Quantifying Anticipatory and Post-Stimulus Mu ERSP The envelope of the amplitude-modulated signal was computed via the Hilbert transform ("hilbert" function in Matlab), which discards phase information and reveals oscillatory power fluctuations over time. A subject-specific approach to identifying peak mu activity was used, with a peak quantified in R as the largest local maximum within the 7-14 Hz range (Goljahani et al., 2014). This value was extracted from individual participant power spectra for C3 and C4, for each condition (right/left).

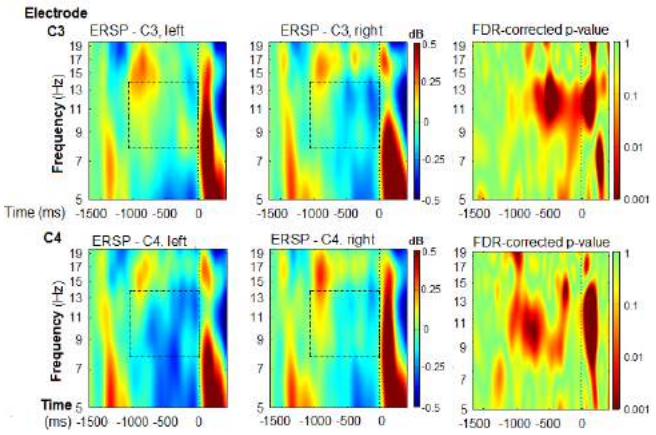

Figure 2. Time-frequency plots showing ERSP (event-related spectral perturbation) at left and right central sites (C3/C4) across a range of 5-20 Hz for the period from 1500 ms before the tactile stimulus (0 ms) to 300 ms after.

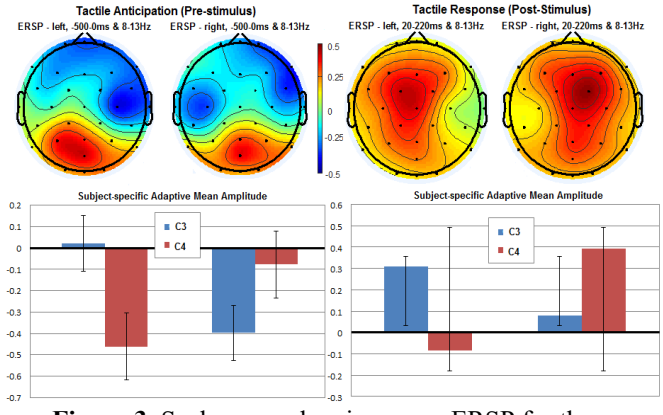

Figure 3. Scalp maps showing mean ERSP for the anticipatory period (-500 to 0 ms) and stimulus response period (20-270 ms) at each of 30 electrodes. Mu power for each participant was calculated for the subject-specific frequency band (+/-2 Hz) at C3 and C4.

The bin with the highest number of observations was centered at 10.5 Hz. The mean alpha peak frequency across subjects was 10.1 Hz with a between-subject SD of 2.1 Hz and the median was 10.4 Hz.

A repeated-measures ANOVA was conducted, comparing anticipatory mean 8-14 Hz ERSP in the -500 to 0 ms window prior to tactile stimulation, by electrode (C3/C4) and cue direction (left/right). No main effects were observed. A significant interaction was observed between cue direction and electrode, $F(1, 39) = 25.757$, $p < .001$, $\eta^{2p} = 0.398$. As suggested by the ERSP scalp maps (Figure 3), this interaction was driven by greater mu ERD at the contralateral site than at the ipsilateral site. When stimulation was expected to the left hand, greater mu ERD was observed at C4 ($M = -0.461$, $SD = 0.988$) than at C3 ($M = -0.022$, $SD = 0.984$, $t = 3.246$, $p < .001$, $d = .588$). When stimulation was expected to the right hand, greater mu ERD was observed at C3 ($M = -0.398$, $SD = 1.026$) than at C4 ($M = -0.077$, $SD = 0.844$, $t = -3.246$, $p < .002$, $d = -0.513$).

A repeated-measures ANOVA was conducted, comparing mean 8-14 Hz ERSP in the 20 to 270 ms window by electrode (C3/C4) and cue direction (left/right). No main effects were observed. A significant interaction was observed between cue direction and electrode, $F(1, 39) = 11.823$, $p < .001$, $\eta^{2p} = 0.233$. Following stimulation of the left hand, mu ERSP was greater at the ipsilateral site C3 ($M = 0.308$, $SD = 1.337$) compared to the contralateral site C4 ($M = -0.083$, $SD = 1.555$, $t = -3.506$, $p = .015$, $d = .403$). Following stimulation to the right hand, mu ERSP was greater at the contralateral site C3 ($M = 0.393$, $SD = 1.545$) compared to ipsilateral site C4 ($M = 0.079$, $SD = 1.686$, $t = -2.240$, $p = .031$, $d = -.354$).

To examine the relations between mu ERSP and scores on the behavioral tasks, the dependent variables used in the previous ANOVA were collapsed into *contralateral* (mu ERSP at C3 for the right hand cue and at C4 for the left hand cue) and *ipsilateral* (mu ERSP at C3 for the left hand cue and at C4 for the right hand cue) mean *mu ERSP* values.

Correlation of Mu ERSP with Behavior

Pearson correlations were computed among ipsilateral and contralateral mu ERSP in anticipation of (*anticipatory*) and in response to (*post-stimulus*) tactile stimulation, and the measures from the NIH Cognitive Toolbox. Contralateral anticipatory (CL TA) mu ERSP was inversely associated with Processing Speed (PS) ($r = -.321$, $p = .02$), while Flanker score was significantly associated with ipsilateral anticipatory (IP TA) mu ERSP ($r = .293$, $p = .03$). Similarly, Card Sort was marginally associated with ipsilateral anticipatory mu ERSP, ($r = .230$, $p = .06$). Processing Speed ability and task-specific reaction time were significantly correlated ($r = .245$, $p = .02$). Language (PVT) was not significantly correlated with other measures; contralateral tactile response (CL TR) mu ERSP was marginally associated with processing speed, ($r = -.219$, $p = .07$), but ipsilateral tactile response (IP TR) did not relate with other behavioral measures.

Table 1. Correlation Matrix of Study Variables.

	CL TA Mu ERSP	IP TA Mu ERSP	CL TR Mu ERSP	IP TR Mu ERSP	Flan-ker (EF)	Card Sort (EF)	PS	PVT
CL TA Mu ERSP	—	.017	**.718**	**.667**	—	—

Regressions of Anticipatory Mu ERSP with Behavior

To address our hypotheses on the relations between cognitive skills and neural indicators of anticipation, multiple regressions were conducted predicting scores on the Flanker, Card Sort, Receptive Language, and Processing Speed tasks from contralateral and ipsilateral mu ERSP. For both Flanker and Card Sort tasks, greater ipsilateral mu ERSP was associated with better EF task performance. Flanker performance was related to ipsilateral mu ERSP, $t(39) = 2.026$, $\beta = 0.531$, $p = 0.046$, but not with contralateral mu ERSP. Card Sort performance was also related with ipsilateral mu ERSP, $t(39) = 2.219$, $\beta = 0.576$, $p = 0.033$, but was not significantly associated with contralateral mu ERSP. Contralateral mu ERSP was related to Processing Speed, $t(39) = -2.418$, $\beta = -0.621$, $p = 0.021$, and marginally associated with ipsilateral mu ERSP. Receptive Language scores were not related to anticipatory mu ERSP, nor were there further significant relations detected among regressions of behavioral measures and contralateral and ipsilateral mu tactile responses. Further, variance accounted for in Card Sort and Flanker by anticipatory ipsilateral mu ERSP remained significant when the extent of mu ERSP during the response to the tactile stimulus was used as a covariate. Similarly, variance in Processing Speed accounted for by anticipatory contralateral mu ERSP remained significant when controlling for variance in post-stimulus mu ERSP.

Discussion

We were interested in whether individuals differed in their neural activity during anticipation of and in response to a tactile stimulus, and whether such differences had meaningful relations with behavior, including indicators of tactile attention relevant to the task and measures of other attentional and cognitive skills. Consistent with previous investigations, sensorimotor mu ERD was observed in the hemisphere contralateral to the expected location of a tactile stimulus, indicating that participants indeed directed their attention to the relevant hand during the anticipatory epoch (Haegens et al., 2011; Anderson & Ding, 2011; Van Ede et al., 2014). The magnitude of contralateral mu ERD was associated with how quickly and accurately participants compared the similarity of two stimuli on a separate task assessing processing speed. In turn, performance on the processing speed task was found to be related to how quickly participants pressed a foot pedal to indicate how many tactile stimuli they perceived in the EEG task. Individual differences in executive function were also associated with variation in the magnitude of anticipatory mu oscillations, but only at central electrodes sites ipsilateral to the cued hand.

Mu activity in the ipsilateral somatosensory cortices is relevant to the coordination of behavioral responses, with animal and human research indicating that somatosensory processing is distributed across bilateral primary sensory cortices (van Ede et al., 2014; Tamè et al., 2016). The dynamic adjustment of bilateral mu modulation to anticipated features of a tactile stimulus indicates that oscillations originating in the somatosensory cortices are acutely sensitive to the load on tactile attention (Gomez-Ramirez et al., 2016; Haegens et al., 2012). In primates and humans, neural responses in bilateral somatosensory cortices may serve to simultaneously managing competing expectancies, reflecting allocation of tactile attention according to goals and bracing for potential distraction (Haegens et al., 2012; Tame et al., 2016)

In interpreting the relation of ipsilateral mu activity (rather than contralateral mu ERD) to executive function, we look to two possible explanations for the generation of alpha oscillations. Global alpha oscillations have been ascribed an inhibitory function (Klimesh et al., 1998; Mahzeri and Jensen, 2010). In past examinations of anticipation in the visual and auditory modalities, the 'gating' function of increases in alpha power has offered an account for the association between anticipatory ipsilateral alpha power with task-relevant stimulus detection rate and speed of behavioral responses across sensory modalities (Frey et al., 2015). Alternatively, and supported by previous investigations of anticipation in visual and tactile modalities (van Ede et al., 2014; Thut et al., 2006), the ipsilateral mu power over the relevant sensory cortices might increase or hover at baseline to suppress sampling of events at the unattended location (Shroeder and Latkos, 2009). These complementary accounts of anticipatory alpha oscillations may provide insight into how variability of neural responses contributes to individual differences in measures of cognitive ability.

The association of processing speed ability and reductions of mu power expands the existing literature focused on relations of mu modulation with task-specific reaction time. A previous investigation of children aged 6-8 found a significant association between executive function abilities and contralateral reductions of mu power (Weiss et al., 2018). There may be developmental differences in how attention is allocated in expectation of a tactile stimulus: speculatively, younger children may deliberately focus on monitoring sensation at the cued location while adults deploy effort into inhibiting sensation at the uncued bodily location. Such task-specific strategies could explain the observed patterns of lateralized mu oscillations and the difference in which hemisphere accounted for a greater share of variance in executive function skills. It is possible that attention to bodily sensations and variability in perceived boundaries between the body, peripersonal space and extrapersonal space contributed to these developmental and individual differences (Bremner & Spence, 2017), or that mu oscillations may have greater inter-individual variability than other alpha-range rhythms (Coll et al., 2017). Regardless, our findings indicate that neural responses during anticipation of a tactile stimulus index variation in stimulus processing speed, which could cascade into meaningful individual differences captured by measures of executive function (Willougby et al., 2018).

Further studies can address the potential utility of mu oscillations as an indicator of individual differences in how attention is deployed to the body. Neural responses during anticipation of a stimulus may offer a potential source of

variation in behavioral responses and stimulus processing speed, which could cascade into individual differences in measures of executive function.

Abstract

Recurrent Neural Networks (RNNs) trained on a language modeling task have been shown to acquire a number of non-local grammatical dependencies with some success (Linzen, Dupoux, & Goldberg, 2016). Here, we provide new evidence that RNN language models are sensitive to hierarchical syntactic structure by investigating the **filler–gap dependency** and constraints on it, known as **syntactic islands**. Previous work is inconclusive about whether RNNs learn to attenuate their expectations for gaps in island constructions in particular or in *any* sufficiently complex syntactic environment. This paper gives new evidence for the former by providing control studies that have been lacking so far. We demonstrate that two state-of-the-art RNN models are are able to maintain the filler–gap dependency through unbounded sentential embeddings and are also sensitive to the hierarchical relationship between the filler and the gap. Next, we demonstrate that the models are able to maintain **possessive pronoun gender expectations** through island constructions—this control case rules out the possibility that island constructions block all information flow in these networks. We also evaluate three untested islands constraints: coordination islands, left branch islands, and sentential subject islands. Models are able to learn left branch islands and learn coordination islands gradiently, but fail to learn sentential subject islands. Through these controls and new tests, we provide evidence that model behavior is due to finer-grained expectations than gross syntactic complexity, but also that the models are conspicuously un-humanlike in some of their performance characteristics.

Keywords: Syntactic Islands, Recurrent Neural Networks, Blocking Effects, Acquisition of Syntax

Introduction

Recurrent Neural Networks (RNNs) with Long Short-Term Memory architecture (LSTMs) have achieved state-of-the-art scores at a number of natural language processing tasks, including language modeling and parsing (Hochreiter & Schmidhuber, 1997; Jozefowicz, Vinyals, Schuster, Shazeer, & Wu, 2016). In addition, they have begun to be used as a plausible sub-symbolic model for a variety of cognitive functions, including visual perception and language processing and comprehension (J. Elman, 1990). However, the distributed representations learned by RNNs and neural networks in general are notoriously opaque, posing a challenge for their interpretability as models of human sentence processing and for their controllability as NLP systems.

One recent line of work aims to uncover what these 'black boxes' learn about language by treating them like human psycholinguistic subjects. In this **psycholinguistic paradigm** RNNs trained on the language modeling task are fed handcrafted sentences, designed to expose their underlying syntactic knowledge (Linzen et al., 2016; McCoy, Frank, & Linzen, 2018). Much of this work has investigated what RNNs trained on a language modeling objective are capable of learning about natural syntactic dependencies. For the purposes of this investigation, we define **dependency** as any systematic co-variation between two words. For example, in one experiment networks were tested as to whether they had learned the number agreement dependency between a subject and a verb. They were fed with the prefix *The key to the cabinet...* and correctly gave a higher probability to the grammatical *is* over the ungrammatical *are*. Networks were shown to successfully complete this task for a number of languages, as well as for sentences whose content words were replaced with random alternatives of the same syntactic category rendering them syntactically licit but semantically implausible (Gulordava, Bojanowski, Grave, Linzen, & Baroni, 2018).

But learning that covariance exists between certain words or word forms, without reference to their relative positions, is not enough to say that the RNN models have fully learned a dependency. Natural language dependencies consist of covariation between two elements in *certain syntactic positions*. Agents must both attend to the structural relationship between the two elements bound by the dependency and filter out intervening material in syntactically irrelevant positions. The subject–verb number agreement task above provides compelling evidence that RNNs are capable of the latter: they were able to maintain correct predictions despite a number of *distractors* that mismatched the subject in number, such as *cabinet* in the example provided (Marvin & Linzen, 2018).

Evidence suggesting that RNN language models are also sensitive to the structural relationship between the two bound elements has emerged from the study of **filler–gap dependencies** (Wilcox, Levy, Morita, & Futrell, 2018; Chowdhury & Zamparelli, 2018). The filler–gap dependency is the dependency between a *filler*—such as *who* or *what*—and and a gap, which is an empty syntactic position. Crucially, filler–gap dependencies are subject to a number of constraints, known as *island constraints*, which are a set of structural positions that prevent the filler and the gap from entering into a dependency with each other (Ross, 1967). (1-b) gives one example island, in which the dependency is blocked by a wh-complementizer.

(1) a. I know what the guide said that the lion devoured __ yesterday. NO VIOLATION
b. *I know what the guide said whether the lion devoured __ yesterday. WH-ISLAND ISLAND VIOLATION

While it has been shown that both simple Elman RNNs and more contemporary LSTMs are able to represent the basic covariance between fillers and gaps, as well as other non-structural aspects of dependency, it is still uncertain whether

the models are sensitive to island constraints (J. L. Elman, 1991). Previous work has demonstrated that two state-of-the-art models are sensitive to three of the most-studied island constraints (wh-islands, complex NP islands and adjunct islands) but insensitive to a fourth (subject islands) (Wilcox et al., 2018). Others have concluded that the models are merely sensitive to syntactic complexity plus order. Chowdhury and Zamparelli (2018) compared sentence-level perplexity scores obtained by RNN LMs for wh-questions that violate island constraints, and yes-no questions and statements that violate no grammatical rules but contain the same syntactic structures. While the models obtained better perplexity scores on the statements compared to the island-violation questions, they performed similarly on the island-violations and non-violating yes/no questions. These results may indicate that RNNs are not learning to attenuate their expectations for gaps in island constructions in particular, but in *any* sufficiently complex syntactic environment.

This paper adjudicates between these two accounts of model behavior by providing control studies that have been lacking so far. In the first section, we demonstrate that two state-of-the-art LSTM models are sensitive to some forms of syntactic complexity, but not to others. Models are able to maintain the filler–gap dependency through **unbounded sentential embeddings** and yet are sensitive to the **hierarchical relationship** between the filler and the gap, suggesting that only specific types of syntactic complexity block gap expectations. In the second section, we turn to **possessive pronoun gender dependencies**, demonstrating that the models are able to maintain general expectations through island constructions—it is not the case that island constructions block all information flow in these networks. In this section we also evaluate three untested islands constraints: **coordination islands**, **left branch islands**, and **sentential subject islands**. Models are able to learn left branch islands and coordination islands gradiently, but fail to learn sentential subject islands. Through these controls and new tests, we provide evidence that model behavior is due to finer-grained expectations than gross syntactic complexity, but also that the models are conspicuously un-humanlike in some of their performance characteristics.

Methods

Language Models

We assess two state-of-the-art pre-existing LSTM models trained on English text for a language modeling objective. The first model, which we refer to as the **Google Model**, was trained on the One Billion Word Benchmark and has two hidden layers with 8196 units each. It uses the output of a character-level convolutional neural network (CNN) as input to the LSTM (and was originally presented as the *BIG LSTM+CNN Inputs*) (Jozefowicz et al., 2016). The second model, which we refer to as the *Gulordava Model* was selected for its previous success at learning the subject-verb number agreement task. It was trained on 90 Million tokens of English Wikipedia, and has two hidden layers of 650 units each (Gulordava et al., 2018).

Dependent Measure: Surprisal

In this work we take a grammatical dependency to be the covariance between an upstream *licensor* and a downstream *licensee*. We assess the model's knowledge of the dependency by measuring the effect that the licensor has on the **surprisal** of the licensee, or on material immediately following the licensee when it is a gap. Surprisal, or negative log-conditional probability , $S(x_i)$ of a sentence's i^{th} word x_i, tells us how strongly x_i is expected under the language model's probability distribution. For sentences out of context, the surprisal is: $S(x_i) = -\log p(x_i|x_1 \dots x_{i-1})$. Surprisal is known to correlate directly with processing difficulty in humans (Smith & Levy, 2013; Hale, 2001; Levy, 2008). In this work, we expect that grammatical licensors set up expectations for licensee, reducing its surprisal compared to minimal pairs in which the licensor is absent. We derive the word surprisal from the LSTM langauge model by directly computing the negative log of the predicted conditional probability $p(x_i|x_1 \dots x_{i-1})$ from the softmax layer.

Experimental Design: Wh-Licensing Interaction

The filler–gap dependency is biconditional: Fillers set up expectations for gaps and gaps require fillers to be licensed. To measure this bi-directionality we employ the 2x2 interaction design proposed in Wilcox et al.. There, the authors measure the **wh-licensing interaction**, which they compute from four sentence variants, given in (2), that contain the four possible combinations of fillers and gaps for a specific syntactic position. Note that the underscores are for presentational purposes only, and were not included in test items. Subsequent examples will be given via the (2-d) example, but all four variants were created in order to compute the licensing interaction.

(2) a. I know that you insulted your aunt yesterday. [-FILLER -GAP]
b. *I know who you insulted your aunt yesterday. [+FILLER -GAP]
c. *I know that you insulted __ yesterday. [-FILLER +GAP]
d. I know who you insulted __ yesterday. [+FILLER +GAP]

If the filler sets up an expectation for a gap, then the filled syntactic position where a gap would typically occur should be more surprising in contexts that contain an upstream filler. That is $S(b) - S(a)$ should be a large positive number. If the gap requires a filler to be licensed, then the transition from the embedded verb to the S-modifying PP 'yesterday' that skips over the otherwise-required grammatical object should be more surprising in contexts without an upstream filler. That is, $S(d) - S(c)$ should also be a large negative number. We can assess how well the model has learned both expectations by measuring the difference of differences: $[S(b) - S(a)] - [S(d) - S(c)]$. This is the wh-licensing interaction. If the models are learning the filler–gap dependency, we expect this to be a large positive number, with typical models showing about 4 bits of licensing interaction in simple object extracted clauses such as (2). Although we might expect the

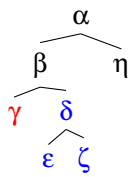

Figure 1: C-Command in a binary-branching tree structure. γ *c*-commands all the nodes in blue, but does not *c*-command the black nodes.

strongest difference in surprisal between (2-a) and (2-b) to be on the filled-gap position, *your aunt*, this material is elided in two of the conditions. Therefore, in order to keep the measurement site the same across all four conditions, we measure wh-licensing interaction in the post-gap prepositional phrase ('yesterday' in (2)).

In previous work using this methodology, RNN knowledge of island constraints was assessed by comparing the licensing interaction in island configurations to that in non-island minimal pairs. Strong evidence for an island constraint would be if the wh-licensing interaction dips to zero for a gap in island position, indicating that the model has decoupled expectations for fillers from gaps in this position. In practice we look for a significant decrease in wh-licensing interaction as indication that the models have learned to attenuate their expectations for gaps within islands. We derive the statistical significance of the interaction from a mixed-effects linear regression model, using some-coded conditions (Baayen, Davidson, & Bates, 2008). We include random intercepts by item but omit random slopes as we do not have repeated observations within items and conditions (Barr, Levy, Scheepers, & Tily, 2013). In our figures, error bars represent 95% confidence intervals of the contrasts between conditions, computed by subtracting out the by-item means before calculating the intervals as advocated in (Masson & Loftus, 2003). [1]

Syntactic Complexity

Unboundedness

The filler–gap dependency can span through a potentially unbounded number of sentential embeddings. To test whether models' expectations were attenuated with greater embedding depth, we created 23 items in five experimental conditions with between 0 and 4 layers of embedding and gaps in either object or indirect object (goal) position, following the examples in (3), and measured the licensing interaction in the post-gap material. (In this and subsequent examples, the material in which the interaction is measured will be highlighted in bold.)

b. I know who the gardener reported the butler said the hostess believed her aunt suspected you insulted __ **at the party**. [OBJECT GAP, 4 LAYERS]

c. I know who you delivered a challenge to __ **at the party**. [GOAL GAP, 0 LAYERS]

d. I know who the gardener reported the butler said the hostess believed her aunt suspected you delivered a challenge to __ **at the party**. [GOAL GAP, 4 LAYERS]

The results for this experiment can be seen in figure 2, with the object gap results on the top and goal gap results on the bottom. First, we find a significant interaction between fillers and gaps resulting in supperaditive reduction of surprisal ($p < 0.001$ for all conditions) indicating that both models have learned the filler–gap dependency. Starting with the object gap conditions: For the google model, we find no effect of embedding depth on the wh-licensing interaction ($p > 0.85$ in all cases); for the gulordava model, we find a significant decrease in wh-licensing interaction only between the *no embedding* conditions and conditions with 3 or 4 additional layers of embedding ($p < 0.001$ in both). When the gap occurs in the goal position, for the google model, we find no significant effect of embedding depth of the wh-licensing interaction. For the gulordava model, we find a generally smaller wh-licensing interaciton, as well as a significant effect of embedding between the *no embedding* condition and conditions with two or more additional embedding layers ($p < 0.05, p < 0.05, p < 0.01$ for 2 ,3 and 4 layers). We take these results to indicate that the google model has learned the unboundedness of the filler–gap dependency whereas the gulordava model has learned only relative unboundedness and shows behavior that reflects human performance more than human competence. However, these results indicate that both models can, in principle, thread their expectations for gaps through complex syntactic structures, if we take the number of syntactic nodes as a proxy measure for syntactic complexity.

Syntactic Hierarchy

Although the filler–gap dependency is unbounded, it is subject to a number of hierarchical constraints, the most basic of which is that the filler must be "above" the gap, structurally. Here, we take this to mean that the filler must *c*-command the gap, although the precise relationship is more complex (Pollard & Sag, 1994). Structurally-speaking node γ *c*-commands node δ if neither node directly dominates the other and every node X that dominates γ also dominates δ. Figure 1 demonstrates this relationship, with the noes *c*-commanded by γ highlighted in blue.

To assess whether the models had learned this constraint on the structural relationship we created 24 variants following the examples in (4) and measured the wh-licensing interaction in the post-gap PP. If the model has learned the structural constraints on the filler–gap dependency, an undischarged filler in the matrix clause should not make a gap in subsequent parts of the sentence more or less likely, leading to near-zero licensing interaction in the *Matrix Clause* condition.

[1] Our studies were preregistered on `aspredicted.org`: To see the preregistrations go to `aspredicted.org/blind.php?=X` where $X \in \{$`sz8f5d,2r2eu7,zt73qt,es8rx7,f9pk9f,se6i2e`$\}$.

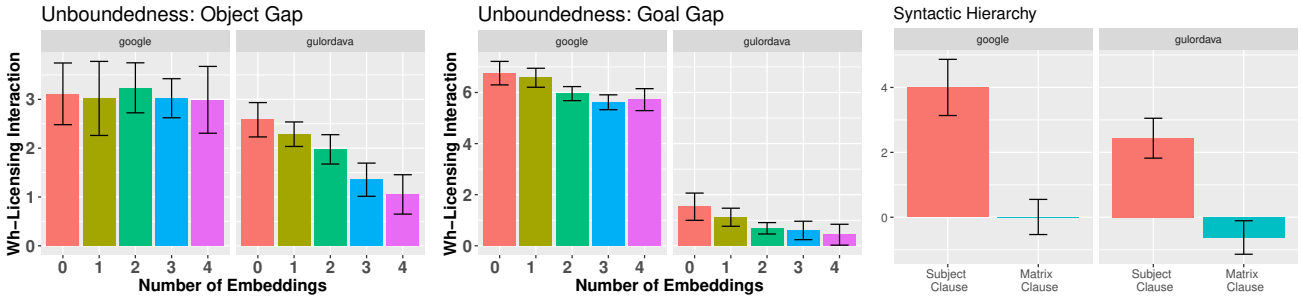

Figure 2: Effect of sentential embedding and syntactic hierarchy on wh-licensing interaction.

(4) a. The fact that the mayor knows who the criminal shot __ **shocked the jury** during the trial. [SUBJECT]
b. *The fact that the mayor knows who the criminal shot the teller shocked __ **during the trial**. [MATRIX]

The results from this experiment can be seen in Figure 2, on the far right panel. We find strong licensing interaction for the grammatical *Subject Clause* conditions (in red), but a striking reduction in licensing interaction for the *Matrix Clause* conditions (in blue), which is significant for both models ($p < 0.001$). As the results in (2) and Wilcox et al. have shown that RNN models are insensitive to linear distance between the filler and the gap, we take these results suggest that it is the relevant structural properties which block the models' expectations for gaps inside the matrix clause.

Island Effects: Gender Expectation vs. Filler–Gap Dependency

Island constraints are specific syntactic configurations that block the filler–gap dependency. One way to show that the RNN models are learning island conditions as constraints on the filler–gap dependency is to demonstrate that they are capable of threading other expectations into island configurations. To do this, we used **pronoun gender expectation** between a gendered noun, such as 'actress' or 'husband', and a possessive pronoun such as 'his' or 'her.'. Nouns that carry overt gender marking or culturally-imbued gender bias set up expectations that subsequent pronominals match them in gender. Previous work has shown that humans thread expectations set up by *cataphoric pronouns* into syntactic islands (Yoshida, Kazanina, Pablos, & Sturt, 2014). Cataphoric pronouns are pronouns that precede the nominal element to which they refer, as in (5).

(5) **Her** manager revealed that the studio notified **Judy Dench** about the new film.

Because cataphoric pronouns are relatively less frequent than anaphoric pronouns, which follow the nominal to which they refer, we use sentences such as those in (6) to assess whether RNN LMs can thread expectations into island environments. We measure the strength of the gender expectation by calculating the difference in surprisal between the matching condition and the mismatching condition, or S((6-b))-S((6-a)). If the models attenuate their expectation for gender agreement in island positions, then we expect an interaction between MISMATCH and ISLAND resulting in supperaditivally lower surprisal.

(6) a. The actress said that they insulted **her** friends. [MATCH, CONTROL]
b. #The actress said that they insulted **his** friends. [MISMATCH, CONTROL]
c. The actress said whether they insulted **her** friends. [MATCH, ISLAND]
d. #The actress said whether they insulted **his** friends. [MISMATCH, ISLAND]

In order to test whether the models maintained their gender expectations through island constructions, we created six suites of experiments following the pattern of (6) for six of the most frequently studied islands constructions. For each of the gender expectation experiments, we created 30 variants, 15 with masculine subjects and 15 with feminine subjects and measured the surprisal at the possessive pronoun. The results are presented on the bottom row in Figure 3 alongside model performance on the filler–gap dependency for the same syntactic constructions (top row). For the filler–gap dependency, results for four islands had already been tested in Wilcox et al. (2018), which we present alongside novel results for *Coordination Islands*, *Sentential Subject Islands* and *Left-Branch Islands*, the latter separately without a gender expectation control. For these experiments, we created between 20-24 experimental items and measured the wh-licensing interaction in the post-gap material. We take a reduction in wh-licensing interaction in island constructions and no such reduction in the gender expectation as evidence that the model has both learned the island constraint, and has applied that constraint uniquely to the filler–gap dependency.

Wh-Islands The wh-constraint states that the filler–gap dependency is blocked by S-nodes introduced by a wh-complimentizer, as demonstrated in the unacceptability of (7-b) compared to (7-a). We created experimental items following the examples in (7) and measured their gender expectation and filler–gap dependency (filler–gap dependency materials were taken from Wilcox et al.).

(7) a. I know who Alex said your friend insulted __ **yesterday**. [CONTROL, FILLER–GAP]
b. *I know who Alex said whether your friend insulted __ **yesterday**. [ISLAND, FILLER–GAP]
c. The actress said they insulted {**his/her**} friends. [CONTROL, GENDER EXP.]
d. The actress said whether they insulted {**his/her**}

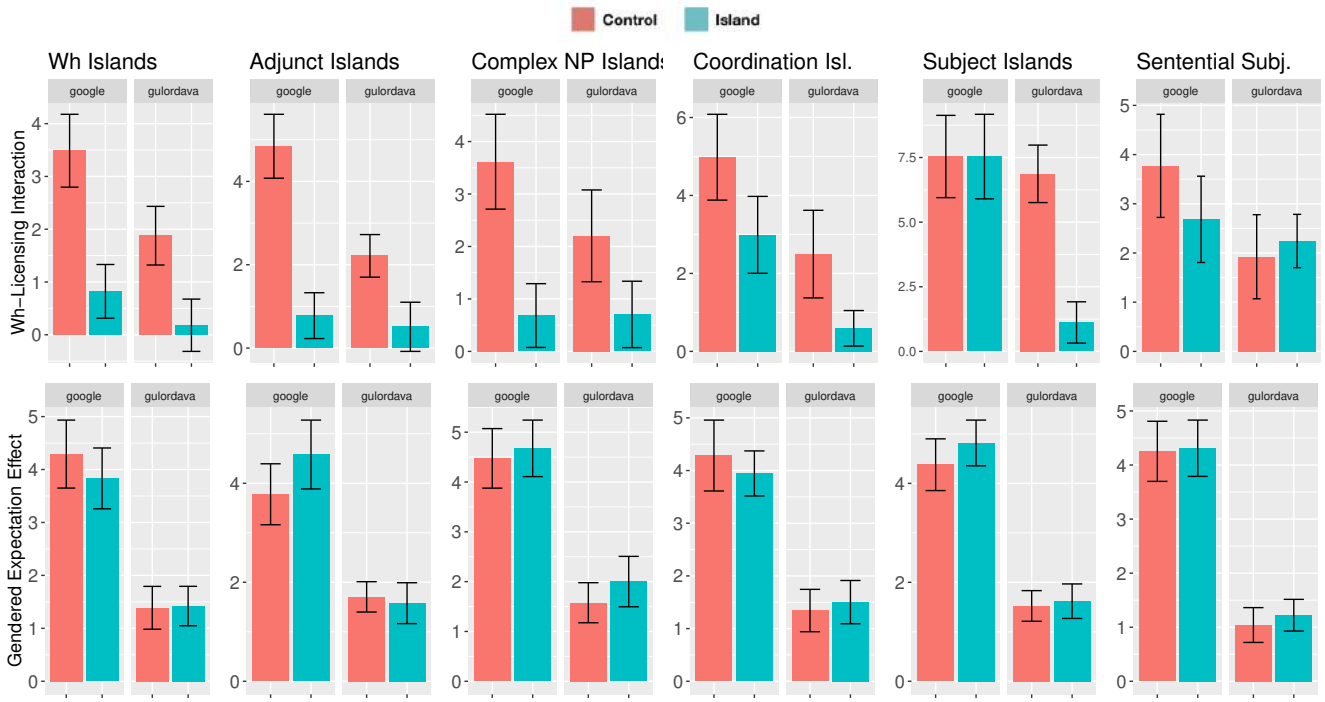

Figure 3: Effect of island construction on gender dependency.

friends. [ISLAND, GENDER EXP.]

The results for this experiment can be seen in the far left panel of Figure 3, with island structures graphed in blue and non-island controls in red. We find a significant difference in licensing interaction between the island and non-island conditions for both the google and gulordava models ($p < 0.001$ for both models), but no such difference in gender expectation.

Adjunct Islands Gaps cannot be licensed inside an adjunct clause, as demonstrated by the relative unacceptability of (8-a) over (8-b).

(8) a. I know what the librarian placed __ **on the wrong shelf**. [CONTROL, FILLER–GAP]
b. *what the patrong got mad after the librarian placed __ **on the wrong shelf**. [ISLAND, FILLER–GAP]
c. The actress thinks they insulted {**his/her**} performance [CONTROL, GENDER EXP.]
d. The actress got mad after they insulted {**his/her**} performance. [ISLAND, GENDER EXP.]

The results for this experiment can be seen in Figure 3, second panel from the left. We find a significant reduction of wh-licensing interaction between the control and island conditions in the case of the filler–gap dependency for both models ($p < 0.001$ google; $p < 0.01$ gulordava; materials taken from]Wilcox et al.). However, we find no effect of syntactic structure on the gender effect.

Complex NP Islands Gaps are not licensed inside S-nodes that are dominated by a lexical head noun, as demonstrated by the relative badness of (9-b) compareid to (9-a).

(9) a. I know what the actress bought __ **yesterday**. [CONTROL, FILLER–GAP]
b. *I know what the actress bought the painting that depicted __ **yesterday**. [ISLAND, FILLER–GAP]
c. The actress said they saw her {**his/her**} performance. [CONTROL, GENDER EXP.]
d. The actress said they saw the exhibit that featured {**his/her**} performance. [ISLAND, GENDER EXP.]

We created items follwing the examples in (9), with filler–gap items adopted from (Wilcox et al., 2018). The results from this experiment can be found in the middle-left panel of Figure 3. We found an effect of syntactic location on wh-licensing interaction for both models ($p < 0.001$ google; $p < 0.01$ gulordava) but no such interaction for gender expectations.

Coordination Islands The coordination constraint states that a gap cannot occur in one half of a coordinate structure as demonstrated by the difference between (10-b) and (10-a), in which a whole conjunct has been gapped.

(10) a. I know what the man bought __ **at the antique shop**. [CONTROL, FILLER–GAP]
b. *I know what the man bought the painting and __ **at the antique shop**. [ISLAND, FILLER–GAP]
c. The fireman knows they talked about {**his/her**} performance. [CONTROL, GENDER EXP.]
d. The fireman knows they talked about the football game and {**his/her**} performance. [ISLAND, GENDER EXP.]

We created experimental items following the examples in (10). Results can be seen in 3 center-right panel. For the filler–gap dependency, in both models there is a significant difference between the *control* condition and *island* conditions ($p < 0.05$ for both models). These results indicate that the models have somewhat attenuated expectations for gaps when they occur in the second half of a coordinate struc-

ture. However, note that, at least for the google model, the wh-licensing interaction is significantly greater than zero, indicating that this model still maintains *some* expectation for gaps in this syntactic location. For both models there is no difference in gender expectation between the *control* and *island* conditions).

Subject Islands Gaps are generally licensed in prepositional phrases, except when they occur attached to sentential subjects. We created experimental items following the examples in (11), with filler–gap materials adapted from Wilcox et al..

(11)a. I know what _ **fetched** a high price. [CONTROL, FILLER-GAP]

b. *I know who the painting that depicted _ **fetched** a high price. [ISLAND, FILLER–GAP]

c. The actress said they sold the painting by {**his/her**} friend. [CONTROL, GENDER EXP.]

d. The actress said the painting by {**his/her**} friend sold for a lot of money. [ISLAND, GENDER EXP.]

The results from this experiment can be seen in Figure 3, second panel from the right. For the filler–gap dependency, we found a significant difference between the *control* and *island* condition in the case of the gulordava model ($p < 0.01$), but no such reduction in the case of the google model. For gender expectation, we found no significant difference between the two conditions.

Sentential Subject Islands The sentential subject constraint states that gaps are not licensed within an S-node that plays the role of a sentential subject. To assess whether the RNN models had learned this constraint we created items following the variants in (12).

(12)a. I know who the seniors defeated _ **last week**. [CONTROL, FILLER–GAP]

b. I know who for the seniors to defeat _ **will be trivial**. [ISLAND, FILLER–GAP]

c. The fireman knows they will save {**his/her**} friend. [CONTROL, GENDER EXP.]

d. The fireman knows for them to save {**his/her**} friend will be difficult. [ISLAND, GENDER EXP.]

The results for this experiment can be seen in Figure 3, in the far right panel. We found no decrease in gender expectation between the *control* and *island* conditions for either model. Likewise, for the filler–gap dependency we found no significant decrease in wh-licesning interaction between the island and non island conditions in either model. These results indicate that neither model suspends its expectations for gaps within sentential subjects.

Left Branch Islands The left-branch constraint states that modifiers which appear on the left branch under an NP cannot be gapped, which accounts for the relative ungrammaticality of (13-b) compared to (13-a). Because possessive pronouns cannot grammatically occur in left-branches under an NP, this experiment examines only the filler–gap dependency. We created 20 items following the examples in (13) and measured the wh-licensing interaction in the post-gap material.

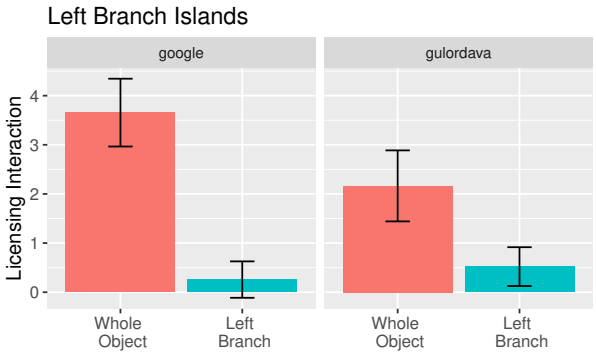

Figure 4: Left Branch Islands.

(13)a. I know what color car you bought _ **last week**. [WHOLE OBJECT]

b. I know what color you bought _ **car last week**. [LEFT BRANCH]

The results from this experiment can be seen in Figure 4 with experimental conditions on the x-axis and wh-licensing interaction on the y-axis. We see strong wh-licensing interaction in the two *whole object* conditions, but a significant reduction in licensing interaction when the gap consists of the Adjective Phrase modifier ($p < 0.001$ for the google model; $p < 0.05$ for the gulordava model). This results indicate that the models have learned the left branch islands, insofar as they do not expect left-branching modifiers to be extracted without the NP to which they are attached.

For every condition tested we found that the expectation set up by gendered subjects for possessive pronouns is not affected by the pronoun's location inside island constructions. For the three novel structures, we found that the two models tested are sensitive to left branch islands and gradiently to coordination islands, but not to sentential subject islands.

Discussion

The filler–gap dependency has been the focus of intense research for over fifty years because it is both far reaching and tightly constrained. It can be threaded through a potentially unbounded number of sentential embeddings; yet the filler must syntactically dominate the gap and the dependency is subject to a number of highly-specific blocking 'island' conditions. In this work we have shown that RNNs trained on a language modeling objective have learned both the power and the constraints imposed on this dependency. First, we provided evidence that they are able to thread the dependency through an unbounded number of sentential embeddings, and have also learned the constraints that govern the syntactic hierarchy of the filler relative to the gap.

Second, using gender expectation effects, we have demonstrated that the models are able to thread some contextually-dependent expectations into island constructions, providing evidence that previously-observed island effects have been learned for the filler–gap dependency *in particular*, and are not due to the model's inability to thread *any* information into syntactic islands. In addition, we have increased the experimental coverage of island effects, demonstrating that the models were able to learn left-branch islands and gradiently

learn coordination islands, but failed to learn sentential subject islands. This brings the total number of islands learned to 5/7 for the google model and 6/7 for the gulordava model. Although some of the model behavior remains strikingly unlike human acceptability judgements (in e.g. coordination islands), these experiments demonstrate that sequence models trained on a language modeling objective are able to separate natural language dependencies from each other and learn different fine-grained syntactic rules for each.

Abstract

Learning constitutes an essential part of human experience over the life course. Independent of the domain, it is characterized by changes in performance. But what cognitive mechanisms are responsible for these changes and how do situational features affect the dynamics? To inspect that in more detail, this paper introduces a cognitive modeling approach that investigates performance-related changes in learning situations. It leverages the cognitive architecture ACT-R to model learner behavior in an interrupted learning task in two conditions of task complexity. Comparisons with the original human dataset indicate a good fit in terms of both accuracy and reaction times. Although interruption effects are more obvious in the human data, they are prevalent as well in the model. Furthermore, the model can map the learning effects, particularly in the easy task condition. Based on the existing mapping of ACT-R module activity with fMRI data, simulated neural activity is computed to investigate underlying cognitive mechanisms in more detail. The resulting evidence connects learning and interruption effects in both task conditions with activation-related patterns to explain changes in performance.

Keywords: Learning; Interruption; Cognitive performance; ACT-R; Simulated neural activity

Introduction

As an omnipresent requirement, learning happens throughout the entire life. From speaking the first words as a child to operating new technical devices as an elderly, the establishment of knowledge structures constitutes a core outcome of learning processes of all kind. Previous research indicated benefits in terms of performance, once already existing knowledge structures can be applied automatically (e.g., Wirzberger, Herms, Esmaeili Bijarsari, Eibl, & Rey, 2018). Besides these internally occurring process-related changes, externally induced situational characteristics such as interruptions also effect cognitive performance. Interruptions are highly prevalent across various contexts in daily life, including learning situations (e.g., Scheiter, Gerjets, & Heise, 2014). They can be described as usually neither planned nor expected cognitive breaks in the task performed up to that time (Brixey et al., 2007). To avoid or at least minimize resulting impairments, the interplay of interruptions and learning effects needs to be inspected in more detail on a cognitive level. On this account, computational cognitive modeling approaches offer a promising way to gain insights into underlying dynamics.

Based on that, the current paper introduces an ACT-R model that performs an interrupted learning task and is inspected in terms of behavioral parameters and underlying neural processes. After briefly describing the modeled experimental task and core results from human data, the paper outlines characteristics of the cognitive architecture ACT-R (Anderson, 2007). Following an explanation of the underlying model concept, the behavioral results obtained from the model runs are presented and compared with the described human data. The subsequent chapter addresses model performance on a neural level by reporting results from simulated fMRI analyses.

In summary, the obtained evidence highlights the connection of observable changes in cognitive performance due to learning and interruption effects with the mechanism of activation.

Task outline

The task setting underneath the cognitive model is reported in more detail in Wirzberger, Esmaeili Bijarsari, and Rey (2017). Participants in this study had to learn four abstract geometric symbol combinations via trial and error by verifying feedback (Shute, 2008) over a total of 64 trials. As outlined in Figure 1, they were shown the first part of the combination at the beginning of a trial and had to select the appropriate response by mouse click. Afterward, they were informed about the correctness of their response as well as

the correct response in terms of errors. Task complexity was represented by the number of symbols in a defined order that formed a combination. In the easy task condition, symbol combinations consisted of two symbols (input-response), whereas in the difficult task condition three symbols (input-input-response) formed a combination.

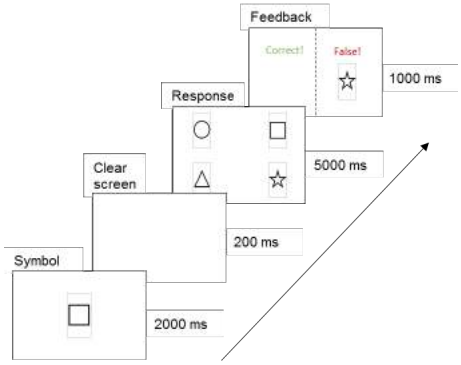

Figure 1: Sample learning trial in the easy task condition (adapted from Wirzberger et al., 2017).

At five pre-defined stages over the task (i.e., after trials 8, 24, 32, 40, and 56), an interrupting visual search task was induced. As displayed in Figure 2, it required participants to count the number of two out of four types of geometric symbols on a visual search screen and provide their responses afterward. The screens were accompanied by an instruction on the target symbols. A high similarity to the symbols used in the learning task (Gillie & Broadbent, 1989; Trick, 2008) and an appropriate task duration (Monk, Trafton, & Boehm-Davis, 2008) should ensure its interrupting potential.

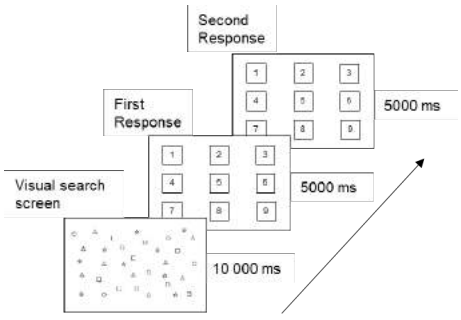

Figure 2: Sample interruption trial (adapted from Wirzberger et al., 2017).

Experimental results

In terms of reaction times in correctly solved trials, Figure 3 shows that participants speed up with increasing task progress in both conditions. Standard errors decrease over trials due to the increasing number of correct reactions. In addition, resumption effects are observable in both conditions, but are more distinctive in the easy task condition. Approaching accuracy, Figure 4 indicates that participants in the difficult task condition learn slower, but in the end both conditions reach a comparable level. Again, resumption effects are more prevalent in the easy task condition. These effects raise the question which cognitive mechanisms underlie the observed learning- and interruption-related patterns.

Computational cognitive modeling

Building on vested psychological evidence on human information processing, computational cognitive modeling approaches offer the opportunity to derive well-founded explanations of behavioral phenomena. The idea of building models to explain cognitive phenomena has already been discussed by Wegener (1967), who outlined the indicative value of an electronic simulation of mental processes for deriving and validating the related hypotheses.

Constituting a prevalent and broadly used production-based approach, ACT-R (Anderson, 2007) is particularly characterized by its modular brain-inspired structure. The included *modules* represent goal planning (goal module), declarative memory (declarative module), intermediate problem states (imaginal module), action coordination (procedural module), the handling of visual and auditory inputs (visual and aural module), and motor and vocal outputs (motor and vocal module). The mapping of these modules on corresponding regions-of-interest (ROIs) in the human brain has been validated with fMRI data by Borst, Nijboer, Taatgen, van Rijn, and Anderson (2015). For instance, when a model retrieves content from declarative memory, increased activity in the declarative module corresponds to activity in the prefrontal cortex, which has proven to be sensitive to both retrieval and storage operations. Activity in the goal module corresponds to activity in the anterior cingulate cortex, which is involved in higher-level control functions such as attentional allocation or performance monitoring. *Buffers* with limited capacity serve as interface between modules and enable their communication. They can hold one information element at the same time, representing existing limitations in information processing resources.

