THE OVEN IS DIFFICULTIES / HAZARDNESS, BANKING SOMETHING OR SOMEBODY IS BEARING IT and TO BE FLYING IS DOING SOMETHING WELL. On a multiple choice online questionnaire 267 Uruguayan female chose the meaning and the frequency that they believe they use previous metaphors. By using Multiple Correspondence Analysis (MCA) as a visual exploratory statistical tool, the study suggested Cultural Immersion and Metaphorical Proficiency as dimensions for explaining the social distribution of the aforementioned metaphors. But even though MCA seems to be a useful tool for understanding the metaphors' vitality, the short percentage of the variance explained by the dimensions suggests introducing additional categories for obtaining an adequate proportion of this variance.

Modulation of mood on eye movement pattern and performance in face recognition

Jeehye An
University of Hong Kong, Hong Kong, Hong Kong

Janet Hsiao
University of Hong Kong, Hong Kong, Hong Kong

Abstract

Research has suggested negative mood facilitates local attention while positive mood facilitates global attention. In face recognition, looking at the eyes has been associated with engagement of local attention as well as better recognition performance. Accordingly, negative mood changes may lead to more eyes-focused eye movements and consequently enhance recognition performance. We tested this hypothesis using mood induction. Through Eye Movement analysis with Hidden Markov Models (EMHMM), we discovered eyes-focused and nose-focused strategies. Although negative mood changes predicted increased eye movement pattern similarity to the eyes-focused strategy, it did not predict changes in recognition performance. Furthermore, most participants did not switch between eyes-focused and nose-focused strategies despite changes in mood. We conclude that mood changes lead to eye movement pattern changes that are not sufficient to modulate recognition performance as individuals may have preferred eye movement strategies impervious to transitory mood changes.

Surprise-Based Learning with Non-Solid Substances

Erin Anderson
Northwestern University, Evanston, Illinois, United States

Natasha Zeigler
Northwestern University, Evanston, Illinois, United States

Susan Hespos
Northwestern University, Evanston, Illinois, United States

Lance Rips
Northwestern University, Evanston, Illinois, United States

Abstract

Violating infants expectations about solid objects (e.g., a ball passing through a wall) leads to increased exploration and learning about the objects properties (Stahl & Feigenson, 2015). How limited is this type of learning? Infants can anticipate how non-solid substances behave and interact (Hespos et al., 2009; 2016), but the non-cohesive nature of substances means that they have less predictable shapes and boundaries. Across four trials, we presented 12- to 14-month-olds with items that looked solid or liquid. For half the trials, the items behavior was consistent with its appearance, so, for example, it looked solid and remained cohesive. For the other half, the behavior was inconsistent. Infants spent significantly more time exploring the inconsistent items, whether solid or non-solid, $F(1, 57) = 24.00$, $p = .001$, $p = .29$. These results suggest that infants preference for learning from violations might be a general mechanism responsible for new knowledge.

Explicit cues lead to reward-related enhancements in motor skill performance

Sean Anderson
University of Michigan, Ann Arbor, Michigan, United States

Taraz Lee
University of Michigan, Ann Arbor, Michigan, United States

Abstract

A large body of evidence suggests that motor sequencing skills can be trained either implicitly or explicitly. That is, participants can learn implicitly outside of conscious awareness or they can be explicitly told and/or cued to existence of repeating sequences. Although explicit learning often coincides with faster skill acquisition, the role of conscious awareness in skill learning is still debated. Some recent work has suggested that the benefits seen from explicit learning are not due to added conscious knowledge per se, but rather an increase in intrinsic motivation. Here we show that although performance-contingent monetary incentives lead to improved performance in all subjects, this effect is larger for explicitly trained subjects. This suggests that intrinsic motivation alone cannot explain the superior performance in explicitly trained tasks and that explicit knowledge can confer an additional benefit in that it can allow individuals to better contextually modulate their behavior.

Childrens Unscientific Conceptions Before and After Instruction in Space Science

Florencia Anggoro
College of the Holy Cross, Worcester, Massachusetts, United States

Benjamin Jee
Worcester State University, Worcester, Massachusetts, United States

Demitria Tsitsopoulos
College of the Holy Cross, Worcester, Massachusetts, United States

Ioli Karageorgiou
College of the Holy Cross, Worcester, Massachusetts, United States

Abstract

Research has documented childrens difficulty reconciling observations of the sky (Earth-based perspective) with scientific models of the solar system (space-based perspective) (e.g., Vosniadou & Brewer, 1994). We developed a coding rubric to capture childrens explanations before and after instruction that emphasized relational learningmapping the spatial, temporal, and causal relations inherent in the day-night cycle. We focused on several key dimensions including the perspective of the child and their causal attributions, focusing primarily on their mental model (e.g., Sun goes up/down). We coded pre- and post-test videos from 3rd graders from two experiments (N=205) using the rubric. Results suggest that (a) consistent with prior findings, children who received the instruction demonstrated fewer unscientific conceptions about Sun motion at posttest, and (b) these conceptions were more pronounced in modeling than in verbal responses. We conclude that topics that require integration between Earth- and space-based perspectives are particularly challenging for young children.

Using Eye Tracking to Examine Morphological Features and Working Memory Capacity in Agreement Processing

Erik Arnold
Brigham Young University, Provo, Utah, United States

Deryle Lonsdale
Brigham Young University, Provo, Utah, United States

Abstract

Morphosyntactic agreement refers to a head-dependent relation where similar features are shared between syntactic constituents. Several grammatical features are expressed in agreement relations through different manifestations of exponence (e.g. separative and cumulative). Whereas prior research has largely examined features in separative exponence (e.g. gender and number), this study investigates differences in the on-line processing of features in cumulative exponence. Using eye tracking, we investigated differences between second language (L2) learner processing of person, number, and tense features in Spanish verbal agreement. We also examined the effect of working memory capacity (WMC) on learners on-line processing of these same features. The results of our linear mixed effects model indicated learners had greater perturbation in processing person and tense agreement violations compared to number agreement violations. The results also revealed that learners with higher WMC demonstrated less perturbation to agreement violations of each feature type than learners with lower WMC.

A computational cognitive modeling approach to understand test-takers strategy use in drag-and-drop math questions

Burcu Arslan
Educational Testing Service, Princeton, New Jersey, United States

Yang Jiang
Educational Testing Service, Princeton, New Jersey, United States

Tao Gong
Educational Testing Service, Princeton, New Jersey, United States

Madeleine Keehner
ETS, Princeton, New Jersey, United States

Irvin Katz
Educational Testing Service, Princeton, New Jersey, United States

Abstract

Computer-based educational assessments often include questions with a drag-and-drop response. Logged data obtained from drag-and-drop responses allow us to go beyond scores, investigating the response strategies test-takers use to reach an answer. There is no previously published research on strategies used by test-takers in answering drag-and-drop questions. We tested 476 MTurk participants under five conditions where key design features of mathematics questions were manipulated. Regardless of the design manipulations, participants mostly used one of the two possible systematic response strategies. Using PRIMs cognitive architecture (Taatgen, 2013), we constructed computational cognitive models to simulate the differences between these two strategies. The models were able to capture participants reaction time patterns. Our conclusion based on the models is that most participants apply a cognitively less demanding strategy by offloading cognition on action, which is in line with the idea of strategy selection as rational metareasoning (Falk & Griffiths, 2017).

Co-thought gestures during abstract relational reasoning

Misha Ash
University of Chicago, Chicago, Illinois, United States

Kensy Cooperrider
University of Chicago, Chicago, Illinois, United States

Dedre Gentner
Northwestern University, Evanston, Illinois, United States

Susan Goldin-Meadow
University of Chicago, Chicago, Illinois, United States

Abstract

When talking about abstract relations like better and worse, people often use gestures arrayed in space to get their point across. But are these analogical gestures solely communicative props that make abstract content more accessible for listeners, or do they also reflect an integral part of reasoning? To address this question, we investigated whether people would produce analogical gestures outside of a communicative context. In a linear syllogism task, participants spontaneously gestured on 52.4% of trials on average; most participants (87.5%) gestured on at least one trial. Trials involving spatial relational terms prompted more gestures per trial than those with non-spatial terms (spatial: M = 2.87; non-spatial: M = 2.29; $F(1, 23) = 7.62$, $p = .011$). Analogical gestures thus do occur outside of communicative contexts, suggesting that they serve to aid the reasoning process itself. An in-progress follow-up study replicates and extends these findings.

Role of Variety in Cognitive Improvement From Action Video Games

Katie Bainbridge
University of California, Santa Barbara, Santa Barbara, California, United States

Richard Mayer
University of California, Santa Barbara, Goleta, California, United States

Abstract

Participants were divided into three groups. One group played Call of Duty: Black Ops Multiplayer in a variety of maps for 9 hours over 2 weeks, another played in the just one map for 9 hours over 2 weeks, and the last did not play any video games for the duration of the study. All groups took three measures of visual attention skill at the start and close of the study: Useful Field of View (UFOV), Multiple Object Tracking (MOT) and Attentional Blink (AB). Results indicate that those who played Call of Duty did not improve more than those who did not from pretest to posttest, regardless of group.

Embodied Measurements of Ideological Positioning

Brandon Batzloff
University of California Merced, Merced, California, United States

Michael Spivey
UC Merced, Merced, California, United States

Abstract

Prior studies have shown tests for scales used to describe an individuals ideological position are not replicable. We examined ideological positioning of individuals through two mouse tracking tasks. First, participants were asked to select from six ideologies, mixed with distractors, they believed described them. They were then shown ten defined traits of these ideologies. Next, participants were asked to choose between pairs of compared traits and assign them to a displayed ideology. The first task was to determine which ideologies participants were most closely associated with, while the second was used to determine how each individual defined ideologies. In this way, we were able to gain insight into how people define themselves when completing discrete tasks, such as answering political questionnaires. Results show differences in individual ideological definitions. We have begun grouping statistically similar responses. It is our hope that this data will help develop realistic scales of ideological positioning.

A multi-study neuroeducational perspective on vocabulary learning

Abstract

We aim to apply cognitive neuroscience insights to vocabulary learning practice. Towards this end, we review current educational methods in relation to important characteristics of the mental lexicon, such as similarity-coding. This shows that methods relate poorly to the mental lexicon, and that especially contrasting - explicitly distinguishing similarities - receives little attention. To remedy this, we run experiments to put these findings into practice. First, we ask participants to learn artificial vocabulary using retrieval practice multiple-choice, manipulating the orthographic and semantic similarity of distractors. The prediction is that learning will be harder but more effective depending on similarity and translation direction. Second, we test whether participants show indications of gradient descent learning when guessing in recall retrieval practice. Thirdly, we use cognitive neuroscience and large scale word learning data to model the mental lexicon. Combined, these studies potentially offer relevant scientific and societal insights, applicable to school settings.

Inferior frontal gyrus involvement during search and solution in verbal creative problem solving: A parametric fMRI study

Maxi Becker
University Medical Center Hamburg-Eppendorf, Hamburg, Hamburg, Germany

Tobias Sommer
University Medical Centre Hamburg-Eppendorf, Hamburg, Germany

Simone Khn
University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Abstract

In verbal creative problems like compound remote associates (CRAs), the solution is semantically distant and there is no predefined path to the solution. Therefore, people first search through the space of possible solutions before retrieving the correct semantic content by extending their search space. We assume that search and solution are both part of a semantic control process which involves the inferior frontal gyrus (IFG). Furthermore, the degree of the IFG involvement depends on how much the search space needs to be extended, i.e. how semantically distant the solution is. To demonstrate this, we created a modified CRA paradigm which systematically modulates the semantic distance from the first target word to the solution via priming. We show that brain areas (left inferior frontal gyrus and middle temporal gyrus) associated with semantic control are already recruited during search. In addition, we found a linear correlation between the BOLD activation of the IFG (pars orbitalis and triangularis) and the search space extension. However, this linear relationship could only be observed during and shortly before the correct solution but not during search. We discuss the role of the IFG in accessing semantically distant information during verbal creative problem solving.

Systematic ambiguity: the effect of creativity and fractal dimension on pareidolia

Antoine Bellemare
Concordia University, Montreal, Quebec, Canada

Yann Harel
Universit de Montral, Montreal, Quebec, Canada

Julien Besle
American University of Beirut, Beirut, Lebanon

Arne Dietrich
American University of Beirut, Beirut, Lebanon

Karim Jerbi
Universit de Montral, Montreal, Quebec, Canada

Abstract

Pareidolia refers to the perception of recognizable forms in noisy or ambiguous stimuli. It has mostly been studied in the context of pathologies such as schizophrenia and dementia. However, pareidolic perception occurs in general population without associated psychotic symptoms. This phenomenon is conceived as a compensatory perceptual mechanism that enables the brain to deal with ambiguous information. It has been hypothesized that pareidolia would be related to the emergence of creative ideation. In this study, we investigated the effect of fractal dimension on pareidolic perception by asking participants to perceive as many recognizable forms as possible in a set of Fractional Brownian Motion images with varying fractal dimensions. In addition, we further investigated, using questionnaires, whether creativity, openness personality trait and schizotypy are linked to pareidolic perception. Results show that creativity facilitates pareidolic perceptions and that this effect interacts significantly with the state of flow.

HOT: Higher Order Tetris, Experts' Subgoals and Activities

Jacquelyn Berry
Rensselaer Polytechnic Institute, Troy, New York, United States

Wayne Gray
Rensselaer Polytechnic Institute, Troy, New York, United States

Abstract

For Tetris, clearing 4 lines at once (a "Tetris") results in 7.5 times as many points as clearing one line four times. Getting a Tetris requires a solid block of filled cells, 9 columns wide and 4 rows high. That block leaves vacant one column. If an I-beam appears, all 4 rows can be cleared. Finalists at the Classic Tetris World Championships have an explicit subgoal structure not seen in lesser players. Among the 32 competitors, the 4 finalists are those who are most adept at maintaining or preparing the board for a Tetris by executing one of these subgoals, as needed. We present a video-based analysis which compares the proportion of time spent on each activity between those eliminated on the first tournament round and those who survive to the final round.

Masterminding in Education: Bringing cognition, emotion and motivation together in a unified mathematical framework

University of Surrey, Guildford, United Kingdom

Abstract

In this research project, a novel app-based version of the code breaking game Mastermind, Entropy Mastermind, was introduced and evaluated as a learning medium in undergraduate cognitive psychology and in primary mathematics education. In a quasi-experimental pre- and posttest design we investigated a) the role of individual differences in game play and learning, b) the effectiveness of Entropy Mastermind for giving students of different age groups experientially grounded access to the fundamental concepts of proportions and mathematical entropy, and c) effects of game play on students academic emotions, motivation and attitudes. Data analyses revealed significant associations between cognitive variables, emotional-motivational factors and game play parameters. We present computational modeling results of students search strategies and entropy intuitions within a unified framework of entropy measures, the Sharma-Mittal space. Potential applications in digitalized learning environments at the interface between mathematics and computer science will be discussed.

Movements and Visuospatial Working Memory: Examining the Role of Movement and Attention to Movement

divya bhatia
Sapienza University of Rome, Rome, Italy

Pietro Spataro
Universitas Mercatorum, Rome, Italy

Clelia Rossi-Arnaud
Sapienza University of Rome, Rome, Italy

Abstract

Previous studies have shown that, under specific conditions, pointed-to arrays can be recognized better than arrays that are only visually observed. In the present study we investigated whether this memory advantage is due to movement per se or to attention to the movement. In two experiments we modulated the amount of attention devoted to the execution of pointing movements by comparing the effects of passive and active pointing in a visuo-spatial working memory (VSWM) task. In Experiment 1, participants were instructed that their hands would be moved by the experimenter (passive pointing); in Experiment 2, participants performed active and passive pointing movements in random alternation. Results showed that passive movements benefitted VSWM only when they were alternated with active movements. This finding suggests that the key factor underlying the positive effect of pointing on VSWM is the increased attention devoted to them in the mixed pointing conditions of Experiment 2.

The Effect of Graphics on Mind Wandering in Online Video Lectures

Laura Bianchi
University of Waterloo, Waterloo, Ontario, Canada

Kristin Wilson
University of Waterloo, Waterloo, Ontario, Canada

Evan Risko
University of Waterloo, Waterloo, Ontario, Canada

Abstract

There is a rising interest in determining the most effective (i.e., the most conducive for learning) way to present online lecture information. The cognitive load model of multimedia learning suggests that learners are capacity limited. Lecture graphics that are interesting but extraneous to the content (e.g., a celebrity), have been shown to impair comprehension of the material (i.e., the seductive detail effect). The seductive detail effect likely results from a lack of cognitive resources available to maintain attention. Across 2 experiments, the use of graphics was manipulated in a psychology online video lecture. We demonstrate no differences across conditions (i.e., no images, relevant images, and seductive images) in overall comprehension and limited differences mind wandering behaviour.

Its About Time: Temporal Problem Solving With Static Drawings in Animation Design

Janet Blatter
Independent Research, Montreal, Quebec, Canada

Abstract

Drawings and diagrams have long been researched as supporting design thinking in many domains. However, real-world design that deals with, in, and about time as part of the process and outcome is less studied. How do designers in authentic practices use static drawings to think about time in different frames of reference? With a view of situated, mediated cognition as in Activity Theory, this presentation is a case study of an expert animator at the National Film Board of Canada. It focuses on the use of static drawings in finding temporal problems in the key frames of references used in creating narrative animation. The study suggests that the icons forming the basis of his drawings are used strategically, as indices to his design process, the fictive motion, and the sequence and duration of actions that must be seen at 24 frames per second.

Improving Fraction Knowledge to Open the Door to Algebra

Julie Booth Ph.D.
Temple University, Philadelphia, Pennsylvania, United States

Kristie J. Newton
Temple University, Philadelphia, Pennsylvania, United States

Christina Barbieri
University of Delaware, Newark, Delaware, United States

Laura K. Young
Temple University, Philadelphia, Pennsylvania, United States

Nicole Hallinen
Temple University, Philadelphia, Pennsylvania, United States

Abstract

Recent studies have established that students knowledge about fractions is predictive of their readiness, performance, and learning in Algebra (Booth & Newton, 2012; Booth, Newton, & Twiss-Garrity, 2013). However, it is yet unknown whether the relationship between fractions and algebra is causal; that is, would improving students' knowledge of fractions cause improvements in their ability to perform in and learn Algebra? The present study examines the impact of improving fraction computation and fraction magnitude knowledge in real world classrooms on middle school students' learning of key concepts and problem-solving techniques in Algebra. Individual differences in the impact of improved fraction knowledge will also be investigated and discussed.

Stability of Core Language Skill from Infancy to Adolescence in Typical and Atypical Development

Marc Bornstein
NICHD & IFS, Bethesda, Maryland, United States

Abstract

Individual differences are a central characteristic of child language, and a conceptual issue in language and developmental science is stability. Language was evaluated at 6 months and annually through 15 years in 5167 (50.2% girls) white, monolingual singletons: 4111 typically developing children; 435 moderate-late and 51 very preterm children; 322 children with dyslexia; 89 children with autism; and 221 children who had mild and/or moderate hearing impairment. Structural equation modelling showed both typical and atypically developing childrens language skills had medium to large average stabilities between successive waves over the span of 15 years, even accounting for child nonverbal intelligence and sociability and maternal age and education. The strong stability of child language skill from early in development across typical and at-risk groups points to a highly conserved and robust individual-differences characteristic and underscores the importance of identifying lagging language skills and promoting childrens language environment well before formal schooling.

The Effect of Multiple Repetitions on Scanning in Long-Term Memory

Ian Bright
Boston University, Boston, Massachusetts, United States

Rebecca DiDomenica
Boston University, Boston, Massachusetts, United States

Rui Cao
Boston University, Boston, Massachusetts, United States

Marc Howard
Boston University, Boston, Massachusetts, United States

Abstract

Cognitive psychologists have hypothesized that episodic recall is caused by the recovery of a gradually-changing state of spatiotemporal context. Little is known about the processes that cause successful recovery of this temporal context. Recent behavioral evidence suggests that in continuous recognition tasks, the retrieval time necessary to recover a previous context depends on the recency of the memory. Previous work has found that the non-decision time to retrieve a memory goes up with the logarithm of its recency. This suggests retrieval of temporal context proceeds via scanning along a compressed timeline but also contradicts earlier work suggesting that recency affects the drift rate of retrieval more than the non-decision time. Here we explore the effect of multiple repetitions on this counterintuitive result in continuous recognition. Our results find that while repeating items speeds up the time to access a memory, the recency effect persists out to at least five repetitions.

A Formalization of Cognitive Continuity/Discontinuity, to Settle the Darwin's-Mistake Debate

Selmer Bringsjord
RPI, Troy, New York, United States

Naveen Sundar Govindarajulu
Rensselaer Polytechnic Institute, Troy, New York, United States

Atriya Sen
RPI, Troy, New York, United States

Christina Elmore
RPI, Troy, New York, United States

Abstract

Darwins /Origin/ doesn't discuss the evolution of the human mind. He saved treatment of this topic for the subsequent /Descent of Man/, in which he advanced two claims: (C1) If the cognitive powers of nonhuman animals are discontinuous with those possessed by humans, then the human mind isnt the product of evolution by mutation and natural selection. (C2) The cognitive powers of nonhuman animals, including specifically reasoning powers, are continuous with those enjoyed by humans; continuity is established. Penn, Holyoak, and Povinelli (2008) have in /BBS/ written "Darwin's Mistake," in which they purport to refute C2 by establishing discontinuity (they don't affirm C1). Many vehemently disagree with PHP, and the debate remains intense, and unresolved. Yet, (1) the hitherto informal concept of continuity can be formalized, and (2) that formalization, applied to the debate, settles it. We provide the formalization, and with it settle the debate (in favor of PHP).

Using Graph Theory to Understand the Structure of Event Knowledge in Memory

Kevin Brown
Oregon State University, Corvallis, Oregon, United States

Nickolas Christidis
University of Western Ontario, London, Ontario, Canada

Jeffrey Elman
University of California, San Diego, California, United States

Ken McRae
University of Western Ontario, London, Ontario, Canada

Abstract

There are several competing theories regarding how event knowledge is represented in the mind, ranging from a strictly temporally ordered list of activities to sets of connected scenes which may themselves consist of ordered activities. We employed a network science approach to provide data-driven insight into event structure. We converted sets of human generated activity sequences, in which roughly 25 participants list up to 12 activities for 81 different events (making a sandwich, cleaning the house, taking money out of an ATM, etc.), into directed, weighted networks. Analyses of the event networks revealed a complex and varied temporal structure to events. In addition, we were able to identify scenes within events, and use graph theory to understand activity centrality, popularity, and influence, as well as the coupling between these activity characteristics. In the aggregate, we find that network science makes multiple data-driven, empirically testable predictions about event structure.

Who are you talking to like that? Exploring adults' ability to discriminate child- and adult-directed speech across languages

John Bunce
University of Manitoba , Winnipeg, Manitoba, Canada

Melanie Soderstrom
University of Manitoba, Winnipeg, Manitoba, Canada

Md Momin Al Aziz
University of Manitoba, Winnipeg, Manitoba, Canada

Marisa Casillas
Max Planck Institute for Psycholinguistics, Nijmegen, Netherlands

Abstract

Child-directed speech (CDS) shows similar characteristics across many languages, but is known to vary across cultural and demographic groups (Lieven, 1994). Is CDS consistently discriminable from adult-directed speech (ADS) despite these differences? Perhaps: adults listening to scripted female CDS can discriminate ADS-vs-CDS in a language they dont speak (Bryant et al., 2012). We build on this finding by asking North American English speakers to classify utterances from the natural language input of 10 Tseltal Mayan children as ADS or CDS (n = 1836 utterances). Binomial mixed-effects regressions of accuracy show that listeners are more accurate on utterances from females (mFemale = .81, mMale = .67) and adults (mAdult = .82, mChild = .72), with a larger gender effect for child speakers (m: Girl-Boy = 0.31, Woman-Man = 0.09). This suggests that (a) ADS-CDS discrimination of natural speech in an unrelated, non-familiar language is reliable (mAll = 0.78) and also (b) modulated by speaker type.

The Effects of Video Interviews on Perceptions of Applicant Quality

Devin Burns
Missouri University of Science & Technology, Rolla, Missouri, United States

Denise Baker
Missouri University of Science & Technology, Rolla, Missouri, United States

Clair Kueny
Missouri University of Science & Technology, Rolla, Missouri, United States

Matthew Jordan
Missouri University of Science & Technology, Rolla, Missouri, United States

Abstract

Previous research has shown that job candidates are rated significantly higher if evaluators are allowed to listen to their pitches rather than just reading the transcript (Schroeder & Epley, 2015). That research did not find any additional benefit from seeing the candidate on video, but did not examine whether watching a video interview was different from watching an interview in-person. Our experiment had 50 participants watch a mock interview in-person while 50 other participants watched the same interviews ostensibly through a live video feed in another room. Those who watched through video rated the job applicant significantly lower on all measured dimensions including agency, hireability, and intellect. These findings indicate that job applicants who are interviewed through a video-conference service or whose interviews are recorded and watched later are at a significant disadvantage to those who can be observed live. Potential causes and ameliorations of these effects are discussed.

Task Characteristics and Individual Differences in Judgments of Relative Direction

Heather Burte
University of Texas at Arlington, Arlington, Texas, United States

Abstract

Judgments of relative direction (JRD) have been frequently used to understand peoples mental representation of outdoor and indoor spaces. In JRD experiments, experimenters need to identify a signal within the trial-by-trial and participant-by-participant variability. However, it is not well understood how characteristics of the task and differences between individuals contributes to performance variability. In this paper, I investigated task characteristics (i.e., reference frames used in instructions, orienting and target headings, and distances between headings) and individual differences (i.e., gender, sense-of-direction, familiarity, and strategy use) to provide insights into the factors that influence JRD accuracy and variability. Using the findings of this study, I make recommendations for best-practices in JRD methods and analyses.

The Role of Task Characteristics and Individual Differences in Pointing to Unseen Locations

Heather Burte
University of Texas at Arlington, Arlington, Texas, United States

Abstract

Pointing tasks have been used for decades to investigate peoples understanding of environmental-scale spaces. Most of this research has used the variability of pointing estimates to provide insights into peoples cognitive maps. In pointing experiments, experimenters need to identify a signal within the trial-by-trial and participant-by-participant variability. However, it is not well understood how characteristics of the task and differences between individuals contribute to pointing variability. In this paper, I investigated characteristics of pointing tasks and individual differences (i.e., gender, sense-of-direction, familiarity, and strategy use) to provide insights into the factors that influence pointing accuracy and its variability. Using the findings of this study, I make recommendations for best-practices in pointing task methods and analyses.

Motivated Reasoning in Causally Ambiguous Explore-Exploit Situations

Zachary Caddick
University of Pittsburgh, Pittsburgh, Pennsylvania, United States

Benjamin Rottman
University of Pittsburgh, Pittsburgh, Pennsylvania, United States

Abstract

Two studies investigated how political attitudes affect causal learning. Participants were tasked with testing economic policies to maximize the economic output of an imaginary country. Based on their political attitudes, participants were either strongly in favor or strongly against the policies (Study 1), or could also have neutral attitudes (Study 2). Some policies had fairly clear positive or negative effects. But some were more ambiguous; they initially had positive effects but eventually had negative effects on the economy, or vice versa. After testing the policies, participants falsely believed that the policies that fit with their political attitudes were more effective, and this bias was exacerbated for the policies that had different short vs. long-term effects. This research shows the power of motivated reasoning and provides a well-controlled method to study the effects of motivated reasoning on causal learning in explore-exploit situations.

A Dynamic Neural Field Model of the McGurk Effect and Incongruous Audiovisual Speech Stimuli

Ryan Cannistraci
University of Tennessee, Knoxville, Knoxville, Tennessee, United States

Jessica Hay
University of Tennessee, Knoxville, Knoxville, Tennessee, United States

Aaron Buss
University of Tennessee, Knoxville, Knoxville, Tennessee, United States

Abstract

Our Dynamic Neural Field (DNF) model aims to simulate audiovisual integration in speech perception, including the well-known McGurk effect (McGurk & MacDonald, 1976). The classic McGurk effect is characterized by a fusion effect, whereby incongruent audio and visual stimuli are fused into a single percept, however other interesting audiovisual effects are present in the extant literature. Our DNF model uses the same architecture and parameters across stimulus combinations to simulate a host of audiovisual illusory effects as well as audiovisually congruent, auditory-only, and visual-only controls. Our simulation results replicate rates of visual-dominant percepts, audiovisual fusion percepts, auditory-dominant percepts, and auditory dichotic fusion found in the extant literature, and illustrate how a complex pattern of responses across different stimuli configurations can arise from common neural dynamics involved in binding information across sensory modalities. We are currently exploring how hemodynamic response predictions generated through our neural simulations relate to real-time behavior.

Origins of cross-domain asymmetries

Daniel Casasanto
Cornell University, Ithaca, New York, United States

Yamur Deniz Ksa
University of Chicago, Chicago, Illinois, United States

Abstract

Why do people use space to talk about time, and to think about time, more than vice versa? On one proposal, this space-time asymmetry arises from the greater perceptual availability of space. Alternatively, a space-time asymmetry in language could give rise to the space-time asymmetry in thought during early language acquisition. If this language-first view is correct, then parents should use space-time words (e.g., long) more often in their spatial senses than in their temporal senses, imparting to children the primacy of the spatial senses. More generally, childrens space-time word use should reflect the statistics of parental input. Results of a corpus analysis contradict both predictions: English speaking adults used polysemous words more often in their temporal senses than in their spatial senses, whereas young children showed the opposite pattern, in the same conversations. Asymmetries between space and time appear to precede and guide the acquisition of spatio-temporal language.