ACT-R uses a hybrid approach of both symbolic and subsymbolic mechanisms: *chunks* of information from declarative memory are retrieved not only on the match of content but also based on their level of activation. Activation is calculated from the history and context of use of a chunk and has to exceed a defined threshold to be eligible for selection. The full equation for each chunk *i* involves the components displayed in the subsequent equation:

$$A_i = B_i + \sum_k \sum_j W_{kj} S_{ji} + \sum_l PM_{li} + \varepsilon. \qquad (1)$$

The recency and frequency of use of the chunk *i* is reflected by the *base-level activation* B_i. Each time a chunk is presented, its base-level activation is increased, which decays as a power function of the time since that presentation. These decay effects are summed up and then transformed

logarithmically. With the *spreading activation* mechanism (Anderson, 2007), ACT-R accounts for the fact that activation is distributed across related chunks that share information elements. It is represented in the equation by W_{kj}, the amount of activation from source j in buffer k, and S_{ji}, the strength of association from source j to chunk i. W_{kj} and S_{ji} are summed over all buffers that provide spreading activation and all chunks in the slot of the chunks in buffer k. As humans sometimes retrieve related but ultimately wrong information from memory, ACT-R further includes a partial matching mechanism. Based on initially defined similarities between chunks, a mismatch between request and actual retrieval is calculated. The higher the mismatch, the more the activity of the chunk is penalized (Lebiere, 1999). In the equation, P reflects the amount of weighting given to the similarity in slot l and M_{li} represents the similarity between the value l in the retrieval specification and the value in the corresponding slot of chunk i. M_{li} is summed over the slot values of the retrieval specification. The value of ε represents noise, which is computed at the time of a retrieval request for each chunk.

Model concept

Each model run starts with an initial set of the task goal to the symbol learning task, which is assumed to result from the previously read instruction. In the following, each learning trial builds upon three task-related steps: at first, the presented symbol is encoded, which is repeated for the second symbol in the case of the difficult condition. This procedure stores an intermediate representation of all encoded visual content in the problem state (Borst, Taatgen, & van Rijn, 2010, 2015; Nijboer, Borst, van Rijn, & Taatgen, 2016), for instance, the input symbols 'square – circle' in the difficult condition. Next, the model attempts to retrieve the associated response symbol from declarative memory. In the second step, a response is selected from the provided opportunities on the screen, either according to the retrieved chunk or by random choice in case of no successful retrieval. In the final step, the model searches for visual feedback on the given response and, in the case of a false response, an update of the existing intermediate representation. The final information contains both the input and the correct response parts of the symbol combinations, such as 'square – circle – square' in case of the previous example.

In the first trials, there is no sufficiently matching content or no content at all to retrieve, resulting in slower and less accurate responses. After being presented the input symbols several times and retrieving related content from declarative memory, the model performance gets increasingly faster and more accurate due to increasing chunk activation. In the current task, the above outlined spreading activiation mechanism particularly effects the difficult task condition. In more detail, symbol combinations including the same input symbols, such as 'square – circle' and 'circle – square', obtain equal activation, independent of the correct symbol order. Following the concept of element interactivity in instructional research (Sweller, 2010), task demands increase with more logically interrelated information elements that have to be processed simultaneously. In the current task, the symbols that form a combination can be regarded as information elements that are related to each other by order. Without considering the order information, a wrong input-response association is more likely to be retrieved, which is then penalized by the partial matching mechanism. In consequence, due to more potentially mismatching information, the chunks in the difficult condition receive less activation and are harder to retrieve.

Following a goal change due to the bottom-up triggered saliency of the interrupting task, the task procedure involves the steps of searching, counting, and responding to the indicated target symbols. Using a color to indicate the task switch followed the model implemented by Wirzberger and Russwinkel (2015) and represents the immediate attention to the related screen change. Tying in with evidence on pre-attentive and attentive processes in the visual module of ACT-R (Nyamsuren & Taatgen, 2013), the second visual-location request in the visual search is enhanced by additional information on stimulus color that relates to distinct characteristics of the presented symbols. After finishing the counting part that also employs the problem state (Borst et al., 2010, 2015; Nijboer et al., 2016), on each of the two response screens the model encodes the requested symbol and attempts to retrieves the potential answer. Again, the possibility to retrieve a wrong answer persists due to the partial matching mechanism. When resuming the learning task, in line with Altmann and Trafton (2002) the model attempts to retrieve the previous task goal and thus restores its representation. Emerging interruption effects can be attributed to a decay in the activation of chunks related to the learning task that slows down subsequent retrieval requests (Borst et al., 2010, 2015; Trafton, Altmann, Brock, & Minz, 2003).

Model comparison

The inspected model data based on $n = 100$ model runs in each condition to obtain robust conclusions from the average model performance. A further goal was to achieve a balanced fit pattern across both accuracy and reaction time in either condition. Compared to a base model[1] that includes neither spreading activation nor partial matching, the overall root mean squared scaled deviation (RMSSD) decreased by almost one standard error and fit indices were quite aligned.

Besides the shared prevalence of interruption effects, in both conditions the model speeds up in reaction time over trials. The visual inspection in Figure 3 indicates that it can map the decreasing progression particularly in the difficult task condition. However, the model performs slightly slower than human participants during most of the trials. On the level of numerical goodness-of-fit indices, the model achieved

[1] In addition to the base model and the reported model, models including either only spreading activation or partial matching were inspected. Due to the superior fit, only the final model that applies both mechanisms is reported.

RMSSD = 2.16 and R^2 = 0.58 in the difficult task condition. Apart from a subtler decrease in the beginning, the mapping also fits quite well for later trials in the easy task condition. On a numerical level, RMSSD = 1.67 and R^2 = 0.52 resulted in this condition.

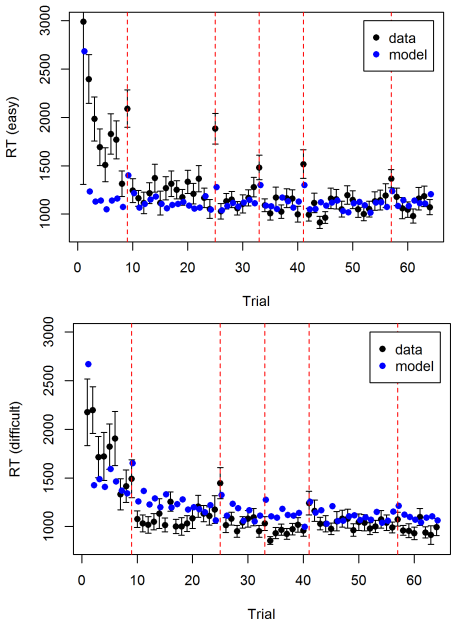

Figure 3: Comparison of human and model behavior in terms of reaction time. Red dashed lines indicate the first trial that immediately follows an interruption.

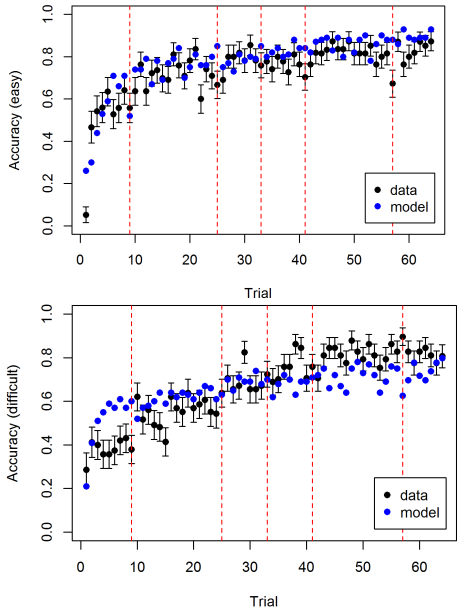

Figure 4: Comparison of human and model behavior in terms of accuracy. Red dashed lines indicate the first trial that immediately follows an interruption.

For accuracy, Figure 4 indicates that the model can map the progression in human behavior quite well in the easy task condition, although it achieves a higher performance in the end and shows a subtler reflection of interruption effects. On a numerical level, RMSSD = 1.51 and R^2 = 0.69 were achieved in this condition. The model in the difficult task condition learns slower compared to the easy task condition, but still faster than the human participants. However, apart from the nearly perfect location match in the last data points, it cannot fully map the final increase in the human data. The goodness-of-fit indices for the difficult task condition resulted in RMSSD = 2.07 and R^2 = 0.57.

Simulated fMRI data

Based upon the already mentioned mapping of activity in ACT-R modules on defined brain regions, simulated neural activity in predefined ROIs is computed to investigate underlying cognitive mechanisms in more detail (Borst & Anderson, 2017). This approach uses the recorded start and end times of module activity to simulate a signal comparable to the blood oxygenation level obtainable via fMRI, which shows peaks about 4-6 s after the occurrence of neural activity. In the first step, the activity of each inspected module is represented as 0-1 demand function and convolved afterward with the hemodynamic response function displayed in Figure 5. As an example, related to the task of the current model, longer retrieval times due to lower levels of chunk activation would result in increased activity in the declarative module. Such patterns are expectable in early stages of the task, with increased task difficulty, or caused by decay during an interruption, and would be observable by higher peaks in the resulting simulated signal.

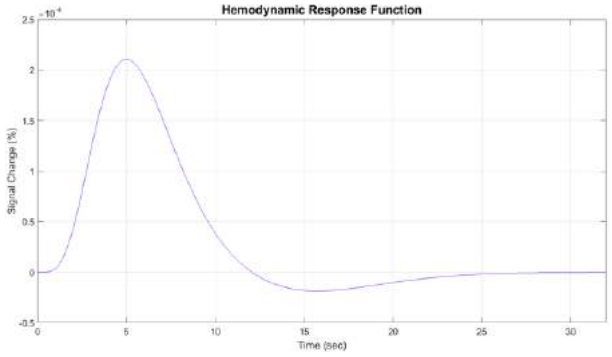

Figure 5: Hemodynamic response function (adapted from Borst & Anderson, 2017).

Prevalent changes in the declarative module activity across the learning task, which simulates activity in the prefrontal cortex, are displayed in Figure 6. Whereas blue lines represent the first third of the trials in the task, the red lines indicate the middle third of the trials, and the black lines refer to the last third of the trials. The curves predict a decrease in cognitive activity in later task stages in both conditions in the prefrontal cortex due to task-inherent learning processes. In the difficult task condition, represented by the dashed lines, a

higher level of activity is prevalent across all stages, with a particularly distinctive peak across early task stages. As already outlined, this relates to increased retrieval demands from lower levels of chunk activation.

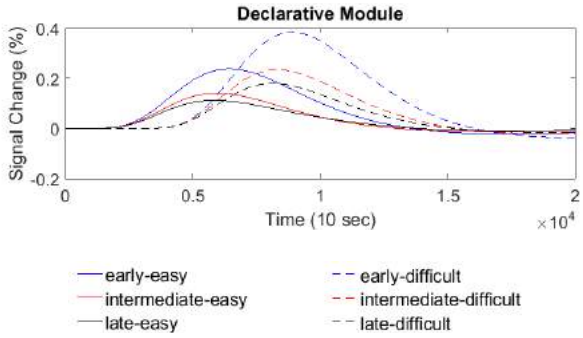

Figure 6: Simulated neural activity in the declarative module (corresponding to activity in the prefrontal cortex) across stages of the learning task.

Comparisons between the interrupting task and the learning task are depicted in Figure 7 and Figure 8. These include a separate visualization of the resumption phase (red lines), defined as the first trial that immediately follows the interrupting task. Across all inspected modules, activity levels in the interrupting task do not differ between both task conditions, since the solid and dashed blue lines overlap almost all the time. For both the declarative module, relating to the prefrontal cortex, and the goal module, relating to the anterior cingulate cortex, a higher activity across resumption trials compared to the remainder of trials in the learning task (black lines) is predicted for both conditions. In addition, differences between task conditions during the resumption phase are predicted for the anterior cingulate cortex and indicate higher levels of activity in the easy task condition. Even if these effects are less obvious in the behavioral model data, this also corresponds to the higher prevalence of resumption effects in the easy condition in the human data.

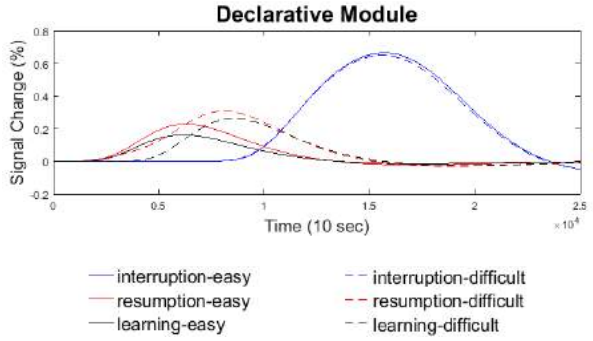

Figure 7: Simulated neural activity in the declarative module (corresponding to the prefrontal cortex) across interruption, resumption, and learning stages.

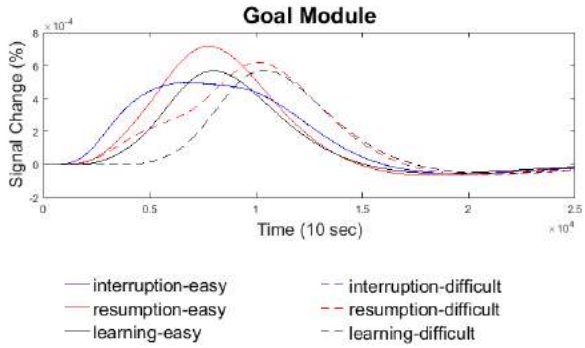

Figure 8: Simulated neural activity in the goal module (corresponding to the anterior cingulate cortex) across interruption, resumption, and learning stages.

Discussion

The current model explores cognitive mechanisms that underlie changes in performance due to the inserted interruptions and task-related learning processes. Comparing model performance across both conditions on a behavioral level, the obtained results indicate a good fit in terms of reaction times and accuracy. The model can map both the learning-related increase in performance and the decrease in performance due to experiencing an interruption. A potential improvement to increase the visibility of interruption effects in the model might involve adjusting when the model starts to retrieve information related to the correct response symbol. For the difficult task condition, the accuracy result pattern hints on a shift in task-related strategies. Due to the small number of learned symbol combinations, over time people in the difficult condition might have applied a more heuristic encoding strategy with focus on the first symbol, directly mapping task execution in the easy task condition. Taking this into account, the current modeling approach offers potential for future work by explaining such strategy shift with a more complex model on both the level of production rules and corresponding selection mechanisms.

The pattern observed in the simulated neural activity relates to the fact that the model needs to invest a higher amount of declarative memory resources upon each retrieval request in the early task stage due to the lack of suitable chunks and lower levels of chunk activation. The smaller level of cognitive activity with increasing task progress emphasizes the prevalence of learning effects in both conditions, as existing content in the declarative memory receives increasingly higher activation and thus can be retrieved faster and more accurately. In the difficult task condition, invested declarative resources are constantly higher across all stages, which by closer inspection relates to effects of spreading activation and the increased influence of partial matching that penalizes chunk activation and extends retrieval times. Increased levels of resumption-related activity in the declarative module arise from the activation decay in chunks related to the acquired symbol combinations. Observable differences in goal activity during the resumption stage align well with predictions stated by the memory-for-

goals model (Altmann & Trafton, 2002). They relate to the demand to rebuild the goal-representation of the learning task after each interruption. The obtained fMRI predictions will be compared with human data sets in the next step.

Conclusion

Taken together, the obtained results emphasize the importance of considering activation-related dynamics when approaching changes in performance in learning situations. The outlined cognitive modeling approach inspects the influence of both internal and external factors in these contexts and can be taken as promising step to investigating related patterns of cognitive resource investment. Since it extends beyond human experiments and model-based behavior on a neural level, it provides a more detailed understanding, which is crucial for developing adequate support and minimizing harmful effects.

Abstract

It is unknown whether modality affects the efficiency with which humans learn novel word forms and their meanings, with previous studies reporting both written and auditory advantages. The current study implements controls whose absence in previous work likely offers explanation for such contradictory findings. In two novel word learning experiments, participants were trained and tested on pseudoword - novel object pairs, with controls on: modality of test, modality of meaning, duration of exposure and transparency of word form. In both experiments word forms were presented in either their written or spoken form, each paired with a pictorial meaning (novel object). Following a 20-minute filler task, participants were tested on their ability to identify the picture-word form pairs on which they were trained. A between subjects design generated four participant groups per experiment 1) written training, written test; 2) written training, spoken test; 3) spoken training, written test; 4) spoken training, spoken test. In Experiment 1 the written stimulus was presented for a time period equal to the duration of the spoken form. Results showed that when the duration of exposure was equal, participants displayed a written training benefit. Given words can be read faster than the time taken for the spoken form to unfold, in Experiment 2 the written form was presented for 300 ms, sufficient time to read the word yet 65% shorter than the duration of the spoken form. No modality effect was observed under these conditions, when exposure to the word form was equivalent. These results demonstrate, at least for proficient readers, that when exposure to the word form is controlled across modalities the efficiency with which word form-meaning associations are learnt does not differ. Our results therefore suggest that, although we typically begin as aural-only word learners, we ultimately converge on developing learning mechanisms that learn equally efficiently from both written and spoken materials.

Keywords: modality effects; word learning; vocabulary acquisition; reading

Introduction

Novel words can be encountered through listening to speech or through reading text. Inherent properties of each modality will have specific processing demands and will pose specific constraints on the learning mechanisms that enable learning in these modalities. It is, however, not yet understood whether these modality-specific demands influence the efficiency of learning in these modalities. The present study aimed at investigating to what extent the modality in which information is presented affects the efficiency of learning novel word form – meaning associations.

The existing literature shows conflicting findings regarding the effect of modality on novel word learning. Concerning word form learning only, benefits have been found in favour of the spoken modality (Bakker, Takashima, Van Hell, Janzen, & McQueen, 2014; Van der Elst, Van Boxtel, Van Breukelen, & Jolles, 2005). Multiple theoretical explanations have been proposed for these observed auditory learning benefits. Firstly, it has been argued that learning from spoken input is more efficient as a result of such mechanisms being developmentally and/or evolutionarily older than those operating on written stimuli (Bakker et al., 2014).

Further, evidence suggests that, relative to the visual modality, in the auditory modality stronger associations develop between sequential events (Penney, 1989) and/or that temporal events are more accurately stored (Glenberg & Jona, 1991). Auditory cortices have been suggested to be more sensitive to sequencing information, due to the sequential nature of auditory information (Frost, Armstrong, Siegelman & Christiansen, 2015).

Cognitive load theory (Sweller, Van Merrienboer & Paas, 1998) also predicts a spoken learning benefit when learning word forms and visual meanings (e.g. a picture or graph) in combination. It argues that cognitive overload is less likely under conditions in which information processing can be divide between the visuo-spatial sketchpad and phonological loop (Baddeley, 1992), compared to conditions in which all information must be processed within the same modality and thus by the same cognitive resources.

In contrast to the above, a written advantage has also been observed particularly when word forms are learned in conjunction with their meanings, (Balass, Nelson, & Perfetti, 2010; Nelson, McEvoy, & Schreiber, 2004; Van der Ven, Takashima, Segers, & Verhoeven, 2015). Multiple theories have also been proposed in explanation for these findings. It is argued that when reading (novel words) phonological representations are automatically activated alongside orthographical representations, therefore, two separate representations of the word form are stored. However, on exposure to the spoken word form, automatic activation of its

orthographic form is less likely (Perfetti, Bell & Delaney, 1988; Paivio, 1991). Further, the spoken modality is fleeting by nature, posing additional demands on attention and working memory capacity. Reading allows rereading and processing at one's own pace and this flexibility leads to greater availability of memory and attentional cognitive resources for learning (Van der Ven, 2015).

Alternatively, in contrast to the above findings it remains possible that learning mechanisms operating on written and spoken stimuli are equally efficient and instead observed contradictory effects result from modality specific biases in the experimental design. Although typically, prior to literacy, word learning is only possible via the auditory modality, it is feasible that proficient readers develop learning mechanisms that overcome modality specific constraints such that learning occurs equally effectively in both modalities.

Previous studies, that have reported modality effects, have potentially generated contradictory findings due to an absence of one or more of the following controls. First, exposure duration was not controlled in studies that found a written learning advantage (Balass et al., 2010; Nelson et al., 2006; Van der Ven et al., 2015). People were given unlimited time with the spoken and written materials, but the exact exposure time was not measured. Participants thus might have exposed themselves more to materials in one modality, evoking a learning effect that does not result from a more efficient modality specific learning mechanism but simply due to a mechanism having greater exposure to the stimulus.

Second, in all studies that found a written benefit the test was presented in a written form (Balass et al., 2010; Nelson et al., 2006; Van der Ven et al., 2015); likewise, some studies that found a spoken benefit performed only a spoken test (Van der Elst et al., 2005). According to Tulving and Thomas's (1973) encoding specificity principle, recall is enhanced if the conditions during retrieval match the conditions during learning. Thus, such modality effects observed in these studies might be evoked by encoding specificity rather than by differences in the efficiency of the spoken and written learning mechanisms. Similarly, studies examining learning of word form-meaning associations only used written meanings. Thus, the congruency of the format between written word forms and written word meanings potentially benefits learning in the written modality.

Fourth, many previous studies have used explicit learning tasks (Balass et al., 2010; Nelson et al., 2006; Van der Ven et al., 2015). Therefore, in such studies, it is difficult to exclude the possibility that observed modality effects do not result from modality-specific conscious learning strategies, such as repeating heard words or rereading written words, rather than differences in the efficiency of modality specific cognitive mechanisms.

Finally, many previous studies (Bakker et al., 2014; Balass et al., 2010; Nelson et al., 2006; Van der Ven et al., 2015; Van der Elst et al., 2005) do not control for cross-modal orthographical and phonological transparency. Therefore, any learning benefit observed may not result from differences in the efficiency of learning mechanisms but instead may result from it being easier to accurately transform the phonological form to the orthographic or vice versa.

In order to gain an understanding of modality effects on word learning it is first necessary to control for each of these potential confounds. The present study aims to do precisely this, controlling for the many confounds that have potentially generated observed modality effects that do not result from difference in efficiency of the spoken and written learning mechanisms.

In two experiments, participants learned 24 Dutch-like, fully transparent pseudowords and pictorial meanings. After a short period of consolidation, participants were tested on their knowledge of the learned word forms and meanings. A between-subjects design generated four participant groups per experiment 1) written training, written test; 2) written training, spoken test; 3) spoken training, written test; 4) spoken training, spoken test. In addition, non-verbal IQ, vocabulary and reading tasks were administered to control for differences across groups. In Experiment 1 written word forms were presented for a time period equal to the duration of the spoken form. In Experiment 2, to control for the fact that a written word can be read quicker than its spoken form takes to unfold, the written stimulus was presented only for the period necessary to read the written stimulus.

Experiment 1

Methods

Participants 60 participants (M = 22.96 years, SD = 2.53; 46 female) were recruited. All participants were right-handed, with no language, sight or hearing disorders. Participants earned €10 for participating.

Design The two between-subjects factors were modality during training and modality during testing. Words could be learned in either modality and also testing could occur in two modalities. There were therefore four between-subjects conditions. Participants were randomly assigned to a condition.

Materials Twenty-four orthographically and phonologically transparent Dutch pseudowords were created using Wuggy (Keuleers & Brysbaert, 2010). The words had a Levenshtein's Distance (Levenshtein, 1966) of above three to avoid confusability. Pilot studies ensured the words were not reminiscent of existing Dutch words. The words varied between five and nine letters and four and eight phonemes and graphemes. Speech duration of the words varied between 664 and 993 ms.

In addition twenty-four pictures of unknown objects from The Novel Object and Unusual Name (NOUN) Database were used (Horst & Hout, 2016). The pictures were not visually similar to each other. To limit item-specific effects, for each group of four participants the pictures were randomly assigned to one of the word forms.

Procedure Participants were trained and tested on the same day. First the training phase was administered. The experiment was designed to minimize opportunities for participants to utilize explicit learning strategies. For this reason no explicit instruction to learn the picture–word form pairs or indication of a later test was provided, images and word forms were presented briefly and in rapid succession, and both auditory and visual masks immediately followed presentation of the word form. In each trial (Figure 1), participants saw a fixation cross (250 ms), a picture (1000 ms), then again saw a fixation cross (250 ms), either heard the word or read the word depending on the condition, and then heard a auditory mask in the form of a continuous tone and saw a visual mask in the form of a grey diamond (500 ms). The exposure to the word form varied for each word: the written word was presented for the speech duration of that specific word (M = 863 ms, SD = 97 ms). The next word in the training sequence always had a Levenshtein's distance above three and a different onset. Each training trial was repeated seven times in a blocked, semi-randomized order. To ensure attention during the training phase, eight pictures of familiar known objects (e.g. a bus) were shown in-between the trials and participants had to press a button as soon as they saw one of these familiar objects. Participants were instructed to pay attention to the pictures and words and press a button if they saw one of the eight familiar objects, but critically were not explicitly told to learn the word form – picture pairs.

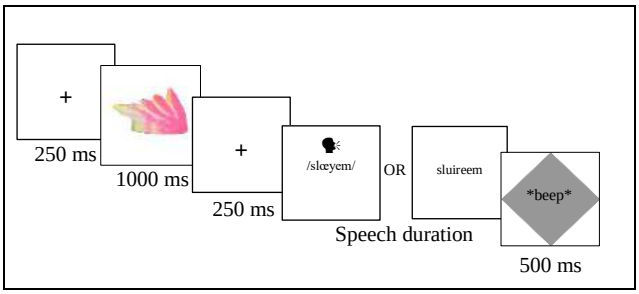

Figure 1: Experimental procedure of a training trial

The training phase was followed by a filler task. This purely visual, nonverbal IQ-task lasted for 20 minutes (Raven's progressive matrices, 1965). Then, in the test phase, participants performed a subsequent matching task. Participants saw a fixation cross (250 ms), a picture (1000 ms), then again a fixation cross (250 ms), heard or saw the word depending on the condition, and had to decide within 2 seconds whether the picture and word matched what they had learned by using a button box. The written words were again presented for a time period equal to the speech duration of that particular word. Each word was presented twice: once with the correct picture and once with a foil picture (i.e., a different picture presented in the training phase). There were several constraints regarding the relationship between the foil picture and the target word form. The corresponding learned word form of the foil picture did not share the onset of the target word form and possessed a Levenshtein's distance of above four. Regarding the order of the trials, the corresponding word form of the next (foil) picture could not be one of the previous ten word forms. Also, half of the target words were first shown with the correct picture before they appeared with a foil picture and vice versa. Participant's ability to identify both matching and mismatch picture-word form pairs was recorded. Then, several individual difference tests were administered, including word reading, pseudoword reading (Van den Bos, Spelberg, Scheepsma & de Vries, 1994; Brus & Voeten, 1973) and vocabulary (Dunn, Dunn, & Schlichting, 2005).

Results

Violin plots depicting, per condition, the proportion of picture–word form pairs that were correctly identified as a match or mismatch can be found in Figure 2.

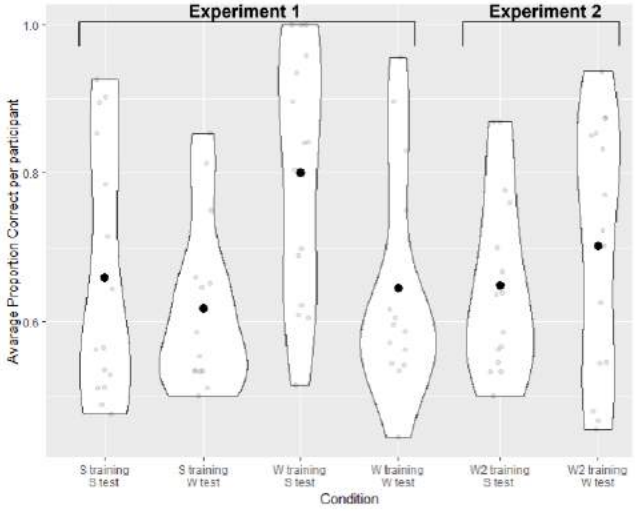

Figure 2: Proportion of correctly identified matching and mismatching picture-word form pairings per participant

A mixed effects logistic regression model (lme4 package: Bates, Maechler, Bolker, & Walker, 2015) using R (R Development Core Team, 2008) was constructed with response on test (match or mismatch) as the dependent variable, i.e. whether a participant recorded the corresponding image and word form pair as matching or mismatching. Model structure was compatible with the conventions of standard signal detection analysis and was consistent with current best practice (e.g. Jacobs, Dell, Benjamin, & Bannard, 2016; Zormpa, Brehm, Hoedemaker & Meyer, 2019). The model included fixed effects of trial type (whether the trial was a match or mismatch), training modality (written or spoken) and test modality (written or spoken), in addition to their interactions. The full random effect structure was also included in the model with random intercepts and slopes by item for trial type, training modality and test modality, and random intercepts and slopes by participant for trial type.

Model results revealed a main effect of trial type, showing participants displayed sensitivity to trained versus untrained picture–word pairs, providing a match more frequently when presented with the picture – word pairs on which they were trained (estimate = -1.03, *SE* = 0.16, *z* = -6.35, *p* < .001). The interaction between trial type and training modality was also significant (estimate = 0.29, *SE* = 0.13, *z* = 2.20, *p* = .03) with participants in trained on written word forms displaying greater sensitivity in identification of trained vs. untrained picture – word for pairs. Finally, a significant interaction between trial type and test modality was also observed (estimate = -0.37, *SE* = 0.13, *z* = -2.78, *p* = 0.006) with participants displaying greater sensitivity when tested on spoken word forms.

Conclusion

Experiment 1 results show that when controlling for exposure time by providing equal exposure duration in both modalities, learning from written materials is greater. One explanation for this might be differences between modalities in the speed with which the full word form can be accessed from the stimulus. The speech duration of the word forms was between 664 and 993 ms, and thus, the written words were presented for a duration of between 664 and 993 ms, depending on the word. First pass single word reading is however much faster than the reading time provided in Experiment 1. Literature using lexical decision or naming tasks show that bisyllabic word can be read at between 525-610 ms, and pseudowords between 575 and 650 ms (Brunswick, McCrory, Price, Frith, & Frith, 1999; De Groot & Nas, 1991; Schilling, Rayner, & Chumbley, 1998; Weekes, 1997). However, these estimates include time necessary to make a decision and speech planning. Studies using ERP and eye-gaze measures, which give a more accurate estimate of reading times, show that frequent, known words can be read around 150 ms and infrequent words within 200-250 ms (Rayner, Pollatsek, Ashby, & Clifton Jr, 2012; Schilling et al., 1998; Sereno, Rayner, & Posner, 1998). This means that, although exposure time to the written and spoken stimuli was equal in Experiment 1, people had more time with the full word form in the written condition.

Experiment 2 tested whether the modality effects found in Experiment 1 would hold if exposure to written and spoken materials was equivalent, taking into account that written information is presented instantaneously and that reading is faster than listening to speech. Literature has shown that people need slightly longer to read infrequent words (200-250 ms) than frequent words (150 ms). Pseudowords are thus likely to be read slightly slower. Therefore, in Experiment 2, the written exposure time was set at 300 ms for all 24 words, which is a written exposure time reduction of 65% on average relative to Experiment 1.

Experiment 2

Methods

Participants 30 participants (*M* = 23.02 years, *SD* = 2.40; 26 female), all right-handed, with no language, sight or hearing disorders participated in this experiment. Participants earned €10,- for participating.

Design Experiment 2 only concerned written modality learning. Testing occurred in both modalities, creating two conditions. Participants were randomly assigned to a condition.

Materials The materials were the same as in Experiment 1.

Procedure The procedure was similar to that of Experiment 1, except for the training phase. In the training phase, the written word was now presented for 300 ms rather than the speech duration of that specific word. This reduced the total duration of the training phase by 560 ms. To ensure that this shortening of the trial did not affect learning, in each trial the first fixation cross was elongated from 250 to 530 ms and the mask at the end of a trial was elongated from 500 to 780 ms. After training participants again performed a non-verbal IQ test, followed by the picture-word form matching task and the individual difference measures.

In addition, to test that 300 ms was sufficient time for participants to read the word-forms, a simple retyping task was added to test whether participants could read 120 additional Dutch pseudowords equally well when presented for either 300 ms or 860 ms (the mean written exposure time of Experiment 1). This retyping task was only administered to the participants in the written training condition.

Results

One participant from Experiment 2 had to be removed, because no buttons were pressed during the matching task. Violin plots of the accuracy data can be found in Figure 2. Four one-way ANOVA's indicated that the six groups (four from Experiment 1 and two from Experiment 2) did not differ regarding average general IQ ($F(5,83) = 0.46$, $p = .81$), vocabulary ($F(5,83) = 0.64$, $p = .67$), word reading ($F(5,83) = 0.69$, $p = .63$) or pseudoword reading ability ($F(5,83) = 0.67$, $p = .65$).

To analyse performance on the retyping task, a frequentist mixed-effect logistic regression model was applied using R package lmer (lme4 package: Bates, Maechler, Bolker, & Walker, 2015) with retyping accuracy as dependent variable, and word length and exposure time (300 or 860 ms) as independent variables, plus a random intercept by participant and word. This analysis showed no difference in accuracy of retyping after a 300 or 860 ms exposure (estimate = 0.54 *SE* = 1.81, *z* = 0.29, *p* = .77).

The mixed-effects logistic regression model used to analyse results in Experiment 1, was extended to analyse results of both experiments, with modality at training now possessing three levels: spoken training in Experiment 1, written training

in Experiment 1 where written exposure time was equal to spoken exposure time, and written training in Experiment 2 where written exposure time was reduced to 300 ms. The bias effects of modality at training and test on hits and false alarms are illustrated in Figure 2.

Analyses revealed a significant main effect of trial type with participants more likely to produce a match response when trials included the picture – word form pairs on which they were trained (estimate = -0.73, *SE* = 0.19, *z* = -3.89, *p* < 0.001). The interaction between trial type and training modality was not significant when comparing the reduced written training condition (Experiment 2) to that of the spoken training condition (estimate = -0.24, *SE* = 0.25, *z* = -0.96, *p* = 0.34) indicating that sensitivity of participants did not differ significantly between groups. Similarly, the interaction between trial type and training modality was not significant when comparing the reduced written training condition (Experiment 2) to the longer written training condition (Experiment 1) (estimate = -0.38, *SE* = 0.25, *z* = -1.52, *p* = 0.13). The three-way interaction between training modality, test modality and trial type was significant when comparing the two written conditions (estimate = -0.73, *SE* = 0.25, *z* = -2.90, *p* = 0.004). The three-way interaction was not significant (estimate = -0.43, *SE* = 0.25, *z* = -1.69, *p* = 0.09) when comparing the longer written training condition (Experiment 1) to the spoken training condition or the reduced written training condition (Experiment 2) to the spoken training condition (estimate = 0.31, *SE* = 0.25, *z* = 1.25, *p* = 0.21). Thus, participants trained in the longer written condition (Experiment 1) displayed greater sensitivity during the spoken test than participants trained in the shorter written training condition (Experiment 2) or spoken training condition.

Conclusion

Experiment 2 aimed to investigate whether the written modality benefit found in Experiment 1 resulted from participants having more time with the word form in the written condition, due to the fact that it takes longer for a spoken word to unfold than to read its written from. By reducing written word exposure to 300 ms per word, we controlled for this inherent advantage of the written modality. Results showed that when the exposure time to the written materials was reduced, learning in the written condition did not differ from that in the spoken condition. Further, this was not a result of participants having insufficient time to read the written form as participants did not differ in their ability to retype written pseudowords when they were presented for 300 ms or 860 ms.

General Discussion

This study aimed to test whether modality specific learning mechanisms, engaged when learning novel picture–pseudoword form pairings, are more effective when words are presented in their written or spoken form. This study is the first to test for such effects of modality while controlling for the following factors, which potentially give rise to modality effects independent of differences in the efficiency of modality specific learning mechanisms: 1) differences in orthographic and phonological transparency, 2) congruence in modality of word form and word meaning, 3) duration of exposure, 4) engagement of explicit learning strategies, 5) congruence in modality of training and modality of test.

Our results showed that when the duration of written and spoken exposure is equal (the written stimulus is presented for a time period equal to the duration of the spoken word), participants' accuracy in identifying picture-word form pairs is greater when trained on written word-forms. This finding replicates earlier findings of a written learning benefit when learning word forms and their meanings (Balass et al., 2010, Nelson et al., 2004, Van der Ven et al., 2015).

However, Experiment 2 shows that the written learning benefit disappears when controlling for the fact that the time required to read a word in its written form is shorter than the time required for its spoken form to unfold. Our results demonstrate that once controlling for this property of reading there is no additional advantage in learning word form – picture associations when words are presented in their written rather than spoken form.

Our conclusions are therefore at odds with previous studies that argue for differences in the efficiency of modality specific learning mechanisms. Based on the results produced by this study we believe such findings are likely driven by an absence of one or more of the confounds listed above (see list 1-5), which alone may generate such observed modality effects.

Bakker et al, (2014), one of few studies to train and test participants in both modalities, provides evidence that auditory benefits of learning novel word forms emerge only at longer periods of consolidation. Within their study phoneme and letter monitoring tasks were used to probe lexical integration of novel word forms after 24 hrs and 8 days. It is feasible therefore that the findings within the current study are limited to short-term episodic memory. This can be tested in a follow up study by extending the current paradigm to include tests of lexical integration at longer periods of consolidation.

Unexpectedly, our results did not produce a modality congruency effect as predicted by Tulving and Thomas's (1973) encoding specificity principle, in that the experimental groups for which the test modality was the same as the training modality, did not show superior performance. Paradoxically, the written benefit observed in Experiment 1 was mainly driven by the written learning spoken test group. However, we believe this to be caused by the perceived erratic response window in the written test condition. Participants were required to respond within 2 seconds plus the speech duration of the written word. Because they did not hear the word, the response time was therefore difficult to predict. This conclusion is supported by participant's performance on the same task in Experiment 2, when participants were habituated in the written training phase to a fixed exposure time which did not appear to result in a decrease in performance on the written test.

Still, our experiments do not provide evidence for Tulving and Thomas's (1973) encoding specificity principle, since participants in all cross-modal conditions were consistently able to recognize words in a modality in which they had not seen the word form before. Further, no interaction was observed between the written reduced training condition of Experiment 2 and the spoken test condition of Experiment 1, indicating that when participants have equivalent exposure to either the written or spoken word form in training, their ability to recognise the novel word form in the alternative, unseen modality does not differ.

Within the current study, attempts were made to limit strategic cross-modal encoding: no explicit instruction to learn the materials was provided, participants were trained in a single modality, stimuli were presented rapidly, and visual and auditory masks immediately followed the presentation of the word form. Thus, our results suggest that proficient readers, such as those tested in our study, automatically rapidly recode novel word forms into both their phonological form when presented with written stimulus (Perfetti et al., 1988) and their orthographic form when presented with an auditory stimulus.

Our findings also do not support a developmental and/or evolutionary advantage for learning from spoken materials. It appears that even though the ability to learn from written materials has developed later in human's lives and their evolution as a species, this ability is sufficiently developed in adult proficient readers to perform equally effectively.

This study set out to test for modality effects on novel word learning. Specifically it tested for differences in the efficiency of modality specific mechanisms engaged when learning novel object - pseudoword pairs, from either spoken or written stimuli. Results showed a written benefit when equal exposure time was provided. However, once we controlled for the fact that reading allows faster access to the full word form than listening to speech, no modality effect was observed. This suggests that modality specific learning mechanisms operating on spoken or written stimuli were equally efficient. Given that we typically begin learning words from auditory input only, the findings of the present study indicate that once we become proficient readers, the cognitive system converges on learning equally efficiently from both modalities.

Abstract

How does time pressure influence attitudes towards uncertainty? When time is limited, do people engage in different exploration strategies? We study human exploration in a range of four-armed bandit tasks with different reward distributions and manipulate the available time for each decision (limited vs. unlimited). Through multiple behavioral and model-based analyses, we show that reactions towards uncertainty are influenced by time pressure. Specifically, participants seek out uncertain options when time is unlimited, but avoid uncertainty under time pressure. Moreover, larger relative differences in uncertainty between options slowed down reaction times and dampened the drift rate of a linear ballistic accumulator model. These results shed new light on the differential effect of uncertainty and time pressure on human exploration.

Keywords: Exploration-exploitation; Uncertainty; Time Pressure; Directed Exploration; Multi-armed Bandits

Introduction

Searching for rewards requires navigating the exploration-exploitation dilemma: Should one exploit options known to produce high rewards, or explore lesser known options to gain information that could potentially lead to even higher rewards? Because optimal solutions (Gittins, 1979) are generally intractable in realistic settings, practical solutions usually rely on heuristics (Auer, Cesa-Bianchi, & Fischer, 2002), which can be classified as directed exploration, random exploration, or both.

Directed exploration is often implemented using an exploration bonus that inflates the expected value of an option proportional to the estimated uncertainty, to encourage the exploration of uncertain options. Whereas earlier studies produced mixed evidence for the use of exploration bonuses in human reinforcement learning (Daw, O'doherty, Dayan, Seymour, & Dolan, 2006), there is now an increasing amount of evidence for directed exploration in vast problem spaces (Wu, Schulz, Speekenbrink, Nelson, & Meder, 2018), planning (Wilson, Geana, White, Ludvig, & Cohen, 2014), dynamic decision making (Knox, Otto, Stone, & Love, 2012), and simple two-armed bandit tasks (Gershman, 2018).

Unlike directed exploration, *random exploration* increases choice stochasticity in accordance to the agent's uncertainty about the value of available actions (Speekenbrink & Konstantinidis, 2015). One recent theory proposed that random and directed exploration can be dissociated, where the balance is influenced by the total and relative uncertainty of available options (Gershman, in press). If there are multiple options with similar expected rewards, directed exploration makes an option more likely to be sampled when its uncertainty is higher relative to the other options (Schulz & Gershman, 2019). We make use of this effect by studying how patterns of decision making and exploration are affected by both uncertainty and expected reward in a four-armed bandit task. Compared to previously studied two-armed bandit tasks, the richer set of options makes exploration more pertinent and observable over more trials. Crucially, we manipulate the presence or absence of time pressure to gain insights into the cognitive processes underlying exploration. If directed exploration is a reasoned and controlled process, which requires taking the uncertainties of each options into account, then time pressure may limit the capacity for directed exploration.

As predicted, we find that participants are more likely to sample options with high relative uncertainty in the absence of time pressure. However, when we impose time pressure by limiting the allowed decision time to under 400 milliseconds, we find that relative uncertainty reduces the probability that an option is chosen. Additionally, relative uncertainty slows down reaction times more strongly and dampens the evidence accumulation process more heavily under time pressure. In other words, time pressure moderates the effect of environmental uncertainty, such that risk-seeking behavior arising through directed exploration transforms into risk-aversion under time pressure. These results enrich our understanding of human exploration strategies under changing task demands.

Experiment

Participants and Design. We recruited 99 participants (36 female, aged between 21 and 69 years; M=34.82; SD=10.1) on Amazon Mechanical Turk (requiring 95% approval rate and 100 previously approved HITs). Participants were paid \$3.00 for taking part in the experiment and a performance contingent bonus of up to \$4.00 (calculated based on the performance of one randomly selected round). Participants spent 13.0 ± 5.6 minutes on the task and earned $\$5.87 \pm \$0.91$ in total. The study was approved by the Ethics Committee of the Max Planck Institute for Human Development.

We used a 2×4 within-subject design to examine how the presence or absence of time pressure and the payoff structure of the task (see Fig. 1b and Tab. 1) influenced choices and reaction times. In total, the experiment consisted of 40 rounds

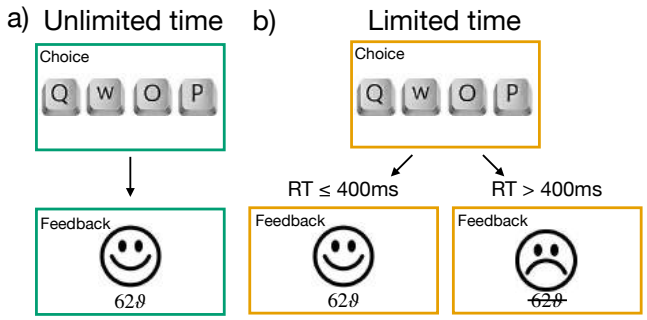

Figure 1: **Experimental design.** We used a four-armed bandit task where each option was randomly mapped to the Q, W, O, and P keys on the keyboard. **a**) In unlimited time rounds, participants could take as long as they wanted to make each selection and received positive feedback (happy face) and were shown the value of the acquired payoff. **b**) In limited time rounds, participants were only given 400 ms to make each selection. If they exceeded the time limit, they would forgo earning any rewards, and received negative feedback (sad face) along with the value of the payoff they could have earned (crossed out).

with 20 trials each. In each round, a condition was sampled (without replacement) from a pre-randomized list, such that each combination of time pressure and payoff structure was repeated five times, with a total of 100 trials in each.

Materials and Procedure. Participants were required to complete three comprehension questions and two practice rounds (one with unlimited time and one with limited time) consisting of 5 trials each before starting the experiment. Each of the 40 rounds was presented as a four-armed bandit task, where the four options were randomly mapped to the $[Q,W,O,P]$ keys on the keyboard (Fig. 1). Selecting an option by pressing the corresponding key yielded a reward sampled from a normal distribution, where the mean and variance was defined by the round's payoff structure (Fig. 2a and Tab. 1). Participants completed 20 trials in each round and were told to acquire as many points as possible.

Before starting a round, participants were informed whether it was an unlimited or a limited time round. In unlimited time rounds, participants could spend as much time as they needed to reach a decision, upon which they were given feedback about the obtained reward (displayed for 400 ms) before continuing to the next trial (Fig. 1a). In limited time rounds, participants were instructed to decide as fast as possible. If a decision took longer than 400 ms, they forfeited the reward they would have earned (presented to them as a crossed-out number with an additional sad smiley; Fig. 1b). We used the same inter-trial period of 400 ms to display feedback about obtained rewards in both limited and unlimited time rounds.

We applied a random shifting of rewards across rounds (i.e., different maximum reward) to prevent participants from immediately recognizing when they had chosen the optimal option. For each round, we sampled a value from a uniform distribution $\mathcal{U}(30,60)$, which was then added to the rewards. Together with random shifting, we also truncated rewards such that they were always larger than zero. In order to convey intuitions about the random shift of rewards, payoffs were presented using a different fictional currency in each round (e.g., ß, Þ, ϑ), such that the absolute value was unknown, but higher were always better.

Table 1: Payoff Conditions

Payoff Conds	Means (μ)	Variances (σ^2)
IGT	$[-10,-10,10,10]$	$[10,100,10,100]$
Low Var	$[-10,-\frac{1}{3},\frac{1}{3},10]$	$[10,10,10,10]$
High Var	$[-10,-\frac{1}{3},\frac{1}{3},10]$	$[100,100,100,100]$
Equal Means	$[0,0,0,0]$	$[10,40,70,100]$

At the end of each round, participants were given feedback about their performance in terms of the bonus they would gain (in USD) if this was the round selected for determining the bonus. The bonus was calculated as a percentage of the total possible performance, raised to the power of 4 to accentuate differences in the upper range of performance:

$$\text{Bonus} = \left(\frac{\text{total reward gained}}{\text{mean reward of best option} \times 20 \text{ trials}}\right)^4 \times \$4.00$$

Payoff conditions We used four different payoff conditions as a within-participant manipulation (Tab. 1 and Fig. 2a). Each payoff condition specified the mean μ_i and variance σ_i^2 of the reward distribution $R_i \sim \mathcal{N}(\mu_i,\sigma_i^2)$ for each option i. Each distribution was randomly mapped to one of the four $[Q,W,O,P]$ keys of the keyboard in each round. The Iowa Gambling Task (IGT) is a classic design that has been related to a variety of clinical and neurological factors affecting decision-making (Yechiam, Busemeyer, Stout, & Bechara, 2005; Bechara, Damasio, Damasio, & Anderson, 1994). We implemented a reward condition inspired by the IGT such that there are two high and two low reward options, with a low and high variance version of each. We also constructed two conditions with equally spaced means, but with either uniformly low variance or uniformly high variance. Lastly, the equal means condition had identical means and gradually increasing variance, such that we can observe the influence of uncertainty independent of mean reward.