Eye-tracking as a Measure of Table Tennis Expert-Novice Differences in Theory of Mind

Ting-Hsuan Chang
National Cheng Kung University, Tainan, Taiwan

Fu-Zen Shaw
National Cheng Kung University, Tainan, Taiwan

Sheng-Fu Liang
National Cheng Kung University, Tainan, Taiwan

Hung-Ta Chiu
National Cheng Kung University, Tainan, Taiwan

Jon-Fan Hu
National Cheng Kung University, Tainan City, Taiwan

Wei-En Chang
National Cheng Kung University, Tainan, Taiwan

Abstract

Theory of Mind (ToM) refers to the ability of individuals to understand beliefs, desires, and emotions of others. Our study is based on the expert-novice paradigm and aims to investigate the operations of ToM of table tennis novices and experts by the patterns of eye movement. Stimuli integrated cognitive and affective ToM dimensions analogical to the table tennis situations and recorded response by eye-tracking technique. Reaction time, accuracy and eye movement data were analysis indexes. Study results revealed that experts could predict the shot actions and emotional states of opponents more quickly and accurately than novices, also there were differences in eye trajectory traces. The findings clearly show that eye-tracking technique can be used to illustrate table tennis expert-novice differences in ToM and provide suggestions for the development of table tennis training programs in use of eye tracker facilities.

The effect of word-by-word presentation on reading of Chinese texts by native Chinese readers and learners of Chinese as a second language

Jenn-Yeu Chen
National Taiwan Normal University, Taipei, Taiwan

Yalin Chuang
Nanya Institute of Technology, Taoyuan, Taiwan

Abstract

There are no spaces between words in Chinese texts and this can present a challenge in reading for learners of Chinese as a second/foreign language (CSL) and native Chinese alike. We designed a self-paced reading computer platform on which individual words were shown or highlighted successively as participants pressed the spacebar to read a text without word spaces. CSL learners could read faster in this way than the traditional way where the entirety of the unspaced text appeared as a whole. Native Chinese readers did not show such a beneficiary effect. The results support the Processing Cost Hypothesis which states that word segmentation when reading unspaced texts consumes processing resources and therefore saving the resources by providing segmentation cues could benefit readers only when processing resources are overtaxed under certain circumstances, e.g., reading difficult texts, under time pressure, for beginner readers, and for foreign learners.

Providing Stroke Sequence of Chinese Characters Facilitates Handwriting Learning in Children with Developmental Coordination Disorder

Rong-Ju Cherng
National Cheng Kung University, Tainan, Taiwan

Yi-Wen Liao
National Cheng Kung University, Tainan, Taiwan

Jenn-Yeu Chen
National Taiwan Normal University, Taipei, Taiwan

Abstract

The study investigated whether providing instruction on the stroke sequence would facilitate the learning of writing Chinese characters in children with developmental coordination disorder (DCD) and typically developing (TD) children. The children wrote six characters, three with stroke sequence instruction and three without. Each character was repeated 40 times. Trajectory, speed, on-paper time, in-air time, and number of changes in velocity direction per stroke (NCV) were measured with Wacom Intuos 5 digitizing writing tablet. The results showed a significant group effect, time (practice) effect and instruction effect but no interaction effects. Both groups of children showed a similar trend of improvement over practice with decreasing trajectory, increasing speed, decreasing on-paper time and in-air time. With stroke sequence instruction, both groups of children learned at a similar rate on most of the writing parameters. Instruction on stroke sequences helped the character writing of both the DCD children and the TD children.

Exploring Aha! moments during science learning

Christine Chesebrough
Drexel University, Philadelphia, Pennsylvania, United States

Jennifer Wiley
University of Illinois Chicago, Chicago, Illinois, United States

Abstract

The Aha! experience has mainly been studied in the context of insightful problem solving, but less work has investigated Aha! experiences that can occur during learning. In these studies, participants were asked to self-report Aha! moments when learning about principles in Biology, such as symbiosis or mimicry, from sets of three divergent examples. In the problem-oriented condition, participants saw the examples and were asked to generate their common principle. In the direct instruction condition, participants were told the principle directly. Participants were significantly more likely to report Aha! moments in the problem-oriented condition. Although having an Aha! experience did not always lead to better learning, the likelihood of having an Aha! moment was positively correlated with several student characteristics, particularly in the problem-oriented condition. These studies offer another perspective on the potential benefits of learning from invention activities.

Modeling the Costly Rejection of Wrongdoers by Children using a Bayesian Approach

Theodore Cheung
University of Toronto, Toronto, Ontario, Canada

Rachel Eng
University of Toronto, Toronto, Ontario, Canada

Daphna Buchsbaum
University of Toronto, Toronto, Ontario, Canada

Abstract

In previous work, young children avoided associating with a wrongdoer, despite incurring a personal cost. Such aversion to wrongdoers, arguably a reflection of moral development, weakens when the cost becomes very large (Tasimi & Wynn, 2016). We model this moral decision-making process using the nave utility calculus (Jara-Ettinger et al., 2016), assuming utility maximization amidst uncertainty using Bayesian framework. The cost is defined as the number of stickers forgone by choosing a nice persons smaller offer over a mean persons larger one, following the ratios of 1:2, 1:4, 1:8, and 1:16. Our model aims to explain previous findings, and test predictions for new ratios. Compared to a baseline condition where no background information is available, children are predicted to choose the nice person when the cost is low, but reverse their preference when the cost becomes increasingly high, which would suggest a utility account for moral decision making.

Math ability varies independently of number estimation in the Tsiman

Samuel Cheyette
UC Berkeley, Berkeley, California, United States

Benjamin Pitt
UC Berkeley, Berkeley, California, United States

Steven Piantadosi
UC Berkeley, Berkeley, California, United States

Edward Gibson
Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Abstract

How do people reason about mathematical concepts like addition and subtraction? According to one proposal, mathematical thinking is supported in part by the approximate number system (ANS), a primitive cognitive system for estimating the numerosity of a set, without counting. Here we tested this proposal in the Tsiman, a culture of farmer-foragers in the Bolivian Amazon. Compared to industrialized societies like the US, the Tsiman have high variability in their level of education and number knowledge. In a large sample of Tsiman adults, math ability was positively correlated with ANS performance, consistent with previous findings. However, this correlation disappeared when controlling for participants education, and when controlling for their ability to sustain attention. These findings challenge the claim that the ANS supports math ability. Rather, performance on ANS tasks and math tasks may both be shaped by non-numerical abilities practiced (or selected for) in educational settings.

L2 learners' phonemic sensitivity: MMN & L2 proficiency

Jeongwha Cho

Kyung Hee University, Youngin, Korea, Republic of

Abstract

This study examined the acquisition of Korean stop sounds /t/(), /t/() and /th/() by Chinese learners of Korean using ERP focusing on the role of L2 proficiency. A total of 28 learners (16 advanced and 11 intermediate) and 18 native controls participated in the experiment with four conditions: (i) standard /ta/ vs. deviant /tha/, (ii) standard /ta/ vs. deviant /t/, (iii) standard /tha/ vs. deviant /ta/, and (iv) standard /ta/ vs. deviant /ta/. The results of the AX discrimination task found no significant differences between groups showing high accuracy rates from 73% to 84%. However, their brain responses were different: P3 was found only for the intermediate group in condition (iii) although MMN was elicited in both groups in the other three conditions. The results indicate that learners sensitivity to the differences of stop sounds develops as their general proficiency improves. Still, their sensitivity is weaker than native speakers.

Comparing the social judgements between American and Taiwanese cultures

Yun Chuang
National Cheng Kung University, Tainan, Taiwan

Jon-Fan Hu
National Cheng Kung University, Tainan, Taiwan

Abstract

While observing others in the society, people make explanations and judgements about others' behaviors. However, there should be cultural differences in affecting behavior judgments. The aim of the present study is to examine whether there are cognitive or emotional differences between Eastern and Western cultures while judging other peoples behaviors. Vignettes stimuli and the questions developed by Knutson et al. (2010) were used to measure how Taiwanese participants think and react while making behavior judgements. Factor analysis is conducted to compare the results with the original study completed in the US. The results revealed that for the Taiwanese participants, emotional aversion was more related to the norm violation, while for the American participants, according to the original study, aversion was more related to the social affect. The results of this comparison have demonstrated cultural differences between Taiwan and the US in how aversion could be evoked by observing others behaviors.

Go big and go grounded: Categorical structure emerges spontaneously from the latent structure of sensorimotor experience

Louise Connell

James Brand
University of Canterbury, Christchurch, New Zealand

James Carney
Brunel University, London, United Kingdom

Marc Brysbaert
Ghent University, Ghent, Belgium

Dermot Lynott
Lancaster University, Lancaster, United Kingdom

Abstract

Many theories of semantic memory assume that categories spontaneously emerge from commonalities in the way we perceive and interact with the world around us. However, efforts to test this assumption computationally have been hampered by use of abstracted features without clear sensorimotor grounding and over-reliance on small samples of concepts from a limited number of categories. Taking a radically different approach, we examined whether categorical structure emerges spontaneously from the latent structure of sensorimotor experience by creating a fully-grounded multidimensional sensorimotor space at the scale of a full-size human conceptual system (i.e., 11 sensorimotor dimensions x 40,000 concepts). We found evidence for (a) a high-level separation of abstract and concrete categories (which was not enhanced by the inclusion of affective information); (b) a hierarchical structure of concrete concepts that separated categories commonly impaired in double dissociations, such as fruit/vegetables, animals, tools, and musical instruments; and (c) a flatter hierarchy of abstract concepts that separated categories such as negative emotions, units of time, social relationships, and political systems. These findings demonstrate that grounded sensorimotor information is fundamental to the representation of all conceptual knowledge.

Metacognitive Modeling; using cognitive modeling to clarify philosophical metacognitive concepts

Brendan Conway-Smith
Carleton University, Ottawa, Ontario, Canada

Robert West
Institute of Cognitive Science, Carleton University, Ottawa, Ontario, Canada

Abstract

Metacognitive research is integral to understanding cognition, but a problem persists metacognition remains poorly defined and its basic terminology contested. To address this problem, we propose a new philosophical method for understanding metacognition in a bottom up, computational way. We follow John Andersons principle that complex problems become systematic when analyzed within a cognitive model. Researchers agree that metacognition is cognition acting upon itself. Accepting this, we first define the fundamental units of cognition and then define how these units act upon themselves. We ground this within human cognition by using the Standard Model of Cognition (Laird et at. 2017, also known as the Common Model). This model defines the mechanisms common to all computational architectures modeling human cognition. Our model is then compared to metacognitive theories within psychology, philosophy, and neuroscience. This method clarifies metacognition by grounding it both within a computational cognitive architecture and present research literature.

Audio-Visual Integration: Point Light Gestures Influence Listeners Behavior

Susan Cook
University of Iowa, Iowa City, Iowa, United States

Abstract

Listeners are influenced by speakers hand gestures. However, it is not clear what processes support gesture processing. We investigated listeners behavior after observing speech with videotaped gestures or with point light gesture trajectories in the Tower of Hanoi task. Listeners were influenced by the synchrony of the visual and auditory information but not the nature of the information both videotaped and point light gestures reliably influenced behavior. Thus, visual information that is not perceived as produced by the speaker nonetheless reliably influences listeners behavior, so long as information is synchronized across modalities. Thus, observers do not appear to rely on functional or biological links between speech and hand gesture but rather on more general processes of multimodal integration. The principles underlying integration of auditory language with visual information from hand gestures appear to different from those underlying integration of auditory language and visual speech.

Scrape, rub, and roll: causal inference in the perception of sustained contact sounds

Maddie Cusimano
Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Josh McDermott
Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Abstract

We experience our soundscape in terms of physical events; for instance, a friend sweeping up after a plate crashed on the floor. The underlying perceptual inferences are typically ill-posed: without constraints, there are infinite possible causes of the observed sound. Thus, a core task for cognitive science is specifying the variables we perceive along with the constraints that allow them to be estimated. We identified sustained contact sounds (e.g., hands rubbing together, scraping a pan) as a rich domain with which to explore perceptual constraints. We developed a simple physics-based sound-synthesis model that can generate a diverse set of realistic scraping sounds. We find that listeners perceive the generative physical variables from scraping sounds, including velocity, motion trajectory, and surface roughness. Further experiments and acoustic analyses will address whether perception is constrained by a holistic generative model of sound or by invariant features that specify each perceived variable.

From wugged to wug: Reverse generalisation of stems from novel past tense verbs

Christine Cuskley
Newcastle University, Newcastle, United Kingdom

Stella Frank
University of Edinburgh, Edinburgh, United Kingdom

Kenny Smith
University of Edinburgh, Edinburgh, United Kingdom

Abstract

When native and non-native English speakers inflect novel verb forms for the past tense, non-natives are more likely to produce irregular (non -ed) forms than natives (Cuskley et al., 2015). We test whether participants can reverse-engineer the correct present tense stem from regular and irregular past tense forms of novel verbs. All participants are better able to identify the stem of regularly inflected forms than irregular forms, but we find no difference between native and non-native speakers. Phonological similarity to existing irregulars interferes with recognition of regularly inflected non-verbs (e.g., proximity of sleened to sling/slung makes it more difficult than drocked). While non-natives are more likely to produce irregular past tense forms, they are not better than native speakers at interpreting them. Non-native over-production of irregulars may reflect statistical patterns in their more limited input, but these factors do not seem to affect the process of inferring stems.

Pupillometry as a Measure of Effort Exertion in Cognitive Control Tasks

Kevin da Silva-Castanheira
McGill University, Montreal, Quebec, Canada

Myles LoParco
McGill University, Montreal, Quebec, Canada

A. Ross Otto
McGill University, Montreal, Quebec, Canada

Abstract

Despite recent interest in pupillometry as a psychophysiological measure, it remains unclear what construct the physiological measure is assessing in cognitive control tasks: task load or mental exertion. This debate is of particular interest as cognitive effort remains an elusive construct partly due to the difficulty in empirically quantifying mental exertion. The current research aims to differentiate these disparate accounts by leveraging rewards as motivation for effort exertion. Using an individual differences approach, a sample of 80 undergraduate students performed a cognitive control taskTask switching. Critically, monetary incentives were used to motivate participants to exercise cognitive control, and found to improve overall performance. Pupillary responses were found to increase in response to trials requiring more cognitive control, and relate to performance improvements in the rewarded conditions. The present findings provide some support for the effort account, and suggest that pupillometry may be a viable index of cognitive effort.

Contextual Effects in Value-Based Decision Making: A Resource-Rational Mechanistic Account

Kevin da Silva-Castanheira
McGill University, Montreal, Quebec, Canada

Ardavan S. Nobandegani
McGill University, Montreal, Quebec, Canada

Thomas Shultz
McGill University, Montreal, Quebec, Canada

A. Ross Otto
McGill University, Montreal, Quebec, Canada

Abstract

A wealth of experimental evidence shows that, contrary to normative models of choice, peoples preferences are markedly swayed by the context in which options are presented. Particularly, there exist a well-known triad of effects, dubbed the contextual effects, which consistently show that preferences change depending on the availability of other options: the attraction effect, the similarity effect, and the compromise effect. In this work, we present the first resource-rational, process-level account of these three contextual effects by extending Nobandegani et al.'s (2018) sample-based expected utility model to the realm of multi-attribute value-based decision-making. Importantly, our work is consisted with two empirically well-supported findings: (1) People tend to draw only a few samples in their probabilistic judgment and decision-making, and (2) People tend to overestimate the probability of extreme events in their judgment.

Towards building AI Life-coach agent for honing creativity

Amarnath Dasaka
IIIT hyderabad, Hyderabad, Telangana, India

Preeti S
Georgia Tech, Atlanta, Georgia, United States

Bapiraju Surampudi
IIIT hyderabad, Hyderabad, Telangana, India

Abstract

World Economic Forum report predicts that 35% of the skills needed to navigate the world of work will have changed by 2020. By 2020, creativity will be the third most sought-after skill, behind complex problem solving and critical thinking. Creative skills are future-proof, in that they cannot be Automated. Art and creativity are essentially what makes us human and this is being backed up by research. (Elaine Rumbol) How do you hone creativity? This seems to be an open question. The present study aims to build an architecture for AI agent(life-coach) that incorporates the latest research on creativity and guides the user based on the users personality traits, context, emotions, mood and cognitive load. The agent will detect the users emotional valance & Motivational Intensity which in turn will influence the attention focus (Broaden the mind (for free floating ideas) or result in narrow focus (linear, step by step goal attainment)). Toward this aim, we plan to run a series of tests for gathering user feedback. Design of the tests are underway.

The Jig-saw of Part-task Training in Dynamic Task Environments

Ropafadzo Denga
Rensselaer Polytechnic Institute, Troy, New York, United States

Wayne Gray
Rensselaer Polytechnic Institute, Troy, New York, United States

Abstract

Part-task training is a technique which involves separating the target task into parts and presenting them during training. This approach has been used to train users to perform optimally in dynamic task environments. The present study investigated the effects of fractionation, a part-task training approach, versus whole-task training to improve performance in the video game Tetris by focusing on an important sub-task element of the game. Seventy-eight young adults were trained on Tetris with one of three training regimens: 1) Part-task training with feedback, 2) Part-task training with no feedback, and 3) Whole-task training in which participants practiced the whole game to obtain the highest overall score. Results show that baseline performance influences training gains and feedback may not be helpful for learning. Training gains from the different training regimens show that tasks with highly interdependent components may benefit most from whole-task training.

Linguistic descriptions of action influence object perception: The role of action readiness

Victoria DiRubba
SUNY at Purchase, Purchase, New York, United States

Tommy Anderson
SUNY at Purchase, Purchase, New York, United States

Alexia Toskos Dils
SUNY at Purchase, Purchase, New York, United States

Abstract

Does hearing a story about performing an action activate corresponding motor representations? If so, can linguistically-activated motor representations affect our visual experience of the world? The present study tested whether hearing a story about performing power or precision grasps would cause people to perceive an ambiguous object in a grasp-congruent manner. Participants listened to a story in which they tossed water balloons either (1) without touching their knots (power grasp condition) or (2) by only touching their knots (precision grasp condition). Afterward, participants interpreted an object that could either be seen as an apple (power grasp) or cherry (precision grasp). To further manipulate participants availability for subsequent action in the story, participants either (1) had just grasped, (2) prepared to grasp, or (3) had repeatedly grasped the water balloons before the ambiguous image appeared. People perceived the object in a grasp-congruent manner only when their hands were available for action.

Modeling Causal Learning with the Linear Ballistic Accumulator

Yuhui Du
Ohio State University, Columbus, Ohio, United States

Nitisha Desai
Ohio State University, Columbus, Ohio, United States

Renlai Zhou
Nanjing University, Nanjing, Jiangsu, China

Abstract

Learning causal relationships is critical in our daily lives. To learn these causal relationships, one strategy we may use is the positive testing strategy (PTS), in which we attempt to confirm a hypothesis about the causal relationship. Also, we may use the expected information gain (EIG) strategy to distinguish between multiple hypotheses. Here we use an experimental paradigm in which subjects decide which of two causal patterns underlies a four-node causal system (Coenen, Rehder, & Gureckis, 2015) and fit the Linear Ballistic Accumulator (LBA) model to our data to investigate the precise mechanisms of different age groups using these strategies. We find that children and the elderly use PTS more than other groups. Yet, comparing drift rate and relative threshold parameters, we find no evidence for biases in strategy selection across age groups, but find that the elderly are more cautious when choosing a strategy.

Lying in public: Revealing the microstructure of real-time false responding through action dynamics

Nicholas D. Duran
Arizona State University, Glendale, Arizona, United States

Denis O'Hora
National University of Ireland Galway, Galway, Ireland

Sam Redfern
National University of Ireland Galway, Galway, Ireland

Arkady Zgonnikov
University of Aizu, Aizuwakamatsu, Fukushima, Japan

Abstract

It is commonly agreed that, in most scenarios, deception involves cognitive demands. Prime amongst these demands is competition between a default true response and an alternative false response. What is less understood are issues surrounding the mechanistic underpinnings of how and when this competition enacts its influence during responding. In previous work (Duran, Dale, & McNamara, 2011), we have used an action dynamics paradigm to capture millisecond-timing information in how people use their mouse movements to respond yes or no to autobiographical information. In the current study, we employed a similar paradigm to collect response data from hundreds of anonymous participants, who freely used an interactive touchscreen exhibit at a public science museum exhibit, aiming to replicate and extend our previous findings. As expected, during false responding, the truth appears to be initially activated and dissipates continuously over the course of the response.

The dark side of conceptual metaphor

Frank Durgin
Swarthmore college , Swarthmore, Pennsylvania, United States

Jessica Lewis
Swarthmore College, Swarthmore, Pennsylvania, United States

Abstract

Zhu (2017) used the implicit association test (IAT) to assess metaphorical alignment between concepts such as black and white and good and evil. Here we asked whether self-identified Black people have similar metaphoric alignments as those who identify as White. In an initial experiment, we tested pairwise metaphoric associations between black and white, dirty and clean, and good and evil. Measured strength of the 3 alignment pairings for these 3 sets of concepts was statistically the same among Black participants as that measured by Zhu for white participants. In a follow-up experiment, we compared self-identified Black and White participants IAT-scores for race (i.e., faces) and for color (i.e., chess pieces) IATs. For White participants, mean strength of white-positive alignment was identical for race and color; Black participants showed only slight white-positive bias for race IATs, and an intermediate level of white-positive bias for color IATs.

The role of affect in sentence perception

Veena Dwivedi
Brock University, ST CATHARINES, Ontario, Canada

Abstract

The role of affect and sentence processing is an understudied topic. In an event-related potential (ERP) language experiment, we investigated modulation of the P300 ERP component by dispositional affect. Using our previous ERP paradigm, we employed a 3x2 design where 32 participants read sentences presented in 1- and 2-word chunks (Berent et al., 2005; Patson & Warren, 2010). Sentences started with subject nouns that were either universally quantified or not, and continued with a direct object which was either indefinite, definite singular, or plural e.g., (i) Every kid climbed a tree/the tree/the trees vs. (ii) The kid climbed a tree/the tree/the trees. Number judgments were required at tree(s), which was always presented alone (and never final). Reduced P300 amplitudes were observed for the plural condition indicating interference; furthermore, low positive affect individuals showed responses sensitive to local high probability features associated with the control singular condition.

Do Humans Look Where Deep Convolutional Neural Networks "Attend"?

Anonymous CogSci submission

Abstract

Convolutional Neural Networks (CNNs) have recently begun to exhibit human level performance on some visual perception tasks. Performance remains relatively poor on vision tasks like object detection. We hypothesized that this gap is largely due to the fact that humans exhibit selective attention, while most object detection CNNs have no corresponding mechanism. We investigated some well-known attention mechanisms in the deep learning literature, identifying their weaknesses and leading us to propose a novel CNN approach to object detection: the Densely Connected Attention Model. We then measured human spatial attention, in the form of eye tracking data, during the performance of an analogous object detection task. By comparing the learned representations produced by various CNNs with that exhibited by human viewers, we identified some relative strengths and weaknesses of the examined attention mechanisms. The resulting comparisons provide insights into the relationship between CNN object detection systems and the human visual system.

Investigating bidirectionality of associations in young infants as an approach to the symbolic system

Milad Ekramnia
Neurospin, Gif sur Yvette, il de france, France

Ghislaine Dehaene
neurospin, Gif Sur Yvette, France

Abstract

Symbolic associations in human children and adults are based on forming equivalence classes which include three main relations between the tokens. 1) A = A (Reflexivity), if 2) A –¿ B and B –¿ C then A –¿ C (Transitivity) and 3) if A –¿ B then B –¿ A or Symmetry (1). Extensive studies on non-human primates have demonstrated success in Reflexivity and Transitivity in several species but a consistent failure in Symmetry in any given association. Comprehension of symmetry of an association can be a key contribution to linking abstract words to their corresponding tokens and later on in coupling writing forms of words to their spoken form (2). However to our knowledge it hasnt been investigated whether infants are capable of spontaneously reversing the direction of an association to any extent. In two EEG studies we investigated if 4.5-month-old infants are capable of applying symmetry in the context of word-learning.

In the first study we trained 2 groups of 25 infants, to two pairs of word-categories (bird or vehicle). At each trial infants were presented with a word and an image. The critical consideration was to introduce a 1 s of SOA between the two stimuli. In one group infants were trained on words always preceding the images (Word-Image group) and in the other group infants were trained on the opposite direction (Image-Word group). In the test blocks 70% of trials were as in the training and the other 30% were either with the incongruent trials in the original direction or the congruent and incongruent trials in the reversed direction. We observed significant cluster of electrodes, mainly in the right temporal, in both the trained and reversed directions while contrasting the congruent and incongruent conditions, with the word-image group showing a stronger effect.

In a 2nd experiment, designed as a comparative study between infants, adult humans and adult macaques, we sought to train each participant on 4 pairs of word-images, 2 pairs following a word-image direction and the other 2 an image-word direction, with a 1s SOA between the two stimuli similar to experiment 1. In this experiment the infants attended the training phase at home prior to the experiment through three YouTube videos on three consecutive days and on the test day, they were being tested either on the trained or the reversed direction of each single pair in a similar ERP design as in study 1. The results in a group of 54 4.5-month-old infants follow the pattern of results in study 1 that infants show an early as well as a late surprise effect relative to the onset of the second stimulus of the trial, while contrasting the incongruent versus congruent trials in both directions. Furthermore we utilized frequency tagging in both studies as an extra measure to compare the conditions of interest. The overall results suggest that contrary to the consistent failure of non-human animals, infants can readily learn an association in a bi-directional manner, which can be suggestive of an early access to their symbolic system.

Aurlie CAMPAGNE
University Grenoble Alpes, Laboratory in Psychology and Neurocognition, CNRS, 38000 Grenoble, France

Abstract

Research on emotion suggests that the attentional preference observed toward the negative stimuli in young adults tends to disappear in normal aging and, sometimes, to shifts towards a preference for positive stimuli. However, this age-related effect called the positivity effect may be modulated by several factors, such as the arousal level of stimuli. The present study investigated visual exploration of natural scenes of different emotional valence in three age groups (young, middle-aged and older adults) depending on arousal level of scenes using an eye-tracking paradigm. Participants visualized pairs of emotional scenes either in low or high arousal condition. In contrast with the literature, the preliminary results revealed a reduction in prevalence of negative stimuli relative to other ones in older adults regardless of the arousal conditions. No difference between young adults and middle aged adults was observed.

Domestic dog understanding of containment and occlusion events

Julia Espinosa
University of Toronto, Toronto, Ontario, Canada

Daphna Buchsbaum
University of Toronto, Toronto, Ontario, Canada

Abstract

Intuitive physical concepts help humans navigate the world. One such concept, object containment, has been studied extensively in infants and nonhuman primates. Evidence indicates objects hidden inside of containers are more difficult to find than covered or occluded objects, possibly due to the prerequisite understanding that containers are hollow. Dogs encounter containers in daily life, and canine studies commonly require subjects to locate hidden treats. The present research provides the first test of the hypothesis that dogs, like primates, find it harder to make inferences about containment compared to other hiding events. To address this hypothesis, across 24 trials dogs (N=90) searched between 2 possible locations, one of which concealed a treat. They watched 3 different methods of hiding: i) inside containers, ii) behind containers, and iii) under containers. As predicted, dogs were less likely to locate treats inside containers. Results will be discussed in a comparative context.

Beyond divergent thinking: Measuring creative process and achievement in young children

Natalie Evans
Temple University, Philadelphia, Pennsylvania, United States

Abstract

Creativity is an elusive construct that is difficult to measure in children, and divergent thinking tasks have been overused and may be unreliable as measures of creativity (Baer, 2011). This study examines creative process and achievement in children using a problem-solving task (Daehler & Chen, 1993). Children (N=98) ages 4 to 6 tried removing a ball from a jar using common objects. Success with retrieving the ball was a measure of creative achievement. Creative process was assessed by coding creative behaviors such as object exploration, combinations, manipulation, and ball retrieval attempts. Results suggest differences in creative behaviors between successful and unsuccessful children. Successful participants created more unique object combinations ($p=0.02$), spent more time manipulating ($p=0.05$), and spent less time attempting to retrieve the ball ($p=0.02$) than unsuccessful children. Results suggest that this task moves beyond divergent thinking assessments by measuring both creative process and achievement in children.

Learned social values modulate representations of faces in the Fusiform Face Area

Ariana Familiar
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Alice Xia
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Sharon Thompson-Schill
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Abstract

Social value processing has been shown to recruit specific neural systems, yet how they are associated with person-specific information, such as facial identity, processed in separate regions remains to be established. The present study examined changes in neural representations in face-selective visual areas due to social value learning. Over four days, participants learned combinations of social (generosity) and reward (point) values orthogonally assigned to naturalistic face images. We found that after learning, activity similarity (measured with fMRI) in the fusiform face area evoked by viewing the faces was related to social value as well as a measure of future social preferences, but was not related to reward value. This shows how learned social values can influence representations in face-selective brain regions thought to primarily encode visual information, and provides a potential neural mechanism for the association of social and visual information relevant to propensities in future social behavior.

Experimental conditions affect how social cues guide the regularisation of unpredictable variation

Olga Feher
University of Warwick, Coventry, Warwickshire, United Kingdom

Simon Kirby
University of Edinburgh, Edinburgh, United Kingdom

Kenny Smith
University of Edinburgh, Edinburgh, United Kingdom

Abstract

Unpredictable variation is widely used to investigate how cognitive and communicative biases impact on language evolution and change. Learning, interactive and cultural biases all contribute to universal linguistic patterns. We explored the effects of social cues using a miniature artificial language exhibiting unpredictable lexical variation distributed either within or between multiple speakers. We compared the effects of testing modality (spoken vs. forced-choice), experimental population (students vs. online workers) and setting (laboratory vs. online). Learners were sensitive to social cues, but reliable differences only emerged in the laboratory. In an online setting, students were much more likely to regularise across conditions. In addition, task difficulty increased rates of regularisation but only online. Online workers showed high levels of regularisation throughout. Our experiments suggest that the conditions in which learning and recall take place have a large impact on the biases which shape language and our ability to measure them.

Improv exercises promote uncertainty tolerance and improve creativity outcomes

Peter Felsman
University of Michigan, Social Work and Psychology, Ann Arbor, Michigan, United States

Sanuri Gunawardena
University of Michigan, Ann Arbor, Michigan, United States

Colleen Seifert
U Michigan, Ann Arbor, Michigan, United States

Abstract

Improvisational theater is defined broadly as a theatrical setting in which, process and product co-occur (Sowden, Clements, Redlich, & Lewis, 2015). Therefore, practicing improvisational theater involves embracing uncertainty (Napier, 2004). In this context, individuals may learn to tolerate uncertainty with greater comfort, a common treatment outcome across many psychological disorders (e.g. Boswell et al., 2013). The current study employs a lab-based paradigm linking brief improvisational theater experience to increased divergent thinking outcomes (Lewis & Lovatt, 2013). We set out to replicate and extend this finding by including an explicit measure of uncertainty tolerance. Across two studies, our results show increased uncertainty tolerance for people who improvised, significantly more than people who participated in a social interaction control with limited uncertainty. Additionally, the improvising condition predicted relative improvement on a subset of divergent thinking measures, offering partial support for the Lewis and Lovatt (2013) finding that improvisational theater exercises can improve creativity.

Space Matters: Investigating the influence of spatial information on subjective time perception

Can Fenerci
McGill University, Montreal, Quebec, Canada

Myles LoParco
McGill University, Montreal, Quebec, Canada

Kevin da Silva-Castanheira
McGill University, Montreal, Quebec, Canada

Signy Sheldon
McGill University, Montreal, Quebec, Canada

Abstract

Although understood that time perception is subjective, the underlying cognitive mechanisms are not well described. Event segmentation theories propose that spatial information serves to segment experienced information in discrete units which then can be used to estimate time. Based on this theory, we explored whether subjective time perception is influenced by the amount of perceived spatial information. A group of young participants viewed short videos of episodes that included a spatial change (e.g., moving through doorways) or no spatial change. In one experiment, participants were asked to estimate a given time duration while viewing the video and in a second experiment, participants estimated the time of the video after viewing. Across experiments, videos with spatial change were associated with more accurate time perception estimates than those without spatial changes. These results highlight the important role of spatial processing in directing the experience of time.

No Morphological Markers, No Problem: ERP Study Reveals Semantic Factors Differentiating Neural Mechanisms of Noun and Verb Processing

Jun Feng[1], Tao Gong[2], Lan Shuai[2], Yicheng Wu[3]

[1] Hangzhou Normal University

[2] Educational Testing Service

[3] Zhejiang University

Abstract

Neural mechanisms behind noun and verb processing are ubiquitously separate, yet it remains controversial which factor, syntax or semantics, is behind such separation. We conducted an ERP study using Chinese sentences with a specific construction, noun phrase + mei ("not/no") + noun/verb/noun-verb-ambiguous-word, and excluding other grammatical or syntactic factors that could hint at the target words' part-of-speech. Results showed significantly distinct P200, N400 and P600 between noun and verb processing in native speakers, indicating that semantic factors are essential for the differentiated neural mechanisms behind noun and verb processing. Similar results were also found between noun-verb-ambiguous-word and noun processing, but not between noun-verb-ambiguous-word and verb processing, suggesting that lacking clues on part-of-speech makes the dynamic properties of the ambiguous words more salient than the static ones, thus causing interpretation of such words more likely as verbs. This further elaborates the crucial role of semantic factors in noun and verb processing.

The impact of frequency on the evolution of category systems

Vanessa Ferdinand
University of Melbourne, Melbourne, VIC, Australia

Charles Kemp
University of Melbourne, Melbourne, VIC, Australia

Amy Perfors
University of Melbourne, Melbourne, VIC, Australia

Abstract

How do category systems reflect the information content of their environments? One basic kind of information in a linguistic environment is the frequency of objects or meanings: some things are just spoken about more often than others. A great deal is known about frequency effects on the evolution of lexical items (e.g. Lieberman et al, 2007); however analogous effects on category systems are not understood. Two theories point in opposite directions: the generalized context model (Nosofsky, 2011) predicts that categories containing high-frequency items will expand over time, while information theory (Cover & Thomas, 2012) predicts tighter boundaries around high-frequency items. We explore the impact of frequency on the evolution of category systems over time in an iterated category learning experiment that manipulates object frequency. How does this manipulation affect category boundaries? Does the result change if transmission is between different individuals or within the same person over time?

How victim framing shapes attitudes towards sexual assault

Stephen Flusberg
Purchase College, SUNY, Purchase, New York, United States

Sarah Husney
Colorado College, Colorado Springs, Colorado, United States

Casey Pollard
Colorado College, Colorado Springs, Colorado, United States

Kevin Holmes
Colorado College, Colorado Springs, Colorado, United States

Abstract

Crimes typically involve a perpetrator and a victim, but alleged perpetrators are often cast as the true victim, as happened recently in the case of U.S. Supreme Court nominee Brett Kavanaugh. Across two experiments, we investigated the efficacy of this type of victim framing. Participants read a brief report about an alleged college campus sexual assault and expressed their support for the male and female protagonists. The report either framed the woman as the victim (of sexual assault), the man as the victim (of false accusations), or was relatively neutral about victimhood (baseline control). Relative to baseline, the framing manipulation was effective at eliciting more support for the character described as a victim, regardless of participants gender or political affiliation. These findings suggest that the language of victimhood, or its co-opting to cast alleged perpetrators in a more favorable light, can shape public opinion about a politically polarized issue.

Language stability and change in age-dependent networks

Stella Frank
University of Edinburgh, Edinburgh, United Kingdom

Kenny Smith
University of Edinburgh, Edinburgh, United Kingdom

Abstract

People's social and linguistic environment changes over the course of their life: infants learn language from a small set of caregivers; children and adolescents practice language skills with their peers; adults speak to other adults and also pass on their language to the next generation (Kerswill, 1996, Sankoff 2018). Population models of language change have explored network effects but neglected changing networks as a function of agent age. We model a population of Bayesian agents that go through life phases of initial learning, subsequent peer interactions, and transmission to the next generation. We find these age-dependent networks to be more stable than other network architectures. This stability counters previous Bayesian modelling results in which languages reliably and rapidly change, converging to the learners prior, suggesting that languages spoken in populations in which interactions are organised assortatively by age may only weakly reflect human priors on language learning.

Investigating the factorial structure of widespread false beliefs

Vincent Frigo
UW-Madison, Madison, Wisconsin, United States

Timothy Rogers
University of Wisconsin- Madison, Madison, Wisconsin, United States

Abstract

Cognitive science often views human learning as rational. Why then do false beliefs arise, and why are they resistant to change? False beliefs might arise when people (1) lack knowledge in some domain, (2) adopt beliefs aligning with implicit causal theories, or (3) encounter, through media or social networks, sets of beliefs that strongly covary. To test these hypotheses we composed a survey assessing beliefs about matters of fact across a wide range of knowledge domains and collected responses from 500 MTurkers. We then conducted a factor analysis to determine which false beliefs co-vary together, clustered respondents to find groups that adopt comparable false belief sets, and used regression to identify sociodemographic and media-consumption features that predict susceptibility to different kinds of false beliefs. The results suggest that some kinds of false belief may arise and persist merely from covariance in the opinions learners encounter in social life.

Inflated inflation and superseded supersession: testing counterfactual sampling accounts of causal strength judgments

Maureen Gill
Princeton University , Princeton, New Jersey, United States

Jonathan Kominsky
Harvard University, Cambridge, Massachusetts, United States

Joshua Knobe
Yale University, New Haven, Connecticut, United States

Thomas Icard
Stanford University, Stanford, California, United States

Abstract

Norm violations have been shown to influence causal judgments. Icard, Kominsky, and Knobe (2017) explained the influence of norms by appeal to a model of norm-weighted sampling of counterfactual possibilities. This model explains two well-known effects (among others): When two agents must act to bring about an outcome (i.e. both actions are necessary), if an agent S violates a norm, they are judged more causal than when they do not violate a norm (abnormal inflation), and the other agent B is judged to be less causal than when S does not violate a norm (causal supersession). In the present study (N = 1008), we find empirical support for two untested further predictions of this sampling model of causal strength judgments: Abnormal inflation of S is greater when B violates a norm (inflation increase), and causal supersession of B is smaller when S violates a norm (supersession decrease).

Spatial-Numeric Associations Distort Estimates of Causal Strength

Kelly Goedert
Seton Hall University, South Orange, New Jersey, United States

Daniel W. Czarnowski
Seton Hall University, South Orange, New Jersey, United States

Abstract

When individuals provide magnitude estimates using numeric scales, they may be influenced by spatio-numeric biases. In Western, English-speaking cultures smaller magnitudes are associated with the left side of space and larger with the right. We demonstrated the impact of spatial-numeric associations on judgments of causal strength in two trial-by-trial causal learning experiments. Causes appeared on either the left or right side of a computer screen. In Experiment 1, participants made casual judgments using a number line either increasing in magnitude from left to right or decreasing in magnitude from left to right. In Experiment 2, participants made judgments using a non-linear circular target with the depth of hue saturation representing causal strength. In Experiment 1, participants gave higher causal ratings to causes appearing in the space associated with larger numbers on the number line. These influences disappeared when the linearity of spatial-numeric associations was removed in Experiment 2.

Can children develop novel tools to solve problems via analogical generalization? Kind of!

Micah Goldwater
University of Sydney, Sydney, Australia

Abstract

Recent research has examined whether children can modify tools to solve novel problems. For example, when children are given a pipe cleaner with the goal to retrieve a little bucket at the bottom of a tube, will they realize that bending the pipe cleaner into a hook will solve the problem? Children younger than 7 almost all fail at this task, and children under 10 are far from ceiling. Because problem solving is often helped via generalization from analogous problems, the current study examined whether children in this task could take advantage of being read a story (with pictures) about fishing, emphasising the importance of hooks. Interesting we found an interaction wherein preschool children were helped by the analogy, while school-aged children were not, who also solved the task at much higher rates overall (but still below ceiling).

Detecting Students Problem Solving Strategies Using Sankey Diagrams

Tao Gong
Educational Testing Service, Princenton, New Jersey, United States

Christopher Agard
Educational Testing Service, Princeton, New Jersey, United States

Gary Feng
Educational Testing Service, Princeton, New Jersey, United States

Gabrielle Cayton-Hodges
Educational Testing Service, Princeton, New Jersey, United States

Luis Saldivia
Educational Testing Service, Princeton, New Jersey, United States

Abstract

Process data (e.g., logs of actions, keystrokes, times, or eye tracks) recording students interactions with digital assessments are available in many digital educational assessments. They have become the primary focus of cognitive scientists to detect and analyze students strategies during problem solving. This study developed a Sankey diagram-based method to visualize process data of multiple-choice items. Such diagram has been widely adopted in industry and ecology to trace flow of information, energy, or resource. Using released items from the 2017 National Assessment of Educational Progress Mathematics Tests, we illustrated how to use such a diagram to elucidate frequent answer formulation patterns of students, their common mistakes, and estimated probabilities of reaching correct/wrong answers at various answering stages. These help reveal the problem solving strategies adopted by students and their underlying cognitive processes. Assessment developers, teachers, and students could use such insights to improve assessments and learning outcomes for confusing concepts.

Evaluating systematicity in neural networks with natural language inference

Emily Goodwin
McGill University, Montreal, Quebec, Canada

Koustuv Sinha
McGill University, Montreal, Quebec, Canada

Timothy ODonnell
McGill University, Montreal, Quebec, Canada

Abstract

Compositionality makes linguistic creativity possible. By combining words, we can express uncountably many thoughts; by learning new words, we can extend the system and express a vast number of new thoughts. Recently, a number of studies have questioned the ability of neural networks to generalize compositionally (Dasgupta, Guo, Gershman & Goodman, 2018). We extend this line of work by systematically investigating the way in which these systems generalize novel words.

In the setting of a simple system for natural language inference, natural logic (McCartney & Manning, 2007), we systematically explore the generalization capabilities of various neural network architectures. We identify several key properties of a compositional system, and develop metrics to test them. We show that these architectures do not generalize in human-like ways, lacking inductive leaps characteristic of human learning.

Experimental Study on the Decision Making process in a Centipede Game

Dhriti Goyal
International Institute of Infromation Technology, Hyderabad, India, Hyderabad, India

Dhiraj Jagadale
International institute of information technology, Hyderabad, Hyderabad, Telangana, India

Kavita Vemuri
International Institute of Information Technology - Hyderabad, Hyderabad, Telangana, India

Abstract

The studys objective was to measure the somatic state response (skin conductance and heart rate) and understand the decision making processes in a two-player Centipede game, an extensive form game, with a modified payoff. The experiment included fixed and random termination for analyzing the effect of players mutual trust on risk-taking behavior. The behavioral results reveal that trust controls the game rounds (that is, the number of pass decisions) in known or random termination game conditions, though the exit points were higher in the former compared to the latter condition. Higher skin conductance and heart rate during the game-play is noticed as compared to the baseline data showing anxiety during the gameplay and interestingly opponents action induced higher skin conductance amplitude than during self-play for the same decision. The data provides strong preliminary evidence of trust influencing cooperative gameplay.

Optimal categorisation: the nature of nominal classification systems

Alexandra Grandison
University of Surrey, Guildford, United Kingdom

Michael Franjieh
University of Surrey, Guildford, United Kingdom

Greville Corbett
University of Surrey, Guildford, United Kingdom

Abstract

Effective categorisation should be simple, to minimise cognitive load, and informative, to maximise communicative efficiency. Nominal classification systems (gender, classifiers) are a functional means of categorisation that vary enormously across languages, revealing a trade-off between simplicity and informativeness. Closely related Oceanic languages of Melanesia show staggering variation in their number and type of classifiers. How does the Iaai language carve up nouns into 23 semantic groups whilst the Merei language uses only two; and what implications do these vastly different systems have for the cognitive representations of their related concepts? We combined typological enquiry and psycholinguistic experimentation (free listing, card sorting, video vignettes, possessive labelling, eye tracking, storyboards, category training) comparing nominal classification systems in six Oceanic languages of Vanuatu and New Caledonia. We discuss how these experiments uncover the nature of nominal classification systems, comparing objective data across languages and experimental contexts to reveal a model for optimal categorisation.

Do You Need More than Two Subjects: Using Cognitive Modeling to Make Accurate Predictions for Individual Subjects

Emily Greve
Carleton University, Ottawa, Ontario, Canada

Elisabeth Reid
Carleton University, Ottawa, Ontario, Canada

Robert West
Carleton University, Ottawa, Ontario, Canada

Abstract

In experimental research, large numbers of participants are used to average out individual differences in the data. However, differences in task performance may be largely due to two factors; lack of task training, and different micro-strategies. We implement a methodology that removes the effect of these factors, requires only 23 participants, and still produces large amounts of data. Other studies have been published using a similar methodology (Cousineau & Shiffrin, 2004; Gray & Boehm-Davis, 2000). Our study is a revision of previous research using a mobile game (West et al., 2018). Participants are trained extensively on the game to ensure they are experts. The study includes a predictive cognitive model and the game-design is based on an apparent micro-strategy. We hypothesize that the same micro-strategies under identical conditions, should produce identical results across participants and the model. Suggesting the model may exist in the mind of human experts.

Language facilitates 2.5-year-olds reasoning by the disjunctive syllogism

Myrto Grigoroglou
University of Toronto, Toronto, Ontario, Canada

Sharon Chan
University of Toronto, Toronto, Ontario, Canada

Patricia Ganea
University of Toronto, Toronto, Ontario, Canada

Abstract

Children and animals successfully reason by elimination: if a reward is hidden in A or B, and they see A empty, they search in B (Call, 2004; Hill et al., 2012). Twenty-seven-month-olds also solve similar tasks when emptiness is conveyed verbally, through negation (The toy is not in the box, Feiman et al., 2017). However, it is unclear whether participants solved these tasks with the disjunctive syllogism (A OR B, NOT A, THEREFORE B); in a 4-cup paradigm requiring disjunctive reasoning only 3-5-year-olds but not 2.5-year-olds succeeded (Mody & Carey, 2016). We used a linguistic version of the 4-cup task to examine childrens ability to reason disjunctively using verbal negation. We found that 3- and 2.5-year-olds performed significantly above chance (58.1%, 54.2%, respectively, ps¡.05). Thus, presenting the negative premise verbally facilitated 2.5-year-olds deductions. We conclude that older 2-year-olds have a robust understanding of negation, which they apply in abstract reasoning.

Exploring cognitive states through real-time classification and sonification of brain data

Yann Harel

Antoine Bellemare
Concordia University, Montreal, Quebec, Canada

Arthur Dehgan
Universit de Montral, Montral, Quebec, Canada

Anne-Lise Saive
Universit de Montral, Montral, Quebec, Canada

Karim Jerbi
Universit de Montral, Montral, Quebec, Canada

Abstract

With the recent advances in EEG technology and the popularization of low-cost mobile EEG devices, brain-computer interface (BCI) systems and neurofeedback tools have become more accessible. Real-time EEG signal processing is increasingly popular in the context of digital arts projects powered by a neuroaesthetic approach. CoCo Brain Channel is one such project : designed to use real-time processing of EEG signal in order to generate a musical environment, it provides the user with a means to hear and control his own brain activity. This is achieved by hooking-up a commercial mobile EEG device to a music generation algorithm built in PureData. The generative algorithm uses features from EEG signals to modulate harmonic and rhythmic structures of multiple oscillators. The result is a continuous musical soundscape reflecting the evolution of EEG signals. Improvements and possible applications for basic research will be discussed.

When circumstances change, update your pronouns

Joshua K. Hartshorne
Boston College, Chestnut Hill, Massachusetts, United States

Mariela V Jennings
Boston College, Chestnut Hill, Massachusetts, United States

Tobias Gerstenberg
Stanford University, Stanford, California, United States

Josh Tenenbaum
MIT, Cambridge, Massachusetts, United States

Abstract

Language is frequently ambiguous, with the same sentence having several possibleinterpretations. One prevalent example is third-person pronouns. Hartshorne, Gerstenberg, & Tenenbaum (2014) HGT2014 model pronoun interpretation as an inference over a generative model of the speaker. An advantage of the generative intuitive theory approach is that it incorporates a flexible, quantitative model of world knowledge rather than a list of facts and heuristics. The authors formalized this world knowledge as inference over a generative model of the world. We directly test this flexibility by changing the rules of the world (e.g., through scenarios that reverse the normal relationship between strength and probability of winning tug-of-war), which according to HGT2014 should directly affect pronoun interpretation. We find that model predictions and participant judgments align well in such scenarios, supporting HGT2014 and challenging other theories of pronoun resolution. We discuss this work in the context of recent work on intuitive theories.

Strategy shifting in navigation: Insights from trial-level effects in a virtual navigation task

Chuanxiuyue He
University of California, Santa Barbara, Santa Barbara, California, United States

Alexander Boone
University of California, Santa Barbara, Santa Barbara, California, United States

Mary Hegarty
University of California, Santa Barbara, Santa Barbara, California, United States

Abstract

In the dual-solution paradigm (DSP), people learn a route through a virtual environment. After learning, people are asked to navigate to locations in the environment. Individuals vary in the degree to which they rely on the learned route (response strategy) versus a shortcut (place strategy). The present study characterizes trial-level features such as relative target locations, Euclidean distance and number of turns or intersections between locations, and uses a Rasch Model to investigate how spatial attributes of these trials influence participants strategy-choice. Additionally, a post-task questionnaire shows a partial disassociation between navigation behaviors in the virtual environment and navigation in daily life. It is proposed that this dissociation can be explained by differences in environment features. This study has unique potential to advance understanding of factors that affect navigation strategy choice, and to inform ecological validity of the Dual Solution Paradigm and other navigation paradigms.

Explaining without Information: The Role of Label Entrenchment

Babak Hemmatian
Brown University, Providence, Rhode Island, United States

Steven Sloman
Brown University, Providence, Rhode Island, United States

Abstract

In categorical explanation a category label is used to explain an associated property. We show that label entrenchment, whether a label is commonly used by ones community, affects the judged quality of a categorical explanation whether the explanation offers substantive information or not. In Experiments 1 and 2, explanations using unentrenched labels are rated as less comprehensive and less natural independent of causal or featural information, even when the label is merely a name for the explanandum. Experiments 3 and 4 replicate the effect with unentrenched labels coined by groups of expert discoverers and rule out explanations like familiarity and communicative principles. Most participants in Experiments 3 and 4 could not report the impact of entrenchment on their judgments. We argue that reliance on entrenchment arose because the community often has useful information. Common use of labels as conduits for this knowledge induces reliance on community cues even when uninformative.

Consequential Consensus: A Decade of Online Discourse about Same-sex Marriage

Babak Hemmatian
Brown University, Providence, Rhode Island, United States

Sabina Sloman
Carnegie Mellon University, Pittsburgh, Pennsylvania, United States

Uriel CohenPriva
Brown University, Providence, Rhode Island, United States

Steven Sloman
Brown University, Providence, Rhode Island, United States

Abstract

Framing issues as matters of non-negotiable values can increase the perceived intractability of debates. Focusing on the concrete consequences of policies instead can facilitate conflict resolution. Using a topic model of Reddit comments from January 2006 to September 2017, we show that the contribution of certain topics concerned with protected values to the debate increased prior to the emergence of a public consensus in support of same-sex marriage and declined afterwards. These topics related to religious arguments and freedom of opinion. In contrast, discussion of certain concrete consequences (the impact of politicians stances and policy implications) showed the opposite pattern, their increased prominence coinciding with improved public support for same-sex marriage after 2012. Our results reinforce the meaningfulness of protected values and consequentialism as relevant dimensions for describing public discourse and highlight the usefulness of unsupervised machine learning methods in tackling questions about social attitude change.

Untangling indices of emotion in music using neural networks

Dorien Herremans

Kat Agres
Institute of High Performance Computing, A*STAR, Singapore, – Select State/Province –, Singapore

Abstract

Emotion and music are intrinsically connected, and researchers have had limited success in employing computational models to predict perceived emotion in music. Here, we use computational dimension reduction techniques to discover meaningful representations of music. For static emotion prediction, i.e., predicting one valence/arousal value for each 45s musical excerpt, we explore the use of triplet neural networks for discovering a representation that differentiates emotions more effectively. This reduced representation is then used in a classification model, which outperforms the original model trained on raw audio. For dynamic emotion prediction, i.e., predicting one valence/arousal value every 500ms, we examine how meaningful representations can be learned through a variational autoencoder (a state-of-the-art architecture effective in untangling information-rich structures in noisy signals). Although vastly reduced in dimensionality, our model achieves state-of-the-art performance for emotion prediction accuracy. This approach enables us to identify which features underlie emotion content in music.

Emotion attributions echo the structure of people's intuitive theory of psychology

Sean Houlihan
MIT, Cambridge, Massachusetts, United States

Max Kleiman-Weiner
Harvard, Cambridge, Massachusetts, United States

Josh Tenenbaum
MIT, Cambridge, Massachusetts, United States

Rebecca Saxe
MIT, Cambridge, Massachusetts, United States

Abstract

We present a generative model of how observers think about the emotions experienced by players in a socially-charged game: a public, high-stakes, one-shot Prisoner's Dilemma. The model extends inverse planning frameworks to capture observers' judgments about players' reactions to hypothetical events. Observers attribute different beliefs and values to players based on what decisions the players make. We model how observers' noisy inferences of players' mental contents bias emotion predictions. Incorporation of non-monetary features into forward planning enables us to model emotions that reflect complex social concerns (e.g. Embarrassment depends on how much players think others will infer that they tried to take advantage of their opponents). In addition to matching the intensities of twenty attributed emotions, the model reflects how observers' emotion judgments covary within single stimuli, indicating that the model captures important aspects of the generative process underlying humans' emotion attributions in this game.

The Intervention of Affective and Cognitive Theory of Mind on Impacting Social Norm Violation Judgements

Nai Ching Hsiao
National Cheng Kung University, Tainan, Taiwan

Jon-Fan Hu
National Cheng Kung University, Tainan City, Taiwan

Abstract

Individual's judgment on the appropriateness of social norm includes perceiving others mental states (theory of mind), but it might differ with the intervention aspects in real social contexts. Therefore, in this study we mainly focus on evaluating whether affective and cognitive theory of mind would affect social norm violation judgments and investigate whether the timing of mentalization involves the judgments. As a result, preconceived intention intervention (both affective and cognitive theory of mind) significantly affected the judgments of the appropriateness. However, only cognitive theory of mind in attributing violation intentions after encountering the social norm statement was found to affect in the judgments of the appropriateness of norm violations. In summary, theory of mind plays an important role on the judgment of appropriateness for social norm violation, but the timing of intervention matters significantly.

A tool to analyze verb phrase and noun phrase relationship in sentences

Te-En Huang
National Cheng Kung University, Tainan, Taiwan

Tao-Hsing Chang
National Kaohsiung University of Science and Technology, Kaohsiung City, Taiwan

ADAT Technology Co.
ADAT Technology Co., Tainan, Taiwan

Jon-Fan Hu
National Cheng Kung University, Tainan City, Taiwan

Abstract

SPACY is a well-known package for NLP analysis for delineating the Verb phrases and Direct Objects in English by applying the default structures to define noun phrase. However, SPACY lacks a function to include the status of adjectives and vast amount of noun phrase structures for identifying the relationship between Verbs and Nouns efficiently. The present study develops a SPACY-based program to customize practical noun phrase structures written in industrial SOPs for machine operations. It performs better at merging overlapping structures, for example, a sentence An important thing of NLP is hard to define can be processed to be An important thing, NLP, thing of NLP; and then automatically merged into one noun phrase An important thing of NLP. The capacity of the program can abstract the core concepts of sentences and recognize the co-occurrences of noun phrases and their associated verbs from the corpus for research and application purposes.

Examining Prefrontal Cortex Contributions to Creative Problem Solving With Noninvasive Electric Brain Stimulation

Kent Hubert
Drexel University, Philadelphia, Pennsylvania, United States

Evangelia G. Chrysikou
Drexel University, Philadelphia, Pennsylvania, United States

Abstract

Cognitive neuroscience studies of creativity typically employ divergent thinking tasks that prioritize bottom-up processes to generate novel responses. However, real-world creative problem solving is guided by top-down thinking that puts an emphasis on the goal to be achieved. Here, we introduce the Alternative Objects Task (AOT)a novel task that incorporates both bottom-up and down-down thought during problem solving. Guided by functional neuroimaging findings, we employed transcranial direct current stimulation (tDCS) over frontopolar cortex to investigate causally the impact of transient changes in activity in this region for problem solving performance on the AOT. Participants were presented with a series of goals and generated either a common or an uncommon object that could satisfy each, while undergoing either excitatory (anodal) or sham tDCS. Analyses of accuracy, reaction times, and semantic distance highlight the importance of goal-orientation during creative problem solving and its reliance on prefrontal cortex.

A Two-Process Model of Semantic Development

Philip Huebner
University of Illinois, Urbana-Champaign, Urbana, Illinois, United States

Jon Willits
University of Illinois at Urbana-Champaign, Champaign, Illinois, United States

Abstract

How do children acquire semantic knowledge? In this work, we explore an old answer to this question: Semantic development is a hybrid of two distinct processes. The first process involves unsupervised learning of relations between objects, providing a representation of objects that is useful for a wide range of possible goals. The second process involves explicitly learning to put objects and their relations into categories. Critically, this second process uses the representations of the first process as its starting point. Here, we demonstrate this using a two-process model, where the first process is a distributional semantic model (e.g. HAL, Word2Vec, RNN), and the second process is a transformation of representations learned during process 1 into a task-specific target space. This approach improves performance on multiple semantic tasks, compared to using the representations learned by process 1 directly. We believe this model demonstrates that a task- or goal-oriented perspective of semantic cognition has promise for furthering our understanding of semantic development.