Behavioral Results

Participants acquired higher rewards in the unlimited than in the limited time condition (Fig. 2b; $t(98) = 3.1$, $p = .002$, $d = 0.3$, $BF = 10$). Participants also improved over trials, signified by an average correlation between trial and rewards (Spearman's $\rho(98) = 0.16$, $p < .001$, $BF > 100$). This correlation did not differ between limited and unlimited time rounds ($t(98) = -1.3$, $p = .196$, $d = 0.1$, $BF = .25$).

We also compared performance across payoff conditions. This is possible, since all games had the same expected reward under the assumption of a random sampling strategy. We found that participants performed better in the IGT-like condition than in the low variance condition ($t(98) = 3.2$, $p = .002$, $d = 0.3$, $BF = 14$). We see an even larger difference when comparing the low variance and high variance conditions, which had the same means but different levels of

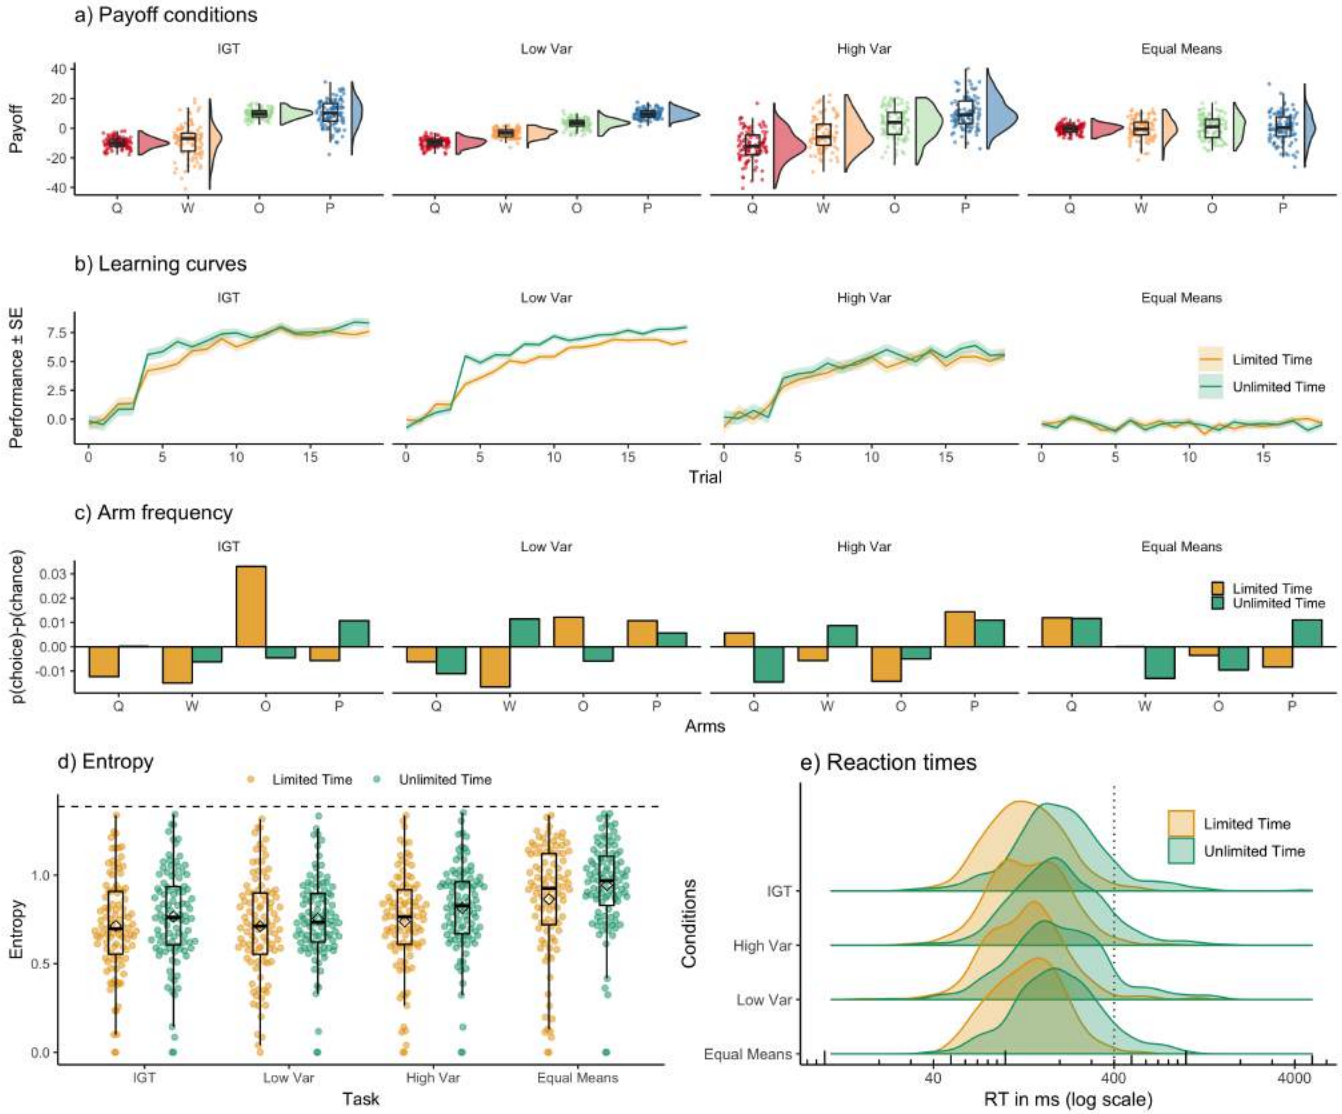

Figure 2: **Payoff conditions and behavioral results**. **a**) Four different payoff conditions were combined with either limited or unlimited time rounds to create 8 different scenarios. Each condition specifies a normal payoff distribution for each option; the means and variances are shown in Table 1. Each dot represents a randomly drawn payoff, while the Tukey boxplots and half violin plots show the distribution for 100 simulated draws. Note that rewards were randomly shifted in each round by adding a constant $\sim \mathcal{U}(30,60)$ to all payoffs. **b**) Learning curves of average participant performance (using unshifted rewards) over trials by payoff condition. Ribbons indicate standard error. **c**) Choice proportions (normalized for chance) for each option, mapped to the canonical ordering shown in panel a). **d**) The entropy of choices in each round, where higher entropy corresponds to more diverse choices and the dotted line indicates random chance (i.e., playing each arm with equal probability). Each dot represents a participant, and overlaid are Tukey boxplots with the diamond indicating the group mean. **e**) Distributions of reaction times in milliseconds (ms) and shown on a log scale. The vertical dotted line indicates the time limit (400 ms) of the limited time condition

risk and uncertainty. Participants performed substantially better in the low variance condition than the high variance condition ($t(98) = 6.2$, $p < .001$, $d = 0.6$, $BF > 100$). Thus, higher variance increased the difficulty of the task. Lastly, participants performed better in the high variance than in the equal means task ($t(98) = 25.5$, $p < .001$, $d = 2.6$, $BF > 100$), which is intuitive since improvement is not possible if all arms have the same mean reward.

Choice proportions. Figure 2c shows the proportion of choices, which illustrates differences across time conditions. We used a Bayesian mixed-effects logistic regression and found that in the IGT condition, participants chose the high reward-low variance option (indicated as 'O' in Fig. 2c) less frequently in the unlimited time than in the limited time condition ($\hat{\beta} = -.22$, 95% Highest Posterior Density (HPD) interval: $[-.28, -.15]$, $BF > 100$)[1].

Additionally, we also find differences across time-pressure conditions in the Equal Means task, where participants selected the highest variance option ('P') more frequently in the unlimited time condition $\hat{\beta} = .11$, 95% HPD: $[.05, .17]$,

[1]We use Bridge sampling (Gronau, Singmann, & Wagenmakers, 2017) to approximate the Bayes Factor by comparing against an intercept-only null model (i.e., without time pressure as a predictor).

$BF = 15$). This illustrates a shift in preferences away from uncertain options when time pressure is introduced. Whereas participants tend to be risk-seeking and choose highly uncertain options under unlimited time, they become more risk-averse and choose them less often under time pressure.

We also calculated the Shannon entropy of participants' choices in each round (Fig. 2d), where higher entropy corresponds to higher diversity of choices and the maximal entropy strategy would be to choose each option an equal number of times (indicated by the dotted line). Averaged across participants, we find higher choice entropy (i.e. more diversity in choice) under unlimited time than limited time ($t(98) = 4.1$, $p < .001$, $d = 0.4$, $BF > 100$). This further strengthens the evidence for reduced exploration under time pressure, since we find a lower diversity of choices.

Reaction times. Figure 2d shows reaction times. Unsurprisingly, participants responded faster in the limited time than in the unlimited time conditions (comparing RTs in logms: $t(98) = 9.7$, $p < .001$, $d = 1.0$, $BF > 100$). There were no differences across payoff conditions ($F(3,95) = 0.12$, $p = .951$, $BF = 0.01$).

Model-Based Analyses

In order to model learning and decision making in our task, we use a *Bayesian mean tracker* (BMT) as a reinforcement learning model for estimating rewards and uncertainties, which are then updated based on prediction error. The BMT is a variant of a Kalman filter, but assumes a time-invariant reward distribution (as is the case in our experiment) instead of a dynamically changing one. Both models use an updating rule based on prediction error, and have been described as a Bayesian extension of the classic Rescorla-Wagner model of associative learning (Gershman, 2015). Variants of the BMT have been used to describe human behavior in a variety of multi-armed bandit and decision-making tasks (Gershman, 2018, in press; Yu & Dayan, 2003; Schulz, Konstantinidis, & Speekenbrink, 2015; Dayan, Kakade, & Montague, 2000; Speekenbrink & Konstantinidis, 2015).

The BMT learns a posterior distribution over the mean reward μ_j for each option j. Rewards are assumed to be normally distributed with a known variance but unknown mean. The prior distribution of the mean is also a normal distribution. This implies that the posterior distribution for each mean is also a normal distribution:

$$p(\mu_{j,t}|\mathcal{D}_{t-1}) = \mathcal{N}(m_{j,t}, v_{j,t}) \tag{1}$$

where $\mathcal{D}_{t-1}$ denotes the previously observed rewards for all options. For a given option j, the posterior mean $m_{j,t}$ and variance $v_{j,t}$ are only updated when it has been selected at trial t:

$$m_{j,t} = m_{j,t-1} + \delta_{j,t} G_{j,t} [y_t - m_{j,t-1}] \tag{2}$$

$$v_{j,t} = [1 - \delta_{j,t} G_{j,t}] v_{j,t-1} \tag{3}$$

where $\delta_{j,t} = 1$ if option j is chosen on trial t, and 0 otherwise. Additionally, y_t is the observed reward at trial t, and $G_{j,t}$ is defined as:

$$G_{j,t} = \frac{v_{j,t-1}}{v_{j,t-1} + \theta_\varepsilon^2} \tag{4}$$

where θ_ε^2, referred to as the error variance, is the variance of the rewards around the mean. For our model-based analysis, we set the error variance to 1 (which led to competitive task performance in prior simulations).

Intuitively, the estimated mean of the chosen option $m_{j,t}$ is updated based on prediction error, which is the difference between the observed reward y_t and the prior expectation $m_{j,t-1}$, multiplied by learning rate $G_{j,t} \in [0,1]$. At the same time, the estimated variance $v_{j,t}$ of the chosen option is reduced by a factor $1 - G_{j,t}$. The error variance (θ_ε^2) can be interpreted as an inverse sensitivity, where smaller values result in more substantial updates to the mean $m_{j,t}$, and larger reductions of uncertainty $v_{j,t}$. We set the prior mean to $m_{j,0} = 45$ and the prior variance to $v_{j,0} = 55$ based on the expectation across payoff conditions.[2]

Results

We followed Gershman (in press) and generated predictions from the BMT by feeding in a participant's observations on a particular round until time t, and then predicting the mean and standard deviation for each option at time point $t+1$. We used the resulting predictions of rewards and uncertainties to conduct three model-based analyses of choices, reaction times, and evidence accumulation.

Choices. In our first analysis, we assessed how the predicted mean and uncertainty of an option affected the likelihood of it being chosen on each trial (estimated separately for limited and unlimited time conditions). We applied hierarchical Bayesian inference to estimate the parameters of a softmax policy, under the assumption that a participant's choice on each trial is influenced by both the predicted mean and uncertainty of an option, where each participant's parameters are assumed to be jointly normally distributed. The probability of choosing option j on trial t is a softmax function of its decision value $Q_{j,t}$:

$$P(C_t = j) = \frac{\exp(Q_{j,t})}{\sum_{k=1}^{4} \exp(Q_{k,t})}. \tag{5}$$

The decision value $Q_{j,t}$ is a linear function of the estimated mean $m_{j,t}$ and uncertainty $\sqrt{v_{j,t}}$ (estimated as a standard deviation) of each option according to the BMT:

$$Q_{j,t} = \beta_1 m_{j,t} + \beta_2 \sqrt{v_{j,t}}. \tag{6}$$

Formally, we assume that the β-coefficients for each participant $\beta_i = (\beta_{1,i}, \beta_{2,i})$ are drawn from a normal distribution

$$\beta_i \sim \mathcal{N}(\mu_\beta, \sigma_\beta^2), \tag{7}$$

[2] We use the shifted reward values that were observed by participants, where the means in each condition were centered on 0 and shifted by $\mathcal{U}(30,60)$.

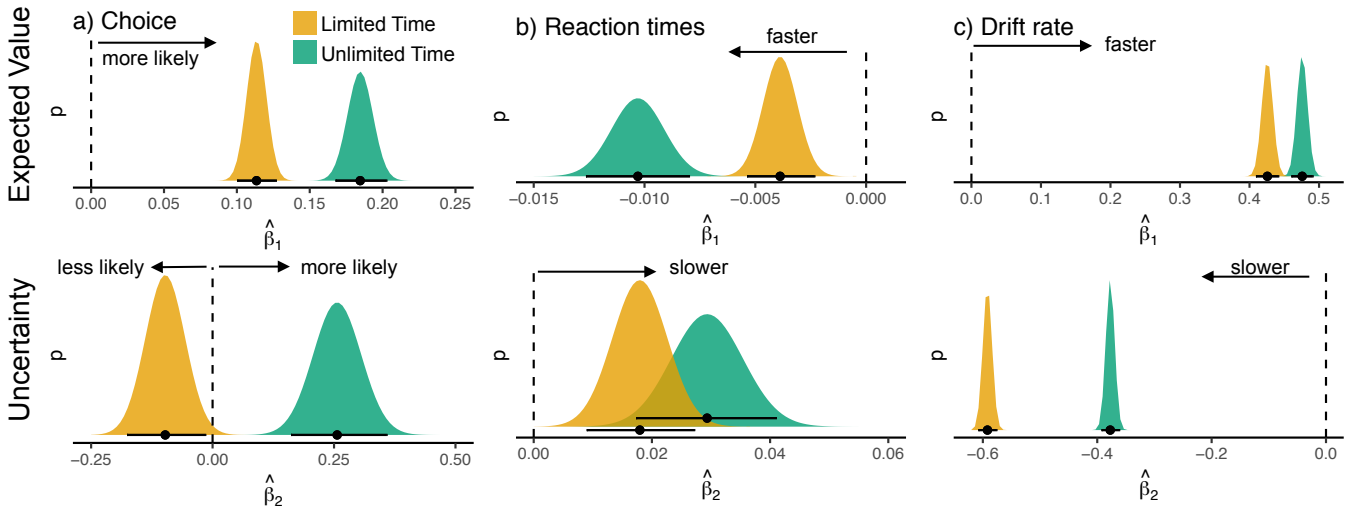

Figure 3: **Posterior parameter estimates. a**) Effects of BMT predicted mean rewards ($\hat{\beta}_1$) and uncertainties ($\hat{\beta}_2$) on an option's probability of being chosen, estimated by a hierarchical Bayesian softmax regression. **b**) Influence of BMT means ($\hat{\beta}_1$) and uncertainties ($\hat{\beta}_2$) on participant response times, estimated by a hierarchical Bayesian linear regression. **c**) Influence of BMT means ($\hat{\beta}_1$) and uncertainties ($\hat{\beta}_2$) on drift rates in a Bayesian Linear Ballistic Accumulator model. In all plots, the vertical dashed line indicates an effect of 0, while the black dot indicates the mean effect and confidence intervals show the 95% highest posterior density (HPD).

and we estimate the group-level mean μ_β and variance over participants σ^2_β. We used the following priors on the group-level parameters:

$$\mu_\beta \sim \mathcal{N}(0, 100) \tag{8}$$

$$\sigma_\beta \sim \text{Half-Cauchy}(0, 100) \tag{9}$$

In each time condition, we arrive at group-level parameter estimates describing how expected rewards (β_1) and uncertainty (β_2) influence choice probability under the softmax policy.

We estimated the hierarchical model using Hamiltonian Markov chain Monte Carlo sampling with `PyMC3` (Salvatier, Wiecki, & Fonnesbeck, 2016). The results (Fig 3a) show that the expected value of an option increased choice probability for both the limited time ($\hat{\beta}_1 = .11$, 95% HPD: $[.10, .13]$) and the unlimited time conditions ($\hat{\beta}_1 = .19$, 95% HPD: $[.17, .2]$). Options estimated to have higher expected rewards were more likely to be chosen in both conditions, with a stronger effect in the unlimited time conditions.

Notably, we found contrasting effects of uncertainty on choice probability. In the unlimited time conditions, uncertainty had a positive effect on choice probability ($\hat{\beta}_2 = .26$, 95% HPD: $[.16, .36]$). This replicates previous findings reported in two-armed bandit tasks without time pressure (Gershman, 2018, in press). However, uncertainty had a negative effect on choice probability in the limited time condition ($\hat{\beta}_2 = -.10$, 95% HPD: $[-.18, -.02]$). Thus, whereas participants sought out uncertain options in the unlimited time condition, they shunned uncertain options in the limited time condition.

Reaction Time. Our second analysis looked at how the estimated means and uncertainties of options influenced reaction times. We normalized the BMT predictions of mean reward and uncertainty by calculating the difference between the chosen option and the average of the unchosen options on each trial. Thus, positive values indicate that expected reward/uncertainty are relatively larger than those of the unchosen options. We regressed these normalized means and uncertainties onto participant log reaction times[3] in a hierarchical Bayesian linear regression, using the same priors over the β-coefficients as before (Eq. 9).

The resulting posterior parameter estimates (Fig. 3b) show that participants were faster at choosing options with relatively higher expected reward in both conditions, but with a stronger effect in the unlimited ($\hat{\beta} = -.01$, 95% HPD: $[-.013, -.008]$) than in the the limited time condition ($\hat{\beta} = -.004$, 95% HPD: $[-.005, -.002]$). Furthermore, participants were slower at choosing options with higher relative uncertainty in both the limited ($\hat{\beta} = .02$, 95% HPD: $[.01, .03]$) and the unlimited conditions ($\hat{\beta} = .03$, 95% HPD: $[.02, .04]$). Thus, whereas higher relative value made participants act faster, higher relative uncertainty slowed them down. This differs from previous findings using two-armed bandits (Gershman, in press), which showed higher relative uncertainty makes participants choose faster.

Evidence Accumulation. In our third analysis, we used the Linear Ballistic Accumulator (LBA; Brown & Heathcote, 2008) to model choices and reaction times simultaneously. This model assumes that choices are the result of a process in which evidence for each option is accumulated continuously over time, and that option is chosen for which the accumulated evidence first exceeds a set decision threshold.

Formally, the LBA assumes that, after an initial period of non-decision time τ, evidence for an option j on trial t accumulates at a rate of $v_{j,t}$, starting from an initial evidence

[3] 1 ms was added to each RT to avoid $\log(0)$. Additionally, RTs were truncated at 5000 ms.

level $p_{j,t} \sim \mathcal{U}(0, A)$. Evidence accumulates for each option j until a threshold b is reached. We follow the Bayesian implementation proposed by Annis, Miller, and Palmeri (2017) and assume that the priors for the drift rates stem from truncated normal distributions

$$v_{j,t} \sim \mathcal{N}(2,1) \in (0,\infty). \tag{10}$$

Additionally, we assume a uniform prior on non-decision time

$$\tau \sim \text{Uniform}(0,1), \tag{11}$$

and a truncated normal prior on the maximum starting evidence

$$A \sim \mathcal{N}(0.5,1) \in (0,\infty). \tag{12}$$

Finally, we reparameterized the model by shifting b by k units away from A, and put a truncated normal distribution as the prior on the resulting relative threshold k:

$$k \sim \mathcal{N}(0.5,1) \in (0,\infty). \tag{13}$$

We estimated the LBA parameters for each participant in every round using No-U-Turn Hamiltonian MCMC (Hoffman & Gelman, 2014), with reaction times truncated at 5000 ms. Participants had higher mean drift rates under limited time compared to unlimited time ($t(98) = 7.1$, $p < .001$, $d = 0.7$, $BF > 100$), consistent with the need to arrive at decisions more quickly. Participants in the limited time conditions also had shorter non-decision times τ ($t(98) = -4.6$, $p < .001$, $d = 0.5$, $BF > 100$), less maximum starting evidence A ($t(98) = -7.8$, $p < .001$, $d = 0.8$, $BF > 100$), and lower relative thresholds k ($t(98) = -5.2$, $p < .001$, $d = 0.5$, $BF > 100$), compared to participants in the unlimited time conditions. Thus, our LBA results confirm the intuition that participants thought more carefully about different options given unlimited time.

We then regressed the BMT predictions of relative expected reward and relative uncertainty for each option onto its estimated drift rate using a Bayesian linear regression. The result of this analysis revealed that the relative expected value of an option had a positive effect on drift rate for both the limited ($\hat{\beta} = .43$, 95% HPD: $[.41, .44]$; see Fig. 3c) and unlimited time conditions ($\hat{\beta} = .48$, 95% HPD: $[.46, .49]$), with a stronger effect in the latter. Conversely, relative uncertainty had a negative effect on drift rate, which was larger in magnitude for the limited ($\hat{\beta} = -.59$, 95% HPD: $[-.61, -.58]$) than for the unlimited time conditions ($\hat{\beta} = -.38$, 95% HPD: $[-.39, -.36]$). Thus, the behavioral patterns in Figure 2b suggest that uncertainty reduced the rate of evidence accumulation, with a stronger effect under time pressure than in the unlimited time conditions.

Discussion and Conclusion

How do people explore uncertain options under time pressure? We investigated this question using several variants of a four-armed bandit task with continuous rewards, while manipulating the available decision time to be either unlimited or limited to less than 400 ms.

Our models showed that higher relative uncertainty made an option more likely to be chosen in the absence of time pressure. This matches previous findings showing evidence for an exploration bonus consistent with directed exploration (Gershman, in press). However, putting participants under time pressure inverted this relationship, and caused uncertainty to reduce the probability that an option was chosen. Thus, the uncertainty bonus found in standard multi-armed bandit tasks can turn into an uncertainty penalty when people are under time pressure. This is similar to findings from description-based gambles, where time pressure increased risk aversion (Nursimulu & Bossaerts, 2013).

We also found that relative uncertainty slowed down choices and dampened evidence accumulation. These results suggest that uncertainty can have reversible effects on preference: sometimes people seek out uncertainty, and sometimes they actively avoid it. Both of these cases suggest people track uncertainty in their expectations, and that uncertainty feeds into the decision-making process. This is similar to what has been observed in tasks that directly elicit confidence judgments (Boldt, Blundell, & De Martino, 2017; Stojic, Schulz, Analytis, & Speekenbrink, 2018; Schulz, Wu, Ruggeri, & Meder, 2018; Wu, Schulz, Garvert, Meder, & Schuck, 2018), while previous work has shown that changing the context from only gains to adding risky options can also cause a shift from actively seeking uncertainty to avoiding it (Schulz, Wu, Huys, Krause, & Speekenbrink, 2018).

Our results provide a richer understanding of the cognitive processes underlying human learning and exploration. While we found evidence that time pressure reduces directed exploration—consistent with directed exploration being a controlled and reasoned process—we did not predict uncertainty avoidance under time pressure. Together with the finding that relative uncertainty slowed down reaction times and dampened evidence accumulation, our results suggest that time pressure does not eliminate the ability to track uncertainty. Rather, it alters attitudes towards it, from seeking out uncertainty to avoiding it. Future studies should therefore investigate the conditions that cause uncertainty-seeking or uncertainty-avoidance and test whether uncertainty-avoidance is a deliberate behavior (Schulz, Klenske, Bramley, & Speekenbrink, 2017).

Preschoolers jointly consider others expressions of surprise and common ground to decide when to explore

Abstract

Prior work on early social learning suggests that children are sensitive to adults pedagogical demonstrations and verbal instructions. Yet, people also display various emotional expressions when interacting with children. Here we show that young children draw rich causal inferences and guide their own exploration based on others expressions of surprise. Preschoolers (age:3.0-4.9) saw an experimenter discover a function of a novel causal toy. Then, either the same experimenter or a nave confederate expressed surprise while playing with the toy behind an occluder. Children explored the toy more broadly to search for a hidden function following the experimenters surprise than following the confederates surprise, suggesting that children integrated others expressions of surprise and others epistemic states to infer the presence of hidden functions and explore accordingly. This study synthesizes perspectives from literature on social learning, exploration, and affective cognition towards a more comprehensive science of learning. Preprint:https://psyarxiv.com/ckh6j

A predictability-distinctiveness trade-off in the historical emergence of word forms

Abstract

It has been proposed that language evolves under the joint constraints of communicative expressivity and cognitive ease. We explore this idea in the historical emergence of word forms. We hypothesize that new word forms that enter the lexicon should reflect a trade-off between predictability and distinctiveness. An emergent word form can be highly predictable if it efficiently reuses elements from the existing word forms, resulting in low cognitive load. An emergent word form should also be sufficiently distinctive from the existing lexicon, facilitating communicative expressivity. We test our hypothesis by examining the properties of 34,478 emergent word forms over the past 200 years of Modern English. We show how word forms at future time $t+1$ are bounded statistically between n-gram generated word forms (highly predictable) and slang words that are outside the standard lexicon (highly distinctive) at time t. Our work supports the view of cognitive economy in lexical emergence.

Keywords: word form; lexicon; lexical emergence; language evolution; cognitive economy

Introduction

The lexicon is a central locus of human thought, but it undergoes constant change over time. In particular, new words may emerge due to changing sociocultural needs, resulting in growth of the lexicon. Taking the English lexicon as an example, it has grown by approximately tenfold over the past millennium, with more than 150,000 word forms having emerged from the period of Old English to the present day (Figure 1a). Here we ask what principles might underlie the historical emergence of word forms above and beyond the external sociocultural factors that could influence lexical emergence.

Our starting point is the idea that language evolves under the dual considerations of communicative function and cognitive effort (Labov, 2011; Jespersen, 1959; Otto, 1956; Kirby, Tamariz, Cornish, & Smith, 2015), a prominent proposal that has been framed similarly in linguistics as the principle of least effort (Zipf, 1949) and in cognitive psychology as the principle of cognitive economy (Rosch, 1978). This proposal also relates to a growing line of research that explores design principles of language through the lens of efficient communication (Piantadosi, Tily, & Gibson, 2012; Kemp & Regier, 2012; Kemp, Xu, & Regier, 2018). Most relevant to the current study is work by Labov who suggests that words may be selected under the joint constraints of least effort (cf. Zipf, 1949)—a drive for cognitive ease of production, and the competing force of communicative informativeness (Labov, 2011). There is evidence for each of these constraints in the design of word forms. For example, it has been shown that word forms that conform to well-formed phonotactic properties can facilitate production (Edwards, Beckman, & Munson, 2004), and words that sound similar to many existing words, or having dense lexical neighbourhoods, tend to reduce speech error (Stemberger, 2004). On the other hand, separate work has suggested that perceptual distinctiveness matters in the lexicon because it minimizes confusion and facilitates clarity in communication (Flemming, 2004; Meylan & Griffiths, 2017).

We extend previous work by exploring principles in the historical emergence of novel word forms. We believe that the same proposal of language evolution should apply to explaining how new word forms enter the lexicon over time. In particular, we hypothesize that the emergence of word forms should trade off *predictability* against *distinctiveness*. An emergent word form is highly predictable if it efficiently recombines elements from existing word forms, resulting in low cognitive effort in production and memory. Our notion of predictability is rooted in classic work by Shannon (1951) on the information analysis of English text. However, this criterion of predictability is likely in competition with distinctiveness: An emergent word form should be sufficiently distinctive from words in the existing lexicon, hence generating minimal confusion and facilitating communicative expressivity. Predictability and distinctiveness trade off against each other because a highly predictable word form is necessarily similar in form to existing words, so it is unlikely to be distinctive. Similarly, a highly distinctive word form is necessarily novel in its composition, so it is unlikely to be very predictable. Here we examine the possibility that the emergent word forms in history are shaped under these two joint forces, such that they appear sandwiched between (plausible) word forms that are highly predictive and those that are highly distinctive (see Figure 1b for illustration).

We test our hypothesis by examining new word forms that entered the Modern English lexicon over the past 200 years. At each future decade $t+1$, we compare the actual emergent words against a control set of computer-generated words and slang words that did not enter the standard lexicon up to the previous decade t. We show how the actual word forms are interleaved between the highly predictable and distinctive control words in terms of their statistical properties.

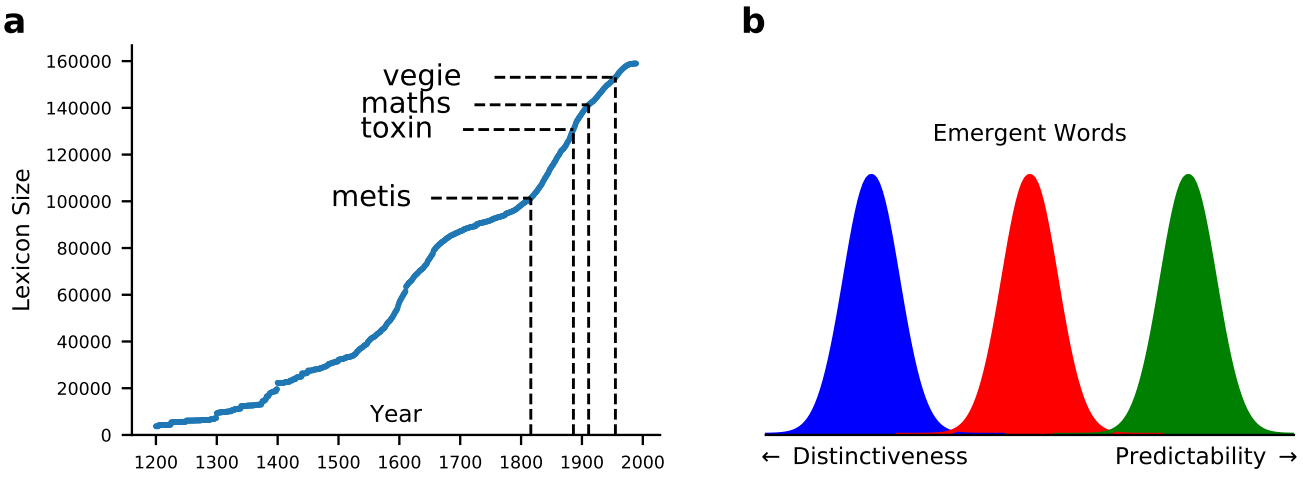

Figure 1: Illustration of the phenomenon of lexical emergence and our hypothesis. a) Growth of the English lexicon over the past 800 years based on data from the Historical Thesauraus of English (HTE). Lexicon size represents the number of unique word forms that exist during this period, and examples of emergent words are shown at respective years of emergence. b) The hypothesis that emergent words (middle) at future time $t+1$ should reflect a trade-off between predictability and distinctiveness among the space of plausible word forms (on the two sides) given the current lexicon at time t, or effectively sandwiched.

Materials and Methods

We analyzed 34,478 word forms during each decade from 1800 to 1980 as recorded in the Historical Thesauraus of English (HTE) (Kay, Roberts, Samuels, & Wotherspoon, 2017) (`https://ht.ac.uk/`) which is based on the Oxford English Dictionary. We considered single-word lexemes that are composed of 26 English letters (a-z) and took the first year recorded in HTE for a given word form as its emerging date. We focused our analysis on the Modern English period due to both orthographic and phonetic changes in words during the remote periods of Old English and Middle English (Baugh & Cable, 1993, p279), and the lack of control words for the same periods that is critical for our analyses. We grouped word forms according to the lengths of their orthographic forms, and we considered lengths ranging from 4 to 9 because lengthier words are more likely formed due to rule-based compositional strategies (Krott, 1996). The grouping by word length is necessary because longer words are by chance more distinctive in form than shorter words, so a principled analysis of our trade-off hypothesis should be independent of length. We focus on reporting results based on orthographic forms, although we observed similar results with phonological forms that we do not include here due to space limit.

We used two standard measures to quantify the statistical properties of word forms along the predictability–distinctiveness dimension: letter n-gram probability and lexical neighbourhood density. We quantify the two measures for word forms at a future decade $t+1$ based on statistical properties of the existing lexicon at a decade earlier at t. Formally, we define the probability of an emergent word form w of length $|w|$ by using the n-gram probabilities of its constituent letters (or phonemes), extending the classic work by Shannon on information analyses of English words (Shannon, 1951):

$$p^{t+1}(w) = \prod_{i=1}^{|w|} p^t(l_i|l_{<i}) \quad (1)$$

$$= p^t(l_1|\cdot) \times p^t(l_2|l_1) \times p^t(l_3|l_2,l_1) \times \quad (2)$$
$$\ldots \times p^t(l_{|w|}|l_{|w|-1},\ldots,l_1)$$

Equations 1-2 effectively estimate how probable a novel word form w would be at decade $t+1$ given the n-gram statistics at the current decade t. We considered n-gram of up to order 5 because statistics of higher orders are sparse and prohibitively expensive to compute. Under this measure, a highly predictable word form at $t+1$ for a given length should be one that maximizes the n-gram probability based on the lexical statistics at t. On the contrary, a highly distinctive word form should have low predictability that minimizes the same probability measure.

To ensure the robustness of our approach, we considered lexical neighbourhood density as an alternative measure. We define the neighbourhood density of an emergent word form w based on how similar it is to existing word forms v in the lexicon at time t (L^t), grounded in the psycholinguistic study of English word forms by Bailey and Hahn (2001):

$$ND^{t+1}(w) = \sum_{v \in L^t} e^{-d(w,v)} \quad (3)$$

Equation 3 effectively estimates how crowded a novel word form w would be at decade $t+1$ given existing word forms at the current decade t. We used the standard Levenshtein

edit distance for calculating $d(\cdot,\cdot)$ that considers if two word forms are similar or distant based on the number of edits required to match the forms via insertion, deletion, or substitution (Yarkoni, Balota, & Yap, 2008; Bailey & Hahn, 2001). For example, the edit distance between "cat" and "maths" is 3 since the edit involves one substitution and two insertions. Similar to the case of the *n*-gram measure, a highly predictable word form at a given length should be one that maximizes neighbourhood density at $t+1$. On the contrary, a highly distinctive word form should not be crowded and hence minimizes its lexical neighbourhood density.

To evaluate the hypothesis that emergent word forms trade off predictability against distinctiveness, we considered a set of control word forms that are representative of the extremities of this dimension yet did not formally enter the English lexicon. Our goal is to assess whether the trade-off hypothesis might explain why certain word forms have entered the lexicon over time, whereas other plausible forms have not appeared. Because the set of all possible word forms is enormous (e.g., there are over 10 million possible word forms of length 5 that did not appear in English up to 1980), we chose control words by focusing on word forms that are either likely to be very predictable or distinctive.

We first obtained the *predictable control set* by generating word forms according to the *n*-gram probability measure in Equations 1-2. At each yet-to-emerge decade, we sampled these word forms from the *n*-gram statistics obtained from the previous decade in a sample size that matches the number of the emergent words. The sample does not intersect with the lexicon, but it can intersect with the set of actual emerging words. We then partitioned these control words by length and calculated their *n*-gram probabilities and neighbourhood densities according to Equations 1-3. This control word set approximates the extremity of predictability because the candidates are directly generated from the distribution of the existing lexicon, so they should be statistically equivalent to the existing word forms in the lexicon. Because *n*-gram probability correlates with neighbourhood density (Sanders & Chin, 2009), we also expect this word set to have high (but not necessarily the maximal) neighbourhood density. If the trade-off hypothesis is correct, the emergent word forms should generally have lower but not near-identical *n*-gram probability and neighbourhood density to this control set.

We next obtained the *distinctive control set* by sampling word forms from slang that did not enter the standard English lexicon. Slang is likely to represent the extremity of distinctiveness because slang words are known to differ from the standard lexicon (Mattiello, 2008, 2013), and 2) they serve as a more conservative measure for plausible word forms (plausible because a subset of slang can eventually become actual words (Baugh & Cable, 1993, p293)) than random samples of non-existent word forms that can be distinctive but not permissible, e.g., "jxyzh" is very distinctive from existing words in English but it is not permissible based on the knowledge of English. We drew data from a large online resource, the Urban Dictionary (`https://www.urbandictionary.com/`), for this control set. We used word forms containing only the letters a-z conforming to the same selection standard with the emergent words. During each decade of interest, we excluded homographs of word forms or words that have overlapping lemma in the lexicon via the lemmatizer from the Natural Language Toolkit (NLTK) (Bird, Klein, & Loper, 2009). We then sampled from the rest of the 317,403 unique word forms in matching size to the emergent lexicon per length, and calculated the *n*-gram and neighbourhood statistics for these word forms. If the trade-off hypothesis is correct, the emergent word forms should generally have higher but not near-identical *n*-gram probability and neighbourhood density to this control set.

Results

We evaluated our hypothesis by first examining whether newly emerging word forms tend to fall between predictable control words and distinctive (slang) control words in terms of *n*-gram probability and lexical neighbourhood density. At each decade, we compared the actual emergent word forms to the two sets of control words of the same length under the two measures separately. We took the average values of the two measures for each word group and every length that we examined.

Figure 2 summarizes the results for these comparisons for every decade from 1800 to 1980 and word forms of lengths 4 to 9. In most cases, we observed that the emergent word group is situated in the middle between the predictable and distinctive control word sets, and the rank order of these three groups based on *n*-gram probability and neighbourhood density conforms to our prediction. Specifically, the predictable control words exhibit the highest mean predictability, manifested in the highest overall *n*-gram probability (or equivalently, the lowest overall negative logarithmic *n*-gram probability) and lexical neighbourhood density among the three groups. In comparison, the slang/distinctive control words exhibit the highest mean distinctiveness, manifested in the lowest overall *n*-gram probability and neighbourhood density. The emergent word group tends to fall in between the two control groups.

To evaluate the significance of these trade-offs, we tested a null hypothesis for each comparison between the emergent group and each of the control groups. The null hypothesis is that the mean estimate of the emergent word set does not differ in *n*-gram probability or lexical neighbourhood density from each of the control sets. We tested this by performing a two-tailed *t*-test for every comparison. Across different word lengths and time periods, we observed consistent evidence for rejecting the null hypothesis (see Figure 3; the variations in the magnitude of p values correlate with time and changing sample sizes, as the number of actual emergent words are different in every decade). These results show that the emergent words are significantly different from the control words.

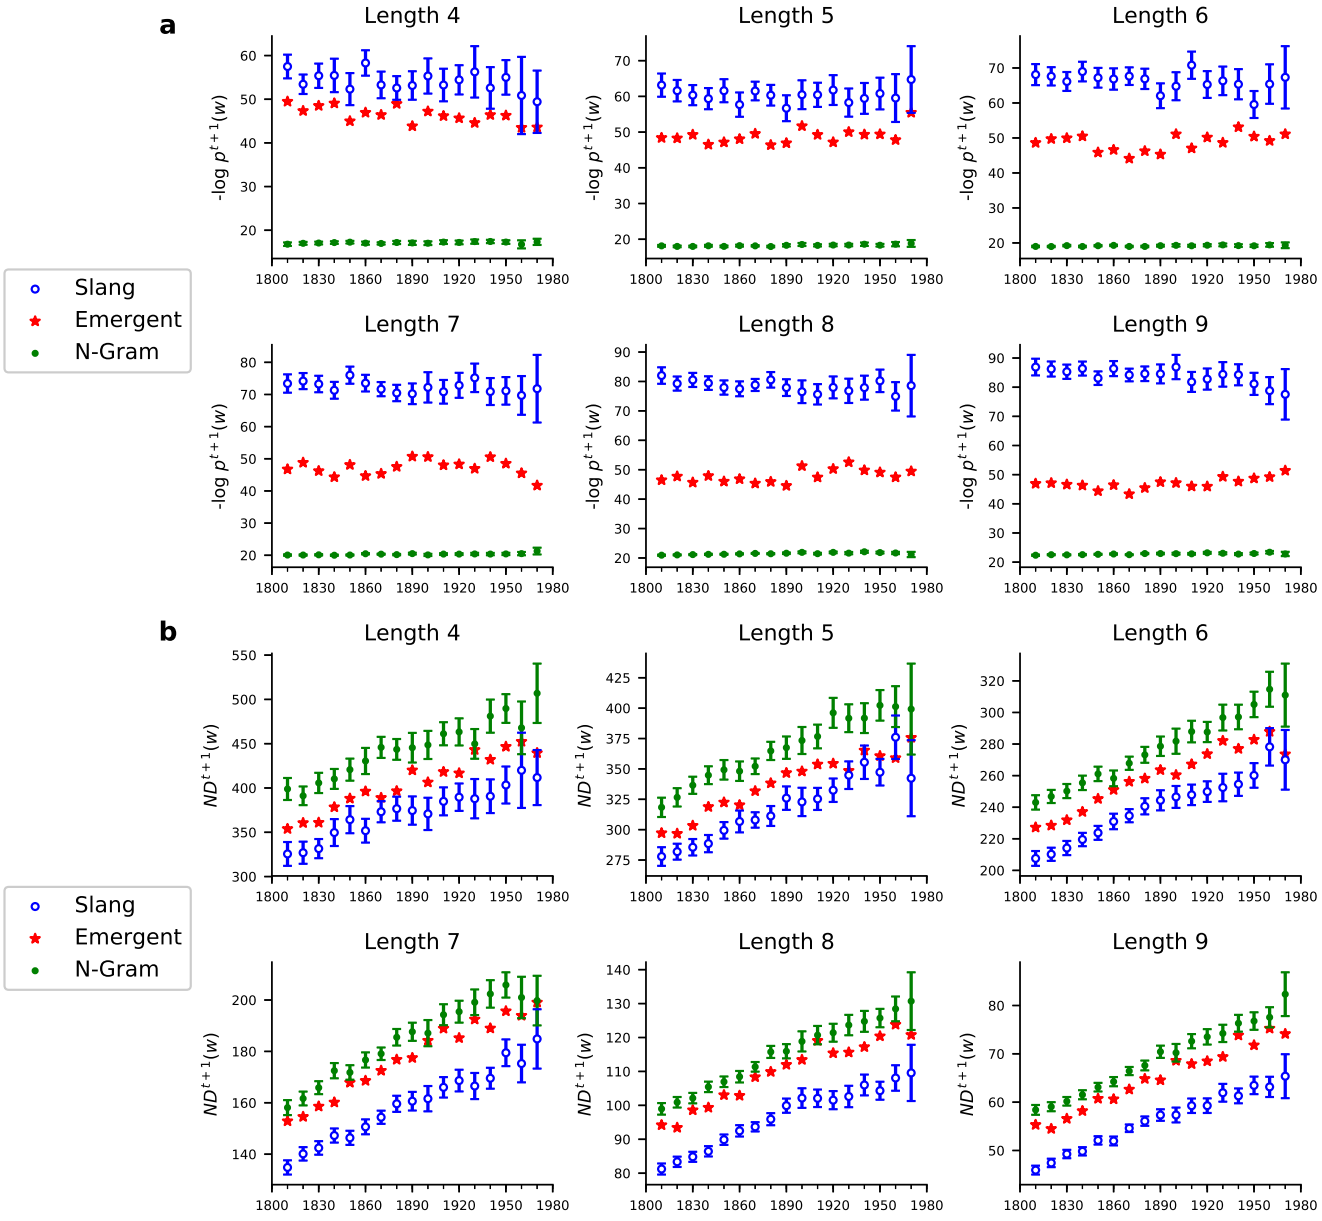

Figure 2: Summary of main results on the trade-off hypothesis of lexical emergence. Each of the panels summarizes the results computed under one of the two measures: a) *n*-gram probability (negative logarithm) and b) neighbourhood density. The vertical axes represent magnitudes under these two measures, and the horizontal axis represents the temporal dimension where each tick corresponds to one decade over the period between 1800 and 1980. Each subplot corresponds to the results for word forms of a different length as specified. Dots (green), stars (red), and circles (blue) correspond to the *n*-gram (predictable) control words, the actual emergent words, and the slang (distinctive) control words, respectively. Each error bar indicates a 95% confidence interval (constructed from the *t*-distribution) for the estimated mean value of the control group. This confidence level is uncorrected for multiple comparisons, and we expect 5% of all intervals to exclude emergent word groups by chance.

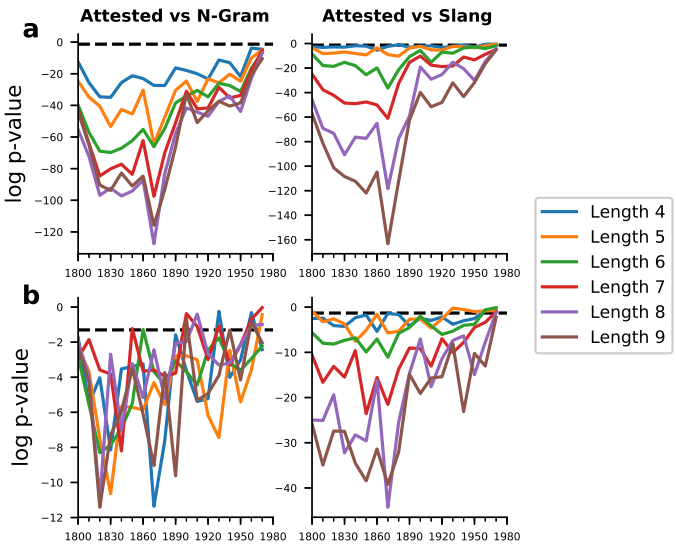

Figure 3: Time courses of p-values. Panels on the left summarize the comparison of the emergent word sets against the corresponding predictable control sets. Panels on the right summarize similar comparisons against the distinctive control sets. The comparisons were based on the measures from a) n-gram probability and b) neighbourhood density. The vertical axis indicates p-values from the t-tests in logarithmic scale, and the horizontal axis represents the time dimension in decades. The black dashed line represents the significance level $p = 0.05$. For each measure, we made 216 simultaneous uncorrected tests, so we expect 11 rejections by chance.

To assess the robustness of these findings, we performed similar analyses based on 1) word forms defined in phonological space as opposed to orthographical space; 2) alternative lexicons obtained by excluding morphologically derived words from the HTE data; 3) an alternative control set based on slang words from a historical resource as opposed to a modern resource. We found that the effects are robust to this variation in design choices, and we omit the details of these analyses due to space constraints. In sum, this set of results provide empirical evidence for our proposal that emerging word forms reflect a trade-off between predictability and distinctiveness and suggest why certain words have entered the lexicon over time, but others have not.

As a follow-up analysis, we assessed whether we can reliably predict emergent word forms from possible words that did not formally enter the lexicon. In particular, we performed a simple logistic regression analysis to predict the identity of each word form from the three groups: emergent words, predictable control words, and distinctive control words. We applied a logistic classifier with $L2$ penalty and the multinomial loss function using the `scikit-learn` package (Pedregosa et al., 2011). For each future decade, we trained the classifier using data from the previous decade t and used the same classifier to make predictions for data from $t+1$. We used three feature sets for classification: 1) n-gram probabilities of words from the three groups; 2) lexical neighbourhood densities of the same words; 3) a combination of their n-gram probabilities and neighbourhood densities.

In general, we observed that predictive accuracies of the three word groups are above chance (33.3% for a three-way classification) under all three feature choices for each decade and length that we considered (predictive accuracy when using neighbourhood density, mean = 43.0%, and standard deviation across word length groups and time periods, SD = 4.2%; using n-gram probability, mean= 61.0%, SD = 3.6%; using the combined features, mean= 61.0%, SD = 3.6%). We noted that the above-chance predictive accuracies are sustained over time, suggesting the trade-off holds generally and not just for certain periods in the history of Modern English. We also noted that the n-gram model performed generally better than the neighbourhood density model, partly because one of the control word groups was directly simulated using n-gram statistics.