The Relationship between Inhibitory control and Creativity

tal ivancovsky
Bar Ilan University, Ramat Gan, Israel

Moshe Bar
Bar Ilan University, Ramat Gan, Israel

Abstract

There is a debate in the literature as to whether inhibitory control improves or hinders creativity. Alternatively, we propose that flexible alterations between these two states would actually benefit creativity best. Therefore, the purpose of the current study was to resolve the debate by inducing inhibited/disinhibited/flexible states of mind and subsequently examine the influence on creative performance. To do so, the Stop-Signal task (SST) was deployed through the use of differential task instructions. Afterwards, participants completed two creativity tasks: a free association task (FAT) and the alternate uses task (AUT). Results indicated that while the inhibited group scored higher in the FAT, the flexible group scored higher in the AUT. Based on the results, we propose that there is an inverted U-shaped relationship between inhibitory control and creativity: while some cognitive control is needed to generate original ideas; excessive control might hinder creativity as it may lead to premature closure of ideas that could otherwise be further developed.

Does Motor Engagement Influence Memory for STEM Abstract Concepts?

Constanza Jacial
Drexel University, Philadelphia, Pennsylvania, United States

Evangelia G. Chrysikou
Drexel University, Philadelphia, Pennsylvania, United States

Abstract

Theories of embodied cognition have suggested that motor activity may influence the consolidation of conceptual knowledge. In line with this prediction, behavioral studies have shown retrieval interference effects of a manual motor task for manipulable object concepts. On the other hand, research investigating such effects for abstract concepts is limited. Here, we examined in a behavioral experiment potential effects of the recruitment of the motor system for the consolidation of different kinds of abstract concepts. Participants were presented auditorily and asked to memorize abstract concepts with movement referents (e.g., fluidity), abstract concepts without movement referents (e.g., theory), and concrete concepts (e.g., microscope) while engaging in a full-body motor task. All concepts were specific to Science Technology Engineering and Mathematics (STEM) disciplines. Analysis of free recall and recognition performance suggests influence of motor engagement for certain types of STEM concepts during memory encoding and subsequent retrieval.

Symbol grounding boosts transfer in addition learning

Clint Jensen
University of Wisconsin - Madison, Madison, Wisconsin, United States

April D. Murphy
University of Wisconsin - Madison, Madison, Wisconsin, United States

Andrew Young
Occidental College, Los Angeles, California, United States

Martha Alibali
University of Wisconsin-Madison, Madison, Wisconsin, United States

Timothy Rogers
University of Wisconsin- Madison, Madison, Wisconsin, United States

Chuck Kalish
University of Wisconsin-Madison, Madison, Wisconsin, United States

Abstract

Early math instruction often prioritizes rapid retrieval of mathematical facts, (e.g. 4 + 6 = __; 10), an approach that promotes quick recall of sums but with limited transfer to unstudied problems. We consider how this pattern changes when the learning scenario highlights the quantities that underlie symbols. Adult participants learned a novel base 8 addition task using alphabetic symbols to indicate quantities (e.g. AG + AF = __). They practiced with symbols only or with symbols grounded in quantitative representations. When tested in the same format as participants were trained, studied problems were learned equally well but symbol-only learners transferred only to identical-elements problems (e.g. AG + AF transferred to AF + AG). Grounded learners showed better transfer to problems involving novel quantities. The results suggest, in contradiction to some other recent findings, that arithmetic transfer is boosted when the learning scenario highlights quantitative meaning denoted by number symbols.

Boundedness in event and object cognition

Yue Ji
University of Delaware, Newark, Delaware, United States

Anna Papafragou
Unversity of Delaware, Newark, Delaware, United States

Abstract

The semantic property of boundedness characterizes the presence of well-defined spatio-temporal boundaries for events or objects in language (Bach, 1986; Frawly, 1992; Jackendoff, 1991). Little research has tested whether this property actually characterizes event and object cognition (but see Wellwood, Hespos, & Rips, 2018). We showed participants videos of bounded events where a salient change in state of the affected object(s) occurred (e.g., dressing a teddy bear) and unbounded events that lacked a salient change (e.g., waving a handkerchief). Participants decided whether a video matched with a picture of a single novel object or a picture of a novel substance (object/substance pictures were adopted from Li, Dunham, & Carey, (2009)). Participants tended to pair a bounded event with an object and an unbounded event with a substance, and were in fact better at establishing the former connection. We conclude that boundedness underlies the cognitive representation of both events and objects.

Pupillometry measures of cognitive load in meta-T dynamic task environment

Chris Joanis
Rensselaer Polytechnic Institute, Troy, New York, United States

Evan Pierce
Rensselaer Polytechnic Institute, Troy, New York, United States

Wayne Gray
Rensselaer Polytechnic Institute, Troy, New York, United States

Abstract

Pupillometry uses pupil diameter as a physiological measure of cognitive effort and load. In static tasks, pupillometry has revealed that cognitive effort varies with expertise, and, combined with gaze analysis, shows that experts can exert effort to focus on non-salient visual input. Much real-life expertise is practiced in dynamic tasks, and expert effort in dynamic tasks remains unstudied. Using tetris as a dynamic task environment, we collected pupil and gameplay data from individuals of varying expertise levels. We then use collected data and examine cognitive workload differences across levels of expertise. Consistent with studies of image saliency and gaze, our results indicate that experts and novices engage differently with the task and do not experience the same cognitive workload. Further inspection will likely reveal strategy-level sources of these differences.

Equanimity moderates approach/avoidance motor-responses and evaluative conditioning

Catherine Juneau
LAPSCO, Clermont-Ferrand, France

Laurent Waroquier
LAPSCO, Clermont-Ferrand, France

Michael Dambrun
LAPSCO, Clermont-Ferrand, France

Abstract

A growing body of research investigates equanimity as an outcome of mediation practices. Equanimity has been defined as a stable and impartial mental state or trait, regardless the affective valence of stimuli or situations (Desbordes et al., 2015). Few experimental studies focused on its understanding. After created and validated an equanimity questionnaire (EQUA-S, N = 265), we conducted a laboratory study (N = 38) to examine the effect of equanimity on both approach-avoidance motor-behavior with positive and negative stimuli (Rougier et al., 2018) and evaluative conditioning. While classical approach/avoidance and evaluative conditioning effects were significantly reproduced with evidence in favor of H1 among the participants with a low level of equanimity (N = 17), evidence in favor of H0 was found among those with a high level of equanimity. Thus, equanimity seems to moderate automatic cognitive responses toward valenced stimuli.

Do children extend pragmatic principles to non-linguistic communication?

Alyssa Kampa
University of Delaware, Newark, Delaware, United States

Catherine Richards
University of Delaware, Newark, Delaware, United States

Anna Papafragou
Unversity of Delaware, Newark, Delaware, United States

Abstract

In conversation, speakers are expected to offer as much information as required by the purposes of the exchange. (Grice, 1975). Classic theories of communication assume that the principle of informativeness extends beyond linguistic interactions (Grice, 1989; Sperber & Wilson, 1986), but relevant evidence so far is limited. We replicated the paradigm of a referent selection study in which preschool-aged children successfully apply the principle of informativeness to linguistic exchanges (Stiller et al., 2015) and added a matched non-linguistic condition in which the referent choice was communicated through pictures instead of verbal descriptions. Children between the ages of 3.5 to 5 performed significantly better in both the linguistic and non-linguistic conditions compared to a control condition, and there were no significant differences between linguistic and non-linguistic conditions for 3-year-olds, 4-year-olds, or 5-year-olds. We conclude that preschool-aged children apply pragmatic principles to pictures as well as words.

When do iconic gestures facilitate word learning? The case of L2 lessons for preschoolers led by a robot or human tutor

Junko Kanero

Cansu Oran
Ko University, Istanbul, Turkey

Smeyye Kokulu
Koc University, stanbul, Turkey

Tilbe Gksun
Ko University, Istanbul, Turkey

Aylin C Kuntay
Ko University, Istanbul, Turkey

Abstract

Gestures help us understand language (e.g., Hostetter, 2011). However, less is known about how good gestures must be to facilitate word learning. Turkish-speaking preschoolers learned five English verbs with corresponding iconic gestures, varying in the verb-gesture match (i.e., how well the gesture represented the verb), in a one-on-one lesson led by either a human adult or the humanoid robot NAO. Our preliminary results (N = 43) suggest that the verb-gesture match predicts word learning, and this match might even be more important when the robot was the tutor (though the interaction was not statistically significant). In addition, while both tutors were effective in teaching verbs, preschoolers learned better with the robot than with the human. This study not only makes a theoretical contribution by demonstrating the effects of the match between words and iconic gestures, but also provides practical implications for designing of robot- and human-led L2 lessons.

Confirmation Bias Trumps Performance Optimization in Overt Active Learning

Yul Kang
University of Cambridge, Cambridge, United Kingdom

Daniel Wolpert
Columbia University, New York, New York, United States

Mate Lengyel
University of Cambridge, Cambridge, United Kingdom

Abstract

When gathering information, different sources typically have distinct levels of informativeness. Therefore, it is optimal to actively select the source of information to learn from (i.e., perform active learning). It has been debated whether humans optimize task performance in active learning or use a simple heuristic of seeking information that confirms their beliefs. Critically, depending on ones subjective beliefs, confirmation bias can in fact be optimal. Thus, without measuring subjective beliefs, previous approaches were unable to distinguish between these alternatives. Using a perceptual decision-making task, we measured participants subjective beliefs before and after a new piece of information was presented. We then characterized confirmation-based and performance optimizing strategies with respect to these subjective beliefs. We found that participants strategy was dominated by confirmation bias, modulated only weakly by the performance optimization. We discuss potential reasons that may limit performance optimization in active learning.

High-Dimensional Vector Spaces as the Architecture of Cognition

Matthew Kelly
The Pennsylvania State University, University Park, Pennsylvania, United States

Nipun Arora
Carleton Univesity, Ottawa, Ontario, Canada

Robert West
Carleton University, Ottawa, Ontario, Canada

David Reitter
Penn State, University Park, Pennsylvania, United States

Abstract

We demonstrate that the key components of cognitive architectures - declarative and procedural memory - and their key capabilities - learning, memory retrieval, judgement, and decision-making - can be implemented as algebraic operations on vectors in a high-dimensional space. Modern machine learning techniques have an impressive ability to process data to find patterns, but typically do not model high-level cognition. Traditional, symbolic cognitive architectures can capture the complexities of high-level cognition, but have limited ability to detect patterns or learn. Vector-symbolic architectures, where symbols are represented as vectors, bridge the gap between these two approaches. Our vector-space model accounts for primacy and recency effects in free recall, the fan effect in recognition, human probability judgements, and human performance on an iterated decision task. Our model provides a flexible, scalable alternative to symbolic cognitive architectures at a level of description that bridges symbolic, quantum, and neural models of cognition.

Offloading memory: serial position effects

Megan Kelly
University of Waterloo, Waterloo, Ontario, Canada

Evan Risko
University of Waterloo, Waterloo, Ontario, Canada

Abstract

Despite the long history and pervasiveness of cognitive offloading as a memory strategy, the memorial fate of offloaded information is not well understood. Recent work has suggested that offloading information may engage similar mechanisms as instructions to forget (directed forgetting). Presently, we test this prediction by examining the serial position effect for offloaded information. Previous research has demonstrated that forget instructions can eliminate the primacy effect while leaving an intact recency effect. Across two experiments, participants completed multiple free recall trials using an external aid and then a final recall trial without the external aid. We compared a group that was expecting to use the aid for the final trial (offloading) with a group that was not (no offloading). We found a memory impairment for offloaded items that was characterized by a reduced primacy effect but intact recency effect, similar to what has been reported in research on directed forgetting.

The reassurance of the Complex Trial Protocol against ecologically validated countermeasures

Hyemin Kim
Korea University, Seoul, Korea, Republic of

Abstract

The P300-based Complex Trial Protocol (CTP), developed by Rosenfeld et al. (2008), is known to compensate for accuracy degradation and countermeasure issues of the Concealed Information Test. Although a myriad of CTP studies using electroencephalogram has been investigated, the lack of crime-related details and the complexity of the previously used countermeasures have revealed the necessity of in-depth experiment. In the present study, fifty participants were divided into three groups: guilty, innocent, and guilty-countermeasure. Participants engaged in a mock-crime scenario and only the guilty-countermeasure group performed ecologically validated countermeasures during the CTP. Participants reaction time and the amplitude of P300 components of event-related potential were analyzed and there was a significant difference ($p_i0.05$). Moreover, using the bootstrapping method, participants were correctly classified as guilty or innocent, regardless of the use of countermeasure, with accuracy above 80%. The results support the possibility of the on-site usage of the CTP.

Making Young Childrens Design Cognition Visible

Mi Song Kim
University of Western Ontario, London, Ontario, Canada

Abstract

There are emerging innovative educational interventions through automated computational analytics so-called learning analytics (LA) to utilize a large amount of student participation. However, LA is a relatively unexplored area in Early Childhood Education (ECE). To respond to this gap, LA is defined as a tool for co-designing pedagogical documentation practices with ECE teachers to visualize student design cognition. Drawing upon a Multiliteracies pedagogy framework, this qualitative study investigates how two kindergarten teachers co-designed pedagogical documentation practices using a digital portfolio app (Seesaw) to leverage 25 young childrens design cognition in multiple modes and technologies. Using the constant comparison method, two themes were emerged from multiple data sources (e.g., digital portfolios on Seesaw, teacher assessment, fieldnotes, interviews): teachers-as-(Co)Designers of LA Interventions; and Portfolio of Student Learning Progression, not Portfolio of Student Work. Our findings suggest the need for effective pedagogical supports for young childrens design cognition and their teachers LA interventions.

Downloading Culture.zip: Social learning by program induction with execution traces

Max Kleiman-Weiner
Harvard University, Cambridge, Massachusetts, United States

Felix Sosa
Harvard University, Cambridge, Massachusetts, United States

Samuel Gershman
Harvard University, Cambridge, Massachusetts, United States

Fiery Cushman
Harvard University, Cambridge, Massachusetts, United States

Abstract

Cumulative culture ultimately depends on the fidelity of learning between successive generations. When humans learn from others in addition to observing inputs and outputs we often observe the process which led to that output. For instance, when preparing a meal we don't just observe a pile of vegetables and then a ratatouille. Instead, we observe a causal process by which those ingredients are transformed. Here we use programs to represent a cultural process and show that the observation of an execution trace speeds up program induction even when learning from only a single example. This mechanism could account for (1) the high fidelity of social learning which leads to cumulative culture in humans (2) unify the role of emulation and imitation in social learning and (3) account for aspects of moral learning such as ritualization.

Curiouser and Curiouser: Childrens intrinsic exploration of mazes and its effects on reaching a goal.

Eliza Kosoy
UC Berkeley , Berkeley, California, United States

Deepak Pathak
UC Berkeley, Berkeley, California, United States

Pulkit Agrawal
UC Berkeley, Berkeley, California, United States

Alison Gopnik
University of California at Berkeley, Berkeley, California, United States

Abstract

Children are naturally curious, and now even reinforcement learning models within machine learning are channeling this child-like curiosity. Pathak et-al (2017) created the ICM (Intrinsic Curiosity Model) in which curiosity serves as an intrinsic reward signal to enable the agent to explore its environment and learn skills, in this case a maze game called Doom. We study this inherent ability in children by having them explore mazes, with and without goals built using DeepMind software. In our pilot data we found that kids are adept at exploring the maze, readily and without prompt. We suggest a relationship between exploration and performance on a maze task, such that performance in the curiosity driven maze exploration task, is correlated with finding a goal in a second separate maze, even when the initial path to the goal is blocked. We also show side-by-side comparisons of the ICM vs. children exploring on our mazes.

Emotional Speech Processing With the Help of F2 Syntactic Parser

Artemy Kotov

Nikita Arinkin
National Research Center Kurchatov Institute, Moscow, Russian Federation

Liudmila Zaidelman
National Research Center Kurchatov Institute, Moscow, Russian Federation

Anna Zinina
National Research Center Kurchatov Institute, Moscow, Russian Federation

Abstract

F2 syntactic parser is a part of F2 emotional robot, designed to support natural emotional communication with the help of gestures, facial expressions and speech. The parser constructs syntactic and semantic representations (frame networks) of an input text, saves them to memory (database) and selects a communicative reaction for the robot in BML (behavior markup language) format. The model of reactions and inferences is based on scripts if-then operators, competing for the processing of semantics. In particular, scripts detect emotionally relevant meanings: when it is declared, that somebody threatens the robot, does not care about it, behaves inadequately 13 negative scripts, and also when the robot is superior, attracts attention, etc 21 positive scripts. Parser may run in a standalone mode, daily processing sentences from news and blogs. Balancing of scripts allows us to tune the understanding and reproduce different emotional profiles for the robot. (Research is supported by RSF, project No 17-78-30029).

Visual, auditory, and temporal sensorimotor discrimination abilities and their relationships with complex cognition

Bartomiej Kroczek

Hanna Kucwaj
Jagiellonian University, Krakow, Poland

Adam Chuderski
Jagiellonian University, Krakow, Poland

Abstract

At dawn of cognitive science, it was hypothesized that performance on diverse sensorimotor tasks is rooted in unitary sensory discrimination ability that shares the same neural resource with complex cognition. A century of research yielded inconclusive evidence. We modelled the factor structure for 33 diverse visual sensorimotor, memory, and reasoning tasks, completed by 234 young adults. Covariance structure models indicated two considerably correlated, yet statistically separate, sensorimotor abilities reflecting temporal vs. non-temporal processing. However, initially moderate relationships of each simple ability with reasoning disappeared when mediated by working memory, suggesting that sensory discrimination plays no explanatory role for complex cognition. These results were replicated in another study of 255 young adults, who additionally attempted auditory sensorimotor tasks. The latter appeared to be separate from temporal and visual abilities. Overall, sensory discrimination does not constitute unitary ability. Moreover, individual differences in complex cognition cannot be reduced to sensory discrimination.

Sizing Up Relations: Dimensions on Which Stimuli Vary Affect Likelihood of Adults' Relational Processing

Ivan Kroupin
Harvard University, Cambridge, Massachusetts, United States

Abstract

Relational reasoning is central to much of human-unique cognition including artistic metaphor, scientific analogy. While much research has addressed the process of relational reasoning, the conditions under which relational reasoning is engaged in at all remains under-explored.

This work examines the relationship between dimensions on which stimuli vary and the likelihood that these stimuli will be processed relationally by adults. We use a modified relational-match-to-sample paradigm: One of the two choices contains a relational match with the target, the other contains a partial object match. Changing dimensions on which the stimuli vary dramatically effects the likelihood that adults process them relationally (i.e. make relational matches) - from 56% when stimuli vary on shape and color to 98% when stimuli vary on size alone. This is despite the relational content of the task remaining identical throughout.

We discuss implications of these results for designing stimuli, and for theories of relational reasoning generally.

Look out, its going to fall!: Does physical instability capture attention and lead to distraction?

Marta Kryven
Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Sholei Croom
MIT, Cambridge, Massachusetts, United States

Brian Scholl
Yale University, New Haven, Connecticut, United States

Josh Tenenbaum
MIT, Cambridge, Massachusetts, United States

Abstract

Physical scene understanding requires not only detecting the current state of the world, but also predicting how the future will unfold. The need for such prediction is especially salient in the context of physical instability as when an object is teetering, about to fall off a surface. Here we asked whether such scenes automatically capture attention, such that the mere presence of instability will impair performance on a central attention-demanding task. Observers viewed scenes in which an object (e.g. an open laptop) was either sitting stably, or was about to fall off a table. Observers simply completed a central Multiple Object Tracking (MOT) task (e.g which could appear on the screen of the depicted laptop). MOT Performance was indeed worse in the presence of physical instability, despite its task irrelevance, and even when observers failed to notice the physical stability vs. instability in the first place.

Verbal Insight Revisited: fMRI evidence for subliminal processing in bilateral insulae for solutions with AHA! experience shortly after trial onset

Simone Khn
University Medical Center Hamburg-Eppendorf, Hamburg, Germany

Tobias Sommer
University Medical Centre Hamburg-Eppendorf, Hamburg, Germany

Maxi Becker
University Medical Center Hamburg-Eppendorf, Hamburg, Hamburg, Germany

Abstract

In insight problem solving solutions with AHA! experience have been assumed to be the consequence of restructuring of a problem which usually takes place shortly before the solution. However, evidence from priming studies suggests that solutions with AHA! are not spontaneously generated during the solution process but already relate to prior subliminal processing. We test this hypothesis by conducting an fMRI study using a modified compound remote associates paradigm which incorporates semantic priming. We observe stronger brain activity in bilateral anterior insulae already shortly after trial onset in problems that were later solved with than without AHA!. This early activity was independent of semantic priming but may be related to other lexical properties of attended words helping to reduce the amount of solutions to look for. In contrast, there was more brain activity in bilateral anterior insulae during solutions that were solved without than with AHA!. This timing (after trial start / during solution) x solution experience (with / without AHA!) interaction was significant. The results suggest that a) solutions accompanied with AHA! relate to early solution-relevant processing and b) both solution experiences differ in timing when solution-relevant processing takes place. In this context, we discuss the potential role of the anterior insula as part of the salience network involved in problem-solving by allocating attentional resources.

An Investigation on the Relationships Among Social Cognition Processes by Eye-Tracking Techniques

Pei-Ling Kuo
College of Social Science, Tainan, Taiwan

Ting Yun Chen

Jon-Fan Hu
National Cheng Kung University, Tainan City, Taiwan

Abstract

The present study integrates four primary social cognition processes Joint Attention(JA), Intention Detection(ID), Perspective Taking(PT), and Social Reference(SR) into lively comic scenarios in order to disentangle their relationships and possible one-to-one connections. By using eye-tracking technique, gaze patterns in terms of Total Fixation Duration were considered as indexes to examine the hypotheses. It is found that PT is positively correlated with JA, ID, and SR whereas JA is positively correlated with ID and PT. As a criteria-related validation, the scores of Geneva Social Cognition Scale(GeSoCS) were used to delineate the gaze performance. Participants with higher score in GeSoCS showed different eye-movement patterns to those with lower score, indicating the pattern of eye movements could be a reliable indicator of social cognition status. Moreover, the correlations revealed in the present study suggest that close connections exist between social cognition processes and eye gaze scanning toward pictorial scenarios.

Automated cognitive modeling with Bayesian active model selection

Tom Griffiths
Princeton University, Princeton, New Jersey, United States

Abstract

Behavioral experiments are often feed-forward: they begin with designing the experiment, and proceed by collecting the data, analyzing it, and drawing inferences from the results. Active learning is an alternative approach where partial experimental data is used to iteratively design subsequent data collection. Here, we study experimental application of Bayesian Active Model Selection (BAMS), which designs trials to discriminate between a set of candidate models. We consider a model set defined by a generative grammar of Gaussian Process kernels that can model both simple functions and complex compositions of them. To validate the method experimentally, we use BAMS to discover how factors such as contrast and number affect numerosity judgements. We compare the rate of convergence of the active-learning method to a baseline passive-learning strategy that selects trials at random. Active learning over a structured model space may increase the efficiency and robustness of behavioral data acquisition and modeling.

Using interpersonal movement coordination to investigate gender differences in adults with autism

Nida Latif
McGill University, Montreal, Quebec, Canada

Cynthia Di Francesco
McGill University, Montreal, Quebec, Canada

Aparna Nadig
McGill University, Montreal, Quebec, Canada

Abstract

When individuals engage in social interactions, they coordinate their nonverbal movements. Atypical movement coordination may contribute to social difficulties in autism. Further, distinct gender differences have been found in autism: males show reduced socio-communicative behaviours relative to females. Here, we explored whether interpersonal movement coordination differs between males and females with autism, compared to neurotypical (NT) adults. Thirteen adults with autism participated. Twenty-six NT controls are currently being tested. Participants complete a semi-structured interview while being video-recorded. Coordination between participant and examiner is measured using a video-based movement analysis. Females with autism demonstrated significantly greater movement coordination with their conversational partner, within a smaller range, than males. Given past findings, we expect that coordination differences between autistic and NT males will be greater than between autistic and NT females. These preliminary results suggest that investigating movement coordination during interaction may provide a tool for better understanding gender differences in ASD.

Novel labels modify visual attention in 2-year-old children

Alexander LaTourrette
Northwestern University, Evanston, Illinois, United States

Miriam A. Novack
Northwestern University, Evanston, Illinois, United States

Sandra Waxman
Northwestern University, Evanston, Illinois, United States

Abstract

Labeling objects enhances fundamental cognitive capacities like categorization, individuation, and memory in young children. However, the mechanism by which labels support these cognitive processes remains unknown. One possibility is that providing a label for an object changes childrens online visual processing of that object. To address this, we considered several indices of visual attention, asking whether 2-year-old children attend to an object differently if it is labeled (Look at the dax) than if it is paired with a non-labeling phrase (Look at that). We find that 2-year-old childrens visual fixations are longer when objects are paired with a labeling phrase, rather than a non-labeling phrase. Indeed, after hearing a label, children showed a sustained increase in fixation duration. However, the number of fixations children made did not change as a function of labeling. This illustrates an attentional mechanism by which language might enhance learning in 2-year-old children.

Modal concepts: developing thoughts of the possible and the impossible

Brian Leahy
Harvard, Cambridge, Massachusetts, United States

Susan Carey
Harvard University, Cambridge, Massachusetts, United States

Abstract

What is it to represent a single world as having alternative, mutually inconsistent possible futures? A large literature explores this question from philosophical and linguistic perspectives, along with a growing literature in developmental psychology. Recent findings suggest that 36 month olds (Redshaw and Suddendorf 2016) or even 14 month olds (Cesana-Arlotti et al. 2018) prepare for multiple alternative possibile futures. These experiments did not require participants to contrast the possible with the impossible. We replicated Redshaw and Suddendorf (2016), and added conditions that required participants to contrast the possible with the impossible. 36 month olds now failed, as did many 48 month olds, suggesting that their representations do not capture the structure of possibilities. 48 month olds tended to pass our test, but their understanding of possibilities was still fragile. These data converge with other results suggesting that concepts of possibility and impossibility are constructed in the late preschool years.

Drawing conclusions from spatial coincidences: a cumulative clustering account

Jennifer Lee
NYU, New York, New York, United States

Wei Ji Ma
New York University, New York, New York, United States

Abstract

Spatial coincidences allow us to infer the presence of latent causes in the world. For instance, an unusually large cluster of ants allows us to infer the presence of a food source. The leading cognitive model for such inferences is Bayesian, but the Bayesian algorithm is computationally taxing. Humans likely employ a more efficient, approximative algorithm. To characterize the cognitive algorithms used, we had subjects judge whether a set of dots was drawn from a uniform distribution or from a mixture of a uniform and a gaussian source (tending to produce clusters). Responses systematically deviate from Bayesian optimality: as the number of dots increase, subjects more often report a latent cause where none exists. The bias is accounted for by a Bayesian clustering algorithm that cumulatively considers the next-nearest dot to a putative source. This finding helps characterize our tendency to perceive causal patterns where none exist.

Brain responses to verbal mismatches and case marking mismatches: adolescents vs. adults

Sogang University, Seoul, Korea, Republic of

Abstract

This study investigated Korean adolescents behavioral and neural responses to the semantic and syntactic anomalies in Korean compared with adults, focusing on the case marking mismatches. EEG data were collected from 16 Korean adolescents (12 males, aged 12-14 years) using a picture sentence verification task regarding (A) verbal mismatch [AGENT-NOM + Verb/*Verb] (e.g., - /*; Brother-ka catches/*bites) and (B) case marker mismatch [AGENT-NOM/*ACC + Verb] (e.g., -/*- ; Brother-ka/*-lul catches). The behavioral results showed 95% accuracy of their judgment regardless of conditions.The ERP data revealed differences between the conditions: N400 was elicited for verbal mismatches as well as for case marker mismatches. The results are different from data collected from Korean adults, where the syntactic anomalies elicited early negativity at the case marker in addition to the N400 at the verb. The different ERP responses between adults and adolescents to the syntactic anomalies provide evidence for the continuous development of human brains.

Evidence for a 30-million-word gap across language environments of children with cochlear implants

Matthew Lehet
Michigan State University, East Lansing, Michigan, United States

Meisam K. Arjmandi
Michigan State University, East Lansing, Michigan, United States

Laura Dilley
Michigan State University, East Lansing, Michigan, United States

Abstract

Hart and Risley (1995) found evidence of a 30-million-word gap by the age of three between children experiencing the most and the least spoken input. In the present study, we investigated the magnitude of differences in amount of linguistic input in environments of a clinical population: children with cochlear implants. We identified a 30 million word gap over three years between children who received the most and the least spoken language input in their home environments. Further, we identified a 22 million word gap in numbers of infant-directed spoken words experienced by children hearing the most and the least input. Together, the results suggest that some children with cochlear implants may be doubly disadvantaged in acquiring spoken language, due to the degradation of the speech signal associated with electronic hearing, and due to the dearth of quality linguistic input in sufficient quantity in their language environments.

Approximate Inference through Sequential Measurements of Likelihoods Accounts for Hicks Law

Xiang Li
New York University, New York, New York, United States

Luigi Acerbi
University of Geneva, Geneve, Switzerland

Wei Ji Ma
New York University, New York, New York, United States

Abstract

In Bayesian categorization, exactly computing likelihoods and posteriors might be hard for humans. We propose an approximate inference framework inspired by Bayesian quadrature and Thompson sampling. An agent can pay a fixed cost to make a noisy measurement of the likelihood of one category. By sequentially making measurements, the agent refines their beliefs over the likelihoods. When the agent stops measuring and chooses a category, they get rewarded for being correct; the agent chooses the category that maximizes probability correct. To decide whether to make another measurement, the agent simulates one measurement for each category. If any of the gains in expected reward exceeds the cost, they make a real measurement corresponding to the simulation with the largest gain. We find that the average number of measurements grows approximately logarithmically with the number of categories, reminiscent of Hicks law. Furthermore, our model makes predictions for decision confidence among multiple alternatives.

Do children really have a trust bias? Preschoolers reject labels from previously inaccurate robots but not inaccurate humans

Xiaoqian Li
Singapore University of Technology and Design, Singapore, Singapore

Wei Quin Yow
Singapore University of Technology and Design, Singapore, Others, Singapore

Abstract

Past research suggests that young children have a bias to believe what they are told so that they often trust an informant regardless of the informants previous accuracy. With the ubiquity of new technology, children regularly come in contact with non-human agents such as robots, yet little is known how children are trusting and thus willing to learn from these artificial beings. In our study, 3.5- to 5.5-year-old children (N=120) watched a single informant (either a robot NAO or a human adult) name familiar objects either accurately or inaccurately. The same informant subsequently tested children on their willingness to accept novel labels for novel objects provided. While children trusted the accurate robot and the accurate human to the same extent, they were less likely to accept information from the inaccurate robot than the inaccurate human. This suggests that preschoolers may not readily extend their trust bias to robots as informants.

Predicting human decisions in a sequential planning puzzle with a large state space

Yichen Li
New York University, New York, New York, United States

Zahy Bnaya
New York University, New York, New York, United States

Wei Ji Ma
New York University, New York, New York, United States

Abstract

We study human sequential decision-making in large state spaces using a puzzle game called Rush Hour. A puzzle consists of a dense configuration of rectangular cars on a 6x6 grid. Each car moves only horizontally or vertically. The goal is to move a target car to an exit. In a given state (board position), a subject (n=86) could move a car, restart the puzzle, or surrender. A move is correct if it reduces the distance (number of moves) to the goal. Using mixed-effects logistic regression modeling, we find that the probabilities of an error, a restart, and a surrender are higher with a longer distance to goal, higher mobility, and when the previous move was an error. The effects of distance to goal and mobility are consistent with tree search. As a next step, we plan to investigate the heuristics that people might use for such tree search.

Scientific knowledge organized through question network

Zhiwei Li
NYU, new york, New York, United States

Kai Ren
National University of Singapore, Singapore, Singapore

Abstract

Research in science is usually built uponcomplex background knowledge and assumptions, making it difficult to organize and overview. We propose using question network to dynamically maintain scientific knowledge, with each nodes being either a question or an answer, linked with relations such as specification, contrast and so on. Publications can then be fitted into nodes of the network. By constructing example networks around cognitive concepts, we observed a big question (e.g. What is curiosity?) being answered with theoretical speculation initially, then specified into the operationalized definition (How to measure curiosity as a personality?) and computational algorithms. Similar patterns are repeated in different branches of the network. We also compare research topics starting with similar questions yet develop differently.

Causal Structure and Probability Information Modulate the Preference for Simple Explanations

Emily Liquin
Princeton Univerisity, Princeton, New Jersey, United States

Tania Lombrozo
Princeton University, Princeton, New Jersey, United States

Abstract

Are simple explanations better? Research has shown that people favor simple explanations (defined as number of unexplained causes; Lombrozo, 2007; Pacer & Lombrozo, 2017), but new findings suggest that under some conditions, complexity is preferred (Johnson et al., in press; Zemla et al., 2017). We explore three features that could affect preferences: causal structure, baserates, and likelihoods. Adults (N=544) read one simple and one complex explanation following one of three causal structures. Simplicity preferences were strongest for one vs. two causes explaining two independent effects, modest for one vs. two jointly sufficient causes explaining one effect, and reversed (to favor complexity) for one vs. two independently sufficient causes explaining one effect. When baserates and likelihoods were specified and matched, simplicity preferences were attenuated, while complexity preferences were sometimes reversed. These findings suggest that simplicity preferences are moderated by several factors and point to a more unified account of explanatory reasoning.

The Development of Children's Understanding of Arguments by Analogy

Nicole Lobo
Arizona State University, Glendale, Arizona, United States

Zachary Horne
Arizona State University, Phoenix, Arizona, United States

Abstract

Analogical reasoning allows humans to make inferences about novel experiences and transfer learning across contexts. There is substantial literature on how analogical reasoning develops, but less is known about how children understand a common use of analogyargument by analogy. Considering the importance argument by analogy plays in politics and the law, we examined the developmental trajectory of the ability to understand arguments by analogy. We measured childrens (N = 128, ages 3-12 years old) performance on a commonly used analogical reasoning task (i.e., a picture-mapping task; see Richland et al., 2006) and their understanding of arguments by analogy. We found that at age 4, children have as much difficulty understanding arguments by analogy as they do performing a picture-mapping task. However, by age five, childrens performance improves more rapidly in an argument by analogy task compared to a picture-mapping task.

Modeling practice-related reaction time speedup using hierarchical Bayesian methods: Evidence for a process-shift account

Jarrett Lovelett
University of California San Diego, San Diego, California, United States

Ed Vul
University of California, San Diego, La Jolla, California, United States

Tim Rickard
University of California San Diego, La Jolla, California, United States

Abstract

In skill-learning tasks, reaction times (RTs) typically decrease with practice. For example, in alphabet arithmetic tasks (e.g. J + 7 = ?), learners respond correctly (e.g. Q) faster on later than on earlier trials. A number of mathematical models have been proposed to account for the functional form of practice-related RT speedup. We aim to evaluate which of two candidates better fits observed speedup data for individual learners across several tasks. In particular, we compare a process-shift account in which learners initially execute an algorithm in constant time, but as trials accumulate, exhibit power-law speedup as they directly retrieve a memorized solution to a delayed exponential model in which RTs decrease exponentially after learners eventually achieve insight into a task-appropriate strategy. Using hierarchical Bayesian models of each account (which can flexibly model learning in individual subjects), we show that the process-shift model better predicts out-of-sample data than the delayed-exponential model.

The Effects of Contextual Cues on the Learning of Prepositions

Michelle Luna
University of California, Los Angeles, Los Angeles, California, United States

Catherine Sandhofer
University of California, Los Angeles, Los Angeles, California, United States

Abstract

Language has the power to shape the way people organize their thoughts and concepts. Some concepts, like spatial words, are categorized differently cross-linguistically. Conflicting language-to-concept mappings, such as the Spanish en translating to both in and on, may pose difficulty to Spanish speakers learning English. This study investigated how contextual cues can help children learn prepositions. Three-year-olds were read preposition books that were arranged in one of two conditions: separation or control. The separation condition had each instance of in appear in one visual context (e.g., Bear put the apple in the box, blue page) and each instance of on appear in a separate context (e.g., Penguin put the ball on the grass, green page). The control condition eliminated the contextual cues by presenting instances of in and on in both contexts. This study informs our understanding of strategies to improve the learning of spatial words in everyday adult-child interactions.

How does temperature affect behaviour? A meta-analysis of effects in experimental studies

Abstract

The surrounding environment has a profound impact on human behaviour. Historically, studies have shown that higher temperatures are associated with increases in antisocial behaviours (aggression, violence). More recently, studies have linked higher temperature experiences to increases in prosocial behaviours (altruism, co-operation). Such contrasting patterns leave the status of temperature-behaviour links unclear. Here we conduct a series of meta-analyses of laboratory-based empirical studies that measure either prosocial (monetary reward, gift giving, helping) or antisocial (retaliation, horn honking, sabotage) outcomes, with temperature as an independent variable. Overall, we found that there was no reliable effect of temperature on the behavioural outcomes measured. In follow-up analyses, there was no reliable effect of temperature on prosocial or antisocial outcomes when analysed separately. We consider why the evidence to support temperature-behaviour links from laboratory-based studies is weak, assess potential moderators, and examine how future studies can attempt to reconcile seemingly contradictory patterns in the literature.

Measuring Creativity in the Classroom: Linking Group Patterns with Individual Outcomes

Leanne Ma
OISE/University of Toronto, Toronto, Ontario, Canada

Abstract

Although creativity has traditionally been measured as an individual trait (Runco & Jaeger, 2012), contemporary research on workplace innovation (Kelley & Littman, 2001; Nonaka, 2008) suggests that creativity is a collaborative process of working with ideas (Amabile & Pratt, 2016). Furthermore, organizational creativity can be measured using social network analysis (Gloor, 2006) the more emergent leaders, the more creative the outcome (Gloor et al., 2016). Gloor's creativity measure was adapted in a grade 1 class (n=22) to explore whether leaders would emerge when students engaged in creative problem-solving through online discussions in Knowledge Forum (Scardamalia, 2017). Social network analysis reveals that 13 students emerged as leaders, and content analysis of the discussion indicates that leaders proposed new ideas that helped deepen the progression of ideas. Additional analyses are underway to explore correlations between leadership and creativity scores. Educational implications for developing the creative potential of young students are discussed.

Deconvolving a Complex, Real-Life Task: Do standard lab tasks predict CPR learning and retention?

Sarah Maa
University of Groningen, Groningen, Netherlands

Florian Sense
University of Groningen, Groningen, Netherlands

Hedderik van Rijn
University of Groningen, Groningen, Netherlands

Abstract

Cardiopulmonary resuscitation (CPR), a basic life-saving skill, requires a combination of procedural and declarative knowledge. CPR proficiency was assessed and re-trained to criterion across four sessions (spaced weeks to months apart). In addition, three laboratory tasks were administered: continuation tapping, paired-associate learning, and Raven matrices. These served as proxies for procedural learning, declarative learning, and general cognitive ability, respectively. Even though a computational model (Predictive Performance Equation, Walsh et al., 2018) predicted long-term CPR performance, none of the lab tasks correlated with any aspect of CPR performance (initial performance, (re-)learning, or retention of CPR; see https://osf.io/m8bxe/ for details). These results highlight the challenges faced when translating lab results into real-world domains and can serve as a benchmark for applying computational models to real-life learning and forgetting.

Controlling Automobiles During Unconsciousness of the Driver using Brainwaves

Nilakshi Mahanta
North Eastern Hill University, Guwahati, Assam, India

Abstract

Introduction: Controlling Automobiles during unconsciousness of the driver using Brainwaves. Brainwave based accident avoidance system is an effective way to prevent accident caused due to drowsy driving. Every year number of road mishaps are caused by drowsy driving. The proposed idea brainwave based accident avoidance system is to avoid this kind of accident using Electroencephalography (EEG) of human brain and speed control in automobiles. Human brain consists of millions of interconnected neurons. The patterns of interaction between these neurons are represented as thoughts and emotional states. According to the human thoughts, this pattern will be changing which in turn produce different electrical waves. A muscle contraction will also generate a unique electrical signal. All these electrical waves will be sensed by the brain wave sensor and it will convert the data into packets and transmit through Bluetooth medium. Level analyzer unit (LAU) will receive the brainwave raw data and it will extract and process the signal using MATLAB platform. Then the control commands will be transmitted to the motor to process. With this entire system, we can control / stop the vehicle according to human thoughts. Electroencephalography (EEG) is the fundamental idea utilized as a part of this framework. Neurosky mind wave sensor is utilized as primitive segment to examine the Brainwave signals. In this way by controlling vehicles it can spare numerous mishaps and can spare numerous lives. Among these bands, theta and alpha are the signals which represent drowsiness to relaxed sleep. Methods: In a brain controlled vehicle, controller is based on Brain Computer Interface (BCI). BCIs are systems that can bypass conventional channels of communication to provide direct communication and control between the human brain and physical devices by translating different patterns of brain activity into commands in real time. With these commands a vehicle can be controlled. The intention of this work is to design and develop a system that can assist the person during their unhealthy condition to avoid the accident on the road. Results: Brainwave based accident avoidance system for unhealthy condition of the drivers which predict the signals and system in engaging with processing of signals to alert the drivers unconscious situation. The biggest challenge about the system is that to determine the signal from the headset. Proper identification is needed for the signals so that wrong signal does not trigger the routine even when driver is not unconscious. Every person is different and every person has different thoughts and emotions so they might have slightly different brainwave signals. So before adapting this system, the interface should be configured according to the brain activity of the driver. Discussion: The research and development of brainwave controlled vehicle during unconsciousness of the driver has received a great deal of attention because they can help to avoid the accident on the road. Improving the BCI system performance to make brainwave controlled vehicles usable in real-world situations. Keywords: Brain Computer Interface (BCI), Brain Wave Sensor, EEG, Bluetooth

Cultural difference of the effect of analytical / intuitive thinking style on reasoning, JDM, and belief tasks.

Yoshimasa Majima
Hokusei Gakuen University, Sapporo, Japan

Abstract

Research within the dual-process framework have repeatedly suggested that individuals thinking style can predict their performance on reasoning, judgment, decision making, and acceptance of religious and paranormal statements. However, some studies also suggested that the link between analytical thinking and epistemically unwarranted beliefs was peculiar to so-called WEIRD societies. The present study aimed to explore the possible cultural (Western and Eastern) difference on the relationship between performance and style of our thinking. Participants were presented with various tasks including belief bias, denominator neglect bias, numeracy, temporal discounting, risk preference, and paranormal belief. They were also presented with tasks measuring their thinking styles (CRT and Rational-Experiential Inventory). Results showed that the effects of thinking style on heuristics-bias and decision-making tasks were almost similar between two cultures, however we find a significant style-culture interaction in paranormal beliefs. This may suggest a cultural difference of the role of analytical thinking on belief-based response.

Testing human use of probability in a visuo-motor conjunction task

Laurence Maloney
New York University, New York, New York, United States

Jinsoo Kim
New York University, New York, New York, United States

Keiji Ota
New York University, New York, New York, United States

Abstract

People overestimate the conjunctive probability of independent events (Bar Hillel, 1973). We examined conjunctive performance in a task involving motor uncertainty and binomial sampling. Human probabilistic judgment is typically near-optimal with either of these sources of uncertainty alone. Four subjects attempted to earn rewards by reaching to circular targets. They chose between a single smaller target and one of N larger targets. Hitting the single target always earned a reward but only one on the N larger targets was rewarded: they chose between P[Smaller] and the conjunctive probability (1/N)*P[Larger] as we varied N and the sizes of the targets. The ideal observer should be indifferent when P[Smaller] = (1/N)*P[Larger]. We also asked observers to estimate the probability of hitting targets of different sizes to verify that they could do so accurately. Remarkably, three out of four observers ignored numerosity N in their preferences.

The Influence of Implicit Normative Commitments in Decision-Making

Alexia Cristina Martinez
Princeton University, Princeton, New Jersey, United States

Abstract

We approach some decisions (e.g., choosing an investment plan) by deliberating about our options, and others (e.g., choosing dessert) by relying on intuition. In a study with 259 participants evaluating hypothetical decisions, we investigate factors that predict whether deliberation and/or intuition is judged appropriate. We find that participants are more inclined to endorse deliberation, and less inclined to endorse intuition, when they believe the means and ends involved in a decision can be objectively evaluated (consistent with Inbar, Cone, & Gilovich, 2010). We also find that violations of coherence (i.e., endorsing contradictory beliefs about a decision) predict higher ratings for intuition, as does belief that a given decision reflects ones identity. These findings hold after adjusting for perceived effort, importance, and stakes. We suggest that deliberation is judged appropriate when people believe that norms governing rational action apply, and we consider the implications for real-world decision-making.

Forming Action-Effect Contingencies through Observation of a Dot-Control Task

Jasmine Mason
Illinois State University, Normal, Illinois, United States

J. Scott Jordan
Illinois State University, Normal, Illinois, United States

Abstract

Previous research suggests the possibility that observers have access to action plans of others (Jordan & Hommel, 2008). To examine this we design three experiments. The first examines action-plan coding in participants performing the task (controllers) using a Hommel-like 'compatibility' test measuring reaction times (Hommel, 1996). We manipulated the inclusion of task irrelevant auditory tones during the dot-control game. The second experiment utilized the same design to examine observer's action-plans after watching the experimenter play the dot control game. Experiment 3 allows us to examine the additional effects of the controller's skill level and observer's level of access to the task. So far the results support the hypothesis that participants can learn action plans by observing the distal effects of another's actions. Further research will help unearth the factors mediating observer's action plan coding and the differences between how controllers and observer's encode actions and their different effects.

Analysis on learning a latent structure in a probabilistic reversal learning task

Akira Masumi
National Institute of Technology, Okinawa College, Nago, Okinawa, Japan

Takashi Sato
National Institute of Technology, Okinawa College, Nago, Okinawa, Japan

Abstract

We need to be flexible to adapt to dynamically changing circumstances. A probabilistic reversal learning task is one of the experimental paradigms to characterize flexibility of a subject. In recent studies, it is hypothesized that a subject may utilize not only a reward history but also a cognitive map representing a latent structure of the task. In this study, we conducted an experiment using the task toward understanding a process of learning a latent structure of the task. We found subjects choose a rewarding option with relatively high frequency in a later phase of the task. Analyzing the subjects decision making, it is suggested that they make decision based on their own estimation about the latent structure. A statistical model selection suggested that a reinforcement learning model with state representations fit behavioral data in the later phase. These results suggest the subjects learn the latent structure during the task.

The role of environment and body in divergent thinking tasks

Heath Matheson
University of Northern British Columbia, Prince George, British Columbia, Canada

Yoed Kenett
University og Pennsylvania, Philadelphia, Pennsylvania, United States

Alexander LePage LePage
University of Northern British Columbia, Prince George, British Columbia, Canada

Mathew Sargent
University of Northern British Columbia, Prince George, British Columbia, Canada

Abstract

Humans are creative tool users. We investigated whether body posture and environmental context influence creative output in the divergent thinking task. Participants adopted either flexion or extension body postures and were shown images of kitchen utensils or work tools. Each image was primed with an image of either a congruent environment or an incongruent environment. Results show that body posture, specifically extension, results in faster generation of responses, especially when the object is primed by a congruent environment, and that extension increases sensitivity to environmental primes, increasing fluency overall. Our results shed light on the cognitive mechanisms of generating creative object uses.

Spatial Alignment Enhances Comparison of Complex Educational Visuals

Bryan Matlen
WestEd, San Francisco, California, United States

Benjamin Jee
Worcester State University, Worcester, Massachusetts, United States

Nina Simms
Northwestern University, Evanston, Illinois, United States

Dedre Gentner
Northwestern University, Evanston, Illinois, United States

Abstract

Grasping relational concepts is facilitated by comparing their representations. Previously, Matlen et al (2014; under review) found that for simple visual figures, the comparison process was optimized when the visuals were placed in direct spatial alignment, such that the main axes of the visuals run perpendicular to their placement (e.g., horizontal figures placed vertically), relative to impeded spatial alignment, when the axes run parallel to their placement. In the present work, we tested this spatial alignment effect using complex naturalistic stimuli, consisting of skeletal structures. Participants identified anomalous bones by comparing a correct skeleton with a skeleton that had an incorrect bone. Participants were more accurate when skeletal structures were placed in direct (M=.90) relative to impeded (M=.84) alignment (p¡.01). Given the relevance of these findings to education, we are formally coding visuals in middle-school science textbooks based on their spatial alignment and will present these results at the conference.

Quality of STEM Learning from Childrens Books

Hilary Miller
Emory University, Atlanta, Georgia, United States

Lucy Cronin-Golomb
Emory University, Atlanta, Georgia, United States

Patricia J. Bauer
Emory University, Atlanta, Georgia, United States

Abstract

Promoting STEM knowledge early in development helps prepare children for school success. Exposing children to STEM books may be a simple and effective means for promoting early STEM knowledge. However, whether preschool-aged childrens STEM books are optimally designed is unknown. Children and adults learn new information more effectively when there is support for encoding and demand for active processing. We have conducted a textual analysis of 50 STEM books designed for preschool-aged children. The books are coded for (a) support for encoding (narratively cohesive and topic maintaining), and (b) demand of active processing (posing questions and including interactive prompts). Preliminary data shows that on average the books include limited support for encoding and demand for active processing. This suggests that these books are not fulling their potential of promoting early STEM knowledge. Next steps in this research involve identifying means for enhancing STEM childrens books efficacy.

The Development of Reasoning About Abductive, Inductive and Deductive Conditionals

Patricia Mirabile
Sorbonne Universit, Paris, France

Zachary Horne
Arizona State University, Phoenix, Arizona, United States

Abstract

Conditionals are statements of the form "If P, Then Q". Reasoning about conditionals is a core component of human cognition. However, studies of how adults and children interpret and use conditionals have highlighted discrepancies between human reasoning and logic inference rules. Recently, Douven and Verbrugge (2010) have found that a classification of conditionals based on the type of inferential connection between the antecedent and the consequent (e.g., deductive, inductive and abductive conditionals) allowed for a finer analysis of adult conditional reasoning. Do these findings extend to child conditional reasoning? We report a study (N=200, ages 4 to 11) that examines how performance in modus ponens and modus tollens tasks depends on the type of conditional embedded in the argument. These results will shed light on how the development of conditional reasoning in children is sensitive to the nature of the inferential relationship of conditionals.

Looks delicious? Cerebral blood flow in young adults with eating disorder tendencies on exposure to food pictures

Kozue Miyashiro

Reiko Ohmori
Utsunomiya University, Utsunomiya-City, Tochigi Prefecture, Japan

Satoko Shiraishi
Utsunomiya University, Utsunomiya-City, Tochigi Prefecture, Japan

Yumiko Ishikawa
Utsunomiya University, Utsunomiya-City, Tochigi Prefecture, Japan

Abstract

We examined the physiological changes brought on by the sight of foods in people with high eating disorder tendencies relative to normal controls. Graduate students were assessed for eating disorder tendencies using a questionnaire. Functional near-infrared spectroscopy was used to observe participants when five pictures were presented, in five categories: popular food (fried chicken), non-popular food (Japanese simmered dishes), inedible object (screw), comfortable animal (rabbit), and uncomfortable animal (cockroach). Most participants oxyhemoglobin density was found to be different in response to two pictures (fried chicken and cockroach). This indicates that this level of cerebral blood flow corresponds to unpleasant feelings. However, students with higher eating disorder tendencies showed high-level oxyhemoglobin density in the same channel, indicating discomfort, in response to popular food, neutral objects, and the uncomfortable animal. Our study implies the attitudes toward foods totally differ at cognition in people with high eating disorder tendencies compared with healthy people.

Interactive Cognitive Modeling: Understanding and Supporting Individual Human Cognition

Junya Morita
Shizuoka University, Hamamatsu, Shizuoka, Japan

Abstract

Cognitive modeling, approximation of human cognitive functions in a computational system, is a traditional methodology in the field of cognitive science. Usually this methodology has been used as a tool for scientific understanding of human mind, and evaluated by fitting to human data. In this presentation, the author proposes a framework of interactive cognitive modeling as an application of the above methodology for understanding and supporting individual human cognition. The framework consists of cognitive architecture, visualization of the model behavior, knowledge database of personal user and sensing devices to include the users reaction. This presentation shows two systems of interactive cognitive modeling in the field of web browsing and photo browsing.

Lexical iconicity facilitates word learning in situated and displaced learning contexts

Yasamin Motamedi
University College London, London, United Kingdom

Elizabeth Wonnacott
University College London, London, London, United Kingdom

Chloe Marshall
University College London, London, London, United Kingdom

Pamela Perniss
University of Cologne, Cologne, Germany

Gabriella Vigliocco
University College London, London, United Kingdom

Abstract

We present an experimental study that examines how lexical iconicity (i.e. onomatopoeia) affects early word learning, across learning contexts. Children aged 24-36 months (N=37) were first trained on labels that are either iconic or neutral with respect to the referent event, and then tested using a forced-choice task to select the correct referent given a label. We assessed learning across two contexts: situated, where label and referent co-occur, and displaced, where children learn the label following the referent event. We predicted that iconicity would aid word learning, and would have a more facilitatory effect in the displaced condition, helping the child to associate label and referent. Our findings demonstrate that children learn iconic labels in the experiment better than they do neutral labels. However, we find no difference across learning contextsiconicity facilitates word learning in both situated and displaced learning scenarios.

The Effect of Alternative Outcomes on Perceived Counterfactual Closeness

Matthew Myers
Northwestern University, Evanston, Illinois, United States

Lance Rips
Northwestern University, Evanston, Illinois, United States

Abstract

Assessing the likelihood that a counterfactual event would have happened involves contrasting a factual outcome with the counterfactual alternative. In many situations, the number of alternatives will influence the perceived closeness of a particular alternative. For example, losers of a game in which participants guess which door conceals a prize will likely believe they were closer to winning when there were three doors compared to six. This reflects accurate probabilistic reasoning because more doors will be associated with a lower probability of winning. However, we test whether the number of alternatives has a unique influence on beliefs about counterfactual closeness. Experiments 1 and 2 show that, even when probability is held fixed, people believe counterfactual closeness decreases when there are more alternatives.

On falsification and Optimal Experimental Design approaches to the value of information

Jonathan D. Nelson
University of Surrey, Guildford, United Kingdom

Vincenzo Crupi
University of Turin, Torino, Italy

Flavia Filimon
University of Surrey, Guildford, Surrey, United Kingdom

Garrison Cottrell
UCSD, La Jolla, California, United States

Abstract

There is a great deal of discussion about whether people intuitively seek to falsify their working hypothesis. But there has been little consideration of the relationships between falsificationist and probabilistic Optimal Experimental Design (OED) approaches to evaluating the usefulness of possible experiments. Recent work has shown that a variety of important OED and heuristic models can be derived as special cases of the generalized Sharma-Mittal framework of information gain measures. We show how falsification-like behavior can also derive from a quasi-information gain model, based on high-degree Tsallis entropies. Our analysis shows that falsificationist and probabilistic approaches are not as far apart as the east and the west. Rather, they can be built out of virtually the same set of ingredients, within a probabilistic framework. We report simulation studies showing how important falsificationist, OED, and hybrid models could be differentiated as possible descriptive accounts of information-seeking behavior.

Effects of implicit processes on conversion from a sub-optimal to an optimal solution

YUKI NINOMIYA
Nagoya University, Nagoya-shi, Aichi-ken, Japan

Hitoshi Terai
Kindai University, Iizuka-shi, Fukuoka, Japan

Kazuhisa Miwa
Nagoya University, Nagoya-shi, Aichi-ken, Japan

Abstract

Conversion from an initial representation for gaining insight has mainly been studied in experimental settings where solution through that initial representation is impossible.Many studies of insight problem solving have shown that an implicit process engage in conversion from an inadequate initial representation. However, few studies exist about such conversion in a situation in which solution by the initial representation is possible. A typical situation is conversion from a sub-optimal to an optimal solution. In such a situation, solution by the initial representation is inefficient, but possible. Therefore, participants received no negative feedback that the solution is impossible.In this study, by measuring eye movement, we investigated the hypothesis that the implicit process also emerges in such a situation. We found that the implicit process related to relaxation of fixedness on the sub-optional solution was observed prior to conscious finding of the optimal solution.

Bayesian Item Response Model with Condition-specific Parameters for Evaluating the Differential Effects of Perspective-taking on Emotional Sharing

Keishi Nomura
The University of Tokyo, Meguro-ku, Tokyo, Japan

Aiko Murata
Nippon Telegraph and Telephone Corporation, Atsugi, Kanagawa, Japan

Yuko Yotsumoto
The University of Tokyo, Meguro-ku, Tokyo, Japan

Shiro Kumano
Nippon Telegraph and Telephone Corporation, Atsugi, Kanagawa, Japan

Abstract

It is known that perspective-taking helps humans recognize anothers emotional state on an individual basis. Here, we investigated how perspectives influence emotional sharing, namely the act of understanding mood, or a relationship between other people in a multiparty conversation. In order to capture the effects of perspectives on sensitivity and bias in responses, we introduced condition-specific parameters in a Bayesian item response model. The model revealed that interlocutors are more sensitive and biased to emotional incongruency when they give ratings for a pair including themselves than that excluding them. This relationship holds for observers who did not participate in the conversation and took the respective perspectives. The findings support the assimilating effects of perspective-taking through which people can perceive mood as the target does.

The influence of mental fatigue on delay discounting

Samuel Nordli
Indiana University, Bloomington, Indiana, United States

Peter Todd
Indiana University, Bloomington, Bloomington, Indiana, United States

Abstract

The capacity to continually exert self control appears to become temporarily depleted over time, leading to mental fatigue and self-control failures. Some researchers have proposed that self control requires limited resources which must be periodically replenished, but no direct evidence supports this theory. An alternative explanation is that mental fatigue is an evolutionarily-adaptive feature for managing motivations, serving to temporarily disincentivize the present course (or type) of action, thereby redirecting behavior towards other goals that may better serve an individuals evolutionary fitness. Since self control is typically associated with delayed gratification and self-control failures with immediate gratification, mental fatigue may generally encourage immediately-gratifying behavior by temporarily increasing the extent to which individuals devalue all future rewards (delay discounting). To test this hypothesis, the present study examines whether delay discounting increases for participants who have recently completed a fatiguing task.