Overall, these findings suggest that there are predictable differences in the compositional structure of emergent word forms and that of n-gram generated and slang word forms from the control groups.

Figure 4 further demonstrates the trade-off idea with three example word forms chosen from the three word groups in the 1930s, along with their nearest-neighbour word forms measured by edit distance from the same period. The emergent word form "macro" reflects a trade-off in neighbourhood density: It has fewer 1-edit lexical neighbours (6) than the highly predictable n-gram generatd word "codet" (9 neighbours), but it has more neighbours than the highly distinctive slang word "porph" that has the fewest neighbours (3).

Figure 4: Demonstration of the predictability-distinctiveness trade-off. Panels a), b), and c) show an example word form and its lexical neighbours from the lexicon in the 1930s under the n-gram control set, emergent word set, and slang control set, respectively. The examples are placed in the center, surrounded by their neighbours. Each example word is exactly one edit distance away from each of its neighbours.

Conclusion

We have shown that the historical emergence of English word forms follows a trade-off between predictability and distinctiveness. This trade-off is manifested in the properties of emergent words that straddle between 1) highly predictable computer-generated word forms that conform to statistical properties of the existing lexicon, and 2) highly distinctive word forms originated from slang that had not yet enter into the standard lexicon. We have suggested that such a trade-off may reflect the general principles of language evolution discussed in prior work, under the joint functional pressures for communicative expressivity and cognitive ease (Labov, 2011; Jespersen, 1959; Otto, 1956). Future research should explore whether the same set of principles holds in the emergence of word forms in languages other than English and how word forms interact with meaning (cf. Ramiro, Srinivasan, Malt, & Xu, 2018) in lexical evolution.

Abstract

The ability to estimate task difficulty is critical for many real-world decisions such as setting appropriate goals for ourselves or appreciating others' accomplishments. Here we give a computational account of how humans judge the difficulty of a range of physical construction tasks (e.g., moving 10 loose blocks from their initial configuration to their target configuration, such as a vertical tower) by quantifying two key factors that influence construction difficulty: physical effort and physical risk. Physical effort captures the minimal work needed to transport all objects to their final positions, and is computed using a hybrid task-and-motion planner. Physical risk corresponds to stability of the structure, and is computed using noisy physics simulations to capture the costs for precision (e.g., attention, coordination, fine motor movements) required for success. We show that the full effort-risk model captures human estimates of difficulty and construction time better than either component alone. Preprint link https://arxiv.org/abs/1905.04445.

Tensions Between Science and Intuition in School-Age Children

Andrew G. Young (ayoung2@oxy.edu), Isabel Geddes, Claire Weider, & Andrew Shtulman (shtulman@oxy.edu)
Department of Psychology, Occidental College

Abstract

Adults with extensive science education exhibit cognitive conflict when reasoning about counterintuitive scientific ideas, such as whether clouds have weight or whether bacteria need nutrients. Here, we investigated whether elementary-school-aged children show the same conflict and whether that conflict can be reduced by targeted instruction. Seventy-eight 5- to 12-year-olds verified, as quickly as possible, statements about life and matter before and after a tutorial on the scientific properties of life or matter. Half the statements were consistent with intuitive theories of the domain (e.g., "frogs reproduce") and half were inconsistent (e.g., "cactuses reproduce"). Participants verified the latter less accurately and more slowly than the former, both before instruction and after. Instruction increased the accuracy of participants' verifications for counterintuitive statements within the domain of instruction but not their speed. These results indicate that children experience conflict between scientific and intuitive conceptions of a domain in the earliest stages of acquiring scientific knowledge but can learn to resolve that conflict in favor of scientific conceptions.

Keywords: conceptual development, scientific reasoning, explanatory coexistence, intuitive theories

Introduction

Our first theories of natural phenomena are often incompatible with the scientific theories we learn later in life. We first conceive of heat as an invisible substance that flows in and out of objects rather than kinetic energy at the molecular level (Reiner, Slotta, Chi, & Resnick, 2000). We conceive of forces as properties imparted to objects, propelling them forward, rather than as interactions between objects, changing their velocity (McCloskey, 1983). Colds and flus are thought to be caused by cold air rather than a virus (Au et al., 2008). And lunar phases are thought to be caused by the earth's shadow on the moon rather than our changing view of the moon's illuminated surface (Trundle, Atwood, & Christopher, 2002).

Our first theories are known as folk theories, naïve theories, or intuitive theories. They are developed by children from a variety of inputs, including innate biases, firsthand experience, cultural artifacts, and cultural beliefs (Carey, 2009; Shtulman, 2017; Vosniadou, 1994). Intuitive theories play the same inferential role as scientific theories, helping us explain past events, predict future events, and intervene on present events (Gopnik & Wellman, 2012). They differ from scientific theories, however, in that they carve up the world into entities and processes that do not align with the true causes of natural phenomena.

One well-studied example of intuitive theories are children's theories of life (Hatano & Inagaki, 1994; Slaughter & Lyons, 2003; Stavy & Wax, 1989). Life is a metabolic state—the consumption of energy to further an organism's survival and reproduction—but young children do not know of the internal components of organisms that make metabolism possible. In the absence of such knowledge, they interpret "life," "living," and "alive" as descriptions of motion. Entities that move on their own are deemed alive, regardless of their metabolic status. Thus, preschoolers mistakenly classify moving but nonliving entities, like the sun and the clouds, as alive, and they mistakenly classify living but nonmoving objects, like plants and trees, as not alive. These mistakes persist until children conceive of life as supported by the interrelated functions of internal organs, typically by age ten.

Another well-studied example are children's theories of matter (Carey, 1991; Nakhleh, Samarapungavan, & Saglam, 2005; Smith, 2007). Matter is anything composed of atoms, but many such substances betray no perceptible sign of their underlying composition. Gases, vapors, and microscopic objects are all composed of atoms, but children can neither see them nor hold them, so they classify them as nonmaterial. They also deny that such entities have weight or take up space. Children also make the converse mistake of classifying nonmaterial entities that they can see or feel as matter, including echoes, shadows, and heat. This pattern persists until early adolescence, when children learn a particulate theory of matter in introductory physical science.

Learning to reinterpret phenomena covered by an intuitive theory through the lens of a scientific theory requires conceptual change, or knowledge revision at the level of individual concepts. Conceptual change has traditionally been viewed as a process of restructuring and replacement (Carey, 1985; Chi, 1992; Nersessian, 1989; Vosniadou, 1994). Intuitive theories are restructured to accommodate counterintuitive scientific information and are thus replaced in the process, in the same way that remodeling a house erases the footprint of its original layout.

This view has been challenged by recent research revealing that intuitive theories are not entirely erased by scientific theories and will, in fact, influence domain-relevant reasoning under cognitive load or cognitive impairment. In the domain of life, for instance, college undergraduates instructed to classify entities as "alive" or "not alive" as quickly as possible are prone to make the kinds of mistakes preschoolers make, classifying moving but nonliving things as alive and living but nonmoving things as not alive (Goldberg & Thompson-Schill, 2009). That is, undergraduates are less accurate at classifying plants as alive relative to animals, and they are less accurate at classifying dynamic objects (like clocks, geysers, comets,

and rivers) as not alive relative to static ones. They are also slower to do so. Similar results have been found for Alzheimer's patients with moderate dementia, who not only misclassify moving but nonliving entities as alive but also explicitly define life in terms of motion rather than metabolic activity (Zaitchik & Solomon, 2008). Even elderly adults without Alzheimer's Disease are inclined to make these errors (Tardiff, Bascandziev, Sandor, Carey, & Zaitchik, 2017), indicating that motion-based conceptions of life are pervasive across the lifespan and must be inhibited to reason about life as a metabolic process.

Early intuitions about matter also reemerge under cognitive load. Adults instructed to decide whether something is material or nonmaterial as quickly as possible will mistakenly classify gases and heft-less objects, like dust and snowflakes, as nonmaterial and mistakenly classify perceptible forms of energy, like rainbows and lightning, as material (Shtulman & Legare, 2019). Adults also make systematic mistakes in deciding whether an object will sink or float. An object's buoyancy is related to its density—a property that makes sense only if matter is composed of smaller particles. When adults are shown two balls of equal size, one made of wood and one made of lead, they judge that the wood ball is more likely to float than the lead one. But shown a large ball of wood and a small ball of lead, they take reliably longer to make the same judgment (Potvin & Cyr, 2017; Potvin, Masson, Lafortune, & Cyr, 2015).

Research over the past decade has revealed that this pattern is widespread (Shtulman & Lombrozo, 2016). Adults verify counterintuitive scientific ideas more slowly and less accurately than closely-matched intuitive ones in several domains, including astronomy, genetics, mechanics, thermodynamics, and evolution (Shtulman & Harrington, 2016; Shtulman & Valcarcel, 2012). And these effects been observed in several populations, including high schoolers (Babai, Sekal, & Stavy, 2010), undergraduate science majors (Foisy, Potvin, Riopel, & Masson, 2015), high school science teachers (Potvin & Cyr, 2017), and elderly adults (Barlev, Mermelstein, & German, 2018). Even professional physicists (Kelemen, Rottman, & Seston, 2013) and professional biologists (Goldberg & Thompson-Schill, 2009) exhibit cognitive conflict when reasoning about counterintuitive scientific ideas. Such conflict indicates that early intuitions about natural phenomena survives the acquisition of scientific knowledge in some form or another.

In previous research (Young, Laca, Dieffenbach, Hossain, Mann, & Shtulman, 2018), we sought to determine whether participants could be trained to verify counterintuitive scientific ideas more quickly and more accurately. We focused our investigation on statements about life and statements about matter. Some statements were intuitive (e.g., "bricks have weight," "goats need nutrients"), and others were counterintuitive (e.g., "dust has weight," "yeast needs nutrients"). Participants completed this task before and after a tutorial on the scientific properties of life or matter. The tutorials helped participants close the gap in accuracy between intuitive and counterintuitive statements within the domain of instruction but not the gap in latency. In other words, the tutorials were ineffective at reducing the immediate conflict elicited by counterintuitive statements (as indexed by response times), but they did help participants favor scientific responses over intuitive ones.

In the present study, we extended this line of research to elementary-school-aged children. Our motivation was threefold. First, children are in the earliest stages of learning science, and it's unclear whether their nascent scientific theories would pose a measurable challenge to their well-worn intuitive theories of the same phenomena. Second, any conflict that children experience between science and intuition may be more malleable than that experienced by adults, either because children's scientific theories are less developed (and thus more easily bolstered) or because their intuitive theories are less entrenched. Third, adapting our task for use with children may have pedagogical value if it proves to be an informative measure of early science learning or early scientific reasoning.

Our study followed the same protocol as Young et al. (2018), which included a pretest, a tutorial, and a posttest. At pretest, we expected children to show conflict between science and intuition, given that the children in our age range were beginning to learn about life and matter in school, but it was an open question whether that conflict would manifest itself in both response accuracy and response latency. Children might, for instance, verify counterintuitive statements less accurately than intuitive ones but show no difference in speed. At posttest, we expected children to verify counterintuitive statements more accurately within the domain of instruction, but it was an open question whether they would also verify those statements more quickly.

Method

Participants

Seventy-eight children in kindergarten through 6th grade participated. Their mean age was 8 years and 7 months, and they were approximately balanced for gender (37 female, 41 male). Children were recruited from public playgrounds and a children's museum, and they completed the study onsite.

Materials

Statement-Verification Task. We measured the conflict between science and intuition using a child-modified version of Shtulman and colleagues' statement-verification task. Children were presented with four types of scientific statements and asked to judge those statements as "true" or "false" as quickly as possible. Some statements were true from both a scientific perspective and an intuitive perspective ("tigers need nutrients"); some were false from both perspectives ("forks need nutrients"); some were true from a scientific perspective but false from an intuitive perspective ("bacteria need nutrients"), and some were false from a scientific perspective but true from an intuitive perspective ("fire needs nutrients"). The first two types of

statements will be referred to as *intuitive* and the latter two types as *counterintuitive*.

For each domain, statements were generated by pairing three predicates with 32 entities. In the domain of life, the predicates were "reproduces," "needs nutrients," and "grows and develops." In the domain of matter, the predicates were "has weight," "takes up space," and "is made of atoms." The biological predicates apply to all living things, but we predicted that children would be more inclined to apply them to entities that appear to move on their own. Likewise, the physical predicates apply to all material things, but we predicted that children would be more inclined to apply them to entities that can be seen or felt. These predictions were derived from prior work with adults (Young et al., 2018), as well as the extensive literatures on intuitive theories of life and matter referenced above.

We created the four types of statements by pairing predicates with four types of entities, as shown in Table 1. In the domain of life, those entities were animals (deemed alive by both science and intuition), inanimate artifacts and inanimate natural kinds (deemed alive by neither science nor intuition), plants and microorganisms (deemed alive by science but not by intuition), and animate natural kinds (deemed alive by intuition but not science). In the domain of matter, those entities were physical objects (deemed material by both science and intuition), abstract ideas (deemed material by neither science nor intuition), gases and other bulk-less or heft-less objects (deemed material by science but not by intuition), and the visible or tangible components of energy transfer (deemed material by intuition but not science).

Children completed the task on an iPad. Statements were displayed on the screen and children responded via touch screen. Twenty-two children opted into a version of the task that played audio recordings of the statements as they were displayed on the screen, thus supporting children who had difficulty reading independently. Audio recordings of each statement were generated via Apple's macOS text-to-speech engine. Children who listened to the audio-recorded stimuli received only four of the six predicates (randomly selected), due to the additional time required to play the recordings.

Tutorials. Children completed a tutorial on life or matter midway through the experiment. The tutorial on life emphasized that all living things need energy and nutrients, grow and develop, react to stimuli in their environment, and reproduce. It also addressed the misconception that life is synonymous with self-directed motion, providing examples of entities that do not appear to move on their own but are alive (e.g., moss) and entities that move on their own but are not alive (e.g., comets). The tutorial on matter emphasized that all matter occupies space, has weight, is made of atoms, and can undergo phase transitions. It also addressed the misconception that matter is synonymous with visibility or tangibility, providing examples of entities that cannot be seen or felt but are material (e.g., gases) and entities that can be seen or felt but are not material (e.g., lightning). Both tutorials contained a mixture of text, images, and videos and took approximately seven minutes to complete.

Table 1: Sample items used in the biological statements (top) and physical statements (bottom), organized by their role in scientific and intuitive views of the domain.

Is it alive?	Intuition: Yes	Intuition: No
Science: Yes	Rabbits Turtles Snails	Mushrooms Grass Bacteria
Science: No	Sun Wind Fire	Hammers Caves Shells

Is it matter?	Intuition: Yes	Intuition: No
Science: Yes	Bricks Ice Logs	Smoke Snowflakes Air
Science: No	Rainbows Shadows Heat	Dreams Songs Numbers

Procedure

Each study session proceeded in three phases. First, children verified 48 statements about life and 48 statements about matter (pretest). Next, they completed a tutorial on life or matter. Last, they verified 48 additional statements about life and 48 additional statements about matter (posttest). Children were randomized to tutorial condition—41 received the tutorial on life and 37 received the tutorial on matter.

Children completed the pretest and posttest in blocks. They saw a screen introducing a particular predicate (e.g., "Does it grow and develop?"), followed by 16 statements with that predicate (e.g., "Seaweed grows and develops"). Four of the statements were scientifically and intuitively true; four were scientifically and intuitively false; four were scientifically true but intuitively false; and four were scientifically false but intuitively true. The statements were randomly ordered within a block, and the blocks were randomly ordered within the testing phase, meaning that biological and physical predicates were intermixed. Children saw the same predicates at pretest and posttest, but those predicates were paired with 16 new entities. The entities presented at pretest for half the children were presented at posttest for the other half and vice versa. This variable was crossed with whether children received the tutorial on life or the tutorial on matter to ensure that the effects of the tutorial were not confounded with the effects of particular pretest or posttest items.

Results

The statement-verification task yielded two outcome measures: response accuracy and response latency. We analyzed each outcome with a linear mixed model (LMM), with statement type (intuitive or counterintuitive), test

(pretest or posttest), instruction (instructed or uninstructed), and their interactions as fixed effects and by-participant and by-predicate random effects. The response latency model additionally adjusted for whether children read or listened to the statements. Models with maximal random effects structures had convergence issues, and thus we followed the procedure recommended by Bates, Kliegl, Vasishth, and Baayen (2015) to guide removal of random effects that were not supported by the data. Inference for fixed effects was carried out via Type 3 likelihood ratio test (LRT) model comparison.

The present analyses collapse across tutorial domain (life or matter) for lack of space and focus instead on whether the statements were targeted by instruction or not. Children did verify biological statements more accurately than physical statements (87% vs. 75%). However, mean response latencies were similar across domains, as were the effects of the tutorial.

Finally, we did not consider age effects in the following analyses. In general, older children were more accurate, faster, and learned more from instruction. However, the overall pattern of reported results was similar across the age distribution of our sample.

Response Accuracy

As seen in Figure 1, there was an effect of statement type, such that children verified intuitive statements more accurately than counterintuitive statements, LRT $\chi^2(1) = 12.18$, $p < .001$. Overall, accuracy for intuitive statements was 18.4% greater than accuracy for counterintuitive statements, 95% CI [12.1, 24.7].

Additionally, there was a three-way interaction between statement type, test period, and instruction, LRT $\chi^2(1) = 25.17$, $p < .001$. We were specifically interested in children's response to instruction. In the instructed domain, children's posttest accuracy for counterintuitive statements was 11.9% greater than their pretest performance, 95% CI [9.4, 14.4]. However, pretest and posttest scores were similar for intuitive statements in the instructed domain and similar for both statements types in the uninstructed domain. Thus, instruction was effective at improving children's accuracy at verifying counterintuitive scientific ideas within the targeted domain.

Response Latency

Following prior research, we analyzed response latencies for correctly verified statements only. Before doing so, we first removed latencies shorter than 250 ms, as responses produced that quickly were unlikely to have been deliberate. Second, we calculated the mean response latency across participants and statements (M = 2743 ms) and removed latencies more than two standard deviations above the mean (i.e., latencies greater than 7565 ms). We then calculated the mean latency for each predicate, separating intuitive statements from counterintuitive statements and pretest statements from posttest statements.

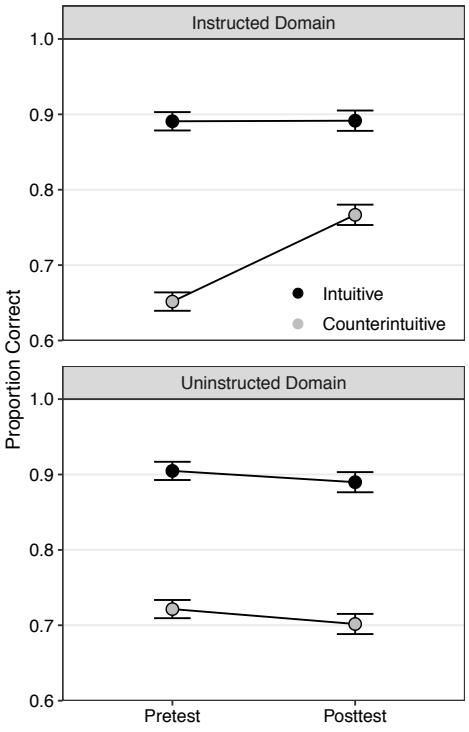

Figure 1: Estimated proportion of correct verifications by statement type, test, and instruction. Error bars represent standard errors.

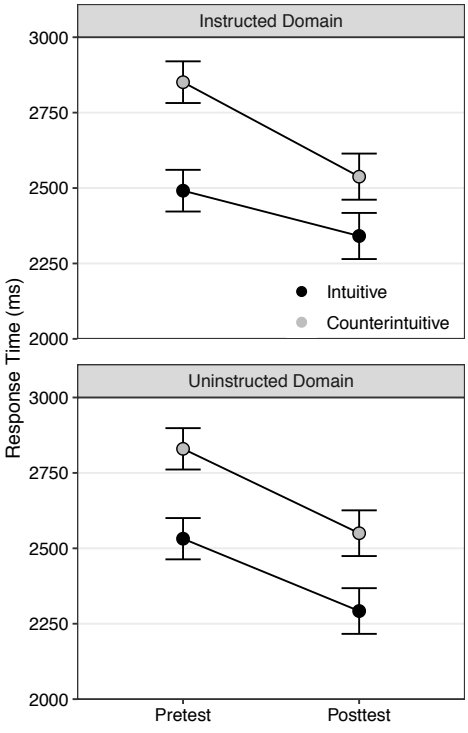

Figure 2: Estimated response latency for correct verifications by statement type, test, and instruction. Error bars represent standard errors.

As seen in Figure 2, there was an effect of statement type, such that children correctly verified counterintuitive statements more slowly than intuitive statements, LRT $\chi^2(1) = 90.16$, $p < .001$. Response latencies for counterintuitive statements were 278 ms slower than response latencies for intuitive statements, 95% CI [222, 335].

Additionally, there was an effect of test, such that children correctly verified statements faster at posttest than pretest, LRT $\chi^2(1) = 6.22$, $p = .013$. Response latencies at posttest were 246 ms faster than response latencies at pretest, 95% CI [70, 421]. We suspect this effect was due to increased familiarity with the task, as it did not vary by instruction and statement type (three-way interaction: LRT $\chi^2(1) = 1.14$, $p = .285$).

Discussion

Do elementary schoolers exhibit cognitive conflict when reasoning about counterintuitive scientific ideas? Our findings suggest they do. Children between ages five and twelve were slower and less accurate at verifying scientific statements that conflict with their intuitive theories of life or matter (e.g., "bacteria grow and develop," "steam is made of atoms") relative to closely-matched statements that accord with those theories (e.g., "tigers grow and develop," "rocks are made of atoms"). Instructing children on the scientific properties of life or matter increased their accuracy for counterintuitive statements in the instructed domain but not in the uninstructed domain. However, instruction did not reduce the gap in response latency between counterintuitive and intuitive statements, at least in comparison to the uninstructed domain. These findings indicate that children experience conflict between scientific ideas and intuitive ideas, despite limited exposure to science, but this conflict can be resolved in favor of scientific ideas with targeted instruction.

Our findings parallel those of Young et al. (2018), who administered the same task to adults. Adults were faster and more accurate overall, but both children and adults verified counterintuitive statements more slowly and less accurately than closely-matched intuitive statements. The effect of instruction was also similar across age groups, increasing participants' accuracy at verifying counterintuitive statements but not their speed. Thus, the same signatures of cognitive conflict observed in adults were observed in children ten to fifteen years younger.

Our findings accord with other findings on the speed and accuracy of children's scientific reasoning, documented by Vosniadou et al. (2018). Vosniadou and colleagues asked third- and fifth-graders to sort physical and biological items into one of two categories: a category that emphasized the item's intuitive features or a category that emphasized its scientific features. The categories were characterized by exemplars rather than by labels. For instance, on one trial participants decided whether water should be grouped with other liquids (coke, lemonade, milk) or with other forms of H_2O (ice, vapor, snow). Children of all ages preferred intuitive categories over scientific categories, and they took longer to make their judgments when they opted for the scientific category instead. Vosniadou et al.'s findings, like our findings, suggest that children must suppress an intuitive conception of the target item in order to endorse a competing scientific conception.

Vosniadou and colleagues did not administer a tutorial to their participants, and it's open question whether instructing participants on the scientific properties of the target items would change the nature of their categorizations. They did, however, measure executive function skills—namely, set-shifting ability and inhibitory control—and they found that children with higher executive function were more likely to categorize the target items by their scientific properties and were also faster to do so. Children with higher executive function have also been found to learn more from science instruction in the domain of vitalist biology (Bascandziev, Tardiff, Zaitchik, & Carey, 2018). Future research is needed to determine whether executive function plays a role in children's statement verifications as well. If it does, executive function tasks could be administered alongside our statement-verification task as a diagnostic for assessing young children's understanding of science and their receptiveness to science instruction.

One limitation of the current study is that we sampled children who had already begun learning the scientific properties of life and matter in school. Younger children (i.e., preschoolers) would likely show a different pattern of results. Without any scientific knowledge of life or matter, they should view statements like "bubbles have weight" and "dandelions need nutrients" as demonstrably false. Their accuracy for such statements would be lower, but their responses should be faster. Thus, in comparison to older children, younger children should show a larger gap in response accuracy between intuitive and counterintuitive statements but a smaller gap in response latency. And teaching preschoolers about the scientific properties of life or matter should increase the gap in latency, not reduce it. There are challenges, however, to adapting the task for use with preschoolers. Preschoolers are unlikely to know the meaning of terms like "atoms," "nutrients," and "reproduces," and the alternative terms they do know may not carry the same meaning. "Has babies," for example, may not be a substitute for "reproduces" because the offspring of plants, fungi, and bacteria are rarely referred to as "babies."

In conclusion, we have shown that tensions between science and intuition emerge early in the acquisition of scientific knowledge. While children can be taught to privilege scientific ideas over intuitive ones, the conflict between them—as manifested in slower response times for statements that elicit both ideas—appears to be immediate and robust.

Abstract

Many studies have investigated the roles that area and number play in visual quantity estimation. Yet, recent work has shown that *perceived* area is not equal to true, mathematical area. This simple fact calls into question many findings in numerical cognition and suggests a new theoretical perspective: that area estimation plays a dominant role in visual quantity estimation. We examine two 'case studies': (1) a 'general magnitude' account of visual quantity estimation, which posits bi-directional influences between area and number. In contrast with prior work, controlling for perceived area reveals a unidirectional relation between area and number (Experiments 1 and 2), and (2) acuity of area and number estimation (Experiment 3). We show how an understanding of the perception of area forces a reevaluation of several findings concerning the relative acuity of number and area estimation. Combined, and in contrast to many prior studies, our findings suggest a dominant role of area in visual quantity estimation.

Keywords: approximate number, number, area, perception

Introduction

The ability of human adults, infants, and nonhuman animals to rapidly approximate large numbers is a cornerstone of research on numerical cognition. This propensity supposedly relies on an evolutionary ancient system -- the Approximate Number System -- which serves as a foundation for downstream numerical and mathematical ability (Cantlon & Brannon, 2007; Dehaene, 1997; Feigenson et al., 2004; Xu & Spelke, 2000).

Yet this widely accepted notion also raises questions: in our evolutionary environment, how often would number have been the most relevant cue for approximating quantity? Area perception rather than number perception would seem to have been prioritized evolutionarily: if foraging for food, for example, would you prefer to have 100 berries, or 50 berries four times in volume? Nevertheless, approximate area has been vastly understudied relative to approximate number (but see Brannon et al., 2006; Lourenco et al., 2012; Odic et al., 2013). In hundreds of studies, numerosity is assumed to be perceived independently of area (and other continuous dimensions; e.g., average size, density, or convex hull), thereby relegating area manipulations to little more than pesky control conditions in 'bigger' questions about number.

However, visual area approximation has recently emerged as an ability in its own right. Recent work has revealed that the visual approximation of area is guided by a cue other than area (Yousif & Keil, 2019). Instead, visual approximations of area are roughly equivalent to the sum of objects' dimensions rather than their product, resulting in potentially large distortions of perceived space. This continues to be true after accounting for confounds such as numerosity and perimeter. This phenomenon is known as the 'Additive Area Heuristic' (AAH).

An area estimation heuristic raises questions about the relation between area and number. While numerous papers have documented bidirectional 'congruity effects' between area and number (e.g., Hurewitz et al., 2006, Walsh, 2003), perceived area (per the AAH) may not be influenced by numerosity; these past results may arise because of a confound between *perceived* area and numerosity (Yousif & Keil, 2019). Only when unconfounded is it possible to understand the relation between number and area in visual quantity estimation.

The AAH calls into question many other findings in the field of numerical cognition, raising the possibility that many of them can also be explained by a failure to account for perceived area. For example: if numerosity does not influence the perception of area, does the perception of area influence the perception of numerosity? Though this question has been asked before (e.g., Hurewitz et al., 2006), it has operated under a false premise: that true, mathematical area accurately reflects the percept of area. Thus, to the extent that area perception is best captured not by mathematical area but by some other means (e.g., the AAH), this question ought to be revisited.

If perceived area is dissociable from mathematical area, it suggests a reinterpretation – and, in some cases, a reexamination – of many prior findings. The present work explores the relation between number and *perceived* area in the context of two 'case studies': (1) a 'general magnitude' account of number and area, and (2) relative area and

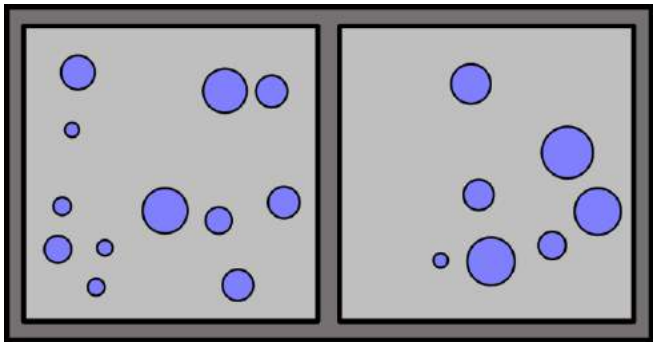

Figure 1. An example display for Experiments 1-3. Most observers report that the left panel is greater in area, despite the fact that the two are equal in true area. However, the left panel is greater in 'Additive Area' (which causes the illusion).

number estimation acuity. In both cases, we demonstrate that accounting for perceived area reveals a qualitatively different pattern from what has been previously observed.

The current study

In a first experiment, we assess the 'general magnitude' account of number and area approximation by examining how increased 'Additive Area' (AA) affects numerosity estimation. To do so, we manipulate AA while number is held constant. Most work has suggested bidirectional interactions between area and number (e.g., Hurewitz et al., 2006), but recent work has shown that manipulating number *does not* influence perceived area (Yousif & Keil, 2019). Here, we show that this relation is in fact unidirectional in that perceived area influences number judgments to a large extent. In a second experiment, we follow up on this by pitting AA and number against each other in a maximally implicit design, by having one group of observers make area judgments and another group of observers make number judgments on the exact same stimuli. Again, we demonstrate influences of area on number perception. In a third experiment, we assess number estimation acuity under different conditions (e.g., controlling AA vs. true, mathematical area). Number acuity appears to differ dramatically depending on how area is controlled.

Experiment 1: Area influences number

Mimicking a design in prior work (Yousif & Keil, 2019), we created stimuli for which additive area, mathematical area (MA), and number could be manipulated independently. AA is used as a proxy for perceived area, given the prior work showing that AA captures perceived area more accurately than MA. Observers viewed two stimuli side-by-side and were simply asked to indicate which was greater in number.

Method

Participants 100 observers were recruited via Amazon Mechanical Turk. Observers were excluded if and only if they began but did not complete the task (5 observers). All observers consented prior to participation, and these studies were approved by the IRB at Yale University.

Stimuli All of the stimuli were generated via custom software written in Python with the PsychoPy libraries (Peirce, 2007). The aim was to create pairs of stimuli that varied in either AA, MA, or number while the other values were equated. For each stimulus pair, we randomly generated an initial set of discs (ranging from 20 pixels to 100 pixels in diameter, with a buffer of at least 10 pixels between any two discs), then pseudo-randomly generated a second set of objects based on a given AA/MA/Number ratio (specific values varied for each experiment; see, e.g., Table 1). The displays always had between 20 and 26 discs (the initial set always having 20). Stimulus pairs were generated randomly until a pair met both the AA, MA, and number criteria, at which point that pair would be rendered another time and saved. The second stimulus always had more area (whether AA or MA) than the initial stimulus. For the details of how AA, MA, and number covaried, see Table 1. All discs were rendered with a thin, black border (4-pixel stroke width). The images depicted in Figure 1 are representative of those used in the experiment.

Procedure The task itself was administered online via Amazon Mechanical Turk, using custom software. On each

Number Ratio	Type	AA Ratio	MA Ratio
1.00	**AA Constant**	1.00	1.00
		1.00	1.05
		1.00	1.10
	MA Constant	1.00	1.10
		1.05	1.10
		1.10	1.10
1.15	**AA Constant**	1.15	1.05
		1.15	1.10
		1.15	1.15
	MA Constant	1.10	1.10
		1.15	1.10
		1.20	1.10
1.30	**AA Constant**	1.20	1.10
		1.20	1.15
		1.20	1.20
	MA Constant	1.15	1.15
		1.20	1.15
		1.25	1.15

Table 1. The number, AA, and MA ratios for Experiment 1.

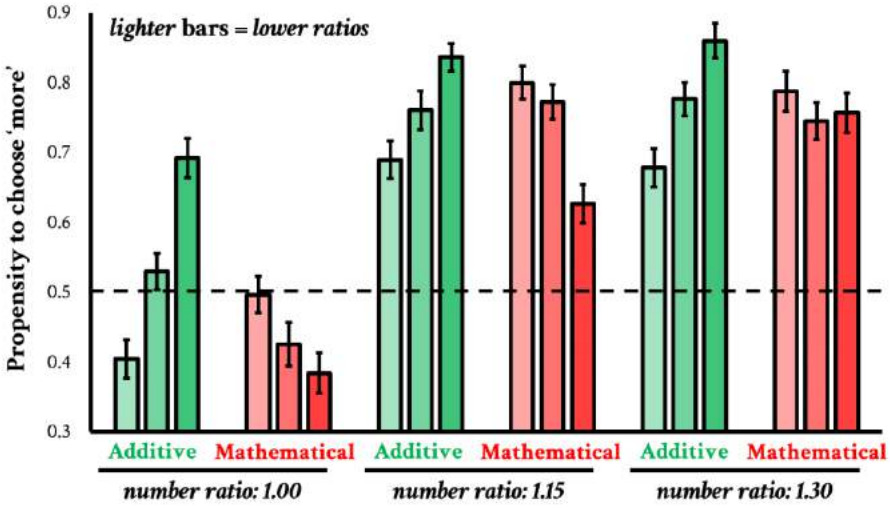

Figure 2. Results from Experiment 1. Three number ratios are represented along the x-axis. Green bars represent MA-controlled sets, where AA varied in three steps. Red bars represent AA-controlled sets, where MA varied in three steps. Lighter bars represent lower ratios. E.g., for the leftmost set of green bars, the lightest bar represents the lowest AA ratio and the darkest bar represents the highest AA ratio. Error bars represent +/- 1 SE. The dashed line represents chance performance.

trial, observers saw two spatially separated sets of lavender-colored dots, presented side-by-side in the center of the screen, with 50 pixels of space in between (see Figure 1). Each stimulus was 400 pixels by 400 pixels. The stimuli were always counterbalanced so that an equal number containing more AA, MA, or number appeared on each side of the screen. Observers were instructed to press 'q' if the image on the left had more cumulative number, and 'p' if the image on the right had more cumulative number. They were also given an additional, explicit warning to respond according to number regardless of area. The stimuli stayed on the screen for 700ms, but there was no time limit on responses. Between each trial, there was a 1000ms ITI. Observers completed 72 trials. All trials were presented in a unique random order for each participant. Observers completed two representative practice trials before beginning the actual task.

Results and Discussion

The results of Experiment 1 are shown in Figure 2. An ANOVA revealed a main effect of numerosity, confirming that observers were able to discriminate on the basis of numerosity, $F(2,93)=149.65$, $p<.001$, $\eta_p^2=.61$. Further, increased MA generally *decreased* the probability that an observer would select a stimulus as more numerous $F(2,93)=12.78$, $p<.001$, $\eta_p^2=.12$. Yet, critically, increased AA *did* increase the likelihood that observers would indicate a stimulus was more numerous, $F(2,93)=49.08$, $p<.001$, $\eta_p^2=.34$ (and this pattern was observed across all ratios, as can be seen in Figure 2). Note that this is in stark contrast to other results showing that changes in numerosity *do not* influence area judgments (Yousif & Keil, 2019).

These results (in combination with prior results) suggest a relation between perceived area and perceived number – but one that is unidirectional (i.e., perceived area influences number, but not vice versa). In contrast to a 'general magnitude' account, which predicts positive relations between various magnitudes, the present results suggest area may play a dominant role in quantity estimation. However, these results do not reveal the extent to which number is perceived independently of AA. The following experiments aim to address that question.

Experiment 2: Number versus area

To understand whether the results of Experiment 1 could be explained by a General Magnitude account (e.g., a 'more-is-more' heuristic), we directly pitted AA and number against each other in a between-subjects experiment. In this way, we can directly assess the effect of increased area on number perception and vice versa. Borrowing from previous work which dissociated AA and MA (Yousif & Keil, 2019we manipulated both AA and number while holding the other constant. In one condition, observers made area judgments; in another condition, a separate group of observers made number judgments.

Method

Participants 200 observers were recruited via Amazon Mechanical Turk (100 for each condition). Observers were excluded if and only if they began but did not complete the task (3 observers, all in the area condition). All observers consented prior to participation, and these studies were approved by the IRB at Yale University.

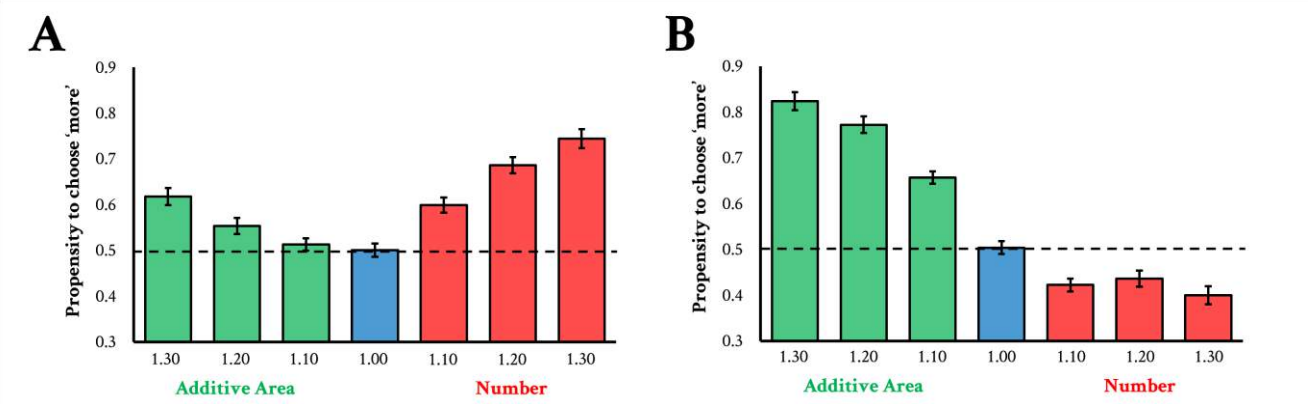

Figure 3. Results from number discriminations (A) and area discriminations (B) in Experiment 2. The green bars represent trials where AA varied (in a 1.1, 1.2, or 1.3 ratio) but number was held constant, while the red bars represent trials where number varied (in a 1.1, 1.2, or 1.3 ratio) while AA was held constant. The y-axis represents the propensity to choose 'more', whether that be more number or more area. Error bars represent +/- 1 SE. The dashed line represents chance performance.

Stimuli The stimuli for this experiment were generated in the same way as those of the prior experiment. The same stimuli were used for each condition. There were seven ratios: three in which number varied (in a 1.1, 1.2, and 1.3 ratio) while AA was held constant, three in which AA varied (in a 1.1, 1.2, and 1.3 ratio) while number was held constant, and one in which both were held constant (to serve as a baseline).

Procedure The procedure is identical to Experiment 1 except that observers completed 84 trials instead of 72. For the number judgment condition, the instructions were the same. For the area judgment condition, observers were told the following: "Your task is simply to indicate which set of circles has **more cumulative area**. In other words: if you printed the images out on a sheet of paper, which would require more total ink?" Later, they were told: "The sets of dots will sometimes vary in number, but the number of dots does not matter. Instead, you should answer only which has more area, regardless of number."

Results and Discussion

The results of the number discrimination condition are shown in Figure 3a. Observers indicated that images containing more discs were more numerous ($t(96)=11.85$, $p<.001$, $d=1.20$). However, observers also indicated that images with greater perceived area (but were equal in number) were more numerous ($t(96)=5.35$, $p<.001$, $d=.54$). In other words, it appears that the perception of area affects the perception of numerosity.

The results of the area discrimination condition are shown in Figure 3b. Observers indicated that images greater in AA were greater in perceived area ($t(96)=17.60$, $p<.001$, $d=1.76$). However, observers were slightly below chance when selecting between displays equal in AA but differing in numerosity ($t(96)=5.81$, $p<.001$, $d=.58$). Thus, all else equal, observers judged displays with more number to have *less* area – replicating the findings of recent work (Yousif & Keil, 2019) but in stark contrast to many existing studies (e.g., Hurewitz et al., 2006).

These results suggest three primary conclusions. First, the results of the number discrimination condition cannot be explained by a response bias to simply pick the image with 'more' on some dimension. Indeed, observers indicated that displays with more number appeared to have less cumulative area. Second, this experiment provides converging evidence with Experiment 1 that perceived area influences perceived numerosity (i.e., people confuse 'more' perceived area for 'more' number). Third, and critically, this experiment shows that number does *not* influence perceived area. This indicates a unidirectional relation between perceived area and number (in contrast to views that posit bidirectional interactions between these domains of magnitude; e.g., Walsh, 2003). There *is* an effect of number on area (such that more number is related to less perceived area) – but our findings challenge a general magnitude account, and are contrary to prior work (e.g., Hurewitz et al., 2006).

Experiment 3: Number and area acuity

A third experiment assessed number discrimination acuity (i.e., the level of precision with which observers can discriminate two non-symbolic numerosities) in a more traditional number acuity task, while controlling for either AA or MA. We predicted that performance will be lower when AA is controlled. The goal of this study is to ascertain whether there is a 'true' number discrimination acuity (or area discrimination acuity, for that matter), as this would bear on studies that have tried to interpret relative acuity in each domain (e.g., Lourenco et al., 2012; Odic et al., 2013).

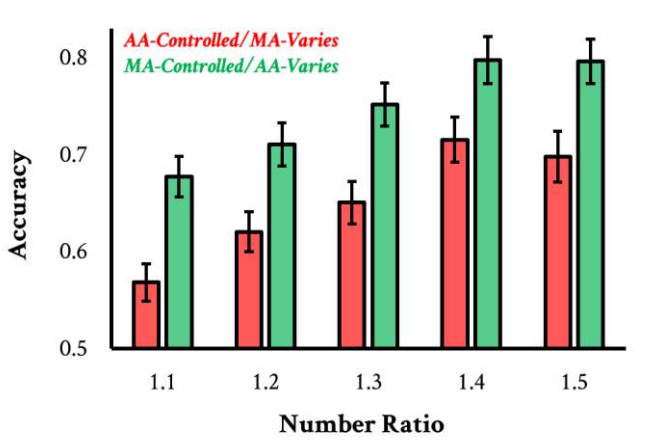

Figure 4. Results from Experiment 3. Five number ratios are represented along the x-axis. Green bars represent MA-controlled sets, where AA varied. Red bars represent AA-controlled sets, where MA varied in three steps. The y-axis represents accuracy for number discriminations, i.e., the proportion of time observers chose the display that was more numerous. Error bars represent +/- 1 SE. The x-axis corresponds to chance performance.

Method

All elements of the experimental design were identical to those of Experiment 1, except as stated below. 80 new observers were tested via Amazon Mechanical Turk. One observer was excluded for failing to complete the task. Observers completed number discriminations at five distinct ratios: 1.10, 1.20, 1.30, 1.40, and 1.50. Half the trials were controlled for AA, and the other half of trials were controlled for MA (while allowing the other dimension to vary). The displays always had between 10 and 30 discs (the initial set having 10 half the time, and 20 the other half of the time). Observers completed 80 trials.

Results and Discussion

The results of Experiment 3 are displayed in Figure 4. Accuracy was indeed lower for the AA-controlled trials, $t(79)=6.97$, $p<.001$, $d=.79$, and this was independently true for each number ratio ($ps<.002$). Of the 80 observers tested, 66 were as good or better at discriminating number in the MA-controlled condition (where AA varied; $p<.001$). Critically, performance across the two different area controls was highly correlated $r(78)=.69$, $p<.001$ – about as highly as performance in each condition was to itself (MA-control: $r=.66$; AA-control: $r=.65$).

Once again, differences in perceived area strongly influenced perceived number. While prior work has made conclusions on the basis of relative acuity (e.g., Lourenco et al., 2012; Odic et al., 2013), these results suggest that comparing acuity across dimensions should be interpreted with caution. In other words: what is 'true' number acuity, if number acuity varies so greatly across different area controls? This is especially relevant for developmental studies which make claims about relative acuity across development (e.g., Odic et al., 2013).

General Discussion

Our first two experiments demonstrate that accounting for perceived area challenges our understanding of the relation between area and number. In particular, we have shown an apparent unidirectional relation between area and number such that area influences number judgments but not the other way around. This contrasts with work documenting a bidirectional relation and forces a reconsideration of the roles of area and number in quantity estimation.

In addition, we have shown how accounting for perceived area challenges our understanding of area and number *acuity*. In particular, number discrimination acuity appears to vary dramatically depending on whether AA or MA is controlled (as revealed explicitly in Experiment 3, but also evident in the results of Experiment 1). This raises questions about prior studies that have interpreted the relative acuity of area and number discriminations (e.g., Lourenco et al., 2012; Odic et al., 2013).

Conclusion: is number special?

Is number special in visual processing? The answer to this question seems obvious: the field of numerical cognition is perhaps one of the largest and most prominent in all of cognitive science, and the ability to discriminate visual number is often thought to be the foundation of our 'core' mathematical competency (Feigenson et al., 2004). Yet, this seemingly obvious conclusion is not evident from first principles. In what evolutionary context would an approximate number system have been more critical for survival than approximate area or volume? Few plausible examples come to mind.

Our studies do not ask whether number is special *somewhere* in the mind. Instead, the question is whether number is special *visually* – or even whether, as more extreme views have suggested, it is a visual feature (like color or orientation; e.g., Anobile et al., 2016; Burr & Ross, 2008). This question has been heavily discussed (e.g., Durgin, 2008; Leibovich et al., 2017). Yet this debate, here and elsewhere, has been plagued by the use of artificial stimuli with a seemingly unbounded number of possible confounds. How can one hope to isolate numbers amidst the continuous dimensions of area, perimeter, convex hull, density, average element size, variance in element size, variability in inter-dot distance, etc. (some of which are often negatively correlated with one another)? This list is only a small subset of all the continuous cues that *may* be related to the perception of number.

The present work is not immune to such confounds. However, our studies do provide clear predictions about a particular cue, AA, (rather than a collection of them) and its relation to numerosity. This prediction is borne out of the theoretical position that visual number estimation is unlikely to have been prioritized in evolution. More consequentially, we find clear influences of area on number, but not the other way around.

What should be said, then, about the perception of number? We have presented evidence for area playing a

dominant role in quantity estimation, automatically and irresistibly influencing the estimation of number. Yet, number discrimination ability across very different displays (i.e., displays controlled for either AA or MA), is highly correlated – suggesting that number estimation cannot be explained by perceived area (or by some superficial strategy that operates differently over different sets of stimuli). Thus, while the human visual system is clearly able to extract number, it does not seem to be wired to do so first and foremost. Indeed, area may play the leading role in quantity estimation. This also suggests that number may not be a true visual feature as has been claimed (see Burr & Ross, 2008).

Across several paradigms and stimuli configurations, one salient pattern consistently emerges: area influences number approximation but not the other way around. This is a fundamentally different pattern from what has been observed in tasks that do not control for AA, and these findings offer a new theoretical perspective on the relation between number and area in vision: that number may not be so special after all.

Statistical learning generates implicit conjunctive predictions

Abstract

The cognitive system readily detects statistical relationships where the presence of an object predicts a specific outcome. What is less known is how the mind generates predictions when multiple objects predicting different outcomes are present simultaneously. Here we examine the rules with which predictions are made in the presence of two objects that are associated with two distinct outcomes. In three experiments, participants first implicitly learned that an object predicted a specific target location in a visual search task. When two objects predicting two different target locations were present simultaneously, participants were reliably faster to find the target when it appeared in the conjunctive location than in disjunctive locations. This was true even if participants were not consciously aware of the association between the objects and target locations. The results suggest that in the presence of multiple predictors, statistical learning generates implicit expectations about the outcomes in a conjunctive fashion.

Keywords: Implicit learning, regularities, conjunctive inference, visual search, attention

Introduction

The visual environment contains widespread regularities in terms of co-occurrences between individual objects or events over time. For example, the red light turns on after the yellow light at traffic intersections, and thunder follows lightening in a thunderstorm. The mind can detect such regularities effortlessly, automatically, or even outside of conscious awareness. One form of extracting these regularities (i.e., A predicts B) is statistical learning, which involves the detection of statistical relationships among individual objects over space or time (Fiser & Aslin, 2001; Saffran, Aslin, & Newport, 1996; Turk-Browne, Jungé, & Scholl, 2005). Statistical learning occurs incidentally to ongoing tasks and quickly after a few exposures to the regularities (Turk-Browne, Scholl, Johnson, & Chun, 2010), and proceeds without explicit awareness or conscious intent (Baker, Olson, & Behrmann, 2004).

The implicit extraction of regularities has a number of consequences on the representations of the individual objects that comprise the regularities. Recent studies suggest that statistical learning spontaneously biases attention to the co-occurring objects in a persistent manner (Zhao, Al-Aidroos, & Turk-Browne, 2013; Yu & Zhao, 2015), interferes with summary perception (Hall, Mattingley, & Dux, 2015; Zhao, Ngo, McKendrick, & Turk-Browne, 2011), updates object representations (Yu & Zhao, 2018a, Yu & Zhao, 2018b), facilitates the compression of information in working memory (Brady, Konkle, & Alvarez, 2009; Zhao & Yu, 2016), and leads to automatic transitive inferences (Luo & Zhao, 2018).

To date, research on statistical learning has predominately focused on the relationship between individual objects or events. However, in the broader visual environment different objects or events are often present at the same time where each predicts a specific outcome. For example, excessive smoking can lead to cardiovascular problems as well as lung complications, while excessive alcohol consumption can lead to similar cardiovascular problems and also potential brain damage. When excessive smoking occurs with excessive drinking, what consequences would follow? In this example, a conjunctive inference would generate an expectation that satisfies both predictors (i.e., cardiovascular problems), whereas a disjunctive inference would generate an expectation that satisfies either one of the two predictors (i.e., cardiovascular problems, lung complications, and potential brain damage). When people are presented with both predictors at the same time, what kind of inference do they make automatically (Mendelson, 2009)? Understanding automatic conjunctive or disjunctive inferences can help illuminate reasoning biases such as the conjunction fallacy where people mistakenly judge a conjunctive statement to be more probable than a disjunctive statement (Tversky & Kahneman, 1983).

In the current study, we examine the rules with which predictions are made in the presence of two objects that are associated with two distinct outcomes. In a visual search paradigm, participants first viewed one color circle and then searched for a target (a rotated T) in an array during the exposure phase. Each color predicted a specific location of the target in the array. For example, after a blue circle the target would always appear in the top half of the array; and after a red circle the target would always appear in the left half of the array. The question is: Where was the target expected to appear when both the blue circle and the red circle were present at the same time? A conjunctive prediction would suggest that the target was expected to appear in the top left quadrant of the array, whereas a disjunctive prediction would suggest that the target was expected to appear in the top half or the left half of the array. Importantly, at the inference phase when both color circles were present, the target was equally likely to appear in any quadrant of the array. We used response time of target search during the inference phase to gauge in which location the target was expected to appear.

In Experiments 1 and 2, we found that participants were reliably faster to find the target when it appeared in the conjunctive quadrant than in the disjunctive quadrant. This was true even if participants were not consciously aware of the association between the color circles and target locations during debriefing. We further replicated the finding in Experiment 3 where the two predictors were two feature dimensions in one object. This effect was equally strong whether participants implicitly learned the association or were explicitly told about the association.

Experiment 1

This experiment examined which type of inference participants would make when they saw a pair of colors, each predicting a different half of the array.

Participants

A total of 120 students (81 female, mean age=20.0 years, SD=2.3) from the University of British Columbia (UBC) participated for course credit.

Stimuli

For each trial in the experiment, participants saw one colored circle first, followed by a search array (Figure 1). The color circle could appear in one of four colors (R/G/B): red (255/0/0), yellow (255/255/0), blue (0/0/255), or grey (192/192/192). Each circle subtended 2.2° of visual angle. For each search array following the circle, 16 objects were presented in an invisible 8-by-8 grid. Each cell in the grid subtended 1.7° of visual angle. The 8-by-8 grid was divided into four 4-by-4 quadrants, where each quadrant was separated from the adjacent two quadrants by 2.2° of visual angle. Each quadrant contained four objects, where no row or column in the quadrant could be empty.

Out the 16 objects in each array, 15 were distractors in "L" shapes, randomly pointing to the left or right. There was only one target in each array, which was a rotated "T", randomly determined to be pointed to the left or right. Participants were asked to find the target "T" and indicate which direction the "T" was pointing (left or right) by pressing a key on the keyboard, as quickly and accurately as possible.

For each trial, the color circle was presented on the screen for 1000ms. Followed by a 1000ms blank screen, the search array appeared on the screen until response. There was a 1000ms blank screen interval between trials.

Procedure

Participants first completed the exposure phase (Figure 1). During exposure, one color circle appeared on the screen at a time followed by a visual search array. Each of the four colors was presented for 40 times during exposure, resulting in a total of 160 trials (the order of the trials was random). Each color predicted that the target "T" in the search array always appeared in a unique half of the array (the top, left, bottom, or right half). For example, after the blue circle, the target always appeared in the top half of the array. After the red circle, the target always appeared in the left half of the array. The target location within each half of the array was counter-balanced between the two quadrants (e.g., counterbalanced between top-left and top-right quadrants for the top half of the array), and the target location within each quadrant was randomly determined. The color-location associations were randomly determined for each participant but remained fixed throughout the experiment for the participant.

We wanted to examine whether there were differences in conjunctive inferences made from explicit knowledge versus incidentally learned predictions. Therefore, half of the participants (N=60) were randomly selected to be explicitly told about the associations between colors and target locations before exposure (explicit condition), and the other half were told to only pay attention to the color circle and search for the target (implicit condition).

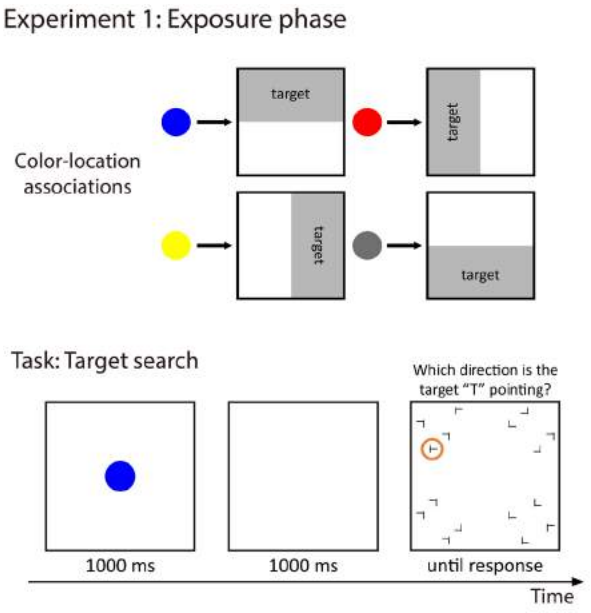

Figure 1. Experiment 1 exposure phase. Each color circle predicted the location of the target in the subsequent search array. In the visual search task, participants saw the color circle first, and then searched for a target (the rotated "T") and judged the direction of target as quickly and accurately as possible.

After exposure, participants completed the inference phase (Figure 2). During this phase, two color circles were presented at the same time in each trial, followed by a search array. There were six unique color pairs. Each color pair and the following search array were presented four times in the inference phase in a random order, resulting in 24 trials in total. In each trial, the target appeared in any of the four quadrants with equal probability (the top-left, top-right, bottom-left, and bottom right quadrant). The location of the target within the quadrant was randomly determined.

Since the target now appeared in the four quadrants with equal probability, faster response time in target search in a given quadrant would indicate that the participant prioritized that quadrant for target search. This would mean that the

participant expected that the target would appear in that quadrant, suggesting a prediction of where the target would appear after seeing the two color circles.

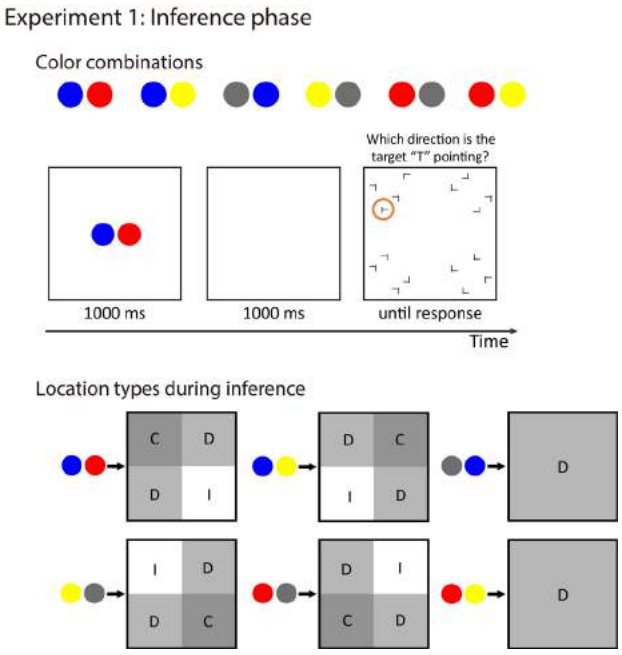

Figure 2. Experiment 1 inference phase. The four colors were combined into six color pairs. The pairs were presented first, followed by a search array. The target appeared in all four quadrants with equal probability following each pair. Based on the color-location associations during exposure, there were four types of target location following each color pair. These include the locations consistent with a conjunctive inference (C), locations consistent with a disjunctive inference (D), and the impossible locations (I).

During the inference phase, the two color circles were presented next to each other horizontally or vertically (randomly determined), and the order of the two colors for each pair was counter-balanced. Based on the color-location associations during exposure, there were four types of target location following each pair: locations consistent with a conjunctive inference (C), locations consistent with a disjunctive inference (D), and the impossible locations where the target would never appear based on the prior color-location associations (I). In both the explicit and implicit conditions, participants were only told that they would now see two color circles appearing simultaneously on the screen before each search array, and they were asked to search for the target as in the exposure phase.

After the inference phase, participants in the implicit condition also completed a test phase to probe their awareness of the color-location associations. They were asked where the target would appear (the top, left, bottom, and right half of the array) after seeing each of the four colors, so guessing would result in an accuracy of 0.25 in the test phase.

Results and Discussion

The test phase accuracy for participants in the implicit condition was 0.51, reliably above chance [chance=0.25, p<.001], indicating that participants in the implicit condition have successfully learned the color-location associations.

We then analyzed the responses time (RT) of correct trials in the inference phase to see what type of inferences participants made when they saw the color pairs. We grouped the trials in the inference phase into four types: conjunction, disjunction (2 quadrants vs. 4 quadrants), and impossible. Take the blue and red pair, the blue circle previously predicted that the target would appear in the top half of the array and the red circle previously predicted that the target would appear in the left half of the array. This means that the top left quadrant was the conjunctive quadrant, the top right and the bottom left quadrants were the disjunctive quadrants, and the bottom right quadrant was the impossible quadrant. For example, faster RT in the conjunctive quadrant would indicate that participants expected the target would appear in that quadrant, suggesting a conjunctive prediction. We plotted the RT in each type of quadrant in the inference phase (Figure 3).

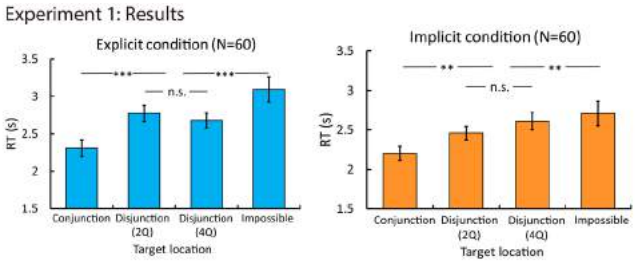

Figure 3: Experiment 1 results. The response time (RT) for each type of trials was graphed separately for the explicit and implicit conditions (Error bar reflect ± 1 SE; **p<.01, ***p<.001).

A 2 (condition: explicit vs. implicit, between-subjects) × 4 (trial type: conjunctive, 2-quadrant disjunctive, 4-quadrant disjunctive, and impossible quadrant, within-subjects) mixed-design ANOVA revealed a significant main effect of trial type [F(3,354)=16.04, p<.001, η_p^2=0.12], but no main effect of condition [F(1,118)=3.27, p=.07, η_p^2=0.03], or interaction [F(3,354)=1.29, p=.28, η_p^2=0.01]. This suggests that participants attended to the four quadrants differently during the inference phase, suggesting that they made specific predictions about where the target would appear. There was no significant difference in RT across different trial types when the knowledge was explicitly told vs. when the knowledge was implicitly learned. Post-hoc Tukey HSD tests showed that RT in the impossible trials was reliably slower than that in the other three types of trials [p's<.03], the RT in the 2-quadrant disjunction trials was not reliably different from that in the 4-quadrant disjunction trials [p=.99], and the RT in the conjunction trials was reliably faster than both the 2-quadrant and 4-quadrant disjunction trials [p's<.01]. We then performed planned contrast analysis separately for the implicit and explicit conditions. The 2-quadrant and 4-quadrant disjunction trials were combined as

one category in the analysis. For both conditions, RT in conjunction trials was significantly faster than that in disjunction trials, which in turn was faster than that in the impossible trials [p's<.01].

Additionally, we examined RT performance separately for learners (whose test phase accuracy>0.25, N=42) and non-learners (whose test phase accuracy≤0.25, N=18). For learners, RT in conjunction trials was significantly faster than that in disjunction trials [p=.014], which in turn was faster than that in the impossible trials [p<.001]. For non-learners, RT in conjunction trials was marginally faster than that in disjunction trials [p=.09], but there was no difference in RT for the disjunction and impossible trials [p=.97]. This suggests that participants with higher test phase accuracy showed the effect more robustly than participants with lower test phase accuracy did.

These results suggest that when two objects each predicting a different outcome were presented at the same time, participants automatically made a conjunctive prediction which contained the shared property of the different outcomes.

Experiment 2

One explanation for faster RT in the conjunction trials in Experiment 1 was that the conjunctive quadrant was smaller in terms of spatial scope than the disjunctive quadrants. The smaller spatial scope might have facilitated visual search, leading participants to prioritize the conjunctive quadrant over the other quadrants. To examine this possibility, in Experiment 2, we aimed to equate the spatial scope of conjunctive and disjunctive quadrants in the inference phase.

Participants

A new group of 120 students (95 female, mean age=20.2 years, SD=1.9) from UBC participated for course credit.

Stimuli and Procedure

The stimuli and procedure in the experiment were the same as those in Experiment 1, except for one critical difference: During the exposure phase, after a color circle, the target could appear in three of the four quadrants. This means that in the inference phase, for each pair of color circles, two of the quadrants on the array would be consistent with a conjunctive inference, and the other two quadrants would be consistent with a disjunctive inference (Figure 4).

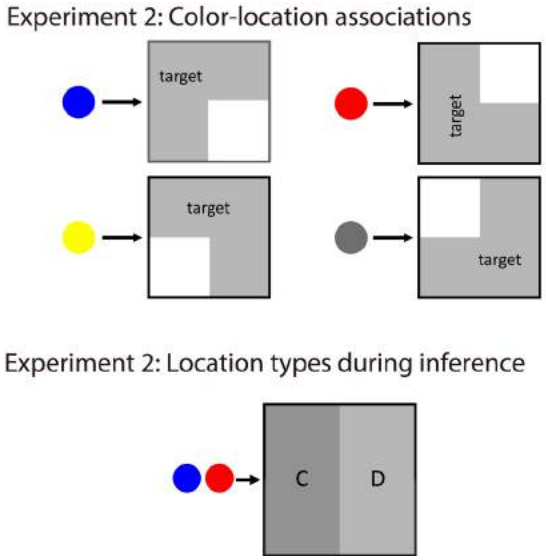

Figure 4: Experiment 2 paradigm. The stimuli and procedure were the same as those in Experiment 1, except that each color predicted the target would appear in three quadrants in the array during exposure. Consequently, two quadrants during the inference phase were consistent with a conjunctive inference (C), and the other two were consistent with a disjunctive inference (D).

Results and Discussion

The test phase accuracy for participants in the implicit condition was 0.31, which was not reliably above chance [p=0.11], suggesting that participants in the implicit condition did not successfully learn the color-location associations during exposure. This may be due to the difficulty of learning that the target could appear in three quadrants instead of two.

A 2 (condition: explicit vs. implicit, between-subjects) × 2 (trial type: conjunctive vs. disjunctive, within-subjects) mixed-design ANOVA revealed a marginal interaction between condition and trial type [$F(1,118)=3.865$, p=.05, η_p^2=0.03], but no main effect of condition [$F(1,118)=0.40$, p=.53, η_p^2=0.00], or trial type [$F(1,118)=1.22$, p=.27, η_p^2=0.01]. We then compared the RT in conjunction and disjunction trials separately for the implicit and explicit conditions. In the explicit condition, RT in conjunction trials was reliably faster than that in disjunction trials [$t(1,59)=2.03$, p<.05, d=0.24], but in the implicit condition, the RT in conjunction trials was not reliably different from that in disjunction trials [$t(1,59)=0.66$, p=.51, d=0.07] (see Figure 5).

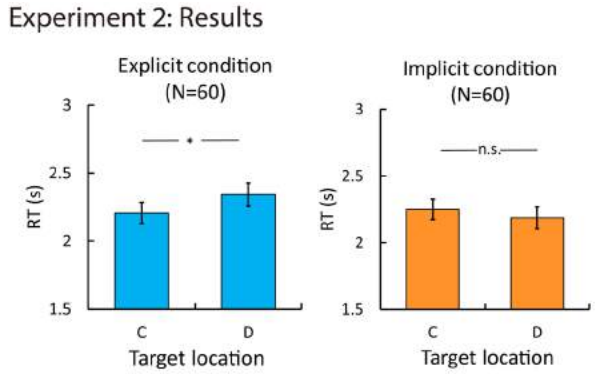

Figure 5: Experiment 2 results. The RT for each type of trials (C for conjunction, D for disjunction) was graphed separately for the explicit and implicit conditions (Error bar reflect ± 1 SE; *p<.05).

These results suggested that when participants learned the color-location associations, they automatically made conjunctive inferences when they saw two color circles, even when the conjunctive quadrants were of the same spatial scope as the disjunctive quadrants. On the other hand, if participants did not successfully learn the color-location associations, they failed to make such conjunctive inferences.

Experiment 3

In Experiments 1 and 2, the two color circles were presented simultaneously side by side during the inference phase to elicit conjunctive predictions. An alternative method to represent conjunctions is to combine two features into one object, such as combing the color red and the shape square into a red square (Treisman & Gelade, 1980; Singer & Gray, 1995). Therefore, in this experiment, we tested this alternative presentation where the two predictors were combined into a new object, rather than manifesting them as two different objects, to elicit conjunctive predictions.

Participants

A new group of 60 students (47 female, mean age=19.6 years, SD=2.6) from UBC participated for course credit. In the current experiment, only the implicit condition was examined (we did not examine the explicit condition due to time constraints in participant recruitment).

Stimuli and Procedure

The stimuli and procedure in the experiment were the same as those in Experiment 1, except for two critical differences.

First, during the exposure phase there were two color circles (red and blue, as described in Experiment 1) and two textured circles (dotted and stripy circles, see Figure 6). The two color circles were always presented with a filled texture, and the two textured circles were always presented in a black color (R/G/B: 0/0/0). The two color circles always predicted two parallel halves of the array (e.g., the top and bottom halves), and the two textured circles predicted the other two halves of the array (e.g., the left and right halves). The assignment of a color or texture to a given half was randomized across participants, but remained constant for a given participant throughout the experiment.

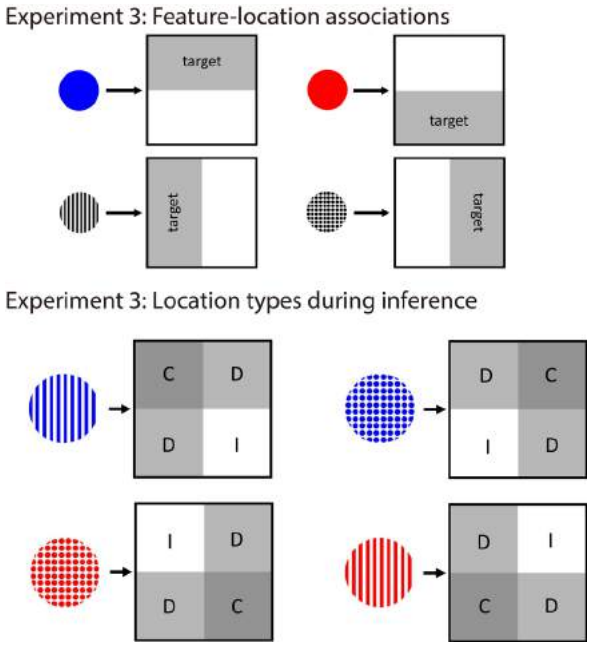

Figure 6. Experiment 3 paradigm. Two unique colors and two unique textures each predicted the target location in the following array during exposure. Circles with both a unique color and a unique texture were presented one at a time during inference. The trial types during the inference phase were the same as those in Experiment 1.

Second, during the inference phase participants saw one circle at a time on the screen. Each circle contained one of the two colors and one of the two textures presented in the exposure phase (i.e., a blue stripy circle, a blue dotted circle, a red stripy circle, or a red dotted circle). There were four trials for each unique colored textured circle. Since a color and a texture never predicted two parallel halves during exposure, there were three types of trials in the inference phase as in Experiment 1: conjunctive trials where the target could appear in a conjunctive quadrant (C), disjunctive trials where the target could appear in a disjunctive quadrant (D), and impossible trials where the target never appeared in a quadrant based on exposure (I).

Results and Discussion

The test phase accuracy in this experiment was 0.33, which was marginally above chance [p=.07], suggesting that learning was weak.

As before, we analyzed RT of correct trials in the inference phase (Figure 7). A one-way repeated-measures ANOVA revealed a main effect of trial type [$F(2,118)=5.32$, $p<.001$, $\eta_p^2=0.24$]. Post-hoc Tukey HSD tests showed that there was reliable RT difference in the conjunction trials and impossible trials [$p<.01$]. Other pair-wise comparisons were numerically similar to those in Experiment 1, but not statistically reliable [p's>.11]. These results suggest that the participants made conjunctive predictions when the two

features were presented in a new object. However, the effect was not as strong as in previous experiments.

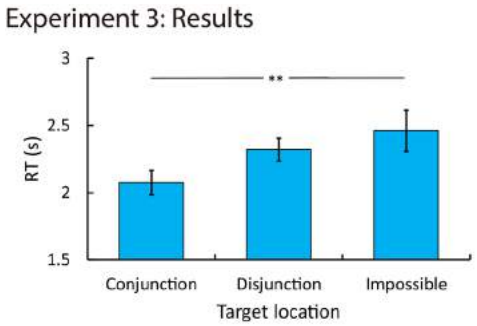

Figure 7: Experiment 3 results. The RT for each type of trials was graphed (Error bar reflect ± 1 SE; **p<.01).

General Discussion

In this study, we examined how predictions were made in the presence of two objects that were associated with two different outcomes. Using a visual search paradigm, unique colors (all three experiments) or textures (Experiment 3) predicted a specific location of the target in the search array in the exposure phase. In the inference phase, we examined where the target was expected to appear when two color circles (Experiments 1 and 2) or a circle with a unique color and a unique texture (Experiment 3) were presented at the same time. Importantly in the inference phase, the target appeared in any location with equal probability.

Based on the speed of visual search (RT), we found that participants were faster to find the target when it appeared in a conjunctive quadrant than in disjunctive or impossible quadrants. This was surprising because the simultaneous presentation of the two circles or features did not necessarily dictate a conjunctive or disjunctive inference. For example, just because the blue circle previously predicted the top half and the red circle previously predicted the left half, the blue and red circles together, in principle, could predict either the top left quadrant (conjunctive inference), or the top left, top right, and bottom left quadrants (disjunctive inference). What we found was that participants automatically prioritized the conjunctive quadrant over the disjunctive quadrant in the visual search task, at the presence of the two predictors. This conjunctive preference occurred without prior instructions, or even explicit awareness of the color-location associations.

Across all three experiments, participants were not told anything about where to look when two color circles or two different features were presented together. Therefore, the differential RT in the conjunctive quadrant indicated an automatic expectation resulting from the previously learned color- or feature-location associations during exposure.

In Experiment 1, the expectation to find the target in a location consistent with a conjunctive prediction was equally strong whether participants implicitly learned the associations or were explicitly told about the associations. However, in Experiment 2 when there was no successful learning of the associations in the implicit condition, this conjunctive prediction was absent. In fact, the conjunctive prediction was only present when participants were explicitly told about the color-location associations in the explicit condition. This suggests that the conjunctive predictions were only made when participants have successfully learned the color-location associations, either after implicit statistical learning, or after explicit instructions of these associations.

It is important to note that the disjunctive quadrants in the current study were exclusively disjunctive, not containing the conjunctive quadrant. The fact that the RT in the disjunction trials was faster than that in the impossible trials but slower than that in the conjunction trials suggests that the impossible quadrant may be inhibited and the conjunctive quadrant may be prioritized during visual search.

We think that both the learning process and the prediction process were implicit. In all three experiments, participants were not told anything about the object-location associations before the exposure phase in the implicit condition. That is, participants were only told to find the target in the search array and were not told that the object before each search array predicted the location of the target. Therefore, learning of the associations in the implicit condition was automatic and implicit. In the inference phase, there was no explicit instruction as to what to do with the two objects. Again, participants were only told to find the target in the search array. Moreover, the target in the inference phase could appear in any quadrant with equal probability, so the two objects were completely task-irrelevant. Finally, the RT was relatively fast so any explicit reasoning process may not occur in the period between object presentation and target search. For these reasons, we think that the conjunctive predictions were implicit.

There are several limitations of the current study. First, we only presented two objects side by side, or two features in a single object as cues. There might be other ways to represent such joint cues using semantic categories (e.g., if object A is associated with the "dog" category and object B is associated with the "small" category, will people automatically predict Chihuahuas and Pomeranians upon seeing A and B?). Second, we only used RT as a measure to probe whether participants made conjunctive or disjunctive predictions. A richer method can involve eye tracking to see the timecourse of attention to the different quadrants in the inference phase. Finally, there was a confound of proximity in the current study, where the conjunctive quadrant was spatially closer to the disjunctive quadrant than to the impossible quadrant. This could explain the RT advantage of the disjunction trials over the impossible trials.

In conclusion, the current results suggest that in the presence of multiple predictors, statistical learning generates automatic expectations about the outcomes in a conjunctive fashion.

Abstract

It has been argued that semantic categories across languages reflect pressure for efficient communication. Recently, this idea has been cast in terms of a general information-theoretic principle of efficiency, the Information Bottleneck (IB) principle, and it has been shown that this principle accounts for the emergence and evolution of named color categories across languages, including soft structure and patterns of inconsistent naming. However, it is not yet clear to what extent this account generalizes to semantic domains other than color. Here we show that it generalizes to two qualitatively different semantic domains: names for containers, and for animals. First, we show that container naming in Dutch and French is near-optimal in the IB sense, and that IB broadly accounts for soft categories and inconsistent naming patterns in both languages. Second, we show that a hierarchy of animal categories derived from IB captures cross-linguistic tendencies in the growth of animal taxonomies. Taken together, these findings suggest that fundamental information-theoretic principles of efficient coding may shape semantic categories across languages and across domains.

Keywords: information theory; language evolution; semantic typology; categories

Introduction

Cross-linguistic studies in several semantic domains, such as kinship, color, and numeral systems, suggest that word meanings are adapted for efficient communication (see Kemp, Xu, & Regier, 2018 for a review). However, until recently it had remained largely unknown to what extent this proposal can account for soft semantic categories and inconsistent naming, that could appear to pose a challenge to the notion of efficiency, and how pressure for efficiency may relate to language evolution. Recently Zaslavsky, Kemp, Regier, and Tishby (2018; henceforth ZKRT) addressed these open questions by grounding the notion of efficiency in a general information-theoretic principle, the Information Bottleneck (IB; Tishby, Pereira, & Bialek, 1999). ZKRT tested this formal approach in the domain of color naming and showed that the IB principle: (1) accounts to a large extent for cross-language variation in color naming; (2) provides a theoretical explanation for why observed patterns of inconsistent naming and soft semantic categories may be efficient; and (3) suggests a possible evolutionary process that roughly recapitulates Berlin and Kay's (1969) discrete implicational hierarchy while also accounting for continuous aspects of color category evolution. However, it is not yet clear to what extent these results may generalize to other semantic domains, especially those that are fundamentally unlike color.

Here we test the generality of this theoretical account by considering two additional semantic domains: artifacts and animals. These domains are of particular interest in this context because they are qualitatively different from color, they have not previously been comprehensively addressed in terms of efficient communication, and at the same time it is possible to apply to them the same communication model that has previously been used to account for color naming.

First, we consider naming patterns for household containers. This is a semantic domain in which categories are known to overlap and generate inconsistent naming patterns (Ameel, Storms, Malt, & Sloman, 2005; Ameel, Malt, Storms, & Assche, 2009). Although it has previously been shown that container naming in English, Spanish, and Chinese is efficient compared to a large set of hypothetical naming systems (Xu, Regier, & Malt, 2016), that demonstration did not consider the full probability distribution of names produced by different speakers, did not explicitly contrast monolingual and bilingual speakers, and was based on a smaller set of stimuli than we consider here. In this work we show that the full container-naming distribution in Dutch and French, including overlapping and inconsistent naming patterns, across a large set of stimuli, both in monolinguals and bilinguals, is near-optimally efficient in the IB sense.

Second, we test the evolutionary account of ZKRT in the case of animal categories. By analogy with Berlin and Kay's implicational hierarchy of color terms, Brown (1984) proposed an implicational hierarchy for the evolution of animal taxonomies based on cross-language comparison. We show that aspects of this hierarchy are captured by a sequence of efficient animal-naming systems along the IB theoretical limit. Our results also support the view that both perceptual and functional features shape animal categories across languages (Malt, 1995; Kemp et al., 2018).

The remainder of this paper proceeds as follows. First, we review the theoretical framework and formal predictions on which we build. We then present two studies that apply this approach to the aforementioned semantic domains.

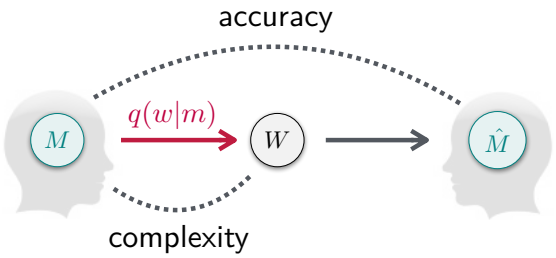

Figure 1: Communication model adapted from ZKRT. A speaker communicates a meaning M by encoding it into a word W according to a naming distribution $q(w|m)$. This word is then interpreted by the listener as $\hat{M}$. Complexity is a property of the mapping from meanings to words, and accuracy is determined by the similarity between M and $\hat{M}$.

Theoretical framework and predictions

We consider here the theoretical framework proposed by ZKRT, which is based on a simplified interaction between a speaker and a listener (Figure 1), formulated in terms of Shannon's (1948) communication model. The speaker communicates a meaning m, sampled from $p(m)$, by encoding it into a word w, generated from a naming (or encoder) distribution $q(w|m)$. The listener then tries to reconstruct from w the speaker's intended meaning. We denote the reconstruction by $\hat{m}_w$, and assume it is obtained by a Bayesian listener.[1] These meanings, m and $\hat{m}_w$, are taken to be mental representations of the environment, defined by distributions over a set $\mathcal{U}$ of relevant features. For example, if communication is about colors, then $\mathcal{U}$ may be grounded in a perceptual color space, and each color would be mentally represented as a distribution over this space.

Under these assumptions, efficient communication systems are those naming distributions that optimize the Information Bottleneck (IB; Tishby et al., 1999) tradeoff between the complexity and accuracy of the lexicon. Formally, complexity is measured by the mutual information between meanings and words, i.e.:

$$I_q(M;W) = \sum_{m,w} p(m)q(w|m)\log\frac{q(w|m)}{q(w)}, \qquad (1)$$

which roughly corresponds to the number of bits used to encode meanings into words. Accuracy is inversely related to the discrepancy between m and $\hat{m}_w$, measured by the expected Kullback–Leibler (KL) divergence between them:

$$\mathbb{E}_q[D[m\|\hat{m}_w]] = \mathop{\mathbb{E}}_{\substack{m\sim p(m)\\ w\sim q(w|m)}}\left[\sum_{u\in\mathcal{U}} m(u)\log\frac{m(u)}{\hat{m}_w(u)}\right]. \qquad (2)$$

Accuracy is defined by $I_q(W;U) = \mathbb{E}_q[D[\hat{m}_w\|m_0]]$, where m_0 is the prior representation before knowing w, and maximizing accuracy amounts to minimizing equation (2).[2]

[1] The reconstruction of a Bayesian listener with respect to a given naming distribution is defined by $\hat{m}_w = \sum_m q(m|w)m$.

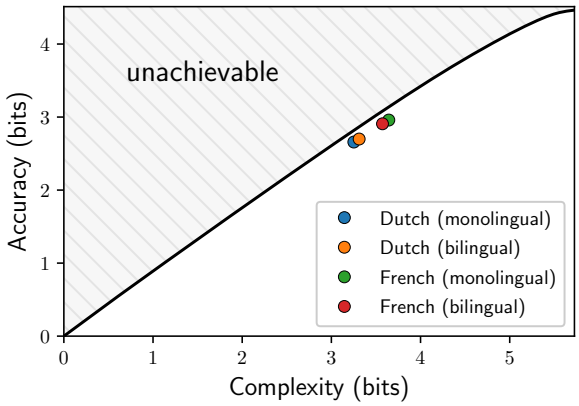

Figure 2: The black curve is the IB theoretical limit of efficiency for container naming, obtained by varying β. Points above this curve cannot be achieved. Complexity and accuracy tradeoffs in the four naming conditions are near-optimal.

Achieving maximal accuracy may require a highly complex system, while minimizing complexity will result in a non-informative system. Efficient systems are thus pressured to balance these two competing goals by minimizing the IB objective function,

$$\mathcal{F}_\beta[q] = I_q(M;W) - \beta I_q(W;U), \qquad (3)$$

where $\beta \geq 0$ controls the efficiency tradeoff. The optimal systems, $q_\beta(w|m)$, achieve the minimal value of equation (3) given β, denoted by $\mathcal{F}^*_\beta$, and evolve as β gradually shifts from 0 to ∞. Along this trajectory they become more fine-grained and complex, while attaining the maximal achievable accuracy for their level of complexity. This set of optimal systems defines the theoretical limit of efficiency (see Figure 2).

If languages are pressured to be efficient in the IB sense, then for a given language l with naming system $q_l(w|m)$, two predictions are made. (1) Deviation from optimality, or *inefficiency*, should be small. This is measured by $\varepsilon_l = \frac{1}{\beta_l}(\mathcal{F}_{\beta_l}[q_l] - \mathcal{F}^*_{\beta_l})$, where β_l is estimated such that ε_l is minimized. (2) The *dissimilarity* between q_l and the corresponding IB system, q_{β_l}, should be small. This is evaluated by a dissimilarity measure (gNID) proposed by ZKRT. In addition, ZKRT suggested that languages evolve along a trajectory that is pressured to remain near the theoretical limit.

These predictions were previously supported by evidence from the domain of color naming. To apply this approach to other domains, i.e. to instantiate the general communication model, two components must be specified: a *meaning space*, which is the set of meanings the speaker may communicate; and a prior, $p(m)$, also referred to as a *need distribution* (Regier, Kemp, & Kay, 2015), since it determines the frequency with which each meaning needs to be communicated. In the following sections we present two studies that

[2] See (Zaslavsky et al., 2018) for detailed explanation.

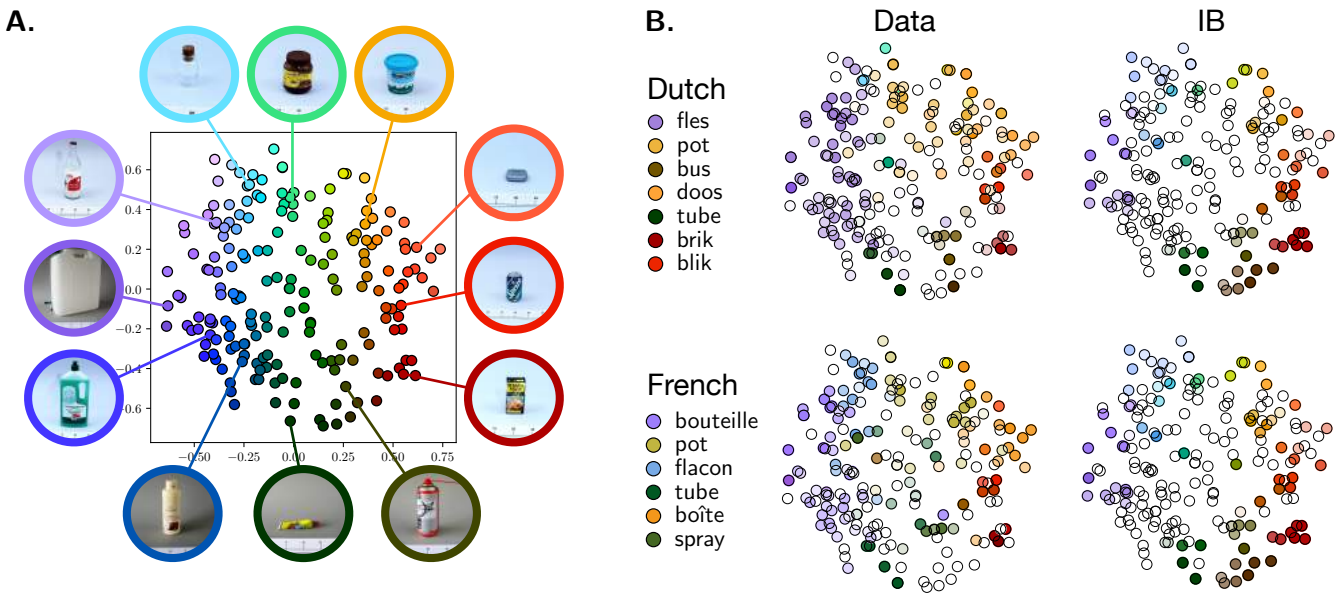

Figure 3: **A**. Two dimensional nMDS embedding and color coding of the containers stimulus set used by White et al. (2017). Images show a few examples. **B**. Monolingual naming distributions for Dutch (upper left) and French (lower left), together with their corresponding IB systems (right column), are visualized over the 2D embedding shown in (A). Each color corresponds to the color centroid of a container category, w, based on the color map in (A). Colors show category probabilities above 0.4, and color intensities reflect the values between 0.4 and 1. White dots correspond to containers for which no category is used with probability above 0.4. Legend for each language shows only major terms.

follow this approach and test its predictions in qualitatively different semantic domains.

Study I: Container names

The goal of this experiment is to test the theoretical predictions derived from IB in the case of container naming. It is not clear whether previous findings for color would generalize to this case for several reasons. First, the representation of artifacts is likely to involve more than just a few basic perceptual features, unlike color. Second, categories in this domain are believed to be strongly shaped by adaptation to changes in the environment (Malt, Sloman, Gennari, Shi, & Wang, 1999). At the same time, container categories tend to overlap, as in the case of color categories, posing a similar theoretical challenge to explain this observation in terms of communicative efficiency. Finally, the bilingual lexicon in this domain has been extensively studied, and it has been shown that bilingual naming patterns tend to converge (Ameel et al., 2005, 2009). However, it is not yet clear whether this convergence, or compromise, comes at a cost in communicative efficiency, or whether it may actually be formalized and explained in terms of efficiency.

Data. To address these open questions, we consider sorting and naming data collected by White et al. (2017), relative to a stimulus set of 192 images of household containers (see Figure 3A for examples). This set is substantially larger than those used in previous container-naming studies (e.g. Malt et al., 1999; Ameel et al., 2005), thus providing a better representation of this semantic domain. In the naming task, 32 Dutch and 30 French monolingual speakers, as well as 30 bilingual speakers, were asked to provide names for the containers in the stimulus set. Bilingual participants performed the task once in each language. The container-naming distribution in each of the four conditions (language $\times$ linguistic status) is defined by the proportion of participants in that condition that used the word w to describe a container c. A separate sorting task was performed by 65 Dutch speakers, who were asked to organize all containers into piles based on their overall qualities. Participants were also allowed to form higher-level clusters by grouping piles together. White et al. (2017) evaluated the similarity between two containers, denoted here by $\mathrm{sim}(c, c')$, based on the number of participants that placed them in the same pile or cluster (see White et al., 2017 for detail). In both tasks, participants were instructed not to take into account the content of the object (e.g., water).

Model. We ground the meaning space in the similarity data, following a related approach proposed by Regier et al. (2015) and Xu et al. (2016). While these data are from Dutch speakers, there are only minor differences in perceived similarities among speakers of different languages (Ameel et al., 2005). Therefore, we assume that these similarity judgments reflect a shared underlying perceptual representation of this domain. We take $\mathcal{U}$ to be the set of containers in the stimulus set, and define the mental representation of each container c by the similarity-based distribution it induces over the domain, $m_c(u) \propto \exp(\gamma \cdot \mathrm{sim}(c, u))$, where γ^{-1} is taken to be the

empirical standard deviation of $\mathrm{sim}(c, u)$. In contrast with the case of color, in which these mental representations were grounded in a standard perceptual space, here there is no standard perceptual space for containers, and so our assumed underlying perceptual representation requires further validation, which we leave for future work. We define the need distribution, $p(m_c)$, by averaging together the least informative (LI) priors for the different languages, as proposed by ZKRT. We used only the monolingual data for this purpose, and regularized the resulting prior by adding $\epsilon = 0.001$ to it and renormalizing.

Results

We estimated the theoretical limit of efficiency for container naming by applying the IB method (Tishby et al., 1999), as ZKRT did in the case of color naming, here with 1500 values of $\beta \in [0, 1024]$. We evaluated the empirical complexity and accuracy in the four naming conditions by entering the corresponding naming distributions in the equations for $I_q(M;W)$ and $I_q(W;U)$. The results are shown in Figure 2 and Table 1. It can be seen that container naming in Dutch and French lie near theoretical limit, both for monolinguals and bilinguals, and that bilinguals achieve similar levels of efficiency as monolinguals (Table 1). In all four cases, the corresponding IB solution is at $\beta_l \approx 1.2$, suggesting that there is only a weak preference for accuracy over complexity in this domain, as also found for color naming.

Consistent with the empirical observations of convergence in the bilingual lexicon, the complexity-accuracy tradeoffs in bilinguals are closer to each other (Figure 2, orange and red dots) compared to the monolingual tradeoffs (Figure 2, blue and green dots). This may be explained by a need to reduce the complexity of maintaining two naming systems simultaneously, while achieving monolingual-like levels of efficiency in each language. To test this possibility, we compared two joint French-Dutch systems that bilinguals may employ: one that randomly selects one of the two monolingual systems to name objects, and another that randomly selects one of the two bilingual systems. We found a 0.16% reduction in the complexity of the joint bilingual system compared to the joint monolingual system. Although this is a small effect, it may accumulate across domains to have a substantial impact. In addition, our simple calculation did not take into account similar word forms, which may also reduce complexity (Ameel et al., 2005). Thus, this finding suggests that the convergence in the bilingual lexicon may be shaped, at least in part, by pressure for efficiency.

The remainder of our analysis focuses on the monolingual systems, as they are more distinct and presumably more representative of each language. To get a precise sense of how challenging it may be to reach the observed levels of efficiency, we compared the actual naming systems to a set of hypothetical systems that preserve some of their statistical structure. This set was constructed by fixing the conditional distributions of words, while shifting how they are used by applying a random permutation of the containers. For each language we constructed $10,000$ such hypothetical systems. Table 1 shows that these hypothetical systems are substantially less efficient than the actual systems, and are also less similar to the IB systems. In fact, both languages achieve better (lower) scores than all of their hypothetical variants, providing a precise sense in which they are near-optimal according to IB. One possible concern is that this outcome may be a result of the LI prior, which was fitted to the naming data. To address this, we repeated this analysis with a uniform need distribution. The results in that case are similar (not shown), although as expected the fit to the actual systems is not as good compared to the LI prior.

Table 1: Evaluation of the IB container-naming model. Lower values indicate a better fit of the model. Values for hypothetical systems are averages $\pm$SD over $10,000$ systems.

		Inefficiency	Dissimilarity
Dutch	monolingual	0.16	0.11
	bilingual	0.17	0.12
	hypothetical	0.29 ($\pm$0.02)	0.59 ($\pm$0.05)
French	monolingual	0.18	0.11
	bilingual	0.17	0.09
	hypothetical	0.31 ($\pm$0.01)	0.56 ($\pm$0.06)

The low dissimilarity scores for the actual languages, shown in Table 1, suggest that the observed soft category structure in this domain may also be accounted for by the IB systems. This is indeed supported by a fine-grained comparison between the naming distribution in both languages and their corresponding IB systems. To see this, we embedded the 192 containers in a 2-dimensional space by applying non-metric multidimensional scaling (nMDS) with respect to the similarity data, similar to Ameel et al. (2009). This was done using the scikit-learn package in Python. We initialized the nMDS procedure with a solution for the standard metric MDS that achieved the best fit to the similarity data out of 50 solutions generated with random initial conditions. For visualization purposes, we assigned a unique color to each container. The resulting 2D embedding and color coding of the containers stimulus set are shown in Figure 3A.

The monolingual systems in Dutch and French are shown in Figure 3B, together with their corresponding IB systems. These two IB systems are very similar, although not identical, which is not surprising given that the naming patterns in Dutch and French are fairly similar. Both the actual systems and the IB systems exhibit soft category structure and similar patters of inconsistent naming, as shown by the white dots. In addition, since each category is colored according to its centroid, similarity between the category colors together with their spatial distribution reflect the similarity between the full naming distributions. For example, the IB systems have a category that is similar to *fles* and *bouteille*, as well as a category that is similar to *doos* and *boîte* in Dutch and French respectively, although these categories in the IB systems are a bit narrower. The IB systems also capture the

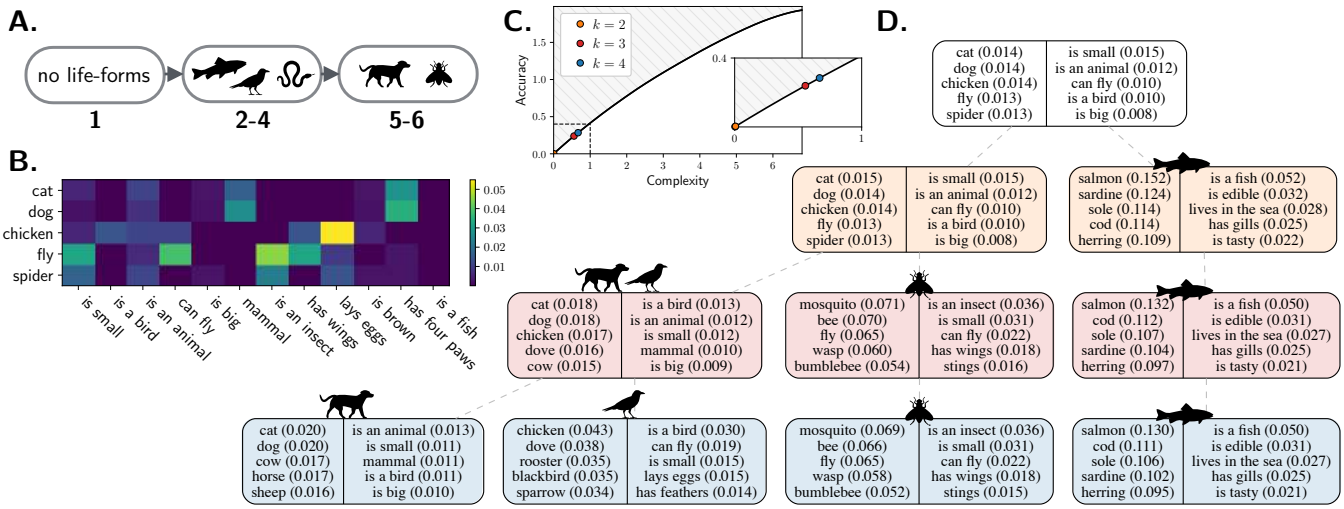

Figure 4: **A**. Brown's (1984) proposed hierarchy for animal categories. **B**. Subset of the conditional probabilities of features (columns) given animal classes (rows), for the 5 most familiar classes and 12 most frequently generated features. **C**. Theoretical limit for animal naming. Colored dots along the curve correspond to the systems shown in (D), with $k = 2, 3, 4$ categories. **D**. Animal category hierarchy derived from IB. Each level corresponds to an IB system. Each box corresponds to a category, which is represented by its top five classes (left) and features (right) and their probabilities given the category.

category *tube* quite well in both languages. However, there are also some apparent discrepancies. For example, the distinction between *bouteille* and *flacon* in French is reflected in both IB systems, although Dutch does not have the same pattern in this case (Ameel et al., 2005).