Learning Preferences as an Index of Individual Differences in Cognitive Flexibility

Hayley O'Donnell
Drexel University, Philadelphia, Pennsylvania, United States

Evangelia G. Chrysikou
Drexel University, Philadelphia, Pennsylvania, United States

Abstract

Recent findings suggest that when solving problems involving cognitive flexibility (CF), individuals who approach a learning task using reinforcement learning (RL), outperform those who approach the task using supervised learning (SL). Based on these data, we hypothesized that CF is a function of individual differences in learning preference and task demands. Healthy native English speakers were administered three CF tasks that incorporated (i) shifting, (ii) divergent thinking, or (iii) both shifting and divergent thinking elements. Participants response selection history on a reward-based learning task, which could be approached either through SL or RL, was used to determine each participants learning style and predict CF performance. Results showed that different CF task components (i.e., whether the task involved divergent thinking) interacted with participants learning preferences as measured by the independent learning task. We discuss how learning preferences might capture individual differences in CF.

An Engineered Approach: Examining the Role of Child-directed Speech With Automatic Speech Recognition and Network Science

Erick Oduniyi
University of Kansas, Lawrence, Kansas, United States

Rebekah Manweiler
University of Kansas, Lawrence, Kansas, United States

Jonathan Brumberg
University of Kansas, Lawrence, Kansas, United States

Abstract

Language acquisition is a significant developmental process children undertake automatically but is only partially understood. Though researchers have long debated the influence of internal knowledge and external stimuli in language acquisition, both features are required for this process. External stimuli are dominated by child-directed speech for the first few years of life. Accordingly, the role of child-directed speech (CDS) in early language acquisition continues to attract cognitive and developmental researchers. Here, we use statistical and computational tools from Automatic Speech Recognition (ASR) and Network Science to explore the statistical nature of CDS. In particular, we examine CDS using two complementary computational approaches: a bottom-up approach using ASR as a representation of auditory processing, and a top-down approach using networks to represent semantic and syntactic knowledge. Exploring CDS with both methods offers the unique opportunity to model the role of CDS in language acquisition from a more holistic perspective.

The Influence of Emotional Cues on Toddler Word Learning

Marissa Ogren
University of California, Los Angeles, Los Angeles, California, United States

Catherine Sandhofer
University of California, Los Angeles, Los Angeles, California, United States

Abstract

Prior research indicates that the physical context in which a word is spoken can influence how well young children learn the word. Yet, it is unclear how variability in social contexts (e.g. emotion) may impact word learning. To assess this, the present study used a novel noun generalization task with 2-year-old children. Participants were randomly assigned to one of four emotional labeling conditions: consistently angry, consistently happy, consistently sad, or variable (one label in each emotional tone per trial). We investigated whether the number of correct responses out of eight trials varied by emotional condition. Preliminary data from 28 (14 female) participants suggests that the percentage of correct responses in the sad (59.4%) and happy (64.3%) conditions may be lower than in the angry (70.8%) or variable (69.6%) conditions. These results hold implications for how emotional contexts may influence childrens ability to learn new words.

Modeling Intuitive Teaching as Sequential Decision Making Under Uncertainty

Pamela Osborn Popp
New York University, New York, New York, United States

Todd Gureckis
New York University, New York, New York, United States

Abstract

Informal teaching is a ubiquitous social behavior with a rich evolutionary history. We model teaching as the decision making problem of planning a sequence of actions to convey information to a naive learner. We compare humans intuitive teaching actions in a simple collaborative game to the optimal solution of a Partially Observable Markov Decision Process (POMDP). In a teaching POMDP, the current state is the latent, unobservable knowledge of the student and pedagogical actions may yield changes in that knowledge or provide partial information about the students state. In our experiment, human teachers balance assessment and instruction while incorporating prior information about student knowledge. Viewing teaching as a POMDP suggests specific predictions for when different teaching actions (e.g., testing versus instruction) should be preferred under different conditions. Improving our understanding of the decision making strategies that underlie intuitive teaching has a range of implications from education to clinical rehabilitation.

Congruency Effects and Individual Differences in Bilingual Experience Influence Simon Task Performance

Pauline Palma

Debra Jared
The University of Western Ontario, London, Ontario, Canada

Debra Titone
McGill University, Montral, Quebec, Canada

Abstract

Prior work examining executive control during the Simon task has focused on global congruency alone and/or has primarily contrasted bilinguals with monolinguals. This is problematic for two reasons: (1) prior trial experience on current trial performance is unaccounted for (Grundy et al., 2017) and (2) bilinguals are not a homogeneous group. Here, we examined the interaction between prior and current trial congruency in the Simon Task for 65 bilingual young adults who varied continuously in bilingual experience. Generally, current trial congruency effects were larger when the prior trial was congruent vs. incongruent. However, as non-L1 experience increased, this interaction diminished; the overall prior trial effect was reduced independently of age of acquisition. Crucially, neither non-L1 experience nor age of acquisition influenced current trial congruency alone. Although preliminary, these results suggest that both congruency effects and bilingual experience influence performance on a non-linguistic executive control task.

Is Font Type and General Recommendation Really Playing Role in Dyslexic Comfortable Reading?

Tereza Pailov
Masaryk University, Brno, Czech Republic, Czech Republic

Bruno Mik
Masaryk University, Brno, Czech Republic

Abstract

Different visualizations of texts have been studies within dyslexia and significant effect of font attributes have been proved. However, the newest studies show that dyslexia is not only a matter of visual or phonological deficit and could be connected to blue cone area spots. We present a study that was designed on the basis of previous published articles and recommendations. Participants were splitted into two groups of dyslexic and nondyslexic readers. We measured reading time, comprehension and personal preferences of font types. The results show that the fastest reading time does not correspond with highest preference. Moreover, we have an interesting observation concerning preferences and reading time of participants with computer science background. This article brings new insights which could serve for further research and new design of effect of font type studies and can support blue cone theory and critical role that different languages play in dyslexia.

Semi-supervised Learning with 2D Categories

John Patterson
Binghamton University, Binghamton, New York, United States

Kenneth Kurtz
Binghamton University, Binghamton, New York, United States

Abstract

Research has shown that 1D category representations acquired through supervision change after unsupervised exposures that suggest a different boundary. However, it is unclear whether this effect generalizes to categories in which multiple dimensions are relevant. To address this question, we trained participants on a 2D information integration structure (a diagonal boundary) under supervision. Participants then classified unsupervised items that implied either a steeper or flatter boundary than that established by supervision creating a conflict region where items should switch membership. Participants classified a grid of the stimulus space both immediately before (pretest) and after (posttest) unsupervised learning to assess for differences. We found that conflict-region items were more likely to be classified as members of the opposite class on the posttest, relative to pretest in a manner consistent with the unsupervised learning condition. Implications of these findings for semi-supervised learning research and theories of category learning are discussed.

Five aspects of compositionality and a universal principle

Steven Phillips
National Institute of Advanced Industrial Science and Technology, Tsukuba, Ibaraki, Japan

Abstract

Compositionality supposedly explains structure-sensitive features of cognition, such as productivity and systematicity. However, the nature of compositionality is still controversial: e.g., symbolic versus subsymbolic. Category theory—a formal theory of structure—provides an explanation for systematicity in terms of universal morphisms: the optimal factorization of cognitive components (Phillips & Wilson, 2010). We survey five aspects of compositionality as they relate to formal properties of universal morphisms. The emerging view is a unified (universal) principle for compositionality. This category theoretical view affords a novel perspective on the emergence of symbol systems, i.e. as the construction of universal morphisms, which is illustrated in regard to some empirical data.

Reference: Phillips & Wilson (2010). Categorial compositionality: A category theory explanation for the systematicity of human cognition. PLoS Computational Biology, 6(7), e1000858. doi:10.1371/journal.pcbi.1000858

Scheduling an Information Search: Heuristics and Meaningful Metrics

Toby Pilditch
University College London, London, United Kingdom

Alice Liefgreen
University College London, London, United Kingdom

Abstract

Many domains involve gathering evidence, from forensic investigations and medical diagnosis, to everyday life. How should one order this collection, given the costs involved (e.g. time, financial, information)? Scheduling theory offers optimal solutions, but requires clear metrics. Evidence can have many influences on it, which affect prioritization, e.g. degradation, contamination, etc. However, to date there has been no clear way to bring this into a unified metric, and thus optimal scheduling has remained out of reach. We propose a new information-based measure, KL, as a way of encapsulating these information costs, and present maximum KL preservation as a clear rule & metric for scheduling. We go on to test several heuristic rules for scheduling evidence collection, based on optimally derived algorithms, providing novel formal backing for a dominant heuristic strategy for scheduling information gathering.

Mental simulation: A cognitive linguistic approach to language teaching

Laura Pissani
Concordia University, Montreal, Quebec, Canada

Abstract

This paper illustrates the neural mechanisms underlying language processing. Based on evidence from neuroscience, the Neural Theory of Language supports the idea that, to fully understand an utterance, one should be able to imagine the scene evoked by that utterance. To achieve that, brain regions responsible for the action associated with that utterance are activated in order to mentally simulate the action that is being described. In this report, I propose four activities that implement these findings to language teaching in order to boost the learning process and provide meaningful content, not only about language itself but also about the processes behind.

Ordinality trumps cardinality: What we spatialize when we spatialize numbers

Benjamin Pitt
UC Berkeley, Berkeley, California, United States

Daniel Casasanto
Cornell University, Ithaca, New York, United States

Abstract

People implicitly map numbers onto space, but what aspect of numbers do people spatialize? When cardinality (i.e. magnitude; 5 objects) is pitted against ordinality (i.e., sequential position; the 5th object), people show an implicit ordinality mapping, at least in lateral space. We hypothesized that if people spatialize numerical magnitude at all, they should do so on the vertical axis, according to the way they talk about numbers (i.e. low, high). Participants memorized sequences of randomized numbers (e.g. 85913) and then classified them (as small or large) using two response keys, oriented either laterally or vertically. Participants showed reliable ordinality mappings on both axes; they were faster to press the left/upper key for numbers earlier in the memorized sequence and the right/bottom key for later numbers, regardless of numbers magnitudes. People map exact numbers onto both lateral and vertical space according to their ordinality.

The Diagram Disconnect: An Examination of Note-Taking Behaviors In College Students

Blaire Porter
Emory University, Atlanta, Georgia, United States

Julia Wilson
Emory University, Atlanta, Georgia, United States

Hilary Miller
Emory University, Atlanta, Georgia, United States

Patricia J. Bauer
Emory University, Atlanta, Georgia, United States

Abstract

Note-taking in college courses is prevalent yet often ineffective. One potential reason is a disconnect between the information in lectures and that recorded in notes. Whereas science-based lectures frequently include diagrams, students notes often fail to include them. This disconnect likely inhibits learning and may be exacerbated by digital note-taking. We investigated students note-taking during two mini neuroscience lectures and its relation to recall. Students were assigned to diagram presence (diagram embedded in notes for first or second lecture) and note-taking method (typed or handwritten) conditions. Students recalled more in the diagram first condition. There was no recall difference based on note-taking method. Including diagrams in notes for the first lecture likely primed participants to attend to diagrams in the subsequent lecture, helping them realize the importance of the diagram. The lack of a note-taking method effect is inconsistent with past research, but may reflect increasing use of digital note-taking.

Parent comparison and contrast speech is affected by variation of present visual display and child language comprehension

Gwendolyn Price
University of California, Los Angeles, Los Angeles, California, United States

Catherine Sandhofer
University of California, Los Angeles, Los Angeles, California, United States

Abstract

Sometimes parents use comparison in speech to children and sometimes they do not. Comparison has been shown to have multiple benefits for learning. This study investigates what types of situations afford and engender parent comparison talk to 12 children 20 to 24 months of age in a free form picture book context. Each page contained three pictures that varied on color and/or object. Parent speech was analyzed for color, object, question/statement use, and comparison/contrast use. Childrens color comprehension and MCDI score were also measured. The results indicated a quadratic relationship where parents used comparison and contrast more often when their children knew few or many color words. Parents also used comparison more when the page had one dimension held constant across pictures. The results of this study inform existing understanding of comparison and demonstrate how this speech correlates with childrens understanding of language, and specifically color words.

(Mis)interpretations of implausible passive sentences pattern with N400 amplitudes

Milena Rabovsky
Freie Universitt Berlin, Berlin, Germany

Kazunaga Matsuki
BEworks (Behavioral Economics Works), Toronto, Ontario, Canada

Ken McRae
University of Western Ontario, London, Ontario, Canada

Abstract

Representations formed during language comprehension do not always accurately reflect the linguistic input, but are sometimes just good enough (Ferreira et al., 2003). Here, we examined the electrophysiological correlates of such heuristic processing. Participants were presented with passive sentences where the plausibility of the fillers of the agent and patient thematic roles was manipulated. As expected, they made more errors in the interpretation of implausible sentences (e.g., The doctor was treated by the patient). Intriguingly, N400 amplitudes patterned with (mis)interpretation, with increased amplitudes to the second noun in correctly processed implausible sentences, and equally small amplitudes in plausible sentences and in incorrectly interpreted implausible sentences. These results are in line with the view that N400 amplitudes reflect the change in an initial heuristic representation of sentence meaning (Rabovsky et al., 2018), but seem difficult to explain by accounts suggesting that the N400 reflects lexical retrieval (Brouwer et al., 2017).

Working memory, strategy, and distraction on gF tasks

Megan Raden
Mississippi State University, Starkville, Mississippi, United States

Andrew Jarosz
Mississippi State University, Mississippi State, Mississippi, United States

Abstract

Recent work suggests that strategy differences may play an important role on gF tasks and are related to WMC. The present study utilized eye tracking to assess the consistency of strategy use across tasks, focusing on constructive matching (CM) and response elimination (RE) strategies. Across two gF tasks (the Raven Matrices and a figural analogies task), participants were highly consistent in their strategy use, regardless of WMC. However, high-WMC individuals were more likely to utilize the CM strategy, though this was influenced by task order. Those who utilized RE were more likely to have their attention captured by salient, incorrect responses in the response bank and time on those responses was negatively related to accuracy. However, on select items where the response bank was necessary to make a response, these relationships disappeared. Results are discussed in terms of the implications of strategy differences on our understanding of WMC and gF.

Modeling students' fraction arithmetic strategies using inverse planning

Anna Rafferty
Carleton College, Northfield, Minnesota, United States

Rachel Jansen
University of California, Berkeley, Berkeley, California, United States

Tom Griffiths
University of California, Berkeley, Berkeley, California, United States

Abstract

Fraction arithmetic is a challenging topic for students. Past work has found that many errors can be accounted for by a limited number of malrules, reflecting both execution errors and incorrect strategies (Braithwaite, Pyke, and Siegler 2017). We develop an inverse planning model for fraction arithmetic that computes students' affinity for particular malrules based on their problem solutions. Inverse planning models people's choices when solving problems, and has been used to model data from solving algebraic equations and playing educational games. The output of the fraction arithmetic inverse planning model gives a more detailed assessment of a student's knowledge than the number of problems she answers correctly, and does not require human interpretation of students' solutions. Applying the model to the two datasets in Braithwaite et al. (2017) and inferring tendencies to use two specific malrules shows that its output is consistent with manual annotations of students' strategies.

Individual spatial reasoning skills support different kinds of physics tasks

Ilyse Resnick
University of Canberra, Bruce, ACT, Australia

Daniel Jackson
Pennsylvania State University Lehigh Valley, Center Valley, Pennsylvania, United States

Abstract

The majority of undergraduate students fail to achieve a basic understanding of fundamental concepts in science, technology, engineering, and mathematics (Bao et al., 2009). A major barrier may be spatial reasoning (Wai, Lubinski, & Benbow, 2009). Spatial reasoning is the ability to mentally manipulate the 2D and 3D relations within and between objects. The current study examines the casual relation between spatial reasoning and performance in an undergraduate introductory physics course. All students enrolled in the course took tests of mental rotation, hidden figures, form board, and perspective-taking at the beginning of the semester and again at the end of the semester. Post-test scores were significantly higher compared to pre-test scores, ts(38) ¡ 10.82, ps¡.02. Growth in spatial reasoning is predictive of exam performance, with performance on individual spatial reasoning tests being correlated with specific kinds of exam items. This suggests individual spatial reasoning skills differentially support different physics understanding.

Geometric Significance of Topological Neighborhood in Standard and Oscillating SOM Models

Spyridon Revithis
UNSW, Sydney, Australia

Abstract

The role of Topological Neighborhood (TN) in SOM cognitive modeling has biological and computational implications. The modeling significance of the TN width function (epoch) is associated with the initial TN width parameter 0. Furthermore, 0 is decisive in determining the geometric area under the TN-width function curve through the epochs of SOM training; measures training "opportunity". From this perspective, what is considered narrow (or wide) TN during SOM formation is a function of the TN width area covered.

In computer simulations of standard-TN SOM and of our previously proposed oscillating-TN SOM models, we calculated the area using the Riemann integral of the corresponding (epoch) function (standard, oscillating) and epoch-interval. The results show: a) for the same 0 and epoch-interval, the value remains unchanged irrespective of the (epoch) function used; b) when reducing 0, it reduces and directly affects the SOM representation of the input space.

Neuromodulation of electrophysiological correlates of reinforcement learning in humans

Patrick Rice
University of Washington, Seattle, Washington, United States

Mathi Manavalan
University of Washington, Seattle, Washington, United States

Andrea Stocco
University of Washington, Seattle, Washington, United States

Abstract

The feedback-related negativity (FRN) is an event-related potential that differentiates between positive and negative feedback, occurring most prominently at frontocentral electrodes 200-300ms after delivery of feedback. The FRN seems to be reflective of a reward prediction error, as the magnitude of the ERP component has been related to the magnitude of prediction error estimated through reinforcement learning (RL) models. We aim to further understanding of the FRN and its relationship to behavior by replicating the study of Reinhart & Woodman (2014), replacing tDCS with focal, targeted transcranial magnetic stimulation (TMS) over the frontocentral region. Preliminary data shows that our participants reliably generate a FRN when presented with incorrect feedback, and that single-trial estimates of theta power are significantly correlated with RL-derived single-trial estimates of prediction error for correct trials. We will examine the effect of stimulation both on participant behavior as well as on RL parameter estimates.

Do Verbal Labels Enhance Detection of Visual Targets?

Catherine Richards
University of Delaware, Newark, Delaware, United States

James Hoffman
University of Delaware, Newark, Delaware, United States

Timothy Vickery
University of Delaware, Newark, Delaware, United States

Anna Papafragou
Unversity of Delaware, Newark, Delaware, United States

Abstract

Cognitive penetrability describes cognition and perception as interconnected, with cognition impacting the process of perception rather than just the interpretation. The current study addresses this claim in the domain of language, asking if language helps people detect nearly-invisible stimuli. Two experiments were adapted from Lupyan and Spivey (2010), where auditory cues were found to be more beneficial than visual cues in recognizing letters. Participants reported the presence of a target letter that was either preceded by an auditory or visual cue (e.g., cues were either hearing emm or seeing M, followed by a visual M as a target). Detection sensitivity was calculated and compared within cue presentation type. Neither visual nor auditory cues helped participants recognize target letters more than the no-cue condition. These results differ from previous work demonstrating linguistic facilitation and indicated that neither linguistic nor visual information aid in perceiving a matching item.

Categorical rhythms shared between songbirds and humans

Tina Roeske
Max Planck Institute for Empirical Aesthetics, Frankfurt, Hessen, Germany

Ofer Tchernichovski
Hunter College, New York, New York, United States

David Poeppel
Max Planck Institute for Empirical Aesthetics, Frankfurt, Deutschland, Germany

Nori Jacoby
Max Planck Institute for Empirical Aesthetics, Frankfurt, Deutschland, Germany

Abstract

Rhythm the organization of sounds in time is a universal feature of human music. Of the infinite ways of organizing events in time, human rhythms are distributed categorically. We compared rhythms of classical piano playing and finger tapping to rhythms of thrush nightingale songs. Across species, we found similar common rhythms, as relative durations of intervals formed three categories: isochronous 1:1 rhythms, small integer ratio rhythms, and high ratio ornaments. In both species, those categories were invariant within extended ranges of tempi, indicating natural classes. In all cases, the number of rhythm categories decreased with higher tempi. Finally, in birdsong, high ratios (ornaments) were derived from very fast rhythms containing inflexible (probably uncontrollable) interval ratios. These converging results indicate that birds and humans similarly create simple rhythm categories from a continuous temporal space. Such natural categories can promote cultural transmission of rhythmic sounds a feature that songbirds and humans share.

Socio-economic related differences in the use of variation sets in naturalistic child directed speech. A study with Argentinian population

Celia Rosemberg Rosemberg
Consejo Nacional de Investigaciones Cientficas y Tcnicas-CONICET- (National Council of Scientific Research, Argentina), Ciudad de Bs. As., Ciudad de Buenos Aires, Argentina

Florencia Alam Alam
National Council of Scientific and Technical Research, Buenos Aires, Capital federal, Argentina

Leandro Garber
CONICET, Ciudad de Bs. As., Argentina

Alejandra Stein
CONICET, Buenos Aires, Argentina

Maia Julieta Migdalek
Consejo Nacional de Investigaciones Cientficas y Tcnicas (CONICET, Ciudad de Buenos Aires, Ciudad de Buenos Aires, Argentina

Abstract

Child-directed speech (CDS), compared to speech between adults, shows a higher amount of repetitiveness, particularly of sequences of utterances with self-repetitions. This phenomena, known as variation sets, has been found to be beneficial for learning. Although previous findings indicated socio-economic status (SES) effects on the quantity of variation sets, they were based on data from child-parent dyadic interactions in play situations. Given that SES comprises interrelated factors affecting childrens quotidianity, here we examine SES effects on the use of variation sets in long recordings of the family naturalistic environment of 30 low and middle SES Argentinian children (8 to 20 months). Variation sets were automatically extracted from CDS provided by all the participants. Results demonstrated the effects of two factors related to SES-differences: while parents education showed a positive relation to the quantity and extension of variation sets, the number of people living in the household influenced it negatively.

Modelling eye tracking dynamics with quantum theory

Agnes Rosner

Abstract

Eye movements during decision making show systematic patterns such as increased fixations to the chosen option (i.e. gaze cascades) and multiple gaze transitions between fixated options. Existing formalisms, such as multivariate decision field theory, only provide limited scope for describing multiple reversals in the attentional focus and it is therefore unclear how they can be applied to the underlying attentional dynamics. Here, we present an open systems dynamical model from quantum theory to describe gaze transitions between choice options and the gaze cascade effect. Our model was tested on a decision task, in which participants repeatedly decided among two complex options (i.e. that lacked easily quantifiable, matched characteristics). The model can describe the gaze patterns on the individual trial level. It reveals structure in the gaze dynamics that is predictive for choice behavior. The explanatory value of this account for studying attentional dynamics during decision making will be discussed.

Priming Effects on the Interpretation of Ambiguous Discourse Relations

Eyal Sagi
University of St. Francis, Joliet, Illinois, United States

Abstract

Many theories of discourse structure rely on the idea that the segments comprising the discourse are linked through inferred relations such as causality and temporal contiguity. These theories often suggest that the information needed to determine the relation can be found when the discourse is interpreted through the application of world knowledge. However, Sanders (1997) found that the interpretation of ambiguous relations can be affected by the discourses genre. Similarly, Sagi (2006) reported that participants were faster to interpret discourse relations when they were preceded by the same discourse relation. The present study demonstrates that exposure to discourse relations such as result (e.g., John passed Mark in a marathon. He won.) or explanation (e.g., John ... He was in great shape.) can affect the interpretation of subsequent ambiguous relations encountered in an unrelated context. This result suggests that discourse relations are represented independently of the context in which they appear.

Animal Vocalization Generative Network (AVGN): A method for visualizing, understanding, and sampling from animal communicative repertoires

Tim Sainburg
University of California, San Diego, La Jolla, California, United States

Marvin Thielk
University of California, San Diego, La Jolla, California, United States

Timothy Gentner
University of California, San Diego, La Jolla, California, United States

Abstract

We propose here a set of machine-learning algorithms to produce a generative low-dimensional and visually-understandable space of the communicative repertoire of vocal species such as songbirds. As opposed to human speech, where individual elements are well defined and grounded in principled ways, the methods for defining units of animal communication systems are often more varied and rely on human-centric heuristics. Using our method, we can automatically discover latent structure in the vocal repertoire of individuals and use these to define-well principled categorical boundaries between vocal elements in communicating species. Further, we can sample from latent representations to generate novel vocal units that can be used to probe perceptual and physiological representations of communication. We demonstrate two use cases: (1) automated labeling of songbird vocal repertoires showing novel structure in vocal communication, and (2) a perceptual task demonstrating that behavioral and physiological representational spaces can be biased by contextual information. Reducing Smartphone Overuse through Behavioural Nudges

Dasha Sandra
McGill University, Montreal, Quebec, Canada

Jay A. Olson
McGill University, Montreal, Quebec, Canada

Denis Chmoulevitch
McGill University, Montreal, Quebec, Canada

Signy Sheldon
McGill University, Montreal, Quebec, Canada

Amir Raz
Chapman University, Orange, California, United States

Samuel Veissire
McGill University, Montreal, Quebec, Canada

Abstract

We identified smartphone usage patterns predicting overuse and developed an intervention to reduce these effects. In Study 1, 54 undergraduate students reported their daily screen time and the reasons for their smartphone use. A cluster analysis revealed two usage patterns: as a tool (e.g., for directions), and to socialize or pass time. Only the latter pattern correlated with daily phone use (r=.35). In Study 2, 28 pilot participants underwent a two-week-long behavioural intervention involving disabling non-essential notifications and keeping their phone out of reach when not in use. All participants complied with these guidelines, leading to a 1.2 hours/day reduction in usage (4h to 2.8h), a decrease in smartphone addiction scores to normal levels, and a 30% decrease of scores on the Beck Depression Inventory-II (10.1 to 7). We explore potential cognitive benefits of the intervention on memory and attention (measured by Operational Span and Sustained Attention to Response tasks).

The Price of Good Intentions

Arunima Sarin
Harvard University, Cambridge, Massachusetts, United States

Fiery Cushman
Harvard University, Cambridge, Massachusetts, United States

Abstract

Prior work has shown that positively intentioned agents are held more responsible, causal, and blameworthy for subsequent bad outcomes than negatively intentioned agents are held for good outcomes. Across a series of studies, we investigate the underlying expectations that produce this asymmetry. We find that, in in the absence of explicit information about the action performed, actions of positively intentioned agents who produce bad outcomes are inferred to be worse than actions of negatively intentioned agents who produce good outcomes (Study 1). While both agents are judged to be incompetent (Study 2), positively intentioned agents are attributed more control over subsequent negative outcomes (Study 3) and are also considered more pivotal in bringing them about (Study 4). Together these results suggest that well-intentioned agents are seen as having more control, perhaps because, we believe they are in a better position to modify their future behavior to bring about positive outcomes.

The posterior probability of a null hypothesis given a statistically significant result

Daniel Schad
University of Potsdam, Potsdam, Germany

Shravan Vasishth
University of Potsdam, Potsdam, Germany

Abstract

When researchers carry out a null hypothesis significance test, it is tempting to assume that a statistically significant result lowers Prob(H0), the probability of the null hypothesis being true. Technically, such a statement is meaningless for various reasons: e.g., the null hypothesis does not have a probability associated with it. However, it is possible to relax certain assumptions to compute the posterior probability Prob(H0) under repeated sampling. We show that the intuitively appealing belief, that Prob(H0) falls when significant results have been obtained under repeated sampling, is in general incorrect and depends greatly on: (a) the prior probability of the null being true; (b) Type I error, and (c) Type II error. Through simulation we quantify uncertainty and find that uncertainty about the null hypothesis often remains high despite a significant result. To help the reader develop intuitions about this common misconception, we provide a Shiny app (https://danielschad.shinyapps.io/probnull/).

Temporal dynamics of preschoolers novel word learning and categorization

Christina Schonberg
UW-Madison, Madison, Wisconsin, United States

Haley Vlach
University of Wisconsin-Madison, Madison, Wisconsin, United States

Abstract

Word learning paradigms often teach children the name of a novel object and then immediately ask them to generalize the label to another object. This study uses a new paradigm that affords the ability to determine how childrens generalization changes over time. Participants (N=22, Mage=3.8 years) saw a novel object labeled by the experimenter (e.g., wug) and then were shown five novel objects that each had an additional feature changed from the exemplar (i.e., the fifth object had five changed features), either immediately after the exemplar or after a five minute delay. Category membership endorsement of the five test objects was higher at immediate test than delayed test, suggesting that children represent novel categories broadly at first but more narrowly over time. We propose that childrens forgetting of exemplars across time leads to shifts in childrens generalization; as children forget exemplar features, category membership becomes more specific.

Spatial Preferences in Everyday Activities

Holger Schultheis
University of Bremen, Bremen, Germany

Abstract

Many everyday activities pose only weak constraints on the order, in which certain actions have to be performed. When setting the table, for example, any order of putting the required items on the table will be fine as long as all necessary items are on the table eventually. Despite the commonality of weakly constrained sequences in everyday activities, little is known about how humans deal with such sequences. In this contribution, we argue that humans do not order weakly constrained actions arbitrarily, but exhibit systematic patterns of orderings, which we term ordering preferences. Moreover, we argue that the task environment's spatial layout and its mental representation are key factors in determining such preferences. An initial empirical study on table setting corroborates this reasoning by revealing ordering preferences that seem to be based on a regionalization of space and the distances between the regions.