This analysis shows that efficiency constraints may to a substantial extent explain the container-naming distribution in Dutch and French, including soft category boundaries and inconsistent naming observed empirically, both in monolinguals and bilinguals. It thus supports the hypothesis that a drive for information-theoretic efficiency shapes word meanings across languages and across semantic domains. However, since this analysis is based only on two closely related languages, we were not able to test how well the results for this domain generalize across languages. Important directions for future research include testing whether these results generalize to other, preferably unrelated, languages, and further testing the extent to which the convergence in the bilingual lexicon is influenced by pressure for efficiency. The next section focuses on another semantic domain for which we are able to obtain broader cross-linguistic evidence.

Study II: Folk biology

Cross-language variation and universal patterns in animal taxonomies have been extensively documented and studied (Berlin, 1992), however this domain has not yet been approached in terms of efficient communication. By analogy with Berlin and Kay's theory, Brown (1984) proposed an implicational hierarchy for animal terms, based on data from 144 languages. Brown identified six stages for animal taxonomies, as illustrated in Figure 4A. Languages at the first stage do not have any lexical representation for life-forms. Languages at stages 2-4 add terms for *fish*, *bird* and *snake*, but Brown does not argue for any particular order for these categories. Terms for *mammal* and *wug* ("worm-bug", referring in addition to small insects) are added in stages 5 and 6, again with no implied order. Much of the data analyzed in this domain is not fine-grained, and Brown's proposal has been criticized (Randall & Hunn, 1984) mainly due to lack of sufficiently accurate data. Nonetheless, his observations can be considered as a rough approximation of cross-linguistic tendencies in this semantic domain. Therefore, in this work we aim at testing whether broad cross-linguistic patterns, as summarized by Brown's proposal, can be accounted for in terms of pressure for efficiency. More specifically, our goal is to derive from the IB principle a trajectory of efficient animal-naming systems, analogous to ZKRT's trajectory for color, and to compare this trajectory to the naming patterns reported by Brown. However, unlike previous comparisons to IB optima, due to the nature of available data, here we only attempt to make coarse comparisons.

To derive a trajectory of efficient animal-naming systems, we first need to specify the communication model in this domain. We ground the representations of animals in high-level, human-generated features. Specifically, we consider the Leuven Natural Concept Database (De Deyne et al., 2008), which contains feature data and familiarity ratings for animal classes (e.g., "cat", "chicken", etc.). These data were collected from Dutch speakers, and then translated to English. We follow Kemp, Chang, and Lombardi (2010), who considered 113 animal classes and 757 features from this database, and for each feature u and class c estimated the conditional probability $p(u|c)$ based on the number of participants who generated this feature for that class (see Figure 4B for exam-

ples). We take $\mathcal{U}$ to be the set of animal features, and assume each animal class is mentally represented by the distribution it induces over features, i.e. $m_c(u) = p(u|c)$, as estimated by Kemp et al. (2010). In addition, we follow Kemp et al. (2010) in using a familiarity-based prior over animal classes, in which the probability of a class is proportional to its familiarity score. We define the need distribution to be this prior.

Given these components, we estimated the theoretical limit for animal naming (Figure 4C) using the same method as before, this time with 3000 values of $\beta \in [0, 2^{13}]$. We then selected the most informative systems with $k = 2, 3, 4$ categories. The number of categories, k, was determined by considering categories w with probability mass $q_\beta(w) > 0.00001$. These systems are shown in Figure 4D, where each layer of the hierarchy corresponds to a system and each box corresponds to a category within that system. The top layer, with a single category, corresponds to a non-informative system that does not distinguish between different animal classes. This can be considered as a stage 1 system in Brown's sequence. The second layer (shown in orange) roughly corresponds to a stage 2 system. It consists of a *fish* category, as can be inferred from the distribution it induces over features and animals, and another category for all other animals. It lies very close to the origin in Figure 4C, as it maintains little information about most animals. The third layer (shown in red) corresponds to a system with categories for *fish* and *wug*, as well as a category that is dominated by birds and mammals. The *bird-mammal* category has greater probability mass (0.8) than the *wug* category (0.14), suggesting that it is more prominent even though these two categories appear together. This transition deviates from Brown's sequence in the early appearance of *wug* (although not strongly weighted here), and in lacking a *snake* category (although animals from that category do appear in the Leuven database). One possible explanation for this deviation is that the feature data on which we relied were obtained from Dutch participants, and are thus strongly biased toward Western societies. In the next layer (shown in blue), the 3-category system evolved to a 4-category system by refining the *bird-mammal* category, resulting in a system that roughly corresponds to a Brown stage 6 system, with the exception of *snake*.

These results suggest that animal naming systems may evolve under efficiency pressure much as color appears to, despite the qualitative difference between these domains. However, in order to test this proposal more comprehensively, fine-grained cross-linguistic animal naming data is required, comparable to the naming data for colors and containers. The fact that systems along the theoretical limit capture some cross-linguistic tendencies in animal taxonomies is notable, given that our characterization of the domain, in terms of features, was necessarily strongly biased toward animal representations in Western societies. This finding supports the idea that to some extent at least there is a shared underlying representation of animals across cultures (Mayr, 1969), while also raising the interesting possibility of some cross-language and cross-cultural differences in underlying representations. It is also worth noting that the salient features in the IB systems tend to be both perceptual (e.g., "is big") and functional (e.g., "is edible"), suggesting that both types of features may shape animal categories across languages, and that this may be consistent with pressure for efficiency (Kemp et al., 2018).

Although we introduced the hierarchy in Figure 4D as an account of category structure across languages, the same hierarchy could potentially serve as a model of hierarchical structure within a single language. This within-language interpretation resembles previous applications of the IB principle to language (Pereira, Tishby, & Lee, 1993), although these applications were based on corpus statistics. The within-language interpretation seems useful in the case of animal taxonomies, a semantic domain with strong hierarchical structure, as opposed to containers and even colors. A possible, yet speculative, reconciliation of the within-language and cross-language interpretations is that speakers may internally represent a hierarchy induced by an evolutionary sequence. For example, Boster (1986) showed that English speakers can recapitulate Berlin and Kay's implicational color hierarchy in a sequential pile-sorting task. Thus, it seems at least possible that a similar phenomenon may also hold for animal categories.

General discussion

Artifacts, animals, and colors are qualitatively different elements of human experience, yet our findings suggest that their semantic representations across languages is governed by the same general information-theoretic principle: efficient coding of meanings into words, as defined by the IB principle. We have shown that this theoretical account, which was previously tested only in the domain of color naming (ZKRT), generalizes to container names and animal taxonomies. This finding resonates with the proposal that word meanings may be shaped by pressure for efficient communication (Kemp et al., 2018). However, it goes beyond that proposal by explaining how pressure for efficiency may account for soft categories and inconsistent naming, both in monolinguals and bilinguals, and how it may relate to language evolution.

An important direction for future research is to test to what extent our results extend to other semantic domains, and ideally, to the lexicon as a whole. While it may not be possible to apply this approach to every aspect of the lexicon, we believe that the theoretical formulation considered here may be broadly applicable across semantic domains.

Acknowledgments

We thank Anne White, Gert Storms, and Barbara Malt for making their container naming and sorting data publicly available. The animal features and familiarity data we used were preprocessed by Kemp et al. (2010). We thank Simon De Deyne for initially sharing these data, and for useful discussions. This study was partially supported by the Gatsby Charitable Foundation (N.Z. and N.T.), and by the Defense

Threat Reduction Agency (N.Z. and T.R.); the content of the study does not necessarily reflect the position or policy of the U.S. government, and no official endorsement should be inferred.

Sampling to learn words: Adults and children sample words that reduce referential ambiguity

Abstract

How do learners gather new information during word learning? We present evidence that adult learners will choose to receive additional training on object-label associations that reduce ambiguity about reference during cross-situational word learning. This ambiguity-reduction strategy is related to improved test performance. We find mixed evidence that children (4-8 years of age) show a similar preference to seek information about words experienced in ambiguous word learning situations. In an initial experiment, children did not preferentially select object-label associations that remained ambiguous during cross-situational word learning. However, this may be explained by some children having relatively high certainty about object-label associations for which they did not see evidence disconfirming their initial hypothesis. In a second experiment that increased the relative ambiguity of two sets of novel object-label associations, we found evidence that children preferentially make selections that reduce ambiguity about novel word meanings.

Keywords: cross-situational word learning; mutual exclusivity; active learning; self-directed learning; sampling

Introduction

What makes us seek out new information during learning? One proposal is that information-seeking behavior is driven by uncertainty reduction (e.g., Kidd & Hayden, 2015). A variety of studies have demonstrated that – at least in some contexts - children are motivated to gather information to reduce the uncertainty after ambiguous or surprising events (Schulz & Bonawitz, 2007; Stahl & Feigenson, 2015).

To what extent does ambiguity-reduction play a role in word learning? A classic problem is how learners disambiguate the meaning of words in potentially ambiguous situations (Quine, 1960). One solution is that children can disambiguate word meanings by tracking co-occurrences of object-label pairs across multiple ambiguous situations (Yu & Smith, 2007). This proposal would be particularly powerful if learners are naturally drawn to isolating object-label associations that have remained ambiguous over the course of past learning (Hidaka, Torii, & Kachergis, 2017). A previous study of cross-situational word learning has shown that being able to actively select sets of object-label pairs to learn about increases participants' accuracy compared to a passive condition in which random sets of objects are presented (Kachergis, Yu, & Shiffrin, 2013). However, we still know little about what sampling strategies adult and child learners display when given the opportunity to control their learning input.

In the current work, we investigated whether adult and child learners seek information that aids in reducing ambiguity about the meaning of novel words. We manipulated the ambiguity of novel word mappings by varying the degree to which object-label pairs co-occurred with one another during cross-situational word learning (Experiments 1A, 1B, 2A) or whether children could use mutual exclusivity to disambiguate the referents of novel words (Experiment 2B). The central question was whether adults and children would choose to learn more about those items that most strongly reduce referential ambiguity.

Experiments 1A & 1B

We tested whether adult learners would seek information that aided in disambiguating reference. Participants completed a cross-situational learning task in which their goal was to learn a set of object-label associations by determining the referent of each label across training. Participants were then given the opportunity to select which object-label association they would hear on the next learning trial. The central question was whether adult learners would make selections that reduce referential ambiguity about the novel object-label associations. We collected data in an online experiment (Experiment 1A) and in an in-lab experiment (Experiment 1B) that we discuss together due to their similarity in design and results.

Method

Participants. For Experiment 1A, we recruited 31 participants through Amazon Mechanical Turk. Three participants were excluded for not passing an initial auditory attention check (2) or for restarting the experiment (1). All participants were assigned to the Fully Ambiguous Condition (n = 28) and paid $0.75 for completing the study.

For Experiment 1B, 62 University of Wisconsin-Madison's undergraduates participated for course credit and were randomly assigned to the Fully Ambiguous Condition (n = 28) or the Partially Ambiguous Condition (n = 34).

Stimuli. The object stimuli were 8 images of novel 'alien' creatures used in previous word learning studies (Partridge, Mcgovern, Yung, & Kidd, 2015). 8 novel word stimuli (*beppo*, *finna*, *guffi*, *kita*, *noopy*, *manu*, *sibu*, *tesser*) were recorded by a female native speaker of English and normalized in duration and average loudness. The association between each label and its target referent and the roles of the stimuli within a condition were randomized across participants. The stimuli were presented using a web-based experiment created using jsPsych (de Leeuw, 2014).

Design & Procedure. The experiment was split into a *Training Phase*, a *Sampling Phase*, and a *Test Phase*.

Training Phase. Participants completed 24 cross-situational learning trials (2 blocks of 12 trials), presented in random order. The goal was to learn the association between eight novel labels and their referents. On each training trial, participants were presented with two referents and two labels. The labels appeared sequentially in random order, both visually and auditorily. Consequently, the association between a particular label and its referent remained ambiguous on any single trial, but could be disambiguated by aggregating information across trials. Each object and its label occurred 6 times across the 24 training trials.

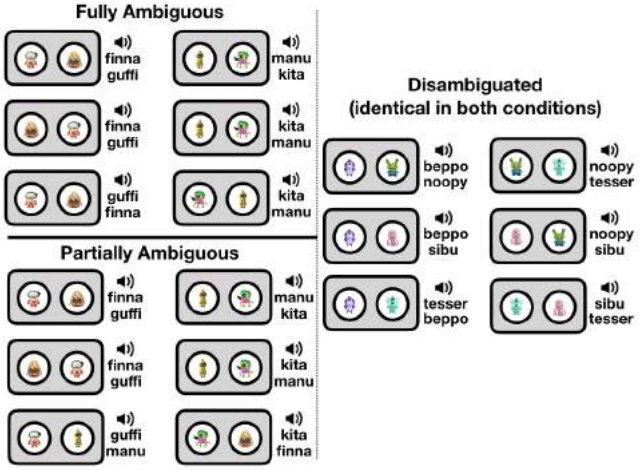

Figure 1. Overview over one block of the Training Phase for the Fully Ambiguous Condition and the Partially Ambiguous Condition

We manipulated whether the object-label associations became disambiguated across trials during training, and therefore, how uncertain participants were at the onset of the *Sampling Phase* about the specific object-label pairs. Across Experiments 1A and 1B, participants were assigned to one of two conditions: the Fully Ambiguous condition or the Partially Ambiguous condition. In the Fully Ambiguous condition, half of the object-label pairs remained ambiguous: two sets of two items were yoked together such that they were never disambiguated across training (ambiguous items; Figure 1, top left). The remaining items in the Fully Ambiguous condition were disambiguated across trials, occurring with three different object-label pairs (disambiguated items; Figure 1, right panel). In the Partially Ambiguous condition, two sets of two objects were grouped such that two specific objects co-occurred on 4 out of their 6 occurrences, but each occurred with one other object from the ambiguous object set on the remaining 2 trials (partially ambiguous items; Figure 1, bottom left). The other four objects were disambiguated as in the Fully Ambiguous condition. Note that across both conditions, participants saw each individual object and label equally frequently.

Sampling Phase. Participants next completed four sampling trials. On each trial, all 8 objects appeared in randomized locations. Participants were instructed to select which of the 8 items they wanted to hear in the next cross-situational learning trial. After participants' selection, a second object was chosen at random from the remaining objects. The two objects and their labels then appeared together in a cross-situational word learning trial with the same structure as in the training phase.

Test Phase. Participants' knowledge of the object-label associations was probed in an 8-AFC recognition test. On each test trial, all 8 objects appeared in randomized locations on the screen, along with one of the 8 labels. Participants were then asked to select the object that went with the label. No feedback was provided after a choice. Participants were tested on each label in random order, for a total of 8 recognition test trials.

Predictions. We predicted that participants would be more likely to choose to learn more about the ambiguous items than about the disambiguated items in the sampling phase. For the Partially Ambiguous condition, we expected participants to have a weaker preference for ambiguous items over the disambiguated items, since adults accurately tracking the co-occurrence evidence could successfully learn all word-referent pairs. We did not predict large differences in test accuracy between items. One possible outcome was that test accuracy would be higher for items that were disambiguated during training. However, another possibility was that ambiguous items could be learned at comparable levels to disambiguated items if participants preferentially sampled ambiguous items.

Results

Sampling choices. We report the results combining the data from Experiments 1A and 1B for convenience – however, qualitatively similar results are obtained when considering the data from Experiment 1A or Experiment 1B separately. We used the lme4 package version 1.1-18-1 in R (version 3.5.1) to fit a logistic mixed-effects model testing participants' likelihood of making an ambiguous selection against a chance level of 0.5 (Bates & Maechler, 2009; R Development Core Team, 2018), including by-subject and by-item random intercepts and a fixed effect for condition. In the Fully Ambiguous condition, participants were more likely to choose ambiguous items than disambiguated items, $b = .59$, $z = 3.61$, $p < .001$. Participants chose an object from the ambiguous set on 63.4% of trials (95% CI = [55.7%, 71.0%] (Figure 2A). Participants in the Partially Ambiguous condition selected the partially ambiguous items on 47.8% of trials (95% CI = [39.1%, 56.5%]), thus showing no sampling preference between the two item types ($p = .64$). Participants were in the Fully Ambiguous condition were more likely than participants in the Partially Ambiguous condition to select the more ambiguous object-label

associations, b = .68, z = 2.64, p = .008. Non-parametric analyses yielded equivalent results.

Test performance. Overall, participants showed learning of the label-object pairs, accurately selecting the correct referent in both the Fully Ambiguous condition (M = 69.2%, 95% CI = [60.8%, 77.5%], chance = 12.5%) and in the Partially Ambiguous condition (M = 77.6%, 95% CI = [67.1%, 88.0%]) (Figure 2B). Notably, within the Fully Ambiguous condition, test accuracy was lower for the ambiguous items (M = 61.6%) than for the disambiguated items (M =76.8%; logistic mixed-effects model with by-subject and by-item random intercepts and a by-subject random slope for item type, z = 3.25, p = .001).

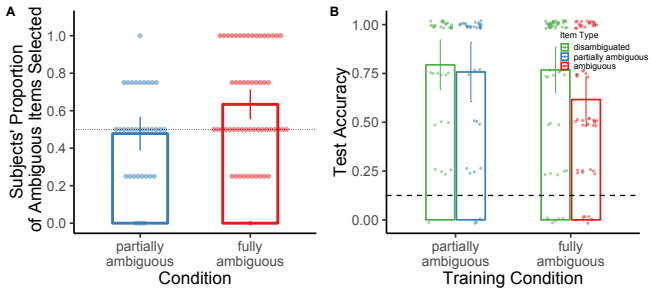

Figure 2. (A) Proportion of more ambiguous items selected in each condition and (B) test accuracy by condition and item type. Error bars in represent within-subject 95% CIs.

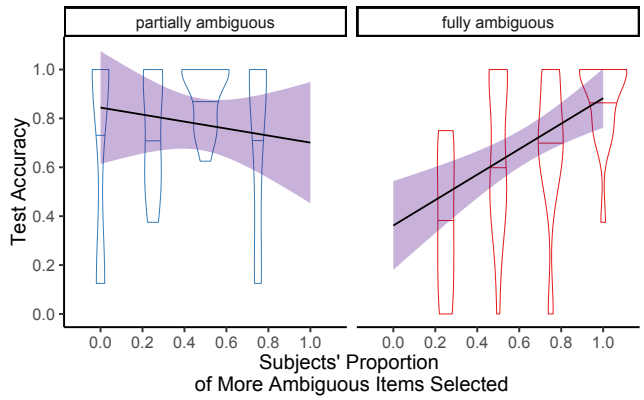

Figure 3. Relationship between choosing more ambiguous items and test accuracy for each condition. Error bands represent +/-1 SE.

Relationship between sampling and test performance. In the Fully Ambiguous condition, participants who chose more objects from the ambiguous set during the sampling phase accurately identified more words at test, r(54) = .48, 95% CI = [0.25, 0.66], p < .001 (Figure 3). There was no significant relationship between participants' tendency to select the partially ambiguous items and their accuracy at test (r(32) = -.11, p = .50).

Discussion

In a cross-situational learning task, adult learners chose to learn more about those object-label pairs that remained ambiguous throughout training. Adults showed this tendency when the object-label pairings were truly ambiguous based on the training evidence (Fully Ambiguous condition), but not when the object-label pairs became disambiguated at any point during training (Partially Ambiguous condition). While participants showed poorer overall learning of the (more difficult) ambiguous object-label pairs, their success at test correlated strongly with the degree to which they chose more ambiguous items during the sampling phase. This experiment provides 'proof-of-concept' evidence that adult learners will seek to reduce ambiguity about object-label associations when given the opportunity to control which items they will learn about.

Experiment 2A

Next, we asked whether children would demonstrate a similar tendency to seek new words that reduce ambiguity during cross-situational learning. As in Experiment 1A, children (4-8 years of age) first completed a cross-situational word learning task. Across training, one set of novel object-label associations could be inferred based on the object-label associations they co-occurred with, while another set of words remained ambiguous. Then, participants were given the opportunity to sample object-label associations presented in isolation, i.e. in unambiguous learning trials. The central question was whether children would prefer to select object-label associations with ambiguous evidence during training, suggesting that children sample words that reduce referential ambiguity.

Method

Participants. We recruited 38 participants (M = 5.9 years, range = 4.1 – 8.1 years, 19 female) at a local children's museum. Two additional participants were excluded due to inattention during experiment.

Stimuli. The object stimuli were 8 images of novel 'alien' creatures used in previous word learning studies (Partridge et al., 2015) and 2 cartoon images of familiar animals (penguin, dog). 8 novel word stimuli (*biffer, deela, guffi, sibu, tibble, leemu, zeevo, pahvy*) and two familiar word stimuli (*penguin*, *dog*) were recorded by a female native speaker of English and normalized in duration and average loudness. The association between each novel label and its novel target referent, as well as the particular roles of the novel word-referent stimuli, were randomized across participants. The stimuli were presented using in a web-based experiment created in jsPsych (de Leeuw, 2014).

Design & Procedure. Children were tested in a quiet room in the children's museum on a 10.1" Samsung Galaxy Note tablet. An experimenter guided children through the experiment by giving instructions at the beginning of each

new phase. The experiment was presented as a game in which a cartoon bear named Teddy would first teach children the names of new alien friends, and then ask children to help her find her friends. The experimenter began with the following introduction:

> In this game, Teddy went up to space and met a bunch of new alien friends. Teddy is going to tell you the names of aliens, and your job is to try to remember which name goes with which alien. Later, you're going to help Teddy find them.

The experiment then proceeded to a Practice Phase, followed by the main experiment consisting of three phases: the Training Phase, the Sampling Phase, and the Test Phase.

Practice Phase. Participants first completed a practice phase in which they encountered the two familiar word object stimuli and two novel object-label associations. We introduced this short practice phase to give children experience with the overall structure of the main experiment under less demanding circumstances, using a smaller set of items and mixing familiar and novel items. First, children were exposed to 4 training practice trials similar in structure to the training trials in the main experiment. On each trial, two referents appeared on the screen on either side of the Teddy character and children heard two labels, one for each object, in random order. On the first trial, children always saw the two familiar items (i.e., the penguin and the dog), followed by a second trial in which children saw two novel object-label associations (i.e., an ambiguous labeling event). On the final two training practice trials, children saw each of the familiar items occur with one of the two novel items (permitting the disambiguation of the novel object-label associations). Next, children saw two sampling practice trials, in which children had the opportunity to select which of the four items they wanted to learn about next, followed by four practice test trials, in which participants' knowledge of the items was tested in a 4-AFC recognition test. The procedure for each of these practice trial types mirrored the procedure for the Sampling Phase and the Test Phase described in more detail below.

Training Phase. Participants completed 9 cross-situational learning trials (3 blocks of 3 trials each). On each training trial, participants saw two referents appear on the screen on either side of the Teddy character and heard the labels of the two objects presented sequentially in random order. Next, the objects switched locations in a brief animation, and participants heard the same two labels presented in the same order. We introduced this trial repetition with flipped locations in order to reduce children's tendency to interpret the labeling event as moving from left to right on the screen, i.e. assuming that the first label went with the object on the left and the second label went with the object on the right.

As in the Fully Ambiguous condition of Experiment 1A, we manipulated whether the object-label associations could be disambiguated across trials during training (Figure 4). Every object-label pair occurred on three cross-situational training trials. Four of the objects occurred with three different object label pairs (disambiguated items). The remaining two object-label associations always occurred with one another (ambiguous items), such that children never saw evidence allowing them to link the two words unambiguously with their respective referent.

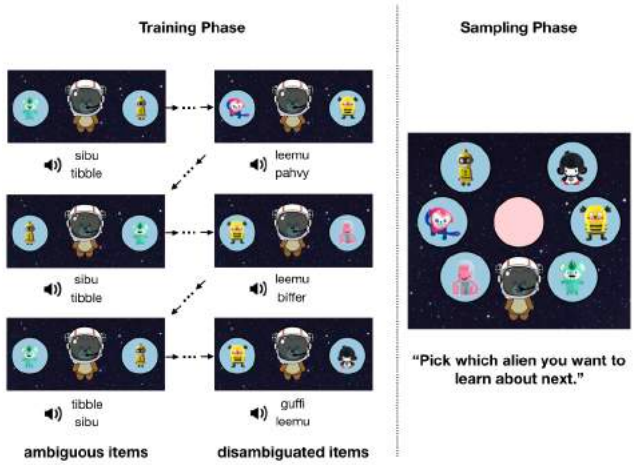

Figure 4. Overview over the design of the Training and Sampling Phase in Experiment 2A

Sampling Phase. After completing the training phase, participants completed four sampling trials. On each sampling trial, all 6 referents appeared in randomized locations on the screen. Participants were instructed to select which of the 6 items they wanted to learn about next (Figure 4). When participants tapped one of the 6 referents, a brief animation moved the item to the center of the screen while the remaining items disappeared, and the referent was subsequently labeled in isolation.

Test Phase. Participants' knowledge of the object-label associations was probed in a 6-AFC recognition test. On each test trial, all 6 referents appeared in randomized locations on the screen surrounding the Teddy character. When participants tapped Teddy in the center of the screen, they heard one of the 6 labels. Participants were instructed to help Teddy by selecting the friend she was looking for. No feedback was provided after a choice. Participants were tested on each label in random order, for a total of 6 recognition test trials.

Predictions. As in Experiment 1A, our main prediction was that children would preferentially select object-label associations that remained ambiguous during the cross-situational word learning trials of the training phase.

Results

Sampling choices. Contrary to our prediction, children did not preferentially select ambiguous object-label associations during the Sampling Phase, b = -0.01, z = -.11, p = .91.

Participants chose an object from the ambiguous set on 32.9% of trials (95% CI = [27.1%, 38.7%]).

Test performance. Overall, participants showed significant learning of the label-object pairs, choosing the correct object to go with a label at above-chance levels (chance = 0.167), M = 38.6%, 95% CI = [30.7%, 46.5%], $t(37) = 5.65$, $p < .001$. However, surprisingly, children performed more accurately on the ambiguous items (M = 48.6%, 95% CI = [36.9%, 60.4%]) than on the disambiguated items (M = 33.6%, 95% CI = [24.9%, 42.2%]), $b = .68$, $z = 2.23$, $p = .028$. When tested on ambiguous items, children had a strong preference to select one of the two ambiguous objects (61.8% of trials, 95% CI = [50.7%, 72.9%]) over the four disambiguated objects (chance = 0.33). When tested on disambiguated items, children tended not to choose the two ambiguous objects, selecting them on only 18.4% of trials (95% CI = [12.8%, 24.1%]).

Discussion

Unlike adult learners, children did not show a preference for selecting object-label associations for which they had experienced ambiguous evidence during training. Interestingly, children performed better at test for ambiguous object-label associations than for object-label associations that were disambiguated across training trials. There are likely two reasons why children showed higher accuracy on the ambiguous items. First, since the two ambiguous items always co-occurred with one another, the training could help learners constrain the set of possible competitors for a given ambiguous label to two objects (compared to four possible objects for the disambiguated items). Indeed, children appeared to constrain their choices to the two objects that co-occurred on ambiguous trials when tested on their respective labels and rarely chose these objects when tested on the labels that occurred with the disambiguated objects

Second, anecdotally, we observed that many children explicitly pointed to specific objects during training while listening to each label and even repeated the respective label for each object. This behavior may indicate that some children were making an explicit hypothesis about each word mapping (Trueswell, Medina, Hafri, & Gleitman, 2013). If a child formed a specific hypothesis about the mapping between the two labels and objects on the first ambiguous trial, they would subsequently hear evidence that would appear to confirm their hypothesis: the two labels and the two objects would occur together again on the subsequent two training trials. "Hypothesis-testers" would never experience evidence disconfirming their initial hypotheses and thus have a 50% chance of responding correctly at test for these items (note that our child participants' test accuracy was 48.6% on average). Crucially, one consequence of learners approaching the task in this manner is that the two object-label associations deemed "ambiguous" according to the experimental design may have actually appeared *less* ambiguous to children performing the task than the putatively disambiguated items. Thus, in our next step, we adapted the task to create a learning situation in which one set of object-label associations would be more clearly ambiguous from the standpoint of the child learner.

Experiment 2B

In Experiment 2B, we sought to increase the likelihood that children would perceive some novel object-label associations as more ambiguous than others. We used mutual exclusivity to increase the ease with which children could infer word-referent pairs for one set of novel objects (Markman & Wachtel, 1988) while maintaining the ambiguity of a second set of novel word-referent pairs as in the previous experiments. By giving children the opportunity to infer the referents for novel objects occurring in mutual exclusivity trials, we aimed to make it easier for children to recognize the referential ambiguity of novel object-label associations that always co-occurred.

Method

Participants. We recruited 53 participants (M = 5.7 years, range = 4.1 – 7.9 years, 32 female) at a local children's museum. One additional participant was excluded due to experimenter error.

Stimuli. The novel object and word stimuli were six images and recordings composed of a subset of the items used in Experiment 2A. In addition, 4 cartoon images of familiar animals (cow, dog, monkey, pig) along with audio recordings of their respective labels were used. All word stimuli were recorded by the same female native speaker of English and normalized in duration and average loudness.

Design & Procedure. The procedure and testing conditions were identical to Experiment 2A. The experiment followed the same structure as Experiment 2A, beginning with a *Practice Phase* and then proceeding through three phases: *Training Phase*, *Sampling Phase*, and *Test Phase*.

Training Phase. Participants completed 9 cross-situational learning trials (3 blocks of 3 trials each) with 6 object-label pairs, two familiar object-label pairs (e.g., pig and dog) and four novel object-label pairs chosen randomly from the set of novel stimuli. As in Experiment 2A, on each trial, participants saw two referents appear on the screen and heard two labels presented in random order. Two novel object-label associations always occurred with one another (ambiguous items), mirroring the ambiguity manipulation from Experiments 1A/B and 2A. The two remaining novel object-label associations were each yoked to one of the two familiar object-label pairs (i.e., one alien always occurred with the dog image, while the other always occurred with the pig image; mutual exclusivity items). We reasoned that children would successfully disambiguate reference for mutual exclusivity items (i.e., when seeing an image of a dog and a novel "alien", on hearing the words *leemu* and *dog*, children would successfully infer that *leemu* referred to

the novel alien). This would make it more likely that the ambiguous items would be perceived by child learners as having high referential uncertainty. As in previous experiments, all novel objects and their labels occurred equally frequently across the training phase.

Sampling Phase. Participants next completed two sampling trials. On each trial, the four novel objects appeared on the screen and children were instructed to choose which object they wanted learn more about. The procedure was otherwise identical to Experiment 2A.

Test Phase. Participants' knowledge of the six words from the training phase (4 novel, 2 familiar words) was tested in a 6-AFC recognition task as in Experiment 2A.

Results

Sampling choices. Children preferentially selected ambiguous object-label associations during the Sampling Phase, b = .58, z = 2.87, p = .004. Participants chose an object from the ambiguous set on 64.2% of trials (95% CI = [55.0%, 73.3%]) (chance level = 0.5; Figure 5A). The likelihood of children making ambiguous selections increased with age, b = .49, z = 2.42, p = .016 (logistic mixed-effects models; Figure 5B).

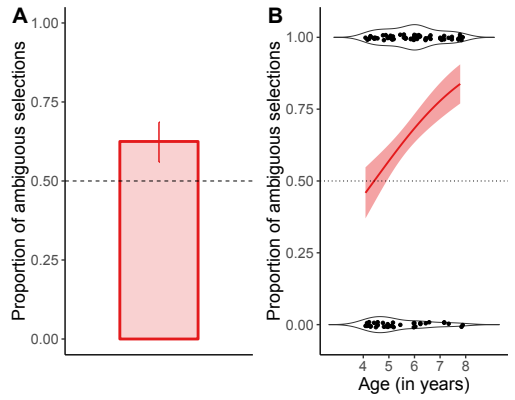

Figure 5. Proportion of ambiguous item selections in Experiment 2B overall (A) and across age (B). Error bars represent 95% CIs and error bands are +1/-1 SEs based on model estimates.

Test performance. Overall, participants showed significant learning of the label-object pairs, choosing the correct object to go with a label at above-chance levels (chance selection of novel object = 0.25), M = 59.9%, 95% CI = [50.4%, 69.4%], $t(52)$ = 7.38, p < .001. Accuracy for mutual exclusivity items (M = 64.2%, 95% CI = [53.2%, 75.1%]) and for the ambiguous items (M = 55.7%, 95% CI = [44.0%, 67.3%]) was similar, b =.45, z = 1.20, p = .23.

Discussion

When given the opportunity to select which object-label pairs they wanted to learn more about, 4-8-year-olds preferentially selected object-label pairs that remained ambiguous during training over object-label pairs that could be disambiguated through mutual exclusivity. These findings demonstrate that – at least in some ambiguous word learning situations – children prefer to select learning events that aid in reducing referential uncertainty. The tendency to make ambiguity-reducing selections began to emerge around 5 years of age in our sample.

General Discussion

When learning the referents of novel labels in ambiguous contexts, adult learners chose to learn more about object-label associations that remained more ambiguous at the end of training. These choices appear to help learners improve performance: participants' learning performance at test was higher if they had selected more ambiguous items during the Sampling Phase. It is interesting to note the modest magnitude of adults' preference on the task: ambiguous items were selected on slightly less than two-thirds of adults' sampling trials. This may be partly related to the design of the sampling phase, which allowed for a number of potentially successful sampling strategies (e.g., selecting a known word on each sampling trial in order to hear that known word in combination with other words). However, another intriguing possibility is that there are individual differences in how adults organize their learning, and that these differences may lead to distinct learning outcomes.

We find mixed evidence that children spontaneously sample object-label associations that reduce ambiguity. When presented with a similar task, 4-8-year-olds did not choose to learn about object-label associations that remained ambiguous during training. However, we think this result may be partially explained by the fact that word-referent pairs occurring in ambiguous contexts also never provided children with evidence that could disconfirm an existing hypothesis about word reference. In a simplified design that highlighted the ambiguous nature of the trials in which two referents always occurred together, older children in our sample chose to learn about items that reduced uncertainty about the words' referents.

Children have substantial control over their "curriculum" as they learn new words in the world (Smith, Jayaraman, Clerkin, & Yu, 2018), with potentially immense consequences for the difficulty of the learning problem they face (Hidaka et al., 2017). The results from Experiment 2B are consistent with results from domains such as causal learning that suggest that children are motivated to explore novel objects when presented with confounded evidence (e.g., Schulz & Bonawitz, 2007). However, the limits on the extent to which children spontaneously make ambiguity-reducing selections also raise important questions about what sampling strategies children employ when in control of what they learn next. A key question for future research will be investigating how children's sampling strategies and the structure of their environment interact to support learning.

Availability-Based Production Predicts Speakers' Real-time Choices of Mandarin Classifiers

Abstract

Speakers often face choices as to how to structure their intended message into an utterance. Here we investigate the influence of contextual predictability on the encoding of linguistic content manifested by speaker choice in a classifier language, Mandarin Chinese. In Mandarin, modifying a noun with a numeral obligatorily requires the use of a classifier. While different nouns are compatible with different SPECIFIC classifiers, there is a GENERAL classifier that can be used with most nouns. When the upcoming noun is less predictable, using a more specific classifier would reduce the noun's surprisal, potentially facilitating comprehension (predicted to be preferred under Uniform Information Density, Levy & Jaeger, 2007), but the specific classifier may be dispreferred from a production standpoint if the general classifier is more easily available (predicted by Availability-Based Production; Bock, 1987; Ferreira & Dell, 2000). Here we report a picture-naming experiment confirming two distinctive predictions made by Availability-Based Production.

Keywords: Language production; speaker choice; Chinese classifiers; noun predictability

Introduction

The simple act of speaking may typically seem effortless, but it is extraordinarily complex. Speakers must plan the message they wish to convey, choose words and constructions that accurately encode that message, organize those words and constructions into linearly-sequenced utterances, keep track of what has been said, and execute each part of their speaking plans at the correct time. Throughout this process, speakers face choices in structuring their intended message into an utterance. One central question for a computationally precise theory of language production is thus: When multiple options are available to express more or less the same meaning, what general principles govern a speaker's choice? To what extent do speakers make choices that potentially facilitate comprehenders, and to what extent do they make choices that are preferable from a production standpoint? Here we approach these questions from the standpoint of contextual predictability, which is known to affect a wide range of speaker choices. Specifically, we investigate the influence of contextual predictability on the encoding of linguistic content manifested by speaker choice in a classifier language. Two major theories of sentence production, Availability-Based Production (ABP; Bock, 1987; Ferreira & Dell, 2000) and Uniform Information Density (UID; Levy & Jaeger, 2007; Jaeger, 2010), make conflicting predictions about the distribution of speaker choices when more than one classifier could be used in a given context. We report a language production experiment on classifier choice that adjudicates between these theories.

In languages with a grammaticalized count–mass distinction, such as English, count nouns such as *table* can be used with a numeral directly and typically exhibit a singular–plural morphological marking (e.g., *one table, three tables*), whereas mass nouns such as *sand* cannot co-occur with numerals directly without some kind of measure word (e.g., *three cups of sand*) and do not have a plural morphology on the noun (e.g., **three sands*). In classifier languages such Mandarin, in contrast, nouns lack obligatory singular–plural morphological marking and cannot directly co-occur with numerals. Instead, a numeral classifier is required when a noun is modified by a numeral or a demonstrative. Linguists generally agree that there is a distinction between two types of Chinese classifiers: count classifiers, which we focus on here, and mass classifiers (Tai, 1994; Cheng, Sybesma, et al., 1998; Li, Barner, & Huang, 2008). [1] Among count classifiers, which are used with nouns that denote individuals or groups of individuals, different SPECIFIC classifiers are compatible with different nouns, but the GENERAL classifier *ge* (个) can be used with almost any noun. Often, the choice of general versus specific classifier for a given noun carries little to no meaning distinction for the utterance, as illustrated in (1) and (2) below.

(1) 我 卖了 三 **台** 电脑
wo mai-le san **tai** diannao
I sold three CL.machinery computer ("I sold three computers")

(2) 我 卖了 三 **个** 电脑
wo mai-le san **ge** diannao
I sold three CL.general computer ("I sold three computers")

In this study, we focus on speaker choice between general and specific count classifiers for nouns where both options

[1] A count classifier (e.g., two CL.top hat ("two hats")) is used to categorize a class of noun entities in reference to their salient perceptual properties, which are often permanently associated with the entities named by the class of nouns. A mass classifier (e.g., two box (of) hat ("two boxes of hats")) creates a unit and form a temporary relationship with the noun. Because using different mass classifiers often change the semantics of the noun phrase, here we only focus on count classifiers (henceforth, classifiers).

convey more or less the same meaning. When the upcoming noun is unpredictable, a specific classifier would constrain the range of possible nouns more than the general classifier, thus increasing the predictability of the upcoming noun and potentially benefiting comprehension. The Uniform Information Density account thus predicts that speakers will prefer specific classifiers for unpredictable nouns. However, Availability-Based Production predicts that the specific classifier may be dispreferred from a production standpoint if the general classifier is more easily available. Which of these two accounts better predict classifier choice in real-time production? In other words, does noun predictability affect classifier choice, and if so, in which direction? Here we use a picture-naming experiment to address this question.

Before diving into the experiment, we first briefly introduce why we focus on predictability effects and how the two accounts predict speaker choices with regard to optional reduction in language.

Predictability Effects on Optional Reduction

It has been shown that contextual predictability plays a role in optional reduction in language, where more predictable content tend to yield a greater rate of reduction in the linguistic form. At the lexical level, predictable words are phonetically reduced (Jurafsky, Bell, Gregory, & Raymond, 2001; Bell, Brenier, Gregory, Girand, & Jurafsky, 2009; Seyfarth, 2014) and tend to have shorter forms (Piantadosi, Tily, & Gibson, 2011; Mahowald, Fedorenko, Piantadosi, & Gibson, 2013). At the syntactic level, optional function words are more likely to be omitted when the phrase they introduce is predictable (Levy & Jaeger, 2007; Jaeger, 2010). For example, in English relative clauses (henceforth RCs) such as (3), speakers can but do not have to produce the relativizer *that*. We refer to the omission of *that* as OPTIONAL REDUCTION.

(3) I created a mobile app dancers like.

(4) I created a mobile app that dancers like.

For optional function word omission, predictability effects have been argued to be consistent with both the speaker-oriented account of Availability-Based Production, where the speaker mentions material that is readily available first, and the potentially audience-oriented account of Uniform Information Density, where the speaker aims to convey information at a relatively constant rate. These two accounts have proven difficult to disentangle empirically. For different reasons, both accounts predict that the less predictable the clause introduced by the function word, the more likely the speaker would be to produce the function word *that*.

Uniform Information Density

Uniform Information Density proposes that within boundaries defined by grammar, when multiple options are available to express the message, speakers prefer the variant that distributes information density more uniformly throughout the utterance, to lower the chance of information loss or miscommunication (Levy & Jaeger, 2007; Jaeger, 2010). Multiple formalizations are possible under this account (Genzel & Charniak, 2002; Aylett & Turk, 2004; Maurits, Navarro, & Perfors, 2010; Levy, 2018).

In (3), where the relativizer *that* is omitted, the first word of the relative clause w_1 (*dancers* in this case) is highly unpredictable and would convey two pieces of information: both the onset of the relative clause and part of the content of the relative clause itself. These both contribute to the information content of w_1, which can be measured using SURPRISAL, the negative log-probability of the word in context: $-\log P(w|\text{Context})$ (Hale, 2001; Levy, 2008; Demberg & Keller, 2008; Smith & Levy, 2013). In (4), having *that* at the onset of the RC splits these two pieces of information apart, offloading the relative clause's onset onto *that* so that *dancers* only conveys relative clause-internal content and thus has lower information content, potentially avoiding a peak in information density and thus facilitating comprehension.

Availability-Based Production

Availability-Based Production proposes that production is more efficient if speaker mentions material that is readily available first. According to ABP, speaker choice is governed by: 1) when a part of a message needs to be expressed within an utterance; 2) when the linguistic material to encode that part of the message becomes available (Bock, 1987; Ferreira & Dell, 2000). Specifically, if material that encodes a part of the message becomes available when it comes time to convey that part of the message, it will be used. However, if that material is not yet available, then other available material will be used, as long as it is compatible with the grammatical context produced thus far and it does not cut off the speaker's future path to expressing the desired content. This is also referred to as THE PRINCIPLE OF IMMEDIATE MENTION (Ferreira & Dell, 2000).

Suppose a speaker has just uttered the word *app* in (3) and has in mind to convey the remainder of the utterance meaning as a relative clause. If the word *dancers* becomes available quickly, then according to the principle of immediate mention, a sentence without *that* should be produced (see (3)). If *dancers* does not become available quickly, however, ABP predicts that the speaker will utter *that* to buy more time for *dancers* to become available. (Note that this account relies on an implicit auxiliary assumption that that *that* will generally become available quite quickly; this assumption is rendered plausible by the fact that it is a high-frequency word used in a wide variety of contexts.) If the first word of the RC takes longer to become available the lower its contextual predictability—an assumption consistent with previous work on picture naming (Oldfield & Wingfield, 1965) and word naming (Balota & Chumbley, 1985)—then the less predictable the relative clause, the lower the probability that its first word, *dancers*, will be available at when the speaker reaches the RC, and the higher the probability that the speaker will use *that*. Since an RC is required after *app* in order for it to be followed by the word *dancers*, the lower the contextual

probability of an RC the lower the contextual probability of its first word, predicting the empirically observed relationship between phrasal onset probability and optional function word omission rate.

Distinguishing theories of predictability-driven speaker choice

Although UID and ABP are substantially different theories of what drives speaker choice, they make the same prediction for the effect of contextual predictability on optional reduction of function words for cases such as (3). It is thus intrinsically difficult to use optional reduction phenomena to tease these accounts apart. Prior work (Jaeger, 2010) acknowledged this entanglement of the predictions and attempted to tease these accounts apart via joint modeling using logistic regression. There are other phenomena for which the accounts make similar predictions, as well. Consider the case of ordering choices for words or phrases, such as subject–object versus object–subject word order for languages in which both options are available, such as Russian. Availability-Based Production predicts that whichever becomes available earlier will be uttered first (Levelt & Maasen, 1981); if the lexical encodings of more contextually predictable references tend to become available more quickly, then more predictable arguments will tend to be uttered first. This prediction is indeed likely to be true: a given-before-new word order preference is widely recognized to influence many languages (Behaghel, 1930; Prince, 1981; Gundel, 1988), and discourse-given entities are generally more contextually predictable than discourse-new entities. But UID turns out to make the same prediction. Two arguments of the same verb generally carry mutual information about each other, so any argument will typically be less surprising if it is the latter of the two. Thus, putting the argument that is more predictable from sentence-external context before the less-predictable argument will lead to a more uniform information density profile and will be preferred.

In the case of speaker choice for Mandarin classifiers, however, UID and ABP turn out to make different predictions as we describe in the next section. The empirical facts regarding speaker choice for classifiers are thus of considerable theoretical interest.

Predictions on Mandarin Classifiers

Zhan and Levy (2018) have argued that UID and ABP make different predictions on Mandarin Classifier use with regard to noun predictability. As regards UID, the choice between a specific classifier and a general classifier will typically affect the contextual predictability of the noun modified by the classifier. In particular, a specific classifier constrains the space of possible upcoming nouns more tightly than the general classifier (Klein, Carlson, Li, Jaeger, & Tanenhaus, 2012), thus generally reducing the actual noun's surprisal. The UID hypothesis thus predicts that speakers choose a **specific** classifier more often when the noun predictability would otherwise be low than when the noun is more predictable. This is because the use of a specific classifier makes the distribution of information density more even between the noun and the classifier.

Availability-Based Production, on the other hand, makes different predictions than UID. The fundamental prediction of ABP is that the harder the noun lemma is to access, the less often the speaker will use a specific classifier, provided two plausible assumptions. First, the general classifier *ge* is always available, regardless of the identity of the upcoming noun, as it is the most commonly used classifier and is compatible with practically every noun. Second, in order to access and produce an appropriate specific classifier, a speaker must complete at least some part of the planning process for the production of the nominal reference: accessing the noun lemma, or minimally accessing the key semantic properties of the referent that determine its match with the specific classifier. On these two assumptions, any feature of the language production context that makes the noun lemma less accessible or that more generally makes noun planning more difficult will favor the general classifier. In out-of-linguistic-context picture naming, for example, noun lemma accessibility is known to be driven by noun frequency (Oldfield & Wingfield, 1965). The lower the noun frequency, the less accessible the noun lemma, thus the less likely a specific classifier will be used. To make predictions about the effect of noun predictability on classifier choice in linguistic contexts, we must add a third, theoretically plausible assumption: that less predictable noun lemmas are harder and/or slower to access than more predictable noun lemmas. On these three assumptions, in corpus data the link between noun lemma accessibility and classifier choice will show up as an effect of noun predictability, which by hypothesis is determining noun lemma accessibility. For less predictable nouns, their specific classifiers will less likely be available to the speaker when the time comes to initiate classifier production. Because noun lemmas need to be accessed in order to produce specific classifiers, and the less predictable the noun, the harder the noun lemma is to access and hence the specific classifier associated with the noun becomes available by the time a classifier needs to be produced.

In other words, the link between noun lemma accessibility and classifier choice will manifest in different predictions depending on whether one we are looking at usage in linguistic context versus picture-naming. Under our assumptions about ABP, we can identify three predictions. First, in out-of-context picture naming, speakers should as described above choose the **general** classifier more often the more frequent the noun (provided there is high naming agreement for the picture, so that there is not competition among nouns that affects the production process). Second, in corpus data, speakers should as described above choose a **general** classifier more often the less predictable the noun. Finally, we can add a third prediction based on the temporal dependence of specific classifier production on noun planning: when speakers are under greater time pressure, they should produce the

general classifier more often, as it can be used even when noun planning has not proceeded far enough for a specific classifier to be available.

Zhan and Levy (2018) tested the second prediction in an investigation of naturally occurring texts, using language models to estimate noun predictability and mixed logistic regression to infer its relationship with classifier choice. They found that the less predictable the noun, the lower the rate of using a specific classifier. While these results lend support for the Availability-Based Production account, the study has some limitations. One limitation is that the corpus being used was a collection of online news texts. Written language may serve as a first approximation of testing theories of language production, but it would be ideal to use real-time language production task to further test the hypotheses. Another limitation is that there was no experimental control of context, so it is possible that predictability was confounded with some other contextual factor that was not included in their regression analysis but that is actually responsible for speaker choice.

In the present study, we use a real-time language production task involving picture naming varying noun frequency and whether speakers are put under time pressure, allowing us to further investigate the two models of language production by testing the first and third predictions described above.

Methods

We used a picture-naming experiment to test the predictions of Uniform Information Density and Availability-Based Production by manipulating noun frequency and whether or not the speaker is under time pressure. This picture-naming experiment offers a simple yet effective way to elicit real-time language production.

Participants

Thirty-six self-reported native speakers of Mandarin Chinese were recruited via Witmart, a China-based online crowdsourcing platform. Participants received compensation for their time.

Materials

We adapted images from the Pool of Pairs of Related Objects (POPORO) (Kovalenko, Chaumon, & Busch, 2012) image set to create our visual stimuli. We selected images from the image set based on the following criteria: 1) the image can be described by a count noun; 2) the preferred count noun is compatible with the general classifier and at least one specific classifier. We developed a web-based version of the experiment using `jsPsych` (de Leeuw, 2015), a JavaScript library for creating behavioral experiments in a web browser. We estimated the frequencies of occurrence of the preferred count nouns from `SogouW` (Sogou, 2006), a word frequency dictionary for online texts in Chinese.

Procedure

Participants were presented with scenes of various countable object kinds such as cabbages and tables. Figure 1 shows a sample display. In each scene, there were several instances of the same object kind. The number of objects in each trial varied from two to four. Participants were asked to describe the number and the name of the object in Mandarin, eliciting utterances such as “three CL chairs” which we recorded.

Figure 1: Sample visual display for the picture-naming experiment. The red dot below the picture is the recording light. Below it is the text indicating the status of the recorder, in this case, it is ”recording stopped”. The English translation for the sentence in the bottom is: “Please describe the number and the name of the objects in the picture.”

Participants were assigned to one of the two conditions. In the **Quick** condition, recording started 50 ms after the picture was shown, indicated by a recording light at the bottom of the picture. Each trial ended after 5 seconds of recording, and the next trial began automatically. In the **Slow** condition, recording stared 3 seconds after the picture was shown, and participants clicked on the screen to move toward the next trial.

Predictions

Availability-Based Production predicts that (1) the rate of specific classifier use will be lower in the **Quick** condition, when speakers are under time pressure, than in the **Slow** condition; and (2) the rate of specific classifier use will be lower for less frequent nouns. This latter prediction derives from evidence that lexical access, as manifested by response latencies, takes longer for lower frequency words in language production experiments requiring word production outside of sentence context; this holds not only for picture naming (Oldfield & Wingfield, 1965), as we require of participants here, but also of visually-presented word naming (Balota & Chumbley, 1985). If lower-frequency nouns are slower to ac-

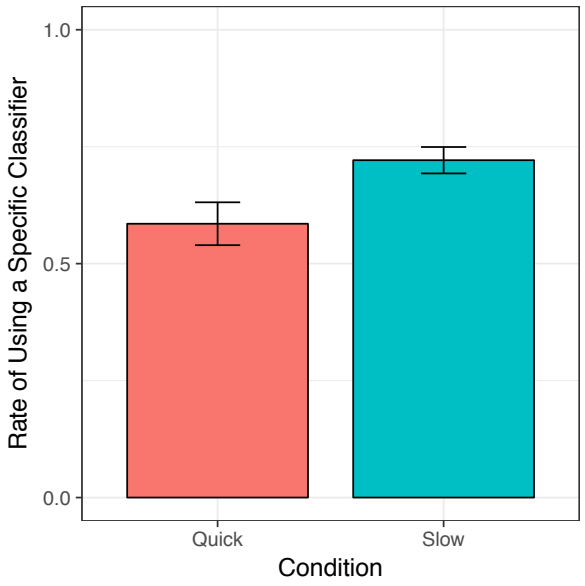

Figure 2: Quick vs. Slow manipulation and rate of using a specific classifier as opposed to the general classifier *ge*. Error bars are standard errors over by-participant means.

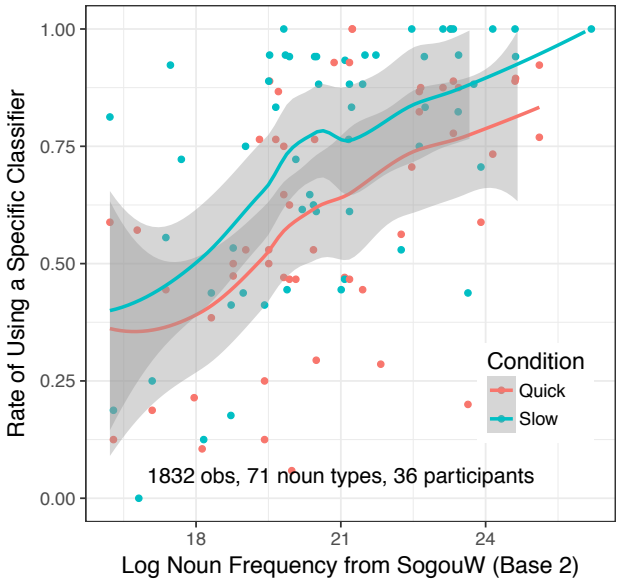

Figure 3: The relationship between noun frequency and rate of specific vs. general classifier use in picture naming.

cess, their specific classifiers may also be slower to access and thus less often used than the general classifier, which is available for all nouns.

The predictions of Uniform Information Density for the effect of the **Quick/Slow** manipulation are unclear. As regards noun frequency, UID predicts that if anything low-frequency nouns should have a *higher* rate of specific classifier usage, as a noun's frequency may effectively serve as its predictability in this experimental setting without broader linguistic context.

Analysis

Audio responses were first transcribed to texts using Google's speech-to-text application programming interface (API), and then checked manually to correct transcription errors. We excluded trials when the participant did not produce a classifier or a noun. For each item, we used the nouns that were most frequently produced as the noun for that item. We also compiled a list of acceptable nouns for each items, and excluded nouns that were not on the list.

We used a mixed-effect logit model to investigate whether noun frequency and time pressure affect classifier choice. The dependent variable was the binary outcome of whether the general classifier or a specific classifier was produced. For each noun type, we also identified its preferred specific classifier (using native speaker introspective judgment and predominant responses by experimental participant, which were concordant). We included two predictors in the analysis: log noun frequency and condition. We included noun, preferred specific classifier, and participant as random factors. We used the maximal random-effects structure with respect to these two predictors (Barr, Levy, Scheepers, & Tily, 2013). For condition, this entailed random slopes by noun and by preferred specific classifier, but not participant because the condition manipulation was between subject. For log noun frequency, this entailed a random slope by participant. The full formula in the style of `R`'s `lme4` is:

```
response ~ log_noun_freq + condition
+(1+condition|noun)
+(1+condition|preferred_spec_cl)
+(1+log_noun_freq|participant)
```

Statistical significance was determined using Markov chain Monte Carlo (MCMC) methods in the R package `MCMCglmm` (Hadfield, 2010) with p-values based on the posterior distribution of regression model parameters with an uninformative prior, as is common for MCMC-based mixed model fitting (Baayen, Davidson, & Bates, 2008).

Results

Looking just at the **Quick/Slow** contrast, we find (Figure 2) that speakers produced more instances of the general classifier when they are under time pressure than when they are not ($p < 0.05$), suggesting that specific classifiers are slower than the general classifier to access and thus supporting the Availability-Based Production account.

Further breaking out our results by noun log-frequency, we find (Figure 3) that the lower frequency the noun, the more likely a **general** classifier is to be produced ($p < 0.001$). This pattern holds within both experimental conditions and is consistent with previous results from the corpus analysis (Zhan & Levy, 2018), and also supports the Availability-Based Production account.

One potential concern arises in the frequencies of the different specific classifiers. One could argue that it was not the noun's frequency that determined the use of the general classifier, rather it was the frequency of the preferred specific classifier that affected the choice of which classifier was used. In the mixed-effect logit model presented above, we included a by-specific-classifier random intercept, which largely rules out the possibility that specific classifier frequency were confounding the effect of noun frequency. To further investigate this issue, we tried a version of our regression model that also includes a fixed effect for the log frequency of preferred specific classifier as a control factor. We did not find any qualitative change to the results. The effects of noun frequency ($p < 0.001$) and condition ($p < 0.05$) on classifier choice remain qualitatively similar to the results of the original model. Furthermore, in this new analysis, there is no effect of specific classifier frequency on classifier choice ($p = 0.483$). This additional analysis suggests that it is unlikely that specific classifier frequency to be driving the effect of noun frequency.

Conclusion

Using a picture-naming experiment, we show that Availability-Based Production predicts speakers' real-time choices of Mandarin Chinese. The lower a noun's frequency, the more likely a general classifier is to be used. We also found that the use of classifier is moderated by whether the speaker is under time pressure when speaking, where the speaker tends to produce more instances of the general classifier if they are under greater time pressure to speak. This real-time effect confirms that the general classifier is easily accessible when the speaker is about to produce a noun phrase with numeral.

Taken together, the present study and previous corpus work on Mandarin classifier (Zhan & Levy, 2018) offer converging evidence regarding the relationship between noun frequency, predictability, and classifier choice, and thus shed light on the mechanisms influencing speaker choice. While the corpus work provides ecological validity through naturalistic data, the experimental work helps us to eliminate potential correlation-based confounds with a clean setup, and enables us to get dense data that are theoretically important but naturalistically sparse. When combined together, this work is complementary with previous corpus work and together paint a more comprehensive picture of language production.

These studies also underscore the importance of investigating a wide variety of speaker choice phenomena, taking advantage of the many types of phenomena offered by the languages of the world. Optional reduction and word order choice are perhaps the best-studied types of such alternations, but they have proven ill-suited to teasing apart the predictions of Uniform Information Density and Availability-Based Production. The approach taken here could be extended to the many types of classifier systems in languages around the world, and might inspire investigation of yet different speaker choice configurations that shed new insights into the mechanisms of language production.

In future work on classifier choice, we plan to investigate other potentially relevant factors such as mutual information. It is possible that some classifier-noun pairs are especially prominent and accessible in memory. If the mutual information between the noun and classifier is high, speakers might be more likely to use that classifier for the noun selected. Although we have not found direct evidence supporting the UID hypothesis, it is possible that this particular experimental setting is not very communicative in nature. In future work, we plan to do an real-time language production experiment in a more communicative setting, with virtual or real listeners in the experiment to further test speaker choice in language production. We also plan to add additional production measures such as phonetic reduction of classifiers, pause durations, and disfluencies to enrich our understanding of language production.

Viewed most broadly, using speaker choice in classifier production as a test case has helped us investigate computationally explicit theories of language production, and advance our understanding of the psychological processes involved in converting our thoughts to speech.

Abstract

Decision makers often reject mixed gambles offering equal probabilities of a larger gain and a smaller loss. This important behavioral pattern is generally seen as evidence for loss aversion, a psychological mechanism according to which losses are given higher utility weights than gains. In this paper we consider an alternate mechanism capable of generating high rejection rates: A predecisional bias towards rejection without the calculation of utility. We use a drift diffusion model of decision making to simultaneously specify and test for the effects of these two psychological mechanisms in a gambling task. Our results indicate that high rejection rates for mixed gambles result from multiple different psychological mechanisms, and that a predecisional bias applied prior to the computation of utility (rather than loss aversion) is the primary determinant of this important behavioral tendency.

Keywords: drift diffusion model; risky choice; predecisional bias; loss aversion

Introduction

Consider a gamble that offers you a gain of $11 if a coin toss lands heads, and a loss of $10 if it lands tails. Would you accept or reject this gamble? Most people choose to reject similar positive expected value mixed gambles (gambles that offer both a possibility of a gain and a possibility of a loss; Kahneman & Tversky, 1979; Samuelson, 1960), suggesting an aversion to risk. Yet risk aversion for such small monetary payoffs cannot be easily explained by conventional applications of expected utility theory. Such models predict that anyone who rejects a 50-50 gamble between a gain of $11 and a loss of $10, displays such a strong degree of risk aversion, so as to also reject a 50-50 gamble involving a loss of $100 (regardless of the magnitude of the corresponding gain; Rabin, 2000).

This (clearly unreasonable) prediction presents compelling evidence against expected utility theory, and indicates that additional psychological mechanisms need to be incorporated into models of risky choice in order to account for high rejection rates in mixed gambles (Rabin, 2000). The psychological mechanism that is widely considered to be responsible for these high rejection rates is loss aversion, which states that losses have a greater impact on utility than gains (Kahneman & Tversky, 1979; Kőszegi & Rabin, 2007; Rabin & Thaler, 2001). For example, in the mixed gamble presented at the start of this paper, loss aversion predicts that individuals experience more negative utility from the $10 loss than positive utility from the $11 gain. Thus the gamble, despite having a positive expected value, appears unattractive, and is rejected.

If loss aversion is the only mechanism responsible for the rejection of mixed gambles, an individual's degree of loss aversion can be estimated by observing how likely he or she is to accept or reject such gambles. This measure can then be used to relate loss aversion to various psychological, clinical, and neurobiological variables. Following this logic, researchers have argued that loss aversion plays an important role in irrational financial decision making, problem gambling, suicidal decision making, and incorrect affective forecasting (Hadlaczky et al., 2018; Kermer, Driver-Linn, Wilson, & Gilbert, 2006; Lorains et al., 2014; Takeuchi et al., 2015); in explaining differences in risky decision making between decision contexts (Polman, 2012; Schulreich, Gerhardt, & Heekeren, 2016; Vermeer, Boksem, & Sanfey, 2014) and between individuals with varying psychological traits, demographic profiles, and life experiences (Barkley-Levenson & Galvan, 2014; Bibby & Ferguson, 2011; Pighin, Bonini, Savadori, Hadjichristidis, & Schena, 2014; Sokol-Hessner, Hartley, Hamilton, & Phelps, 2015a); and in determining physiological and neural responses to risky prospects (Canessa et al., 2017; De Martino, Camerer, & Adolphs, 2010; Gelskov, Henningsson, Madsen, Siebner, & Ramsøy, 2015; Lazzaro, Rutledge, Burghart, & Glimcher, 2016; Markett, Heeren, Montag, Weber, & Reuter, 2016; Sokol-Hessner, Lackovic, Tobe, Camerer, Leventhal, et al., 2015b; Tom, Fox, Trepel, & Poldrack, 2007). An influential example of this approach is presented in Tom et al. (2007): In this paper, neural activity is correlated with loss aversion, measured using gamble rejection rates, and is used to identify brain regions that encode loss aversion in risky choices involving mixed gambles.

However, loss aversion may not be the only mechanism responsible for the rejection of mixed gambles. Another possibility, one which we explore in the present paper, is that

individuals exhibit a predecisional bias towards rejecting such gambles. Psychologically, this form of behavior may reflect a general preference for the status quo, whereby a decision to accept a lottery is regarded as a departure from one's status quo (Gal, 2006; W. Samuelson & Zeckhauser, 1988). We refer to this tendency as a *predecisional* bias to capture the intuition that individuals may be predisposed towards maintaining the status quo in mixed gamble tasks even *before* they have inspected and learnt about the monetary amounts that could be gained or lost. Although such a tendency could be overridden after monetary amounts are evaluated, we would nonetheless expect the predecisional bias to influence people's decisions and, in many settings, lead to a higher probability of rejection than acceptance. An important prediction of this account is that the effect of such a bias would be greatest early on in the decision, and would diminish as the decision maker deliberates about the money that could be gained or lost.

Although the predecisional bias mechanism provides a fairly intuitive explanation for high rejection rates in mixed gambles, it hasn't yet been formally compared against loss aversion, which remains the dominant explanation for this important behavioral phenomenon. The reason for this is that predecisional biases cannot be accommodated within the types of economic models used to specify loss aversion and predict risky choice. Typically, these models assume that choices depend entirely on *utility*, which itself is a product of the gains and losses offered by the gamble in consideration (e.g., Kahneman & Tversky, 1979). Thus there is no place for a mechanism that influences choice prior to the formation of utility.

There are, however, neurocomputational models of decision making that permit a more nuanced understanding of the deliberation process underpinning people's choices. One such model is the drift diffusion model (DDM), which assumes that individuals gradually accumulate evidence over the time course of the decision, with the decision being made when evidence reaches a threshold value (e.g., Bhatia, 2014; Dai & Busemeyer, 2014; Krajbich, Armel, & Rangel, 2010; Ratcliff, 1978). The evidence being accumulated depends on features of the choice alternatives, such as gains and losses, and subsequently on relative utilities. However, the start of this accumulation process can be biased towards a response (such as rejection), even before these utilities have been evaluated by the decision maker.

Mathematically, DDM implements a sequential probability ratio test, and with this interpretation, its predecisional bias can be seen as a biased prior. The DDM has also been shown to capture aspects of neural information processing, for which a predecisional bias corresponds to a bias in baseline firing rates (Bogacz, Brown, Moehlis, Holmes, & Cohen, 2006; Gold & Shadlen, 2007). In either case, a predecisional bias in the DDM generates unique patterns in response times, and can be quantitatively estimated and differentiated from other DDM parameters (including those that govern the use of decision features like gains and losses) with a combination of choice and response time data (White & Poldrack, 2014). In prior work, psychologists and neuroscientists have used these estimates to compare predecisional biases against alternate decision mechanisms in a variety of perceptual, lexical, and motor choice tasks (Leite & Ratcliff, 2011; Mulder, Wagenmakers, Ratcliff, Boekel, & Forstmann, 2012; A. Voss, Rothermund, & Voss, 2004; White & Poldrack, 2014). The goal of this paper is to use a similar methodology to establish the extent to which a predecisional bias can account for choices in the popular mixed gamble task.

As an example of this task, consider the decision to accept or reject a gamble i, offering a 50% chance of gaining G_i and a 50% chance of losing L_i. The utility for accepting the gamble in the presence of loss aversion is given by $U_i = G_i - \lambda \cdot L_i$ (as the probabilities of the gains and losses are identical, they can be ignored without any effect on model predictions). Here λ is the loss aversion parameter, where $\lambda > 1$ indicates the larger impact of loss than gains. Assuming that the utility for rejecting the gamble is 0, the decision maker will accept gamble i when $U_i > 0$, and reject the gamble when $U_i < 0$. Stochasticity in choice can be modelled with a logistic response function. With such specification, the magnitude of λ (the loss aversion parameter) can be estimated using a logistic regression: $A_i \sim \beta_G \cdot G_i - \beta_L \cdot L_i$. Here A_i is the participant's binary response to the i^{th} gamble (1 if Accept, 0 if Reject), and β_G and β_L are regression coefficients that yield $\lambda = \beta_L/\beta_G$. In practice, researchers often include an additive intercept (α) in the logistic regression: $A_i \sim \alpha + \beta_G \cdot G_i - \beta_L \cdot L_i$. Here the additive intercept corresponding to a fixed impact on utility favoring acceptance or rejection.

Although commonly used to make inferences regarding the psychological and neural underpinnings of risky choice (Tom et al., 2007), the logistic model outlined above neglects the possibility that decision makers may be predisposed towards one of the choice options (acceptance or rejection) prior to evaluating the underlying utilities. To permit this possibility, we model the decision using a drift diffusion process, which is illustrated in Figure 1A. This model assumes that decision makers accumulate evidence in favor of accepting vs. rejecting the gamble over time, with a *drift rate* that relates the utility of the gamble to the accumulation process. To keep model specifications consistent with the static logistic model outlined above, we write the drift rate for a trial involving gamble i, as $v_i = \alpha + \beta_G \cdot G_i - \beta_L \cdot L_i$. Choices are made when the accumulated evidence reaches a positive threshold $+\theta$ (corresponding to acceptance) or a negative threshold $-\theta$ (corresponding to rejection). The magnitude of θ quantifies the amount of evidence required for reaching a decision. Mechanistically, this threshold captures the speed-accuracy tradeoff in decision making, with higher value of θ generating slower but more accurate choices.

In the DDM, the predecisional bias takes the form of a starting point $\gamma > 0$, that is closer to $+\theta$ (predisposing the decision maker towards accepting the gamble), or $\gamma < 0$, that is closer to $-\theta$ (predisposing the decision maker

towards rejecting the gamble). When $\gamma = 0$, the preference accumulation process starts from a neutral state, and the choice probabilities generated by the DDM are identical to those predicted by the static logistic model introduced above. Allowing for the gradual accumulation of evidence prior to the decision enables the DDM to predict response times (RTs). The response time in a trial is assumed to be the time taken for the accumulating evidence to reach a decision threshold added to a fixed non-decisional time τ (which captures the time taken to perceive the stimuli, execute motor responses after the decision has been made, and so on).

The response times predicted by the DDM depend critically on the gamble that is offered on a given trial. Responses times on trials with extremely desirable or undesirable gambles (which generate large positive or negative drift rates) will be shorter, capturing the fact that easier decisions are made relatively quickly compared to more difficult decisions. Besides the influence of the specific gamble at hand, response times also depend on the predecisional bias. If there is a predecisional bias in favor of rejection ($\gamma < 0$), response times associated with rejection will tend to be shorter than those associated with acceptance, and correspondingly, the rejection rates in quicker choices will be higher than those in slower choices, controlling for the difficulty of the choice in consideration (see Figure 1A). Intuitively, the effects of the drift rate (i.e. the utilities used in evaluation) persist throughout the preference accumulation process; whereas the impact of a non-neutral starting point (predecisional bias) gets gradually washed out over time. Crucially, such a prediction cannot be made by the DDM in the absence of the predecisional bias (i.e. when $\gamma = 0$, and DDM choice probabilities mimic the standard logistic specification), indicating that the choice-RTs patterns can be used as a behavioral marker to infer the existence of a predecisional bias (White & Poldrack, 2014).

Methods

Our main experimental task incentivized accept-reject decisions for mixed gambles with a 50% chance of a gain and a 50% chance of a loss. We preregistered our study at OSF(https://osf.io/varx6/?view_only=b9b9f84bd9fc4a56b8df19ea02998fec). In addition to our preregistered study, we also conducted three additional non-incentivized studies (Experiments 1A-1C), which we do not report in the paper due to space limit. The main conclusions of Experiment 2 were replicated in those studies.

Experimental design

Participants. 49 participants were recruited from a paid participant pool at the University of Pennsylvania.

Procedures. Participants were instructed to accept or reject a sequence of 200 gambles, presented in four blocks of 50 gambles. Each gamble had two possible outcomes: A gain of some amount of tokens occurring with a 50% chance and a loss of some amount of tokens occurring with a 50% chance. The outcomes were displayed side by side, with positive/negative values indicating gains and losses (see Figure 1B). Participants pressed up or down arrow keys on a keyboard to indicate acceptance or rejection, with the specific key-response associations alternating across blocks to control for response biases favoring one of the keys. Choices and reaction times were recorded.

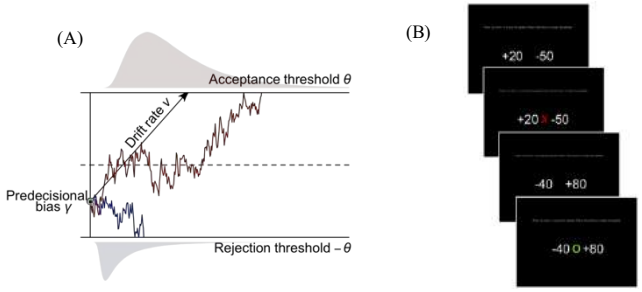

Figure 1 A: The drift diffusion model. B: Task presentation.

Each token was worth US$0.10, and participants began the experiment with an endowment of 100 tokens (US$10). Participants were informed that their choices in the experiment would determine their bonus payment, which they would receive on top of a fixed show-up fee of US$8. This was accomplished by selecting one of the gambles at random. If the participant rejected the gamble, the bonus payment would be 100 tokens (US$10). If the participant accepted the gamble, then they would flip a coin in front of the experimenter to play out the gamble. Their received token amount would be their initial endowment (100 tokens = US$10) plus or minus the gain or loss associated with the coin flip. Average total payments in the experiment were US$ 10.43 per participant.

Stimuli. The possible gain and loss values were taken from the set of {10, 20, 30, 40, 50, 60, 70, 80, 90, 100} tokens, or equivalently US$ {1, 2, 3, 4, 5, 6, 7, 8, 9, 10}. With this stimuli set we were able to generate a total of 100 unique gambles. We counterbalanced the positions of the gain/loss outcomes across blocks, resulting in 200 total trials.

Model Fitting

The models were fit to choice and RT data using HDDM (Wiecki, Sofer, & Frank, 2013), a Python package for hierarchical Bayesian estimation of drift-diffusion models, using its default priors. To fit the models, 4 chains of 50,000 samples were generated, where the first 25,000 were burn-ins, and a thinning of 2 was applied.

Results

Overall, the average rejection probability across participants was 71.5%, with 79.6% of participants being more likely to reject than accept the gambles. These probabilities are significantly different to 50% which is the rate we would expect if choices were made by chance or if individuals did not display loss aversion or predecisional biases ($p < 0.001$ when compared to 50% using t-tests). On average, participants accepted the gambles only when the size of the gain exceed 1.75 times the size of the loss. This pattern of behavior can be explained by both the loss aversion and the

predecisional bias mechanisms. According to a model with loss aversion but no predecisional bias, the probability of acceptance is greater than the probability of rejection only when the utility for the gamble exceeds 0, which happens only when the size of the gain exceeds the size of the loss by a large enough margin to counteract loss aversion. According to a model with a predecisional bias but no loss aversion, the probability of acceptance is greater than the probability of rejection only when the utility of the gamble is large enough to override the starting point bias favoring rejection. This happens only when the size of the gain exceeds the size of the loss by a large enough margin, giving a sufficiently positive utility.

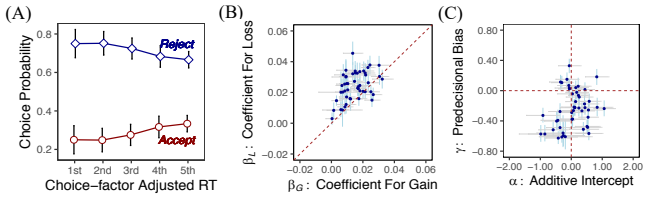

Figure 2. A: Choice-RT relationships. Error bars indicated 95% CI. B: Loss aversion in the DDM. C: Predecisional bias and additive intercept in the drift rate. Most participants have negative posterior means for predecisional bias (i.e., bias towards rejecting gambles). In panel B and C each dot represents a participant and the error bars indicate 95% posterior credible intervals for the parameters in the two figures.

We also found that rejections were quicker than acceptances. Overall, the average rejection decision took 1.30 seconds, whereas the average acceptance decision took 1.72 seconds (the difference is significant: $t(46) = 4.04, p < 0.001$). Additionally, 74.5% of participants took less time to reject than to accept. The RT distributions for acceptance and rejections are different from each other (Wilcoxon signed rank test: $V = 935, p < 0.001$).

Although the observed response time pattern appears consistent with those generated by a predecisional bias favoring rejection, they do not control for choice factors (gains and losses) of the gamble, and thus can also be generated by a DDM model without this bias. More specifically, it is possible that trials on which gambles are rejected involve highly undesirable gambles (and therefore quicker response times), whereas trials on which gambles are accepted involve only moderately desirable gambles (and thus slower response times). To address this issue, Figure 2A shows these choice-RTs patterns, with RTs adjusted for choice factors. These adjusted RTs are residuals from participant-level regressions, in which log RTs are regressed on gain values and loss values of the mixed gambles for each participant. With choice factors controlled for, we observe a negative relationship between choice probability and response time for rejection decisions, and a positive relationship between choice probability and response time for acceptance decisions, showing that decision makers are quicker to reject and slower to accept. This is a novel behavioral pattern that suggests that our participants displayed a predecisional bias favoring rejection. Importantly, this pattern cannot be generated by a DDM model with only loss aversion and no predecisional bias (or by the standard logistic specification of the loss aversion mechanism).

A more rigorous comparison of the loss aversion and predecisional bias mechanisms requires quantitative model fitting. We did so using hierarchical Bayesian techniques applied to choice and RT data. This approach allows for three flexible parameters for the drift rate (α, β_L and β_G) as well as a flexible starting point bias (γ), threshold (θ) and non-response time (τ). Thus this model can simultaneously display both loss aversion and a predecisional bias. We also allowed the threshold (θ) to be dependent on the monetary loss, in order to capture the effect of losses on attention (as specified in our preregistration plan; Yechiam & Hochman, 2013).

Overall, we observe best-fit parameter values such that $\beta_L > \beta_G$ for 85.7% participants, with 57.1% of participants having a 95% credible interval for $\beta_L - \beta_G$ that is strictly positive. The posterior mean of $\lambda = \frac{\beta_L}{\beta_G}$ averaged across our participants is 2.11 ($SD = 1.35$). We also observe a negative posterior mean of γ for 77.6% participants (significant for 69.4% of participants as indicated by 95% credible intervals). The averaged participant-level posterior mean of γ is -0.24 ($SD = 0.25$) across all participants. Finally, we observe a negative posterior mean of α for only 40.8% participants (significant for 12.2% of participants as indicated by 95% credible intervals), with a mean value of $\alpha = 0.05$ ($SD = 0.45$) across our participants. This analysis indicates that most participants display loss aversion and predecisional biases favoring rejection, but do not display any systematic additive intercepts in the drift rate. The posterior means for participant-level parameters are shown in Figures 2B and 2C.

To better understand the descriptive power of the predecisional bias, and to compare it against the descriptive power of loss aversion, we also fit three restricted variants of the DDM. The first constrained model set $\beta_L = \beta_G$ (eliminating loss aversion while permitting flexible values of γ, as well as other DDM parameters). The second set $\gamma = 0$ (eliminating the predecisional bias while permitting flexible values of β_L and β_G, as well as other DDM parameters). The third constrained model is a baseline model that set both $\beta_L = \beta_G$ and $\gamma = 0$ (but permitted flexible values for the remaining DDM parameters). We compared the relative fits of these three constrained models against each other, and against the full model. The model comparisons were performed using the deviance information criterion (DIC; Spiegelhalter, Best, Carlin, & van der Linde, 2002), which measures model fits while penalizing model complexity to avoid over-fitting. Smaller DICs indicate better model performance. This measure revealed that despite having more parameters than the remaining models, the full model ($DIC = 16{,}871$) generated the best fit to the observed data (indicated by DIC differences between this

model and the remaining models, which we denote as ΔDIC). Conversely, despite having fewer parameter than the other models, the baseline model generated the worst fit to the observed data ($DIC = 18{,}456$, $\Delta\text{DIC} = 1{,}586$). This indicates that loss aversion and predecisional biases are useful for describing behavior in our experiment. However, out of the two constrained models, the one that set $\beta_L = \beta_G$ ($DIC = 17{,}332, \Delta\text{DIC} = 461$) yielded much better fits than the one that set $\gamma = 0$ ($DIC = 17{,}979, \Delta\text{DIC} = 1{,}108$), indicating that the predecisional bias plays a more important role than loss aversion.

Although our quantitative fits do provide strong evidence in favor of the predecisional bias mechanism, using such fits as a single piece of evidence for theory testing is problematic (Roberts & Pashler, 2000). Ideally, we should also compare our models in terms of their ability to account for a qualitative behavioral marker, in this case, the finding that rejection rates are higher for trials with shorter RTs compared to trials with longer RTs (Figure 2A, and solid blue lines in Figures 3A-D). As discussed above, this pattern is consistent with the effect of a predecisional bias towards rejecting mixed gambles. A model without such a bias cannot account for RT differences between acceptance and rejection, controlling for choice factors. To establish this more rigorously, we used simulated data from the best-fitting full and constrained models. In line with our intuition, we found that the choice-RT relationship can be captured by the best-fit full model (Figure 3A), as well as by the best-fit constrained model with flexible predecisional bias but no loss aversion (Figure 3B). However, both the best-fit model with loss aversion but no predecisional bias (Figure 3C) and the best-fit baseline model (Figure 3D) fail to capture this relationship. This finding provides one explanation for why the predecisional bias plays a more important role than loss aversion in our quantitative model fits.

In our final analysis we tested the relationship between individual-level model parameters and observed heterogeneity in participant behavior. For this purpose, we correlated best-fitting participant-level estimates of loss aversion ($\lambda = \beta_L/\beta_G$) and predecisional bias (γ) with average participant-level rejection rates. The Pearson correlation between acceptance rates and the predecisional bias is 0.91 ($t(47) = 14.79, p < 0.001$; $Spearman\ Corr = 0.92, p < 0.001$); whereas the correlation between acceptance rates and loss aversion is -0.25 ($t(47) = 1.78, p = 0.08$; $Spearman\ Corr = -0.43, p = 0.002$). These correlations are displayed in Figures 3E and 3F. From the perspective of describing participant heterogeneity, the predecisional bias is clearly the more important psychological mechanism.

Did the participants develop the predecisional bias over the course of the experiment, or did they already have a predecisional bias for gamble choices based on previous life experiences? To test this, we examined the choice-RT relationship (the behavioral marker for predecisional biases) in the first 25 trials of the experiment (first half of the first block). As Figure 3G shows participants were quicker to reject gambles than accept gambles when choice factors are controlled for. In other words, participant already had a predecisional tendency to reject gambles, even when they had limited knowledge regarding the gain and loss value distributions involved in the experiment.

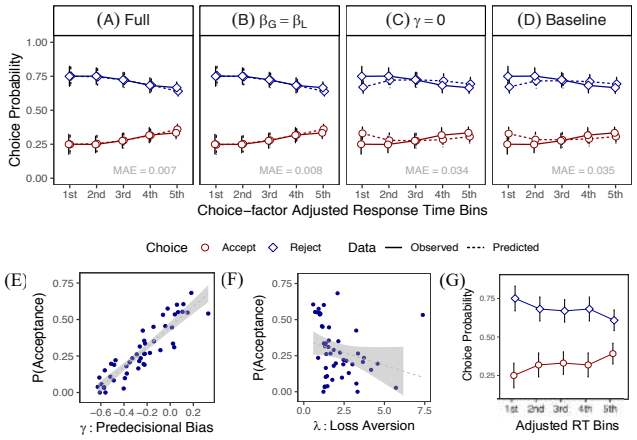

Figure 3. A-D: Choice-RT relationships for observed data (solid lines) and model simulated data (dashed lines). Rejection rates are higher in quicker trials compared to slower trials, controlling for choice factors (gain and loss values). This pattern can only be generated by models that permit a predecisional bias (panels A and B). MAE: Mean absolute error. E-F: Relationships between the DDM mechanisms and acceptance rates. Each dot represents a participant. The predecisional bias is more strongly correlated with the observed choice outcomes, compared to loss aversion. G: Choice-RT relationship for observed data in the first 25 trials of the experiment.

Discussion

The results presented above have a number of important implications for the study of risk preference. First, these results shed light on the psychological underpinnings of one of the most important behavioral findings pertaining to risk: The rejection of small scale 50-50 mixed gambles with positive expected values (Kahneman & Tversky, 1979; Samuelson, 1960). They show that this phenomenon is not just a product of loss aversion (i.e., higher weights attached to losses relative to gains), but is also due to a predecisional bias favoring the status quo. This bias generates a tendency to reject the gamble even before the gamble's payoffs are evaluated, and the effect of this bias is the strongest early on in the decision process. For this reason, the predecisional bias makes unique predictions regarding the relationship between response time and rejection probability. Our experiments provide novel evidence in support of these predictions, indicating that a model equipped with a predecisional bias is necessary to account for behavioral patterns in mixed gamble tasks.

We also used model fitting to evaluate the relative contributions of the loss aversion and predecisional bias mechanisms. Although both loss aversion and predecisional bias play a valuable quantitative role, a model with the predecisional bias but without loss aversion fits better than a model with loss aversion but without predecisional bias. A

second test evaluating the predictive power of best fit model parameters shows that individual-level predecisional bias parameters correlate more strongly with individual-level rejection rates than do individual-level loss aversion parameters. These findings provide strong quantitative evidence that predecisional biases are the primary determinant of high rejection rates in mixed gamble tasks. In doing so they complement recent experimental results showing that loss aversion is not as good of a descriptor of choice behavior as has been previously assumed (Bhatia, 2017; Birnbaum, 2008; Erev, Ert, & Yechiam, 2008; Ert & Erev, 2013; Walasek & Stewart, 2015).

Our findings have important implications for how we interpret people's tendency to reject mixed gambles. A lot of prior work in psychology, economics, and neuroscience infers loss aversion through mixed gamble rejection rates, and subsequently uses this measure of loss aversion to explain the effect of social, cognitive, emotional, developmental, demographic, clinical, physiological, and neural variables on risky choice (e.g., Bibby & Ferguson, 2011; Canessa et al., 2017; Engelmann et al., 2015; Gelskov et al., 2015; Hadlaczky et al., 2018; Kermer et al., 2006; Lazzaro et al., 2016; Lorains et al., 2014; Markett et al., 2016; Pighin et al., 2014; Polman, 2012; Tom et al., 2007; Vermeer et al., 2014). Yet our results indicate that these explanations may be incorrect, and that these variables may be better understood in terms of predecisional bias tendencies. Thus, for example, the well-known finding that ventral striatum activity correlates with mixed gamble rejection rates (Tom et al., 2007) could be due to the relationship between brain activity and predecisional bias rather than the relationship between brain activity and loss aversion, as is commonly assumed. Additional research is needed to untangle these relationships, and future work should consider the possibility that gamble rejection rates, as well as the psychological and neurobiological correlates of high rejection rates, can be understood in terms of multiple different psychological mechanisms.

The tests presented in this paper rely critically on response time data: without this type of data, it would be impossible to identify and measure the predecisional bias. Our analysis uses the drift diffusion model to account for trends in response time data, and by doing so, illustrates the descriptive power of this popular neurocomputational theory (Ratcliff, 1978). The DDM has been previously used to model perceptual, lexical, motor phenomena, and the predecisional bias has been shown to be an important parameter in these low-level tasks (e.g., Forstmann, Ratcliff, & Wagenmakers, 2016; Mulder et al., 2012; Ratcliff et al., 2004; Ratcliff, Smith, Brown, & McKoon, 2016; White & Poldrack, 2014). Additionally, this bias has a theoretically compelling interpretation in terms of baseline firing rates in neural models and statistical priors in optimal sequential evaluation tasks (Bogacz et al., 2006; Gold & Shadlen, 2007). Recent work applying DDM and related models to preferential choice data has also shown that these models provide a powerful account of a variety of choice anomalies. We recommend that future research utilizes the DDM, alongside response time data, to obtain a more comprehensive understanding of the psychological and neurobiological determinants of risky choice.

Abstract

Choice behavior can be influenced by many different types of incidental contextual effects, including those pertaining to presentation format, emotion, social belief, and cognitive capacity. Many of these contextual effects form the basis of nudges, used by academics and practitioners to shape choice. In this paper, we use data from a very large-scale choice experiment to uncover a space of contextual effects. We construct this space by analyzing fifteen contextual effects using the parameters of the drift diffusion model (DDM). DDM is a quantitative theory of decision making whose parameters offer a theoretically compelling characterization of the cognitive underpinnings of choice behavior. By representing a large number of contextual effects in terms of how they influence the parameters of the DDM, our space is able to precisely measure, quantify, and compare the contextual effects, and interpret these effects in terms of their behavioral, mechanistic, and statistical implications.

Does Video Content Facilitate or Impair Comprehension of Documentaries? The Effect of Cognitive Abilities and Eye Movement Strategy

Abstract

It remains unclear whether multimedia facilitates or impairs knowledge acquisition. Here we examined whether subtitles and video content facilitate comprehension of documentaries consisting of statements of facts and whether the comprehension depends on participants' cognitive abilities and eye movement strategies during video watching. We found that subtitles facilitated comprehension regardless of participants' cognitive abilities or eye movement strategies for video watching. In contrast, with video content but not subtitles, comprehension depended on participants' auditory working memory, task switching ability, and eye movement strategy. Through the Eye Movement analysis with Hidden Markov Models (EMHMM) method, we found that a centralized (looking mainly at the screen center) eye movement strategy predicted better comprehension as opposed to a distributed strategy (with distributed regions of interest) after contributions from cognitive abilities were controlled. Thus, whether video content facilitates comprehension of documentaries depends on the viewers' eye movement strategy in addition to cognitive abilities.

Keywords: multimedia; eye-movement; hidden Markov model

Introduction

Multimedia learning refers to knowledge construction from both verbal and pictorial information, with the verbal form including spoken words or printed texts, and the pictorial form including illustrations, graphs, pictures, photos, animations, and videos (Mayer, 2014a). The modality principle suggests that it is generally beneficial to receive both visual and audio information in the learning process (Low & Sweller, 2014). Similarly, subtitles have been shown to enhance learning: same-language subtitles in video advertisements were shown to enhance the viewers' memory of the brand and slogan (Brasel & Gips, 2014), and watching recorded lectures with subtitles was associated with better comprehension performance (Kruger & Steyn, 2014).

The cognitive theory of multimedia learning further posits that learning would be undermined if multiple sources of information are received from the same perceptual channel, and would be facilitated if different sources of information are received from independent channels (Mayer, 2014b). For example, people displayed worse learning outcome when watching animations with on-screen texts than without because both text and animation information came from the visual modality (Mayer, Heiser & Lonn, 2001). However, some more recent research reported no trade-off between image and text processing (Perego, Del Missier, Porta & Mosconi, 2010; Kruger, Soto-Sanfiel & Doherty, 2017), and that participants learning through multimedia displayed better knowledge acquisition and improved content comprehension as compared with those who learned through text reading or traditional lectures in academic learning (Starbek, Erjavec, Starcic & Peklaj, 2010).

The inconsistent findings in the literature may be due to differences in the type of learning materials used and learners' language proficiency across studies. The effect of multimedia learning may depend on how the most important information for comprehension was delivered. For example, for documentaries containing mainly statements of facts, the auditory narratives may contain most of the information, and thus video content may be distracting and impair comprehension whereas same-language subtitles may be helpful especially for second-language learners. Indeed, unsubtitled videos were reported to create a higher cognitive load (as indicated by pupil diameter change) and frustration levels (as measured by EEG) than subtitled versions for students learning English as a second language (Kruger, Hefer & Matthew, 2013). In contrast, for learning involving graphic demonstrations, video content may contain additional information, which may compete with on-screen texts for cognitive resources.

In addition, individual differences in cognitive abilities and strategies may also influence whether multimedia helps or impairs learning. For example, the ability to flexibly

switch attention among various sources of information and to focus on the relevant information while inhibiting irrelevant information may be important for successful multimedia learning (Miyake et al., 2000). Indeed, research has reported that readers with high working memory capacity were more effective in selecting and integrating information and achieved better comprehension in multimedia learning (Schnotz, 2005; Fenesi, Kramer & Kim, 2016). Similar results were found for those with better task switching ability (Baadte, Rasch & Honstein, 2015).

Another possible factor is individual differences in cognitive strategy or perception style, which may be better revealed through eye tracking (Hyona, 2010; van Gog & Scheiter, 2010). Previous research using eye tracking to understand multimedia processing typically only focused on group level comparisons, such as comparing adults' and children's learning (D'Ydewalle & De Bruycker, 2007). However, recent studies have reported significant individual differences in eye movement patterns that can reflect differences in cognitive strategy and perception style (e.g., Chan, Chan, Lee & Hsiao, 2018). It is possible that participants adopting different eye movement strategies during multimedia learning differed in whether multimedia facilitates or impairs learning.

Here we aimed to examine how individual differences in cognitive abilities and eye movement strategies modulate multimedia learning of documentaries consisting of mainly statements of facts, and thus the important information would be mainly in the auditory narratives. Specifically, we examined how adding subtitles and video content would influence participants' comprehension of auditory science documentaries, and whether participants' working memory capacity, switching ability, and eye movement strategy for video watching could predict the comprehension of the documentaries. We recruited native speakers of the language used in the documentaries to control for language experience. To discover common eye movement strategies for video watching from the participants and quantitively measure individual differences in eye movement pattern, we used the Eye Movement analysis with Hidden Markov Models (EMHMM, Chuk, Chan, & Hsiao, 2014) method to analyze eye movement data. In this method, each participant's eye movement pattern during a visual task is summarized using an HMM, including personalized regions of interest (ROIs) and transition probabilities among the ROIs. Individual HMMs then can be clustered according to similarities to discover common strategies in the participants (Coviello, Chan & Lanckriet, 2014). The similarity between a participant's eye movement pattern to a common strategy can be assessed as the log-likelihood of the participant's eye movement data being generated by the HMM of the common strategy. This quantitative measure of eye movement pattern similarity then can be used to examine the associations between eye movement patterns and other cognitive measures. We hypothesized that (1) subtitles are helpful in the comprehension of the documentaries because of the exact match to the content of the documentaries, which may facilitate retrieving the meanings of the auditory narratives, (2) people with higher working memory capacity or task switching ability may show better comprehension when learning from documentaries with video content, and (3) people with more explorative eye movement patterns during video watching may be more distracted by video content, leading to worse comprehension performance.

Methods

Participants

Sixty native Mandarin speakers (40 females, 18 to 30 years old, M = 21.07, SD = 3.32) were recruited from the University of Hong Kong. Participants were from different majors except for ecology, astronomy, geography and chemistry, which were the topics of the documentary clips used here. All participants reported normal or corrected-to-normal vision.

Materials

The materials consisted of 16 documentary video clips in ecology, astronomy, geography, and chemistry, with 4 clips in each topic. The length of each clip was 75 s, and the resolution was 1920 x 1280 pixels. All clips used were produced by China Central Television (CCTV) and Shanghai Education Television (SETV) and were accessible to the public. The clips were selected based on the following criteria: a) Mandarin narratives; b) with simplified Chinese subtitles; c) not translated from foreign languages; d) produced as statements of facts, as to ensure the understandability of the clips to native speakers and to avoid possible linguistic biases.

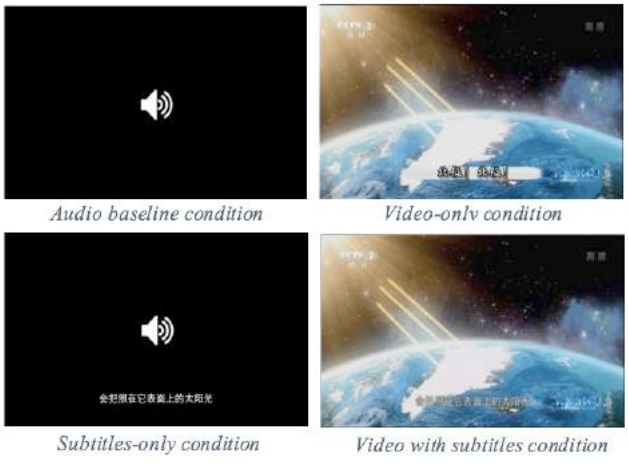

Figure 1: Four conditions of documentary presentation.

Each documentary could be presented in 4 different conditions: a) *Audio baseline* condition (i.e., narrated sound only without video content or subtitle, with a static icon presented at the center of a black screen); b) *Subtitles-only* condition (i.e., Audio baseline condition with original subtitles); c) *Video-only* condition (i.e., narrated sound with full-screen video content, with a fixed title masking the original subtitles); and d) *Video with subtitles* condition (i.e., narrated sound with both video content and original subtitles; Figure 1). Among the 16 original video clips, half of them had subtitles located on the bottom left of the screen, while the other half set the subtitles on the bottom center.

Design

Here we examined how video content and subtitle affected comprehension of documentaries. The independent variables were video content (with vs. without) and subtitle (with or without), resulting in four experimental conditions: audio baseline, subtitles only, video only, and video with subtitles. Each participant viewed 16 clips in total with 4 clips in each condition (one from each topic); the clips used in the 4 conditions were counterbalanced across participants. The dependent variable was accuracy in answering comprehension questions related to the clips. Repeated measures ANOVA was used for the data analysis.