Using eye-tracking to examine the role of fluency in the number line placement task

Samantha Schwarz
Susquehanna University, Selinsgrove, Pennsylvania, United States

Jennifer Asmuth
Susquehanna University, Selinsgrove, Pennsylvania, United States

Abstract

The number line placement task, in which individuals are presented with a target number and mark where it would be located along a number line, has played an important role in the investigation of numerical cognition. However, recent work suggests that different factors may influence performance on the task, making it a poor proxy for mental representation of number. In this study, adults completed a computer-based number line placement task with either standard or non-standard endpoints. Consistent with previous research, responses in the standard condition were best fit by a linear model, while responses in the non-standard condition were best fit by a logarithmic model. In addition, eye-tracking data revealed different looking patterns between conditions, including greater fixations on and more frequent alternation between endpoints in the non-standard condition and a leftward bias in the standard condition. This behavior may reflect differences in number familiarity and strategy use.

The Visual Representation of Abstract Verbs: Merging Verb Classification with Iconicity in Sign Language

Simone Scicluna
University of Trento, Trento, Italy

Carlo Strapparava
FBK-Irst, Trento, Italy

Abstract

Theories like the picture superiority effect prove that visual information is vital in the acquisition of knowledge, such as in language learning. Words can be graphically represented to illustrate the meaning of a message and facilitate its understanding, but this rarely applies to abstract words. The current research turns to sign languages to explore the common semantic elements that link abstract words to each other, pointing towards the possibility of creating clusters of iconic meanings. By using sign language insight and VerbNets organisation of verb predicates, this study presents a novel organisation of 500 English abstract verbs classified by visual shape. Graphic animation was used to visually represent 20 classes of abstract verbs (see on www.vroav.online). An online survey was created to achieve judgements on the graphic visuals representativeness. Significant agreement between participants suggests a positive way forward for further research and applications within multimodal communication and computer assisted learning.

Mathematical Creativity: Incubation, Serial Order Effect, and Relation to Divergent Thinking

Stacy Shaw
Univeristy of California, Los Angeles, Los Angeles, California, United States

Gerardo Ramirez
Ball State University, Muncie, Indiana, United States

Abstract

The current study explored whether creative processes specifically incubation and the serial order effect extend to creativity in mathematics, and if there is a relation to divergent thinking. A total of 155 postsecondary students completed an unusual use task and a multiple-strategy math task. Participants were given 8 minutes to generate as many strategies as they could for the math task, and then after a brief break, were given another problem with the same underlying structure for 4 minutes. We find evidence for a serial order effect in math, whereas across trials it became more difficult for participants to generate a new strategy, but the strategies were rated as more creative. The brief break also provided some evidence of incubation, as there was a boost in the number of overall strategies and creativity. We also found that divergent thinking and mathematical creativity were significantly related.

When Experts Err: Using Tetris Models to Detect True Errors From Deliberate Sub-Optimal Choices

Catherine Sibert
Rensselaer Polytechnic Institute, Troy, New York, United States

Wayne Gray
Rensselaer Polytechnic Institute, Troy, New York, United States

Abstract

Error detection and correction is a vital part of skill acquisition, but when training a complex, real time, dynamic task, it can be difficult to isolate a true mistake in a sequence of decisions without clear correct choices. We use previously developed high-performing, human-like models of the video game Tetris (Sibert et al., 2017) to analyze individual piece placement decisions for players of high and low skill. In cases where the model's choice differed from the human's choice, we examine the eye fixations made during the placement decision to determine if the disagreement is caused due to the player performing at lower level than the model (i.e. not being aware of a better placement), the player performing at a higher level than the model (i.e. deliberately making a suboptimal move in service of a long term strategy), or the player making a true error.

Instructions to Incorporate Music Themes into a Haiku Increases Perceived Creativity of the Haiku

Cynthia Sifonis Sifonis
Oakland University, Rochester, Michigan, United States

Paul Sullivan
Oakland University, Rochester, Michigan, United States

Abstract

The current research examines the degree to which thematic/referential music affects performance in Amabiles American Haiku task. Thematic music conveys meaning to the listener by activating concepts associated with the music in semantic memory. Ward (1994) demonstrated that generating novel exemplars is influenced by activated concepts in memory. Consequently, participants listening to thematic music before writing a haiku should be more likely to incorporate thematic elements into the haiku which increases the perceived creativity of the haiku. Participants specifically instructed to incorporate thematic elements into the haiku should include more thematic elements and write more creatively than participants not instructed to include thematic elements and participants who wrote their haiku without having listened to thematic music beforehand. 206 undergraduates listened to a 90 second sample of unfamiliar lullaby- or war-themed music. Participants were instructed to write a haiku inspired by the music (Inspire), write a haiku after listening to the music (Neutral) or write a haiku before listening to the music (Control). We found a significant main effect of the Inspire instruction on incorporation of thematic elements into the haiku. Participants in the Inspire condition included significantly more thematic elements of the music into their haiku than participants in the Neutral condition or Control conditions. Participants in the Inspired condition wrote haikus that were marginally more likely to be rated as more negatively valenced and were more creative than the haikus written in the Neutral and Control conditions. Results suggest ways of increasing creativity through use of thematic music.

Flexible Strategy Use in ACT-R's Tic-Tac-Toe

Julian Skirzyski
McGill University, Montreal, Quebec, Canada

Dr Piotr Wasilewski
University of Warsaw, Warsaw, Poland

Abstract

Modeling cognitive processes is one of the major tasks of cognitive science. This work presents a computer model of a study described in "Flexible Strategy Use in Young Children's Tic-Tac-Toe" (Crowley & Siegler, 1993) in which authors made an attempt to characterize decision-making in a conflict-of-interests-like environment. In the experiments, kindergarten/primary school children and an algorithm-based opponent played a series of games in Tic-Tac-Toe. The outcomes seemed to indicate existence of a hierarchy of rules that is constructed with experience. Although already tested algorithmically, the simulation detailed in the paper was applicable to a narrow class of problems only. The model shown in this work was built using a cognitive architecture, i.e. computer-based structure mimicking general functioning of the human mind. We used a rule-based system ACT-R that operates in mental rules paradigm and successfully replicated results of the mentioned study.

Adult Prediction Error Processing is Associated with Vocabulary Size

Katherine Snelling
Queen's University, Kingston, Ontario, Canada

Stanka Fitneva
Queen's University, Kingston, Ontario, Canada

Abstract

How do individuals learn language when there are so many possible potential referents for each word? Prediction-based theories of language learning propose that predictions enable individuals to learn from implicit negative evidence by comparing the predictions to outcomes. However, the role of prediction errors for learning has yet to be established. Traditionally, prediction errors have been believed to hinder learning. Recently though, prediction errors have been associated with improved novel word acquisition in cross situational learning. This present study used a cross-situational word learning task to examine the relation between prediction error-based processes during word learning and vocabulary size. The results showed that learners who switched their gaze more quickly from the non-target to the target image when they had to detect and correct prediction errors had higher productive vocabularies. This research supports the theory that productive vocabulary is strongly tied to predictive processes.

Introducing Recursive Linear Classification (RELIC) for Machine Learning

Sean Snoddy
Binghamton University, Binghamton, New York, United States

Kenneth Kurtz
Binghamton University, Binghamton, New York, United States

Abstract

Numerous classifiers for machine learning are powerful and effectivean important path forward is decreasing the complexity and increasing the transparency of the solutions achieved. RELIC (REcursive LInear Classifer) consists of recursively applying a classifier to the training items not successfully accounted for in the previous iteration to find subsets within the training data that yield simpler classification schemes. Chooser models are iteratively added and trained on item-to-subset assignments to learn a mapping between input space and the classifier ensemble. Test examples are passed through the set of choosers to select the appropriate subset-classifier pairing to generate a classification. While applicable to any classifier, we begin by evaluating RELIC using logistic regression and linear SVM to determine whether they perform better under the recursive approach and become competitive with non-linear classifiers. Application of this approach to non-linear classifiers and potential implications for the broader science of learning are also addressed.

Compositionality in emerging multi-agent languages: Marrying Language Evolution and Natural Language Processing

Kees Sommer
Leiden University, Leiden, Netherlands

Jae Perris
Leiden University, Leiden, Netherlands

Arianna Bisazza
Leiden University, Leiden, Netherlands

Tessa Verhoef
Leiden Institute of Advanced Computer Science, Leiden, Netherlands

Abstract

The mainstream approach in NLP is to train systems on large amounts of data. Such passive learning contrasts with the way language is learnt by humans. Human language is acquired within communities, it is culturally transmitted and changes dynamically. These evolutionary mechanisms have been extensively studied in the field of Language Evolution. Despite limited prior interaction between fields, such mechanisms are now increasingly incorporated into NLP systems. Such models have the potential to both study the evolution of language in multi-agent simulations with state-of-the-art (deep) learning systems in more naturalistic settings and improve NLP systems by having language emerge organically. We examine how findings from a model by Havrylov & Titov (2017) compare to those from traditional Language Evolution models and quantify the emerging compositionality using an existing Language Evolution method (Tamariz, 2011). This approach reveals novel insights into the generated data, the applied methodology and the nature of compositionality.

Using Occam's razor and Bayesian modelling to compare discrete and continuous representations in numerostiy judgements

Jake Spicer
University of Warwick, Coventry, United Kingdom

Adam Sanborn
University of Warwick, Coventry, United Kingdom

Ulrik Beierholm
Durham University, Durham, United Kingdom

Abstract

Previous research has suggested that numerosity judgements are based not just on perceptual data but also past experience, and so may be influenced by the form of this stored information. The representation of such experience is unclear, however: numerical data can be represented by either continuous or discrete systems, each predicting different generalisation effects. This study therefore contrasts discrete and continuous prior formats within numerical estimation using both direct comparisons of computational models using these representations and empirical contrasts exploiting different predicted reactions of these formats to uncertainty via Occam's razor. Both computational and empirical results indicate that numeroisty judgements rely on a continuous prior format, mirroring the analogue approximate number system, or number sense. This implies a preference for the use of continuous numerical representations even where both stimuli and responses are discrete, with learners seemingly relying on innate number systems rather than symbolic forms acquired in later life.

Creativity and Machine Learning: Divergent Thinking EEG Analysis and Classification

Carl Stevens
University of Arkansas, Fayetteville, Arkansas, United States

Darya Zabelina
University of Arkansas , Fayetteville, Arkansas, United States

Abstract

Prior research has shown that greater EEG alpha power (8-13 Hz) is characteristic of greater creativity. This study investigates the potential for machine learning to classify more and less creative brain states. Participants completed an alternate use task, in which they thought of normal or uncommon (more demanding) uses for everyday objects (e.g., brick). We hypothesized that alpha power and reaction time would be greater for uncommon uses, and that a trained machine learning model would be able to reliably classify data from the two conditions. Participants responded much faster in the normal condition, compared to uncommon; alpha was significantly greater for the uncommon condition; and 73.3% classification accuracy was attained when a trained model was applied to new data. Future research will attempt to implement neurofeedback training to maintain optimally creative states.

Effects of Instructor Presence in Video Lectures: Rapport, Attention, and Learning

Andrew Stull
University of California, Santa Barbara, Santa Barbara, California, United States

Logan Fiorella
University of Georgia, Athens, Georgia, United States

Rebecca Similuk
University of California, Santa Barbara, Santa Barbara, California, United States

Stevi Ibonie
University of California, Santa Barbara, Santa Barbara, California, United States

Richard Mayer
University of California, Santa Barbara, Goleta, California, United States

Abstract

Do students learn better from video lectures when an on-screen instructor is socially presentthat is, when students can see the instructor's face and eye gaze during the lecture? The present study explores how access to the instructors face and eye gaze affects students feelings of social rapport, attention to the lesson, and learning outcomes. The study compares a video lecture about the human kidney where students either have access to the instructors face and eye gaze during the lecture or do not (i.e., the instructor does not face the camera). Students reported higher levels of engagement, directed more eye fixations to the lecture material rather than the instructor (based on eye-tracking metrics), and performed better on both retention and transfer posttests after viewing a video lecture with a socially present, on-screen instructor. Results suggest that social cues play a role in guiding academic learning from instructional video.

Aha! Under Pressure: Is the Aha! Experience Constrained by Cognitive Load?

Hans Stuyck
Catholic University of Leuven, Leuven, Belgium

Axel Cleeremans
Universit libre de Bruxelles, Brussels, Belgium

Eva Van den Bussche
KU Leuven, Leuven, Belgium

Abstract

Suddenly comprehending the solution to a vexing problem is often accompanied by an Aha! experience. The driving mechanisms behind this experience are unclear. One way to address this, is to study Aha! under cognitive load. If Aha! is the result of the same explicit process that we use to solve everyday problems, it should be influenced by cognitive load in a similar way. However, if it constitutes a different, more implicit process, cognitive load might not affect it at all. Using a dual-task paradigm where participants solved word puzzles under different memory loads, we found that word puzzles solved with Aha! were more accurate and led to higher solution confidence. When memory load increased, only puzzles without Aha! were solved more slowly. The fact that solution retrieval with Aha! was unaffected by memory load, implies that Aha! experiences rely on a process that does not compete for limited cognitive resources.

Eye Movement Assessment in High and Low Social Anxiety Individuals: An Eye-Tracker Study

Abstract

Previous studies have suggested that, socially anxious individuals tend to avoid eye contact while looking toward faces. The study designed an emotional faces task consisted of human and comic face stimuli with 6 different emotions (happy, angry, sad, scared, stunned, confused), and recorded the eye movements to examine the hypotheses above. The results revealed that high social anxiety (HSA), medium social anxiety (MSA) and low social anxiety (LSA) individuals have no significant difference on total fixation duration of the eyes, nose, and mouth among 6 different emotions. However, while focusing on the angry expression, LSA have significantly higher total fixation duration, visit count and area normalized score on the nose. It shows that LSA tend to focus on the nose intentionally when a person shows an angry face. Furthermore, HSA show lower proportion of eyes to eyes, nose and mouth fixation duration than MSA in happy, sad and stun faces.

Keywords: eye tracking, social anxiety, emotional faces

Learning to calibrate age estimates

Jordan Suchow
Stevens Institute of Technology, Hoboken, New Jersey, United States

Abstract

Age is a primary social category and, with little effort, we can quickly approximate it from photographs. Here, we analyze 1.5 million age judgments derived from a popular online website where participants estimate the age of a person depicted in a photograph, with feedback. We find that median age judgments across participants are linear in the actual age, with little bias. However, the slope is considerably less than one, such that the aggregate overestimates the age of younger people and underestimates the age of older people. Age estimates are found to be unbiased at 37.5 years, which coincides with the median age across all the depicted persons. These results are consistent with an account in which, over time, participants learn to calibrate an analogue magnitude to the learned distribution of encountered ages, combining photographic evidence with distributional information to arrive at an estimate that balances the two.

The development of compound word processing in young children

Takayo Sugimoto
Aichi University, Toyohashi, Aichi, Japan

Abstract

Hirose & Mazuka (2015 & 2017) demonstrate that Japanese speaking adults and first graders both show anticipatory compound processing, using the language-specific compound accent rule (=CAR). That is, six- to seven-year-old children can exploit compound prosody to disambiguate the structure and meaning of a given compound. However, we do not know exactly when and how children start exploiting the CAR to properly comprehend compounds. Thus, we investigated Japanese-speaking childrens acquisition of the CAR and their development of compound processing. We conducted longitudinal experiments using compound comprehension tasks on 65 Japanese-speaking children aging from two- to four-years. We found that childrens compound processing strategies changed after their acquiring the CAR. Before acquiring it, children could not identify the compound head; instead they showed a language-general parsing preference for the left-most part of a compound. Our results suggest that childrens acquisition of the language-specific CAR enables their compound processing.

Shame on you! A computational linguistic analysis of shame expressions

Anonymous CogSci submission

Abstract

The current study explored the unique linguistic characteristics of the self-conscious emotion shame. The data used for the analyses were part of two larger studies in which semi-structured interview techniques were used that had learners describe shameful or frustrating experiences in the context of psychology and engineering courses. Results revealed when describing an experience of shame, learners use significantly more positive emotional words, significantly more words associated with anxiety, and significantly fewer words associated with anger. Additionally, learners use simpler syntax, more abstract words, and have less cohesive speech. Educational implications are discussed.

Keywords: emotions; shame; learning centered emotions; cognition; computational linguistic analysis

Objective

A gap currently exists in the literature regarding a quantitative exploration of the self-conscious emotion of shame. Adding to the body of literature on negative emotions, this study explored the unique linguistic characteristics of shame and frustration with the hope that we can better understand students' experiences of these emotions.

Theoretical Framework

Language is a powerful cognitive communicative process that has been the focus of research for centuries. Speaking and writing are expressive through the specific words chosen by individuals, as well as the frequency of specific words, and become one's "style". One's linguistic style in speech and writing has been suggested to be indicative of individual differences and personality (Groom & Pennebaker, 2002). We explored differences with respect to descriptions of the emotions of shame and frustration to better understand cognitive aspects of these emotions through speech-analysis.

Linguistic Analyses

From the study of dead languages to the biological nature of language within the brain, researchers have sought to understand how humans possess complex language abilities, the impact of language on humans, and countless other aspects of human language-use. Human language is undeniably expressive in content and dialect, however, this does not account for the full expressive power of language. The style of which we speak and write is also critically expressive but is frequently unnoticed. Speaking and writing is expressive through the particular words chosen by individuals and the frequency of specific words; these linguistic styles in speech and writing have been suggested to be indicative of individual differences and personality (Groom & Pennebaker, 2002; Pennebaker & King, 1999).

The study of linguistic style and content has numerous applications, but, until recently, conducting these analysis has been a difficult task that consisted of counting and organizing words with the use of individual judges (Pennebaker, Mehl, & Niederhoffer, 2002). However, an objective analysis of language patterns through word counting software has led to an increase in our understanding of what particular parts of speech contain a deeper level that is not naturally perceived (Pennebaker & Graybeal, 2001). We believe that using this type of analyses, we can gain insight into students' experiences of emotions.

Shame

Although there are many ways to define shame, for the purposes of this study, shame is an acutely painful affective state that is brought on by a failure to meet internally set rules, ideals, goals, or standards (Turner, Husman, & Schallert, 2002). A gap currently exists in the literature regarding a quantitative exploration of shame. Of the research that has been conducted, much has been qualitative in nature and not focused on "academic" shame (i.e., shame affiliated with learning and education). One possible reason for the underdeveloped exploration of this construct is due to the difficulty in studying it. More specifically, research has shown that individuals may deny their feelings of shame, they tend to self-isolate when they feel shame, and they may be unwilling or unable to express themselves when they feel shame (citation needed). In fact, one's difficulty in communicating a shameful experience may be a distinctive characteristic of shame (Turner, 2014; Babcock & Sabini, 1990, Lunde, 1958).

Although research has suggested the *difficulties* in studying shame, the difficulty does not detract from the *importance* of studying shame. Tangney and Dearing (2002) suggested that, "Guilt, and especially shame ... are powerful, ubiquitous emotions that come into play across most important areas of life." (p. 8). Contemporary research has shown that experiences of shame can have a "negative impact on interpersonal behavior and functioning" (Tangney &

Dearing, 2002, p. 5). Within the context of education, a number of educational psychologists have asserted that feeling shame can interfere with motivation, and negatively impact students' academic goals and achievement (Pekrun, Frenzel, Goetz, & Perry, 2007; Weiner, 1986). Indeed, once students experience shame, their ability to become cognitively engaged may be hindered, they may lose motivation for studying, and, they may feel reluctant to attend class (Turner, Husman, & Schallert, 2002).

Given the importance of gaining a better understanding of this self-conscious emotion, the current study sought to compare the unique linguistic characteristics of shame with that of frustration. Our intent was to better understand the underlying composition of shame expressions.

Data Sources, Evidence, Objects, or Materials

Linguistic Inquiry and Word Count (LIWC)

The present study used a program called Linguistic Inquiry and Word Count (LIWC) to analyze speech. LIWC allows researchers to efficiently enter text files into the program in order to obtain outputs that cover a number of language indices. For example, if we were to convert *Of Mice and Men* by John Steinbeck into a text file and enter it into LIWC we would obtain the exact word count, words per sentence, and a description of approximately 90 indices. These indices are extremely insightful in objectively understanding what a text consists of and the mental state of the author or speaker (Groom & Pennebaker, 2002). For the current study, we focused only on indices that were theoretically relevant: 1) Affective processes (e.g., happy, cried) 2) Positive emotion (e.g., love, nice, sweet) 3) Negative emotion (e.g., hurt, ugly, nasty) 4) Anxiety (e.g., worried, fearful) 5) Anger (e.g., hate, kill, annoyed) and 6) Sadness (e.g., crying, grief, sad).

Coh-Metrix

Coh-Metrix, is a system for computing computational cohesion and coherence for written and spoken texts. For the purpose of the current study, we explored five specific indices within a Coh-Metrix: Narrativity, Syntactic Simplicity, Word Concreteness, Referential Cohesion, and Deep Cohesion. Narrative text tells a story, with characters, events, places, and things that are familiar to the reader. Syntactic simplicity reflects the degree to which the sentences in the text contain fewer words and use simple, familiar syntactic structures, which are less challenging to process by the reader. Word concreteness refers to texts that contain content words that are concrete, meaningful, and evoke mental images. Texts high in referential cohesion contain words and ideas that overlap across sentences and the entire text. Deep cohesion reflects the degree to which the text contains causal, intentional, and temporal connectives (McNamara, Graesser, Cai, & Kulikowich, 2011). The theoretical purpose of focusing solely on these five indices is because previous research has found that dozens of measures funnel into these five major factors (Graesser, McNamara, Cai, Conley, Li, & Pennebaker, 2014).

Methods

The data used for analysis are subsets from two larger studies. As part of one study, participants were recruited from an upper-division psychology course at a midwestern R1 university. Five-weeks into the semester, after obtaining in-class feedback on their midterm exam, students completed a survey (Experiential Shame Scale, Turner, 2014, Cronbach's alpha = .86) to determine the extent to which they perceived their grade was a failure and if they were experiencing the emotion of shame. Eight students, who indicated they experienced shame after their midterm exam, agreed to participate in semi-structured interviews two weeks before the final exam. All interviews were recorded and transcribed verbatim.

We compared the shame interviews with that obtained in a second study, one that used an interpretative phenomenological analysis (IPA) of students' experiences of frustration in the context of college-level science and engineering courses. The semi-structured interviews were conducted by an undergraduate student who had been extensively trained to conduct phenomenological interviewing. Select portions of these interviews comprised our frustration corpus (n = 5) (Huff & Clements, 2018).

The interviews from both studies were approved by the IRB offices of each investigator for the respective studies. Additionally, the procedures of the present investigation were approved by lead author's institutional IRB.

Results

Results from our LIWC analysis indicated that students describing a shameful experience tended to use more positive emotional words than students describing a frustrating experience, t (11) = 1.629, p = .06 (one-tailed), d = .92. Shame-describing students also used significantly more words associated with anxiety than students who described their frustration, t (11) = 2.644, p = .023, d = 1.50. Lastly, results showed that when describing a frustrating experience, students tended to use significantly more words associated with anger, t (4.409) = 2.623, p = .05, d = 1.49. See Figure 1.

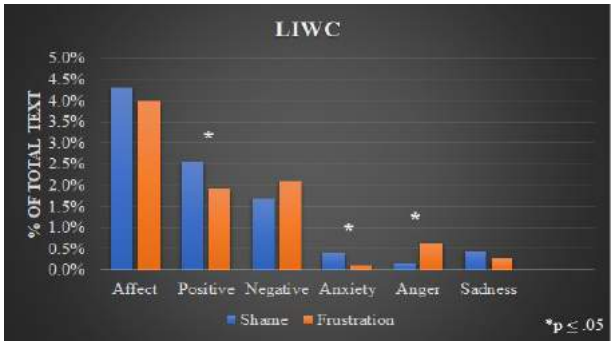

Figure 1: Linguistic Inquiry and Word Count (LIWC) results.

The results from the Coh-Metrix revealed that, when discussing an experience of shame, students tended to use significantly simpler syntax, t (11) = 6.616, p = .000, d = 3.77. They also used more abstract words, t (4.326) = -2.909, p = .04, d = 1.66, and had less referential cohesion, t (3.062) = .01, d = 1.75. See Figure 2.

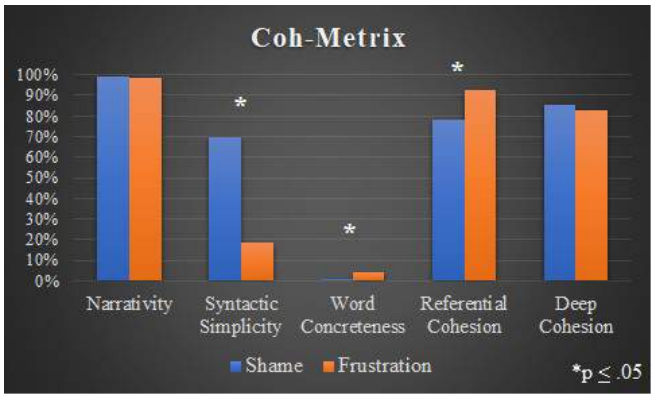

Figure 2: Coh-Metrix results.

Scholarly Significance

The results from the current study revealed that shame does in fact have a unique linguistic profile when compared to frustration. Surprisingly, learners who described an experience of shame tended to use significantly more positive emotional words (e.g., love, nice, sweet), along with more words associated with anxiety (e.g., worried, fearful). Additionally, students who described a shameful experience used significantly fewer words associated with anger compared to learners describing frustration. The Coh-Metrix results revealed that, when discussing a moment of shame, learners tended to use significantly simpler syntax, more abstract words, and demonstrated less referential cohesion.

Our results supported the notion that, when individuals talk about shame shame-experiences, the use of language is difficult. Students spoke abstractly about their shame experiences, while they were more able to articulate their frustration experiences. Shame-experiencing students also used less linguistic complexity and their narrative had less cohesion than students describing frustration. A teacher could learn to pick up on these linguistic elements and use this information to help students bounce back from the debilitating effects of experiencing academic shame.

Imagine a student who, after having failed an exam is staying after class to talk to the instructor about his/her performance. What if it could be determined, based on speech alone, whether these individuals are experiencing shame? What if a teacher was able to figure out which subset of students were actually experiencing shame and were able to be *proactive* to the potential negative consequences? Mitigating shame-consequences by understanding linguistic components of the *what*- and *how*-indicators of shame experiences, could facilitate teachers' ability to provide motivational interventions. Recognizing linguistic components of shame may be especially important given that individuals may deny their feelings, and may be unwilling or unable to express themselves, particularly if they self-isolate. In other words, as of now, we have no reliable way (other than perhaps self-report measures) to determine who is experiencing shame. Thus, intervention is near impossible without perceiving reliable indicators.

We do note that this study is limited in making comparative claims between the two sets of interview transcript-data. While the two sets of transcripts used in this analysis did, indeed, focus on different constructs (i.e., frustration and shame), they also differed according to other characteristics, such as the overall study-design, the methodology driving the investigations, and the institutions in which the data collection occurred. Thus, we make our claims with sensitivity to the multiple ways in which the two interview datasets can be compared. Yet, even with these limitations considered, we maintain that the linguistic profile that accompanies students' experiences of discussing shame provides compelling implications for educators.

Event Perception Differs Across Cultures

Khena Swallow
Cornell University, Ithaca, New York, United States

Qi Wang
Cornell University, Ithaca, New York, United States

Abstract

Event segmentation divides continuous experience into meaningful events and guides attention, memory, and learning. Culture could impact event segmentation by emphasizing the importance of different aspects of experiences (attentional focus), and by providing different exemplars of everyday activities (familiarity). In this study, Indian and US viewers identified large (coarse) and small (fine) events in videos of everyday activities recorded in Indian and US settings. Analyses revealed that US viewers segmented the activities at a higher rate than Indian viewers. In addition, while the boundaries identified by US viewers were more strongly associated with visual change, boundaries identified by Indian viewers were more strongly associated with changes in actions and goals. However, there was no evidence that familiarity with an activity, as indicated by the match between a viewers culture and the activity setting, impacted segmentation. Culture appears to affect how people define events during perception, independent of familiarity.

A re-examination of the interrelationships between attention, eye behavior, and creative thought

Shadab Tabatabaeian
University of California Merced, Merced, California, United States

Colin Holbrook
University of California, Merced, Merced, California, United States

Carolyn Jennings
University of California, Merced, Merced, California, United States

Abstract

Internally focused attention, characterized by reduced sensory input, is often correlated with memory retrieval and the ability to combine memories to generate new ideas. Accordingly, the attenuation of external distractors (e.g., via reduced visual input) may be expected to enhance idea generation. We conducted a study requiring participants to perform an alternative uses task, in either a well-lit or totally dark environment. We also measured eye movements, as they have been linked with idea generation and attention. Departing from prior studies, our participants were not presented with visual stimuli, but received auditory task instructions. Preliminary analyses replicated the eye behavior attributed to internal attention in previous research, including more and shorter fixations and greater saccade amplitude in the dark. While these results suggest a positive relationship between darkness and internal attention, task performance was not significantly influenced by darkness manipulation. The findings and suggestions for future studies will be discussed.

Incorporating Semantic Constraints into Algorithms for Unsupervised Learning of Morphology

Abi Tenenbaum
Commonwealth School, Boston, Massachusetts, United States

Roger Levy
Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Abstract

A key challenge in language acquisition is learning morphological transforms relating word roots to derived forms. Unsupervised learning algorithms can perform morphological segmentation by finding patterns in word strings (e.g. Goldsmith, 2001), but struggle to distinguish valid segmentations from spurious ones because they look only at sequences of characters (or phonemes) and ignore meaning. For example, a system that correctly discovers ¡add -s¿ as a valid suffix from seeing dog, dogs, cat, cats, etc, might incorrectly infer that ¡add -et¿ is also a valid suffix from seeing bull, bullet, mall, mallet, etc. We propose that learners could avoid these errors with a simple semantic assumption: morphological transforms should approximately preserve meaning. We extend an algorithm from Chan (2008) by integrating proximity in vector-space word embeddings as a criterion for valid transforms. On the Brown CHILDES corpus, we achieve both higher accuracy and broader coverage than the purely syntactic approach.

Individual Differences in Second Language Age of Acquisition and Language Entropy Predict Non-Verbal Reinforcement Learning Among Bilingual Adults

Mehrgol Tiv
McGill University, Montreal, Quebec, Canada

Jason Gullifer
McGill University, Montreal, Quebec, Canada

A. Ross Otto
McGill University, Montral, Quebec, Canada

Debra Titone
McGill University, Montreal, Quebec, Canada

Abstract

We investigated whether bilingualism affects non-verbal model-free vs. model-based reinforcement learning (RL). This dual-systems theory posits independent valuation systems in controlling choices and may overlap with systems of bilingual executive control. Forty-five bilingual adults completed a two-stage decision making task with transition and probability of reward dynamically varying. First, we calculated a model-based index to measure how much participants integrate environmental structure with reward when planning choices. Consistent with monolingual results, we found that bilinguals display model-free and model-based RL to differing degrees. Next, we assessed whether individual differences in second language (L2) age of acquisition (AoA) and language entropy interact with these RL systems. Bilinguals with earlier L2 AoA and greater language entropy demonstrated model-free RL, whereas bilinguals with later L2 AoA and lower language entropy demonstrated greater sensitivity to model-based reward frequencies. This suggests an interesting link between bilingual experience and how reward shapes decision-making strategies.

Emergent Compositionality in Signaling Games

Nicholas Tomlin
Brown University, Providence, Rhode Island, United States

Ellie Pavlick
Brown University, Providence, Rhode Island, United States

Abstract

Understanding the origins of linguistic compositionality is a fundamental challenge in evolutionary linguistics. Prior work has explored this topic through dynamical computational modeling and experiments in iterated learning. We explore these questions using RL agents tasked with developing cooperative communication strategies in a signaling game. We analyze how various mechanisms (such as Bayesian pragmatic reasoning) and constraints (such as limited memory) may affect compositionality and generalizability in the invented communication protocols. In particular, our preliminary results suggest that incremental pragmatic reasoning induces a bias towards lexical compositionality. To evaluate the extensibility of our model, we compare the behavior of the RL agents to the behavior of humans on the same task. That is, we ask humans to coordinate in a reference game task by repeatedly composing non-linguistic symbols. We discuss ways in which the resulting protocol mirrors and differs from that produced by the RL agents.

Agent-based modeling of how national identity affects party preferences in voting

Taiji Ueno
Takachiho University, Tokyo, Japan

Ryu Hakche
Neo Career, Co. Ltd., Tokyo, Japan

Nobuko Asai
Kyoto-Bunkyo University, Uji, Japan

Minoru Karasawa
Nagoya University, Nagoya, Aichi, Japan

Abstract

Attitudes concerning national identity (e.g., nationalism, patriotism) are known to correlate with various social behaviors such as party preferences in voting. For instance, survey data indicates that Japanese citizens who are proud of being Japanese (i.e., patriots) and those who are high in a right-wing tendency are more willing to vote for the conservative party (Liberal Democratic Party). In this study, we employed an agent-based modeling approach to understand how national identity affects individual voting intentions. The individual agents and the political party agents interacted with each other by spreading their political attitudes (e.g., VAT should be increased to maintain the pension insurance system), and the recipients of the messages changed their attitudes (e.g., persuasion). The simulation revealed that the effects of persuasive messages were moderated by the strength of its own national identity attitudes, and the resultant individual agents voting preferences simulated the human participants data more precisely.

Exploring the role of visuospatial processes in surgical skill acquisition: A longitudinal study

Tina Vajsbaher

Abstract

Surgical error is the most frequent and costly type of medical error, posing a direct threat to patient safety. Surgical errors have been described as a 'cognitive phenomenon', as it is largely the shortcomings of the surgeons cognitive processing that leads to error. In laparoscopic surgery, visuospatial processes are known to be crucial for skill acquisition, although it remains unclear as to which exact processes are important, how these develop over time and intraoperatively, and how they influence competency development. We will report interim spatial cognitive baseline results of 35 surgeons, 17 residents and 18 specialists, taking part in an on-going longitudinal study at two major hospitals in Germany. Our results offer new insight into the role of visuospatial cognition in domain-specific expertise, and shed new light on the malleability of visuospatial processes in the skill acquisition process.

RunTheLine: An infinite runner serious game to train comprehension of societally relevant large numbers

Frank Leone
Radboud University: Donders Institute for Brain, Cognition and Behavior, Nijmegen, Netherlands

Abstract

Large numbers play a significant role in personal and political financial choices and the understanding of exponential growth. Large numbers are also often misjudged, showing a logarithmic number understanding. Small numbers are however represented in a linear fashion, due to direct experience on for example number lines. Earlier, it was shown that large number comprehension can be trained, influencing societally relevant choices. We trained large number comprehension using a serious game (RunTheLine): an infinite runner game where an avatar runs on a number line ranging till one billion. Due to the game mechanics, the players walk the number line at both small and large numbers in small steps, making them aware of the continuity of the number line. Pre-post test differences show a change in economic judgments compared to a control group. This offers a scientific manipulation of behavioral and cortical number line representations and potential educational applications.

Automatic Model Generation with Symbolic Deep Learning

Vladislav Veksler
DCS Corp, U.S. Army Research Laboratory, Aberdeen, Maryland, United States

Norbou Buchler
U.S. Army Research Laboratory, Aberdeen Proving Ground, Maryland, United States

Abstract

Automatic model generation based on user-task interactions is of great use for behavioral predictions and understanding of cognition. Mapping which environment features cause which actions seems like a classification problem suited for Deep Learning (DL). Unfortunately, DL does not create an observable model, and is more suitable to making predictions from billions of examples than from limited observations. There are, however, many tasks that lend themselves to symbolic input, allowing an alternative approach - Symolic Deep Learning (SDL). Symbolic hierarchical representations have a long history in Psychological literature, though some of these were integraged as models of memory without action-selection (e.g. EPAM/CHREST), and some have run into computational limitations (e.g. configural-cue). SDL stands to benefit from better model integration and modern growth in computational power and algorithmic efficiency, and promises to be the right paradigm for automatic model generation from limited user observations.

The Importance of Explanations in Guided Science Activities

Vaunam Venkadasalam
University of Toronto, Toronto, Ontario, Canada

Nicole Larsen
University of Toronto, Toronto, Ontario, Canada

Patricia Ganea
University of Toronto, Toronto, Ontario, Canada

Abstract

This study examined whether embedding explanations in guided activities promotes conceptual change about a physical science concept. One common misconception that children have is that heavy objects fall at a faster rate than light ones. We used a pre-, post-, and delay test design to address this misconception. Forty 5-year-old children were assigned to one of two conditions: a guided play activity that included an explanation about gravity, or the same guided play activity but with no explanation provided. Childrens explanations improved immediately at post-test (p =.001, 95% CI [0.58, 2.33]) and after a one-week delay test (p ¡.001, 95% CI [1.23, 2.95]) when the explanation about gravity was embedded in the activity. There was no improvement at post-test (p =.36) or delay-test (p =.93) when children completed the activity only. This study shows that conceptually rich explanations are an effective pedagogical tool for promoting belief revision in children.

Exploring the linguistic landscape: How individual differences among bilingual adults modulate eye movements when viewing multilingual artificial signs

Naomi Vingron
McGill University, Montral, Quebec, Canada

Jason Gullifer
McGill University, Montreal, Quebec, Canada

Debra Titone
McGill University, Montreal, Quebec, Canada

Abstract

Eye movement research reveals how people allocate visual attention when reading, scanning the environment around them (Rayner, 2012). These cognitive processes come together when people view what sociolinguists refer to as, the linguistic landscape, consisting of signage in the public space. Linguistic landscapes around the world are jointly determined by top-down socio-legal provisions, and bottom-up capacities and attitudes of individual people (Leimgruber, Vingron, & Titone, 2019). In a preliminary study, we found that bilinguals differed in how they viewed naturally occurring linguistic landscape images (Vingron et al., 2018). We are currently analyzing data from a follow-up study that investigated whether individual differences in language experience among bilinguals modulate their eye movements to artificial linguistic landscape images that systematically manipulate text language, position, and size, while controlling for linguistic content.

Integrating stereotypes and individuating information based on informativeness under cognitive load

Thalia Vrantsidis
University of Toronto, Toronto, Ontario, Canada

William Cunningham
University of Toronto, Toronto, Ontario, Canada

Abstract

When making inferences about another person (the target), perceivers often have to integrate multiple sources of information. This can include stereotypes about the targets groups (e.g., age, race, occupation) as well as other information about the target (individuating information). In simple situations, perceivers approximate ideal Bayesian information integration, relying more heavily on information that is more informative for the judgement. However under cognitive load with cognitive resources taken up by other demands people may instead rely on simplifying heuristics. We investigate several possible heuristics that people may use under load, including relying primarily on stereotypes rather than individuating information, as suggested by previous research, and we test if and how these heuristics depend on how informative each source of information is. By clarifying how stereotypes are used in less-than-ideal cognitive conditions, this work has implications for when stereotypes will tend to be overused in real-world situations.

Children with immature intuitive theories seek domain-relevant information

Jinjing (Jenny) Wang
Rutgers University-Newark, Newark, New Jersey, United States

Yang Yang
Rutgers University-Newark, Newark, New Jersey, United States

Carla Macias
Rutgers University-Newark, Newark, New Jersey, United States

Elizabeth Bonawitz
Rutgers University - Newark, Newark, New Jersey, United States

Abstract

A growing body of research suggests that infants and children are sensitive to signals of information gain. However, the value of a piece of information may also change as the learner knows more. How do changes that occur naturally in childrens intuitive theories contribute to their subsequent learning? Here we tested whether children who are at different stages of understanding an intuitive theory also differ in their interest in acquiring more information in the same domain. We tested childrens performance in three distinct domains, including intuitive biology, psychology, and beliefs about psychosomatic events. We found that children at earlier stages of their intuitive theories were more likely to seek information in the related domain than children with mature knowledge. These results are the first to show the relationship between natural changes in childrens existing knowledge and childrens future learning preferences.

Visual Statistical Learning Contributes to Word Segmentation during Reading of Unspaced Chinese Sentences

Tsanyu Wang
National Taiwan Normal University, Taipei, Taiwan

Jenn-Yeu Chen
National Taiwan Normal University, Taipei, Taiwan

Abstract

We investigated whether Chinese readers learn to segment words automatically while reading unspaced sentences through statistical learning. Experiment 1 replicated Saffran et al.s (1997) study using Chinese monosyllables presented auditorily to foreign learners of Chinese. The learning outcome was .57 on a two-alternative forced-choice test, statistically better than guessing (.5). Experiment 2 repeated Experiment 1 but presented the Chinese monosyllable string visually as a character string. Experiment 3 repeated Experiment 2 but doubled the exposure. Experiment 4 repeated Experiment 2 with characters of fewer numbers of strokes. The learning outcomes were .53, .52, and .52., not significant when tested individually, but was significant when the data were combined. At least 60% of the participants in each experiment showed the effect. We conclude that visual statistical learning does contribute to automatic word segmentation in Chinese reading.

A tradeoff between generalization and perceptual capacity in recurrent neural networks

Taylor Webb
Princeton University, Princeton, New Jersey, United States

Steven Frankland

Jonathan Cohen
Princeton University, Princeton, New Jersey, United States

Abstract

In a classic paper, Miller (1956) summarized findings showing that people can only identify a limited number of distinct stimuli at a time. One puzzling aspect of this capacity limitation is that it is approximately invariant to range. That is, the number of accurately identifiable stimuli is approximately the same regardless of how far apart the stimuli are spaced. Models of this phenomenon have suggested that people operate in a context-coding mode when performing these tasks, effectively carrying out a form of contextual normalization, but why such normalization might take place is unclear. Here, we propose an explanation by appealing to a tradeoff with generalization. Specifically, we implement contextual normalization in a recurrent neural network and show that this normalization enables stronger generalization in a relational reasoning task, but also results in a perceptual capacity limitation which captures many of these classic phenomena.

Wriggly, Squiffy, Lummox, and Boobs: What Makes Some Words Funny?

Chris Westbury
University of Alberta, Edmonton, Alberta, Canada

Geoff Hollis
University of Alberta, Edmonton, Alberta, Canada

Abstract

Theories of humor suffer from insufficient operationalization. We build on the Engelthaler & Hills (2017) humor rating norms, by analyzing the semantic and word form factors that play a role in the judgments. Our model can predict the original humor rating norms and ratings for previously unrated words with greater reliability than the split half reliability in the original norms. The model is consistent with several theories of humor, while suggesting that those theories are too narrow. In particular, it is consistent with incongruity theory, which suggests that experienced humor is proportional to the degree to which expectations are violated. Words are judged funnier if they are less common and have an improbable orthographic or phonological structure. We also describe and quantify the semantic attributes of funny words that are judged funny and show that they are partly compatible with the superiority theory of humor, which focuses on humor as scorn.

Language in Math Problem Solving

Renee Whittaker
Carleton University , Ottawa, Ontario, Canada

Chang Xu
Carleton University, Ottawa, Ontario, Canada

Jo-Anne LeFevre
Carleton University, Ottawa, Ontario, Canada

Helena P. Osana
Concordia University, Montreal, Quebec, Canada

Jill Turner

Anne Lafay
Concordia University, Montreal, Quebec, Canada

Sheri-Lynn Skwarchuk
University of Winnipeg, Winnipeg, Manitoba, Canada

Abstract

Children enrolled in language-immersion programmes may be required to learn math in the immersion language. Following the framework of the Pathways Model (LeFevre et al., 2010; Sowinski et al., 2014), the goal of the present study was to understand how instructional language supports math learning by comparing patterns of performance of immersion and non-immersion students. Participants included 182 grade 2 students (Mean age= 7.8 years): 108 students were enrolled in French immersion programs and were learning math in French (their second language) and 74 were enrolled in non-immersion programs and were learning math in English (their home language). Participants were tested on a number of general cognitive measures as well as math specific outcome measures. Results show that overall, across both immersion and non-immersion students, linguistic, quantitative and working memory components contributed to math problem solving. However, within the linguistic component there were differences between the direct and indirect pathways.

Using low-level sensory mechanism to bootstrap high order thinking in EFL reading

HingYi Wong
The Education University of Hong Kong, Hong Kong, China

Duo Liu
The Education University of Hong Kong, Hong Kong, Hong Kong

Zi Yan
The Education University of Hong Kong, Hong Kong, China

Abstract

The goal of the study was to compare potential changes in architecture when different set sizes were manipulated as a function of age difference and reading group difference in the Visual Search Task in Coglab. Based on the RT performance of Chinese EFLs aged 11 15 years old in feature and conjunction search when target was absent/present across three different set sizes (display size 4, 16 & 64), we conducted tests for architecture, stopping rule and dependency in visual search between typical and poor readers. What we are interested in are as follows: First, how a parallel/serial mental architecture in visual search might be predicted by both item features and person characteristics; and second, if stopping rule in target absent search is self-terminating/ exhaustive in nature. The aim of the study was to find cognitive behaviour that would accommodate developmental deficiency in EFL reading.

Semantic structure of infant first-person scenes changes with development

Ziyu Xiang
Indiana University, Bloomington, Indiana, United States

Linda Smith
Indiana University, Bloomington, Indiana, United States

David Crandall
Indiana University, Bloomington, Indiana, United States

Abstract

The co-occurrence of objects in visual scenes reflects the semantic structure of the world: cups are more likely to appear in scenes with tables than airplanes, for example. Both human and machine vision use these co-occurrences to support recognition of individual objects. A reasonable assumption is that these co-occurrences are ubiquitous and present for all perceivers. However, the scenes observed by infants are highly dependent on their body postures and locations, both of which change dramatically over the first year of post-natal life. To measure these changing co-occurrences in infant-perspective scenes, we collected images from infants wearing head cameras in everyday home environments comparing three age groups: 1-3, 6-8 and 11-12 months. Using graph theoretical analysis, we conclude that the semantic structure of scenes in 6-8 months differs from whats in younger and older infants.

Abstract Syntactic Knowledge or Limited-Scope Formulae: A Computational Study of Childrens Early Utterances

Qihui Xu
Graduate Center, City University of New York, New York, New York, United States

Martin Chodorow
Graduate Center, City University of New York, New York, New York, United States

Virginia Valian
Graduate Center, City University of New York, New York, New York, United States

Xiaomeng Ma
Graduate Center, City University of New York, New York, New York, United States

Abstract

Do childrens early utterances reflect abstract syntactic knowledge or slot-filler formulae developed through word imitation? This study compares development of part-of-speech (POS) sequences with word sequences using language models (LMs) trained on mothers utterances (N=1,272,139) from CHILDES English corpora, in which POS tags are automatically assigned by MOR and POST programs (MacWhinney, 2000). Word-based and POS-based LM probabilities for childrens multi-word utterances in the Providence corpus (Brschinger et al., 2013, 15-36 months, Nchildren=6, Nutterances=50,717) were calculated as a function of age. Word-based LM probability of childrens multi-word utterances first increases with age and then levels off after 23 months. By contrast, POS-based probability remains high and stable across all ages. This suggests children have adult-like syntactic knowledge even at a very early age when their word sequences are still not adult-like. The pattern of results supports the abstract syntax view. Additional studies will use more accurate POS-taggers and larger datasets.

The effects of object motion observations on physical prediction

Moyuru Yamada
Fujitsu Laboratories Ltd., Kanagawa, Japan

Kevin Smith
Massachusetts Institute of Technology, Cambridge, Massachusetts, United States

Josh Tenenbaum
MIT, Cambridge, Massachusetts, United States

Abstract

People use knowledge about physical objects to predict and plan their actions, but this knowledge about objects can be directly perceived or simply inferred. In this experiment, participants chose the direction to shoot computerized cannons to hit targets. These cannons differed in how fast they shot the cannonball, but participants could learn this information either from observing the full trajectory of a prior shot, or just observing the outcome. While the cannonballs initial speed can be determined from the end state alone, additional information in the full trajectory might improve these estimates. We find that performance is only worse in the end-state trials if these trials were tried first; if participants judged the full trajectory trials first, their performance did not decline on the end-state trials. We explore this order effect using a model of noisy physical inference that assumes learning from prior trial blocks.

Commonality search shares processes with alternative categorization

Mayu Yamakawa
Nagoya University, Nagoya, Japan

Sachiko Kiyokawa
Nagoya University, Nagoya, Japan

Abstract

We investigated how people find commonalities between unrelated objects as a basis of generating creative ideas by examining the relationship between performances on commonality search and alternative categorization tasks. We predicted a positive correlation between performances on the two tasks because one needs to focus on some obscure features of objects to do both tasks well. Thirty-one undergraduates were asked to engage in both commonality search and alternative categorization tasks. They were asked to list as many as commonalities between nine unrelated object pairs for 90 seconds for each pair. They were then asked to list as many categories as possible that each of five objects belong to for 60 seconds per object. The results showed a significant positive correlation between the performances on these tasks. We concluded that commonality search and alternative categorization both focus on obscure features of objects.

Minimal but meaningful: Probing the limits of randomly assigned social identities

Xin Yang
Yale University, New Haven, Connecticut, United States

Yarrow Dunham
Yale University, New Haven, Connecticut, United States

Abstract

The present studies (total n = 151) experimentally manipulated meaningfulness in novel social groups and measured any resulting ingroup biases. Study 1 showed that even when groups were arbitrary and presumptively meaningless, 5- to 8-year-olds developed equally strong ingroup biases as did children in more meaningful groups. Study 2 explored the lengths required to effectively reduce ingroup biases by stressing the arbitrariness of the grouping dimension. Even in this case ingroup bias persisted in resource allocation behavior, though it was attenuated on preference and similarity measures. These results suggested that one has to go to great lengths to counteract childrens tendency to imbue newly encountered social groups with rich affiliative meaning.

Corpus-based topic modeling for the cognitive study of the 21st century sociocultural challenges

Vera Zabotkina
Russian State University for the Humanities, Moscow, Russian Federation

Boris M. Velichkovsky
Kurchatov Institute, Moscow, Russian Federation

Artemy Kotov
Kurchatov Institute, Moscow, Russian Federation

Dmitry Orlov
Russian State Univercity for the Humanities, Moscow, Russian Federation

Alexander Piperski
Russian State University for the Humanities, Moscow, Russian Federation

ELENA POZDNYAKOVA
Russian State Univercity for the Humanities, Moscow, Russian Federation

Abstract

The results were obtained in the course of a two-stage study. At the first stage (2018) linguists analyzed the conceptual domain sociocultural challenges on the basis of purposely elaborated Russian language THREAT-corpus (10.4 m words) and built a frame of the domain. At the second stage (2018-2019) the research was carried out with methods of automated topic modeling for two Russian language corpora: THREAT-corpus and alternative corpus collected using WebBootCaT tool in the SketchEngine corpus management system. Methods of topic modeling (PLSA, LDA, BigARTM et al.) allowed eliciting thematic profiles for texts of both corpora. Comparison of two datasets was carried out by applying set theory, graph theory, and probabilistic analysis. Combining topic modeling with linguistic frame analysis resulted in more precise configurations of cognitive models in the conceptual domain sociocultural challenges. Word frequency for lexemes manifesting sociocultural challenges proved to be an important factor of conceptual structures representation.

Communicative need and color naming

Noga Zaslavsky

Naftali Tishby
Hebrew University of Jerusalem, Jerusalem, Israel

Terry Regier
UC Berkeley, Berkeley, California, United States

Abstract

Color naming across languages has traditionally been held to reflect the structure of color perception. At the same time, it has often, and increasingly, been suggested that color naming may be shaped by patterns of communicative need. However, much remains unknown about the factors that drive communicative need, how need interacts with perception, and how this interaction may shape color naming systems across languages. We engage these open questions by building on general information-theoretic principles, and on a recent account of color naming that integrates the roles of need and perception. On this basis, we present a systematic evaluation of several factors that may influence need, and that have been proposed in the literature: capacity constraints, linguistic usage, and the visual environment. Our findings suggest that communicative need and resulting patterns of color naming are shaped more by linguistic usage than they are by the visual environment alone.

Constructing a category prototype from statistical regularities under uncertainty

Haiyun Zeng
University of Pennsylvania, Philadelphia, Pennsylvania, United States

John Trueswell
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Sharon Thompson-Schill
University of Pennsylvania, Philadelphia, Pennsylvania, United States

Abstract

Learning the meaning of a word requires forming a semantic representation that characterizes the referential exemplars encountered with that word. However, each learning instance is ambiguous in that the word may plausibly refer to multiple entities. To the extent that learners consider multiple referents under conditions of referential uncertainty, how do these alternatives enter into learning word meaning? We employed a cross-situational word-learning paradigm with novel creatures to investigate whether co-occurring exemplars that were considered but not selected as the words referent would influence the category prototype. We contrasted a condition where all exemplars were labeled with a word and a condition where only some of the exemplars of a category were labeled with the word later in the learning phase. Preliminary results are consistent with the prediction that referents that are considered but not selected contribute less to the semantic representation of the word than do the selected referents.

Interpretation of Generic Language is Dependent on Listener's Background Knowledge

Xiuyuan Zhang
University of Chicago, Chicago, Illinois, United States

Dan Yurovsky
University of Chicago, Chicago, Illinois, United States

Abstract

Generic statements, like "birds lay eggs" or "dogs bark" are simple and ubiquitous in naturally produced speech. However, the inherent vagueness of generics makes their interpretation highly context-dependent. Building on work by Tessler & Goodman (in press) showing that generics can be thought of as inherently relative (i.e. more birds lay eggs than you would expect), we explore the consequences of different implied comparison categories on the interpretation of novel generics. In Experiments 1 and 2, we manipulated the set of categories salient to a listener by directly providing them the comparison sets. In Experiments 3 and 4, we collected participants demographic information and used these naturally occurring differences as a basis for differences in the participants' comparison sets. Our results confirmed the hypothesis that prevalence judgments of features in novel categories are sensitive to differences in their corresponding comparison categories. These results suggest a possible source for well-intentioned miscommunications.

Deep Learning of Chinese Characters

Xiaowei Zhao
Emmanuel College, Boston, Massachusetts, United States

Abstract

In this study, the printing forms (different fonts) of about 3000 common Chinese characters were sent into a Deep Neural Network (DNN), along with their sounds. The network can successfully learn the association between the form and the sound of these characters. It also develops certain generalizability when facing new characters. In addition, the internal representations on different layers of the network show the emergence of basic writing structures of Chinese characters (i.e. strokes, radicals, left-right, top-down structures). The learning pattern of the network is further compared with that of the elementary school students.

Bayesian Inference Causes Incoherence in Human Probability Judgments

Jianqiao Zhu
University of Warwick, Coventry, United Kingdom

Adam Sanborn
University of Warwick, Coventry, United Kingdom

Nicholas Chater
University of Warwick, Coventry, United Kingdom

Abstract

Human probability judgements appear systematically biased, in apparent tension with Bayesian models of cognition. But perhaps the brain does not represent probabilities explicitly, but approximates probabilistic calculations through a process of sampling, as used in computational probabilistic models in statistics. The Bayesian sampling viewpoint provides a simple rational model of probability judgements, which generates biases such as conservatism. The Bayesian sampler provides a single framework for explaining phenomena associated with diverse biases and heuristics, including availability and representativeness. The approach turns out to provide a rational reinterpretation of noise in an important recent model of probability judgement, the probability theory plus noise model (Costello & Watts, 2014; 2016; 2017; Costello, Watts, & Fisher, 2018), and captures the empirical data supporting this model.

A resource-rational model of physical abstraction for efficient mental simulation

Abstract

Physical simulation enables people to make intuitive predictions about physical scenes and interact flexibly with the objects around them, from a stack of books balanced on a ledge to the turrets and moats of a sandcastle. We hypothesize that when the number of possible objects makes simulation intractable, people use chunked abstractions that reduce the number of objects they need to simulate while also minimizing simulation error. We tracked participants gaze while they viewed complex towers of blocks and predicted whether the towers would remain stable under gravity. We developed a resource-rational model of how people might optimally partition towers into chunks of blocks. Subsequently, we compared this model to participants fixations over the scene. We explore how efficient, resource-rational chunkings of physical scenes might underlie peoples ability to make rapid and robust inferences in this domain.

Modeling of Complex Communicative Behavior for F-2 Companion Robot

Anna Zinina
National Research Center Kurchatov Institute, Moscow, Russian Federation

Nikita Arinkin
National Research Center Kurchatov Institute, Moscow, Russian Federation

Liudmila Zaidelman
National Research Center Kurchatov Institute, Moscow, Russian Federation

Artemy Kotov
Kurchatov Institute, Moscow, Russian Federation

Abstract

We design F-2 companion robot, supporting natural multimodal communication. The robot is operated by a set of scripts, triggered by input speech and generating behavioral patterns in BML format. To make robots behavior as close as possible to humans, we extract natural communication patterns from the Russian Emotional Corpus REC (over 400.000 annotations), reproduce key patterns in Blender 3D editor and export them to MySQL database (n = 220). For each generated BML the software retrieves the corresponding movement from the database, joins compatible patterns and performs them on the robot. Robot can also receive the coordinates of surrounding human faces and simulate direct gazes towards the eyes of the addressee. It can also perform oriented (pointing) gestures: switch between directions or between several interlocutors. This allows us to model complex robot behavior, as shown in our experiment, increasing human satisfaction from robot-to-human interaction (Research is supported by the Russian Science Foundation, project No 19-18-00547).

A Visual Remote Associates Test and its Initial Validation

Faheem Zunjani
Freie Universitt Berlin, Berlin, Germany

Ana-Maria Olteteanu
Freie Universitat Berlin, Berlin, Germany

Abstract

The Remote Associates Test (RAT) is a test used for measuring creativity as relying on the power of making associations, and it normally takes a linguistic form (i.e., given three words, a fourth word associated with all three is asked for). While other visual creativity tests exist, no creativity test to date can be given in both a visual and linguistic form. Such a test would allow the study of differences between various modalities, in the creativity domain. In this paper, a visual version of the well known Remote Associates Test is constructed. This visual RAT is validated in relation to its linguistic counterpart in a study with 42 participants. A significant correlation of 0.431 (p ¡ 0.01) between visual RAT scores and comRAT-G scores was observed.