In a separate analysis, we examined whether eye movement strategies used in the video only and video with subtitles conditions could predict comprehension of documentaries. The EMHMM approach was used (Chuk et al., 2014). More specifically, for each of the two video conditions separately, we used one HMM to summarize a participant's eye movement pattern across all clips. We then clustered the individual HMMs into two groups according to similarities to discover two representative eye movement strategies among the participants. Participants' eye movement pattern similarity to the two strategies then could be quantitatively assessed by calculating the log-likelihood of their data being generated by the HMM of the representative strategies. We examined whether this eye movement pattern similarity measure could predict participants' comprehension.

We also examined whether participants' cognitive abilities could predict comprehension of documentaries. Participants completed a n-back task for testing working memory capacity (Owen, McMillan, Laird & Bullmore, 2005), a Tower of London task for assessing executive function and planning abilities (Shallice, 1982), and a multitasking task for testing task switching abilities (Pashler, 2000). We then performed a hierarchical analysis to examine whether eye movement pattern could still predict comprehension after variation due to cognitive abilities was controlled.

Procedure

Comprehension of Documentaries During the task, participants' eye movements were recorded by an eye tracker, Eyelink1000. The tracking mode was pupil and corneal reflection with a sampling rate of 1000 Hz. Stimuli were displayed on a 22" CRT monitor with a resolution of 1920 by 1440 pixels and 150 Hz frame rate. The viewing distance was 60 cm. The standard nine-point calibration procedure was carried out before the experiment and whenever the drift correction error was larger than 1° of visual angle. Each trial started with a white solid dot appearing at the center of the screen. Participants were asked to look at the dot whenever it appeared for drift correction. Afterwards, a documentary clip was played in full screen. After each clip, participants were asked to answer 6 aurally-presented multiple-choice questions (MCQs) according to the content. The MCQs were presented one at a time binaurally in Mandarin, and the voice was synthesized by the online Baidu voice producer. Participants could replay each question unlimited times before their response. Participants performed the task in the 4 different documentary presentation conditions in separate blocks, with the block order counterbalanced across participants. They proceeded to the cognitive tasks described below after the comprehension task.

Cognitive Tasks

1. N-back Test: Two-back tests with 3 types of stimuli, including visual English letters, spoken numbers, and irregular shapes (Figure 2A) were used to test visual and verbal working memory. For each type of stimuli, participants were presented with 30 items one at a time, each for 2.5 s with a 0.5 s interval (Lau et al., 2010), and asked to judge whether the item presented in a trial matched the one that appeared 2 trials back.

2. Tower of London Test: Participants were asked to move 3 color discs one at a time from an initial position to match a goal position with the minimum number of moves, and to plan the moves in mind before execution (Figure 2B; Phillips, Wynn, McPherson & Gilhooly, 2001). Participants completed 10 trials. The total number of moves, total execution time, and total preplanning time before executing the first move were measured. Five practice trials were provided.

3. Multitasking Test: Four types of figures with different combinations of shapes and fillings were used as the stimuli (Figure 2C). The stimuli were presented one at a time in either the top or the bottom half of a box at the center of the screen (Figure 2C, left). Participants were asked to perform a dual task where they judged the shape of the figure (the shape task) as fast and correctly as possible when the figure was presented in the top half of the box, and judged the number of dots in the filling of the figure (the filling task) when the figure was presented in the bottom half of the box (Stoet, O'Connor, Conner & Laws, 2013). The figure was

presented for 2500ms, followed by a 500ms blank screen. Participants were asked to respond by the end of the 3-second trial. A shape-only and a filling-only task were tested sequentially before the dual-task to measure participants' baseline behavior where no task switching was involved. Their task switching ability was measured as the response time (RT) in the dual task minus the average RT during the two no-switching tasks.

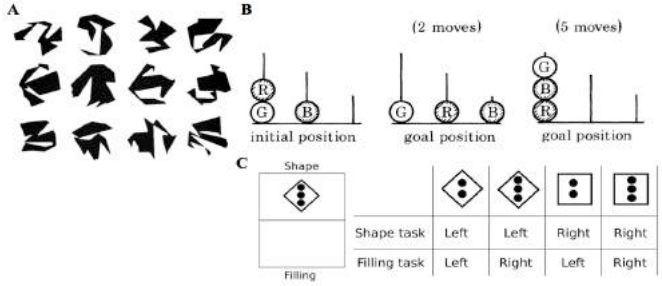

Figure 2: (A) 12 pictorial stimuli (Attneave and Arnoult structures) in the 2-back test, (B) Example of Tower of London test, (C) Stimuli used in the multitasking test.

Results

Effect of Video Content and Subtitle

The results showed a significant main effect of subtitle, F (1, 59) = 13.359, p = .001 (Figure 3). There was no main effect of video content or interaction between video content and subtitle. This result suggested that subtitles, but not video content, facilitated comprehension of documentaries.

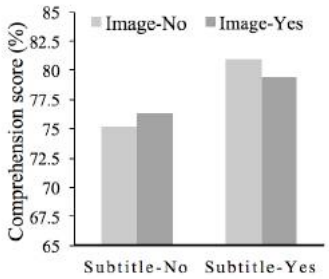

Figure 3. Effect of video content and subtitle on the comprehension of documentaries.

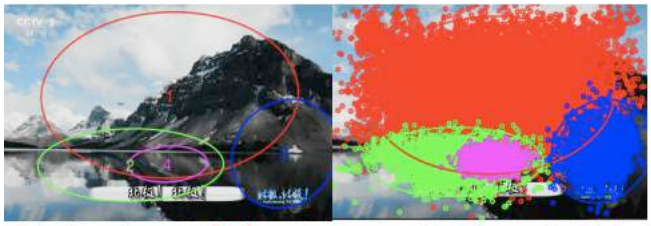
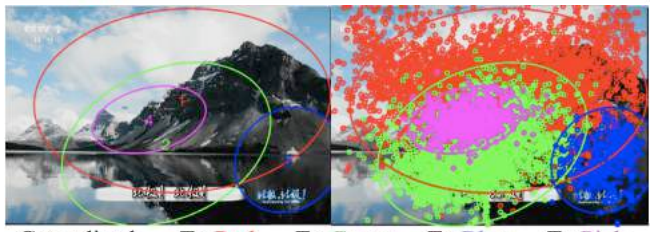
Eye Movement Strategies for Viewing Videos

Using the EMHMM method, for the video-only and video with subtitles conditions separately, we summarized each participant's eye movement pattern using an HMM. For each HMM, a variational Bayesian method was used to determine the optimal number of ROIs. More specifically, we ran each HMM with a different number of ROIs (ranging from 1 to 6) 300 times with a random initialization each time and selected the model with the largest log-likelihood given the data. We then clustered all individual HMMs into two groups and generated a representative HMM for each group with the number of ROIs set to 4.

Figure 4 shows the results of the *Video-only* condition. In the strategy on the top, after an initial fixation at the center of the video, participants had 8% of probability to look at either the blue ROI containing a logo on the bottom right or the green and the pink ROIs containing the fixed title on the bottom center of the screen. Afterwards, they tended to stay in the same ROI or switch back to the red ROI, or occasionally switched among the green, blue, and pink ROIs. We referred to this strategy as the distributed strategy. 46 participants were classified in this group. In contrast, in the strategy on the bottom, there were overlapping ROIs around the screen center, and participants mainly focused at the center of the screen. We referred to this strategy as the centralized strategy. There were 14 participants in this group.



Distributed	To Red	To Green	To Blue	To Pink
Priors	1.0	.00	.00	.00
From Red	.92	.05	.02	.01
From Green	.37	.56	.07	.00
From Blue	.38	.12	.47	.04
From Pink	.27	.00	.08	.64



Centralized	To Red	To Green	To Blue	To Pink
Priors	.46	.44	.01	.00
From Red	.91	.08	.01	.00
From Green	.18	.78	.04	.01
From Blue	.17	.39	.44	.00
From Pink	.03	.04	.00	.93

Figure 4. Distributed (top) and centralized strategies in the video only condition. Ellipses show ROIs as 2-D Gaussian emissions. The table shows transition probabilities among the ROIs. Priors show the probabilities that a fixation sequence starts from the ellipse. The image on the right shows raw eye fixation data and their ROI assignments.

To better understand the relationship between eye movement pattern and comprehension performance, following previous studies (e.g., Chan et al., 2018), we defined a Distributed-Centralized scale (D-C scale) for each participant as

$$Distributed\text{-}Centralized\ scale = \frac{D - C}{|D| + |C|}$$

Where D is the log-likelihood of the participant's eye movement data being generated by the representative HMM of the distributed strategy, and F is the log-likelihood of the participant's data being generated by the representative HMM of the centralized strategy. This log-likelihood measure reflects the similarity of the participant's eye movement pattern to the representative strategies. A more positive value in the D-C scale indicated higher similarity to the distributed strategy, whereas a more negative value indicated higher similarity to the centralized strategy. We found that participants' D-C scale was negatively correlated with comprehension performance in the video-only condition, r = -.291, p = .024: the more distributed the pattern, the lower the performance in comprehension (Figure 5A).

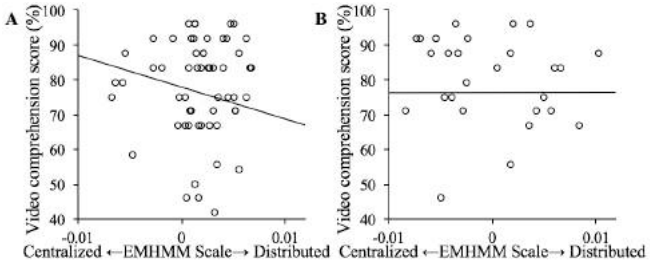


Figure 5. Correlation between eye-movement pattern and comprehension performance in the (A) video-only, and (B) video with subtitles condition.

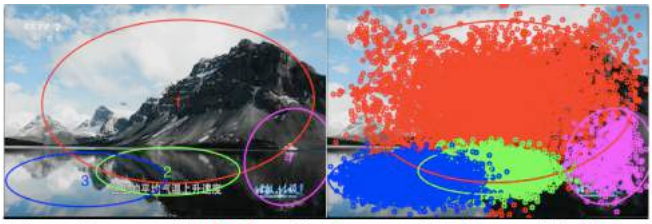
A similar analysis was conducted with eye movement data in the video with subtitles condition. Figure 6 shows the results of clustering participants' eye movement patterns into 2 groups. The 2 groups showed similar concentrations on the ROIs on the bottom left and bottom center of the screen, where the subtitles were located, in addition to the screen center. Group 1 strategy showed a higher probability to look at the subtitle regions after looking at the screen center. One-third of the participants (20 out of 60) adopted Group 1 strategy (one participant's eye movement data was invalid due to technical problems). We also measured participants' eye movement pattern similarity using the Group 1-2 scale in the same way as the D-C scale, and found that it did not correlate significantly with comprehension performance (Figure 5B).

Effect of Cognitive Abilities and Eye Movement Strategy on Comprehension

The above results suggested that in the video-only condition, participants' online eye movement pattern (D-C scale) predicted participants' comprehension. In addition to eye movement strategy, we found that comprehension performance was also significantly correlated with auditory working memory ability as measured in the n-back task, r = .337, p = .008, and task switching ability as measured in the multitasking test r = .262, p = .043. To examine whether eye movement pattern significantly contributed to comprehension after variation due to cognitive abilities was controlled, a three-stage hierarchical multiple regression was conducted to predict comprehension score. At stage one, auditory working memory capacity (N-back test) contributed significantly to the regression model, F(1,58) = 7.432, p = .008, and accounted for 11.4% of the variation. Adding task switching ability (Multitasking test) to the regression model explained an additional 5.5% of the variation in comprehension and the change in R^2 was significant, F(2,56) = 5.813, p = .005. Finally, introducing eye movement pattern (D-C scale) explained an additional 7.9% of the variation in comprehension score and this change in R^2 was significant, F (3,57) = 6.172, p = .001. Thus, when watching video documentaries without subtitles, participants' online eye movement behavior played an important role in comprehension in addition to cognitive abilities. A similar regression analysis was conducted for predicting comprehension performance in the video with subtitles condition, and no significant predicting variable was found.



Group1	To Red	To Green	To Blue	To Pink
Priors	0.98	.00	.02	.00
From Red	.74	.14	.11	.02
From Green	.22	.76	.01	.01

Discussion

The present study aimed to investigate the role of video and subtitle in knowledge-based multimedia learning, with the effect of individual differences in multimedia processing including cognitive abilities and eye movement strategies considered. We hypothesized that for documentaries consisted of statements of facts, where auditory narratives provide most of the information, subtitles would facilitate comprehension due to the exact match to the content. In contrast, with video content, the comprehension may depend on participants' working memory, planning, and task switching abilities, as well as their eye movement strategy. Consistent with our hypothesis, we found that subtitles facilitated comprehension whereas video content did not. Through the EMHMM method, we discovered the distributed and centralized eye movement strategies in watching videos without subtitles. Interestingly, the more similar participants' eye movement pattern to the distributed strategy, the worse their comprehension in the video-only condition. Hierarchical regression analysis further showed that, while both auditory working memory and task switching abilities were significant predictors for comprehension, participants' eye movement pattern contributed significantly to comprehension after variation due to these cognitive abilities was controlled. This result showed that the facilitation of video content in the comprehension of documentaries depended on participants' online eye movement strategy in addition to working memory and task switching abilities. In contrast, participants' comprehension in the video with subtitles condition did not depend on either cognitive abilities or eye movement strategy.

Our results showed that adding subtitles is beneficial to knowledge acquisition of documentaries consisting of statements of facts. Previous studies on the effect of subtitles have reported inconsistent findings, with some showing that on-screen text is distracting (Mayer, Heiser & Lonn, 2001) whereas others suggesting facilitating effects (Starbek et al., 2010). This inconsistency may be due to differences in the amount of information carried in each medium during multimedia learning. In cases where pictorial stimuli contain important content for knowledge acquisition, simultaneous on-screen texts may be distracting (e.g., Mayer, Heiser & Lonn, 2001). In contrast, for materials where auditory narratives already provide most of the information for learning, such as the documentaries used in the current study, subtitles that match well with the auditory narratives may help maintaining participants' attention to the content of the knowledge and consequently facilitate comprehension (Kruger, Hefer & Matthew, 2013).

The finding that the distributed eye movement strategy, as opposed to the centralized strategy, was correlated with worse comprehension may be related to how attention was allocated in these two cases. According to the cognitive theory of multimedia learning (e.g., Mayer, 2014), engaging in active eye movement planning as demonstrated in the distributed strategy where there were specific ROIs located at different regions of the video may increase the cognitive load, resulting in decreased attentional resources for listening comprehension. The EMHMM method allows discovery of representative eye movement strategies from individual patterns in a data-driven fashion and provides a quantitative assessment of eye movement pattern similarities, leading this novel finding.

We also observed that in the video with subtitles condition, most participants focused on the subtitle locations in addition to the screen center, and participants' comprehension could not be predicted by either eye movement strategies discovered in this condition, working memory ability, or task switching ability, in contrast to the video-only condition. This result suggests that subtitles with video may help maintain participants' attention to a specific location of the video and reduce the possibility of active eye movement planning to other regions of the video, resulting in more attentional resources to listening comprehension and reduced task switching requirements. The redundancy effect from subtitles may also decrease the demands on working memory.

Previous research has suggested that cognitive abilities such as working memory capacity could modulate multimedia learning effects (Fenesi, Kramer & Kim, 2016). Here we further showed that in addition to working memory and task switching abilities, comprehension performance in the video-only condition could be predicted by online eye movement strategy: people who adopted a more centralized eye movement pattern had better comprehension. Future work will examine whether an explicit instruction of using a centralized eye movement strategy during video documentary viewing will facilitate comprehension.

To conclude, here we showed that for knowledge acquisition from auditory narratives, subtitles facilitated comprehension, whereas with video content, comprehension depended on participants' working memory and task switching abilities, as well as online eye movement strategy. When watching videos without subtitles, participants' comprehension could be facilitated by better auditory working memory and task switch abilities, and a more centralized eye movement pattern. In contrast, when watching videos with subtitles, subtitles seemed to have attracted and stabilized eye movements as well as reduced the demands on working memory and task switching, and thus neither cognitive abilities nor eye movement strategy could predict comprehension performance. These findings demonstrated the importance of taking individual differences into account in the research on instructional design and science of learning, and eye tracking with EMHMM provides a useful tool for revealing and quantitatively assessing these individual differences.

Abstract

Manufacturing systems of the future need to have flexible resources and flexible routing to produce extremely personalized products, even of lot size equal to one. In this paper we have proposed a framework, which is designed to achieve this goal. Towards this we have integrated an established cultural evolution model to achieve desirable flexibility of resources and acceptable routing time. Promising results are evidenced through a simple proof-of-concept agent-based simulation. The simulation results reveal that the products need to move less in more diversified cultural groups when looking for suitable resources. It was also observed that the more time we provide for cultural dissemination, the cultural groups become increasingly coherent due to homophily. For scenarios, which require diversification of resources, we need to find a balance between coherence and diversification. This paper provides first insights into these aspects for a production shop floor.

Keywords: Industry 4.0; resource flexibility; routing flexibility; personalized production; cultural dissemination; group coherence.

Introduction

The industrial manufacturing paradigm has already evolved from mass production to mass customization. Fueled by initiatives like Industry 4.0 (Lee, Bagheri, & Kao, 2015), we foresee a further improvement in coming years, namely the paradigm of personalized production. Personalized production targets an extremely flexible manufacturing system which could respond to predicted and unpredicted changes in the production environment and allows customers to create and design themselves (Hu, 2013; Mourtzis & Doukas, 2014). Manufacturing systems supporting personalized production should exhibit the following features (Ogunsakin, Mehandjiev, & Marín, 2018):

- Resource Flexibility: flexibility of processing stations (or machines) to make multiple parts, which means that one processing station is not designated for one task and can perform different tasks as required.
- Routing Flexibility: flexibility to execute same operation (or function related to a task) using multiple processing stations, which means that a single task can be performed by many processing stations.
- Lot Size Flexibility: ability to produce a very small customized and/or personalized lot size in a non-batch mode, which is a direct consequence of at least (if not any other dimension) the above two features.

The progress towards a truly flexible manufacturing system (FMS) is naturally driven by technological needs from industrial process management viewpoint, which falls into general knowledge areas of scheduling (Wang, Zhong, Dai, & Huang, 2016; Marichelvam, Prabaharan, & Yang, 2014), resource optimization (Ogunsakin et al., 2018; Beruvides, 2017), constraint satisfaction (Ezpeleta, Colom, & Martinez, 1995), and related.

Still, the body of work considering the aspect of "personalization" is quite lean and requires further attention. Realizing this, several projects and activities are already under progress. One significant effort endeavours to develop cognitive products and production systems incorporating *human-like* capabilities like "perception, understanding, interpretation, memorizing and learning, reasoning, planning and hence cognition-based acting" (Pro2Future, n.d.). The project is about complex cognitive modalities of humans, products and machines and their interrelationships. In this paper, we argue that one does not need to have high-level cognitive capabilities to be effective. At a scale of a population or a group, a very basic level cognition of interacting agents may result in a desirable global situation. We just need to find the conditions in which this may happen.

Agent-based modeling (ABM) (Bonabeau, 2002) is a method used for modeling such inquiries. One particular area of interest of a production unit is the layout of shop floor which should be optimized for maximum gain in productivity, particularly in case of FMSs. This case study is adopted in our paper. At a conceptual level, a group of agents comprising an interactive social network is augmented with the notion of culture to ground them with the physical world.

Most optimization mechanisms (as stated above) either consider a mathematical abstraction or imitate a real-world situation as their manufacturing environment (which is

mostly *static*) while modeling, and then proposing a solution within these presumptions. A more recent work (Ogunsakin et al., 2018) also considers mobile processing stations as a mean to achieve flexibility of shop floors. The idea is to make resources available as and where these are required. Although, this approach addresses the challenge of routing flexibility to an extent, the capabilities of resources still remain static.

In our research, we are mostly focusing on resource flexibility, which means that the processing units are able to dynamically change their *capabilities* and therefore a resource is able to perform several tasks. The goal is to keep resources stationary (and avoid expensive process of mobility) and arrange resources in groups of *complementing* capabilities. Ideally, a resource would designate itself for a capability that would optimize the manufacturing process in several dimensions, such as production rate, lead-time per order and reactivity index (Ogunsakin et al., 2018). However, we only focus on resource availability and mobility of products.

We postulate that flexibility in resources, routing and personalizing relate to evolution of culture as it emerges at the physical level due to local interactions of *mostly* stationary individuals. In the context of resources (processing units) of a production shop floor, we seek for groups of *complementing* capabilities, self-organizing to produce an approximately optimized layout for the products, which ensures availability of resources and reduces products' mobility. This novel idea would provide an entirely new perspective for the future research in this domain.

In the next section, formal definition of culture and cultural diversification is presented; followed by detailed description of the methods. Next, we present details about our model and simulation; followed by discussion on initial findings. We end the paper with an elaborate outlook of future work.

Culture, Diversification and FMS

A culture is a multi feature system evolving in time. One characteristic of culture is its coherence when seen from outside. Definitely, this coherence results due to a majority of people trying to acquire a similar behavior (often termed as a trait) in a certain context (often termed as a feature).

Relating these concepts to FMS, we need to conceptualize features and traits of resources and products, where a resource is a processing unit in the production line, whereas a product is obviously a product under production. Although a product can also be considered as a cultural entity, it is not the case for the purpose of this paper. Only a resource is a cultural entity.

Resources are flexible, initially having some randomly chosen features and a randomly chosen trait against a feature. For example, a processing unit may have ability to perform one, two or more tasks T_1, T_2, ... with certain levels of precision P_1, P_2, ... Here, a tuple consisting of n values is a set describing capabilities of a resource. For example, the set $\{P_2, P_1, P_3\}$ can be interpreted as: this resource can perform task 1 with precision 2, task 2 with precision 1 and task 3 with precision 3. Furthermore, it cannot perform any other task.

Further, all products have a *sequential* list of capability requirements. For example, a product with set $\{P_1, P_1, P_2\}$ requires task 1 with precision 1, followed by task 2 with precision 1, finally followed by task 2 with precision 2. The question is: would cultural diversification be able to generate a physical layout that would ensure availability of capable resources with minimal mobility for all the products in the system? Technically, what are conditions which lead us to an acceptable (and approximate) solution of the problem?

Such a scheme is naturally compatible with the requirement of a flexible manufacturing system stated above, namely, flexibility in resources, routing and personalizing. Axelrod provides evidence in his seminal work (Axelrod, 1997) for such a simple configuration of cultural descriptions which can result into a locally coherent, but globally polarized culture as a consequence of localized interactions of participating entities.

Our intuition is that unbounded coherence between cultural groups would not help in this scenario. The reason is that limitless coherence has no control over where the boundaries of the global polarization would occur, which is not compatible with a system which seeks for economy of resources and optimizations in several dimensions. That is the reason, we try to find conditions which end up in approximately acceptable structuring in terms of coherence (termed as limited coherence) vs. polarization. To achieve this, we have taken motivation from Centola et. al's work (Centola, Gonzalez-Avella, Eguiluz, & San Miguel, 2007) in which a random drift is used to deviate a highly coherent environment. This drift is achieved through change in the neighborhood of an agent. Theoretically it is possible to do it, however in scenarios like FMS it is not practical as we cannot move processing units so frequently after deployment. Hence, we have fine tuned Axelrod's model of cultural dissemination (Axelrod, 1997) with focus on limited coherence between cultural groups and tried to find out how much we can achieve and in which conditions. Definitely, at run time, the dynamics of requirements and products may change and make a particular layout extremely inefficient. To address it, a further investigation is required, which is planned for the future.

Methods

Axelrod's Model of Cultural Dissemination

Axelrod's model (Axelrod, 1997) thrived for cultural homogeneity (Bednar, Bramson, Jones-Rooy, & Page, 2010), where adjacent cultures get influence from each other. The model is based on cultural components defined by three factors: features, traits and persons. A culture has many features, such as habits of eating, recreation and leisure. These features may not be identical across different cultures. Each of these features have several traits, which may differ across cultures. A person is a placeholder of a culture described by one of f features and t traits. Axelrod proposed a model seeking for cultural homogeneity proclaiming that different cultures are

destined to cohere together so that they appear as a cultural unity, but at the same time, there exists a clear-cut differentiation between cultures.

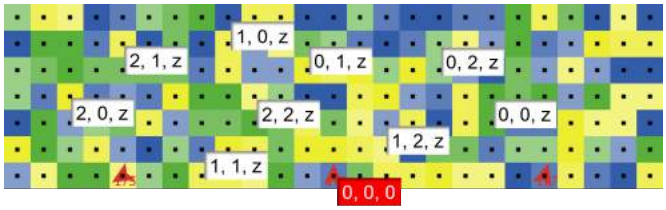

Figure 1: Initial distribution of a 25×7 grid constituted by blocks of culture (anchored on central black persons); each block is a tuple of 3, representing three features (green, blue, yellow) of three traits each (3 shades of a color). Each cell's color has a meaning; for example, all green cells have capability to perform task 1 with precision value 0, which is followed by precision values of task 2 (0, 1 or 2); last value is not path dependent and represented by z. Possible combinations of colors are shown with values; each tuple relating to a person on the top-left corner. A product has a unique sequence of task to perform represented with an arrow shape (at the bottom center of the space).

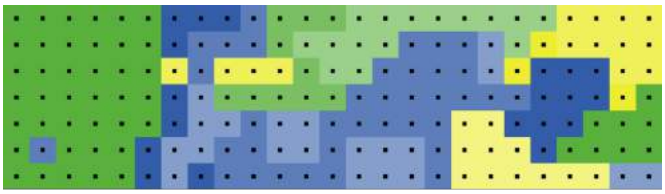
Axelrod model was able to demonstrate that the above two (rather contradictory) goals can be achieved by a simple interaction model (realized through N coordination games) between neighboring persons. Axelrod showed that N coordination games are necessary for a broader scale evolution of a culture. Furthermore, groups' consistency across different aspects of societal norms makes a group culturally coherent and different from others.

We developed a simple simulation model for demonstration purposes using NetLogo (Tisue & Wilensky, 2004). Figure 1 presents a grid of 25×7 cells. Each cell is represented by a person (in black) and the corresponding culture acquired, depicted by cell color of the cell the person is occupying.

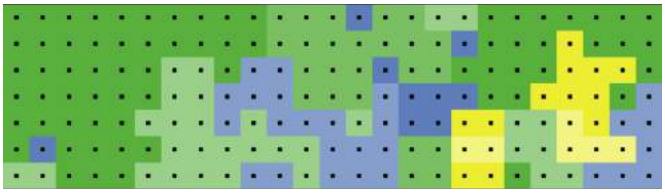
Axelrod's model calculated similarity s between neighboring cultures (based on Von Neumann's neighborhood). If s is not 1 (100%), with a probability p, the value of a $different$ column of a person is replaced by the corresponding value of the neighboring person. This simple mechanism is able to generate clusters of coherent cultures as shown in Figure 2. If we define **diversity index** as the mean diversification of cultures of all persons when compared to their neighbors, the Axelrod model would converge into a single culture most of the time with diversity index equal to 0. This is not desirable in the context in which we want to use this model. Therefore, the model was extended as detailed in the following.

Model Motivation: Constrained, N-Coordination Games for Cultural Diversity

Before describing the model, we will emphasize the scenario given in Figure 1. Given that a processing unit is able to perform three possible tasks with three possible precision values,



(a) Axelrod Model: diversity index = 0.34 at 10000th iteration



(b) Axelrod Model: diversity index = 0.25 at 20000th iteration

Figure 2: Axelrod's Model: Evolution of cultures shown in Figure 1. (a) at simulation iteration 10000 showing clusters of cultures starting to form. (b) at simulation iteration 20000 showing further consolidation of clusters of cultures. The evolution is destined to end up in very few cultures (1 or 2).

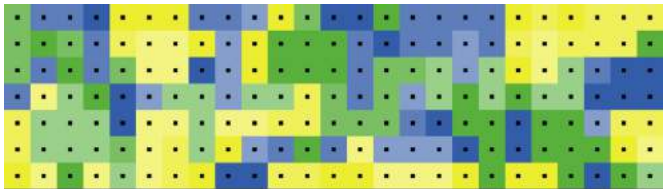
we can see a clear capability matching through colors. Furthermore, a product is introduced which need to complete a sequence of three tasks offered by different resources. We hypothesize that using the constraint, N coordination games, we can achieve cultural diversity closer to what is desirable. This would directly impact products' traversing efforts in a positive way.

The Proposed Diversity Dissemination Mechanism

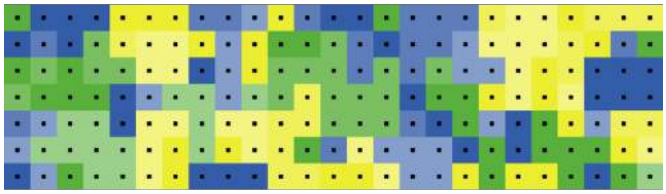
The Axelrod model is too skewed towards coherence and would end up in too few cultures. Hence we propose to refine the Axelrod model in the following way. Axelrod model seeked for similarity s between neighboring cultures. If s is not 1 (100%), with a probability p, the value of a $different$ column of a culture is replaced by corresponding value of the neighboring culture. We extend this model by applying an extra constraint. That is, the replacement is only possible if s is also less than a threshold th, which is for now given a static value of 0.5. This obviously increases the overall *diversity_index* of the system as shown in Figure 3. Before analyzing the impact of this refinement we explain the mechanism of product traversing.

Traversing Mechanism

All products have a sequence of tasks to perform in the form [x, y, z]. A product first gets the value x, and maps it onto resources with identical capability and residing close to its position. Let's denote the resource with r. After visiting r, the product seeks for the next nearest resource corresponding to y. It is assumed that y has a relationship with x. This means that, in terms of colors, this cell (and the resource residing on top of it) should have the same color. The last task z is independent and just show the range of flexibility that the system



(a) Proposed Model: diversity index = 0.50 at 10000th iteration



(b) Proposed Model: diversity index = 0.44 at 20000th iteration

Figure 3: Proposed Model: cultural diversity at iteration (a) iteration 10000 and (b) 20000.

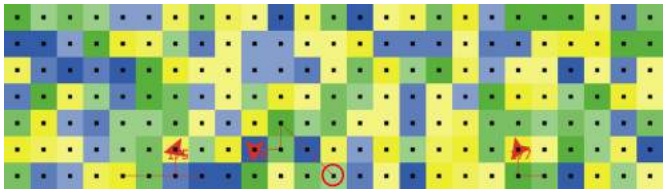


Figure 4: Traversing behavior in random configuration of resource capability.

may have.

An Example Walk-through on Random Configuration (without applying diversification mechanism): Referring to Figure 4, each resource (black agent at the center of a cell) is randomly populated with vector [x y z], where x, y and z may have three possible values 0, 1 and 2. Products have to perform three tasks in a sequence. One product (at the center) has to perform task 1 with precision 0, task 2 with precision 1 and task 3 with precision 1. It starts at the position marked with red circle. First it performs task 1 with precision 0. That takes it 2 steps to the top left cell, which has the nearest resource with this capability. Next, it has to perform task 2 with precision 1. The nearest resource, which has first column equal to 0 (assuming a connection between task 1 and 2) and second column equal to 1 is the resource at the bottom; hence the product would move there. Next task is task 3 with precision 1. Assuming that it is an independent task, the product would try to find the nearest resource that has the third column equal to 1 (any color). This can be any resource (cell at the left is selected). Hence, the **mobility index** of this product is 4, the total number of hops traversed. The other two products also traverse to complete their tasks. The average mobility index turns out to be 3.94.

It seems that random configurations would be the best, but this cannot be the case in a structured environment, particularly in case of an assembly line type of manufacturing.

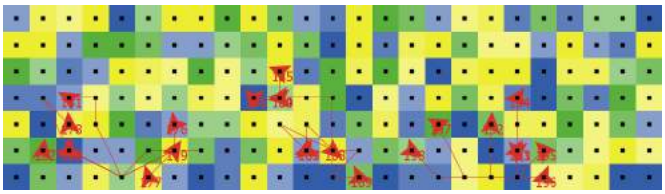

Figure 5: Traversing behavior in random Layout without diversification applied.

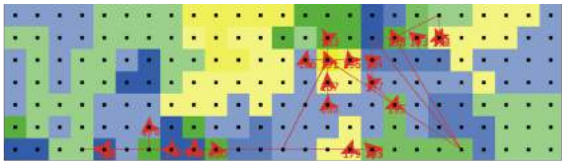
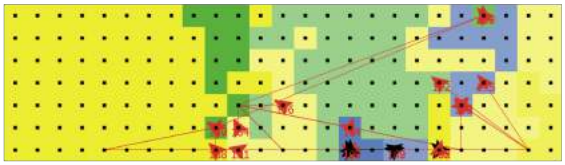


(a) Axelrod Model (10000th iteration): diversity index = 0.34, mobility index = 6.78



(b) Axelrod Model (20000th iteration): diversity index = 0.24, mobility index = 8.66

Figure 6: Traversing behavior in Axelrod's Model.

Analysis of Initial Findings

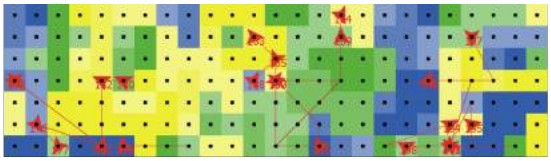
Definitely, the introduction of *th* retains diversity index in case of extension of Axelrod's model. This helps in task completion capability of the system. This claim can be verified by analyzing the mobility of products and the diversity index in three cases. We have used 25 products distributed at three places. In each case, the simulation was run for 100 times and the results were averaged. In the following, we present a sample visualization for each case which is close to average values, at two sampling points (iteration 10000 and iteration 20000) if applicable.

Random Layout

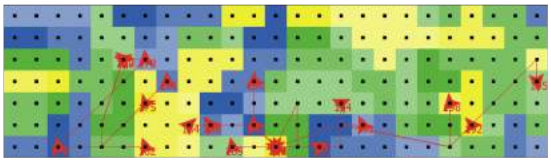
In Figure 5, the system has a diversity index equal to 0.70 and a mobility index equal to 3.4. This is also confirmed by the graphs shown in Figure 8 (diversity index) and Figure 9 (mobility index). As we mentioned already, random configuration is most flexible and would always be best in its task completion capability. However, this configuration is unrealistic. In reality, we need to plan placement of resources and deploy them accordingly.

Axelrod's Model

In case of Axelrod's model, we have analyzed the results for diversification period of 10000 and 20000 iterations. These two situations are represented in Figure 6. With increasing polarization and decreasing diversity index, the average mobility index drops. After running the simulation for 100 runs and averaging, it was observed (see Figure 8 (diversity index) and Figure 9 (mobility index)) that mobility index is just less



(a) Proposed Model (10000th iteration): diversity index = 0.47, mobility index = 5.00



(b) Proposed Model (20000th iteration): diversity index = 0.24, mobility index = 8.66

Figure 7: Traversing behavior in proposed Model.

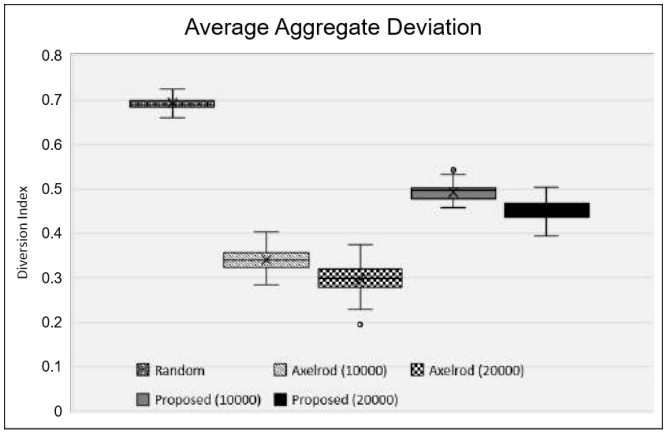


Figure 8: Graph showing diversity index of 100 simulations runs.

than 8 (diversity index = 0.35) in case the diversification happens for 10000 iteration, whereas, mobility index is slightly higher than 8 (diversity index = 0.30) in case the diversification happens for 20000 iteration. As shown in Figure 6, this decrease is due to nonavailability of resources indicated by products turning into black color.

Proposed Model

Lastly, the proposed model solves the above issue. We can see a smooth performance of tasks for all the products, which is evident from Figure 7. Again, we have analyzed the results for diversification period of 10000 and 20000 iterations. These two situations are represented in Figure 7. After running the simulation for 100 runs and averaging, it was observed (see Figure 8 (diversity index) and Figure 9 (mobility index)) that mobility index is equal to 4.57 (diversity index = 0.49) in case the diversification happens for 10000 iteration, whereas, mobility index is about 5 (diversity index = 0.45) in case the diversification happens for 20000 iteration.

Comparative Analysis

As diversity decreases, the availability of resources becomes more difficult. In this particular scenario, the products need

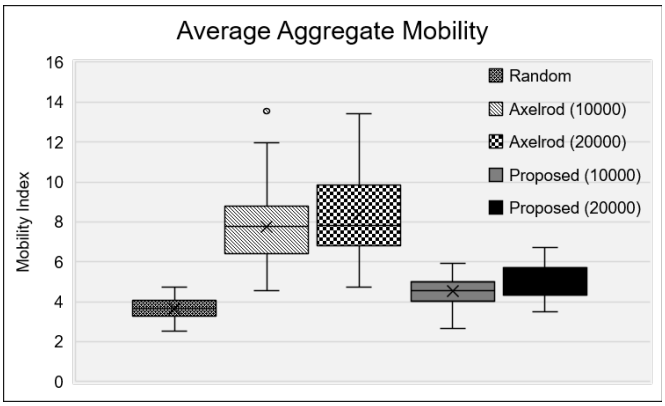

Figure 9: Graph showing mobility index of 100 simulations runs.

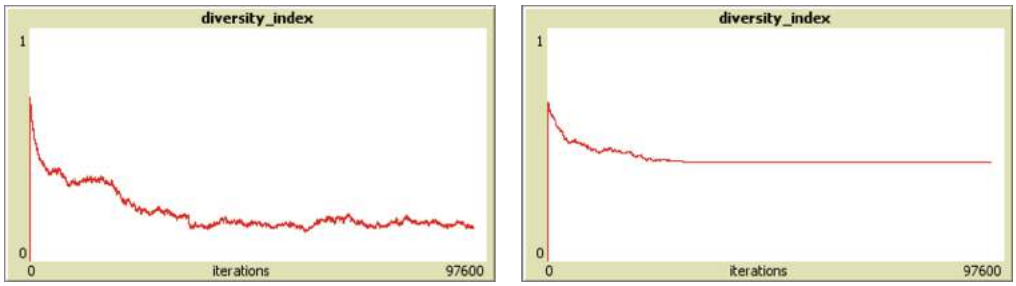
to move less in more diversified cultural groups. The ideal case is random layout in which the products need to move the least. As diversity decreases from random layout to Axelrod's model, the mobility increases substantially. In case of Axelrod's model, it was also observed that the more time we provide for cultural dissemination, the cultural groups become increasingly coherent. In the simulation world's geometry used, the number of culture clusters goes down to a few if the number of iterations is increased to 100000. Obviously, this is not an interesting case to show. However, in the case of the proposed model, this does not happen with such high intensity. In fact, the diversity index never drops below 0.4 and interestingly it reaches an equilibrium in most runs. Hence, it is possible to provide a drift against unbounded homophily effect resulting into an extremely low diversification by using a simple threshold based control mechanism. The graphs shown in Figure 10 validate our claim.

Conclusion and Outlook

Manufacturing systems of the future need to have flexible resources and routing to produce extremely personalized product, even of lot size equal to one. What we have seen is that flexible manufacturing systems can be realized without moving the resources (processing units) by enabling reconfiguration of capabilities of resources based on dissemination of culture concept proposed by Axelrod. However, the Axelrod model has a focus on coherence of cultural groups, which most of the times ends up in one or very few cultures. If we equate such an instance of a culture with a single capability of a resource, we are left with extremely limited resources and products cannot complete their production life cycle.

Hence, we proposed to have a constrained cultural coherence mechanism by introducing a threshold. This tiny development has a significant impact on the increase in diversity of the culture along with related resources being in close vicinity to each other on average. This not only ensured an increase in resource availability as a whole, but also managed to decrease the mobility of products in search of suitable resources.

However, the real contribution of the paper is integration of



(a) Axelrod's Model (b) Proposed Model

Figure 10: Comparative Analysis of diversity index: Axelrod's Model vs. Proposed Model.

manufacturing processes with cultural considerations, which naturally fits into the problem. In our view this is a novel approach of real significance. However, the work reported in this paper is just a proof-of-concept. We need to have more thorough experiments to measure the efficiency of the model in challenging environments such as environments having inflow and outflow points, more in-depth capabilities and richer relationships between tasks.

In the next phase of the project, we will induct models of dynamics, which include timing of tasks, conflict and deadlock resolution between products seeking for identical resources, and more realistic analytics such as production rate, lead-time per order and reactivity index. Lastly, we would also include an autonomous learning system, which would help resources learn and change their configurations on the fly based on product types, requirements and trajectories.

The price of knowledge: Children infer epistemic states and desires from explorations cost

Abstract

When deciding whether to explore, people must consider both their need for information, and the cost of obtaining it. Thus, to judge why someone explores (or decides not to), we must consider not only their actions, but also the cost of information. Do children attend to the cost of agents exploratory choices when inferring what others know or desire to know? In Experiment 1, four- and five-year-olds judged that an agent who rejected an opportunity to gain low-cost information must have already known it. In Experiment 2, four- and five-year-olds judged that an agent who incurred a greater cost to gain information had a greater epistemic desire. In two control experiments, we show that these results cannot be explained by a low-level heuristic linking competence with knowledge. Our results suggest that childrens Theory of Mind includes expectations about how costs interact with epistemic desires to produce action.

Ignorance = doing what is reasonable: Children expect ignorant agents to act based on prior knowledge

Abstract

When deciding how to act in new situations, we expect agents to draw on relevant prior experiences. This expectation underlies many of our mental-state inferences, allowing us to infer agents' prior knowledge from their current actions. Do children share this expectation, and use it to infer others' epistemic states? In Experiment 1, we find that five- and six-year-olds (but not four-year-olds) attribute additional knowledge to agents whose prior experiences cannot explain their success. In Experiment 2, we find that six-year-olds (but not younger children) also attribute greater knowledge to agents whose prior experience cannot explain their failure. We show that by age five or six, children expect ignorant agents' beliefs (and therefore their actions) to be guided by their prior knowledge. This work adds to a growing body of research suggesting that, while infants can represent mental states, the ability to infer mental states continues to develop throughout early childhood.

Keywords: Ignorance; Knowledge; Social Cognition; Theory of Mind

Introduction

To discuss someone's ambitions, frustrations, or disappointments is to talk about a mind that works much like our own, except that we cannot see it or know what it knows. Yet, we make surprisingly accurate inferences about what others think or want, just by watching how they act. For example, if your friend gives you her keys but later rummages in her bag upon reaching the car, you might infer that she forgot you have them. If she doesn't slow for a pedestrian at a crosswalk, you'd probably assume she didn't see them. And if she suddenly takes a detour, you might suspect she knows something you don't (perhaps the usual route is under construction).

The ability to infer other people's thoughts and desires from their behavior involves building a working model of how their mental states relate to their actions. The foundations of this capacity, called a Theory of Mind (Dennett, 1987; Gopnik & Wellman, 1992), are in place and at work early in infancy (Woodward, 1998; Liu, Ullman, Tenenbaum, & Spelke, 2017) but continue to mature throughout early childhood (Wellman, Cross, & Watson, 2001), and well into adolescence (Richardson, Lisandrelli, Riobueno-Naylor & Saxe, 2017).

Within Theory of Mind, our ability to reason about other people's beliefs—what they know, what they don't, and what they think they know—is particularly slow to develop. While infants can represent other people's beliefs (Onishi & Baillargeon, 2005), knowledge (Surian, Caldi & Sperber, 2007), and ignorance (O'Neill, 1996), children do not use these representations explicitly until several years later (Bartsch & Wellman, 1995; Wellman, et al., 2001).

As adults, we understand that other people's past experiences shape their current beliefs, and that these beliefs guide their actions. If, for example, your friend starts their car by inserting and turning a key, you can reasonably predict they will try the same the first time they drive yours. And you'd expect this even if you know your car works differently (for example, starting when a button is pushed in proximity to the key fob).

This expectation not only allows us to predict how others will act: it also allows us to infer what they know by observing how they act. In the example above, if your friend defied your expectations by immediately locating the button that starts your car, you might wonder if they had some prior experience you didn't know about (perhaps they've driven other cars like yours before). Such reasoning may seem intuitive, but how exactly do we predict what actions agents are likely to take in new situations? Prior research suggests that adults solve this problem by integrating over agents' uncertainty (Baker, Jara-Ettinger, Saxe, & Tenenbaum, 2017). For instance, when we reason about an agent who does not know whether a car starts via a key or a button, we consider what they would do in each situation, and we expect them to choose a plan weighted by their confidence.

While effective, these types of inferences are computationally complex. They require considering multiple possible worlds (at least implicitly), and deciding what an agent would do in each. Perhaps unsurprisingly, children's expectations for how ignorant agents are likely to act appear to rely on simpler strategies. Children sometimes equate being ignorant with getting things wrong (Ruffman, 1996; Saxe, 2005); although, in other contexts, their intuitions reverse (Friedman & Petrashek, 2009; German & Leslie, 2001).

While expecting ignorant agents to fail may support accurate inferences and useful predictions, such strategies are limited. Even ignorant agents can make reasonable guesses based on past experience. For instance, even if you've only used PC's, you probably have some idea of what you'd try if you had to turn on a Mac. And ignorant agents can always get lucky, succeeding by chance.

Do children understand how previous experiences affect agents' future actions? And do they leverage this expectation to infer what an agent knows based on what she does? In the current work, we investigate these questions with four- to six-year-olds. The ability to explicitly and flexibly represent beliefs emerges in the mid-preschool years (e.g., Rubio-Fernández, 2019; Wellman et al., 2001). Therefore, if children have expectations about the relation between ignorance and action, we might expect them to emerge in this age range.

In two experiments, participants watched two puppets learn how to activate a novel toy. Each puppet later attempted to activate a different (but outwardly identical) toy. One agent's actions were consistent with their prior experience, while the other agent's actions were inconsistent with their prior experience. In Experiment 1, both agents succeeded in activating a toy. If children expect agents to act based on their prior knowledge, they should judge that the inconsistent agent (whose actions cannot be explained by their experience with the initial toy) must have had additional knowledge. We find that five- and six-year-olds (but not four-year-olds) attribute additional prior knowledge to this agent.

To control for the possibility that children attribute knowledge to agents who teach them something new, in Experiment 2, children learned how a toy worked, and then watched two agents fail to activate this toy. Children again judged that the inconsistent agent (whose action couldn't be explained by his experience with the initial toy) had *greater* additional knowledge. These results suggest that by age five, children expect ignorant agents to act according to their prior knowledge, and further, that children leverage this expectation to infer what others know from what they do. All experiments' procedures, predictions, exclusion criteria, and analyses were pre-registered.

Experiment 1

In Experiment 1, children watched two puppets learn how to activate a novel toy. Next, each puppet was given the chance to activate a different toy (always outwardly identical to the original). One puppet stated that his chosen toy worked the same as the original, and pressed the same button he had seen activate the original toy. The other puppet stated that his chosen toy worked differently to the original, and pressed a different button. Both puppets succeeded in activating their chosen toy. Children were then asked which of the two agents already knew how the toys worked.

If children expect ignorant agents to behave in accordance with their prior beliefs, then they should judge that the agent who acted inconsistently with their prior experience is more likely to be knowledgeable. But if children attribute epistemic states by relying on a rule of thumb (e.g., expecting ignorant agents to be wrong), or have no representation of what it means to be ignorant, then children should have no preference for either agent.

Method

Participants 72 four-, five- and six-year-olds (mean age: 5.46 years, range: 4.05 – 6.99 years; n = 24 participants per age group) were recruited at a local children's museum. 22 participants were excluded from the analyses and replaced because: they did not pass the pre-registered inclusion questions (n = 9), due to experimenter error (n = 5), interruptions from other children (n = 3), because the participant did not answer the test question within 30s (n = 2), distraction (n = 1), interference with the procedure (n = 1), or due to developmental delays (n = 1).

Stimuli Stimuli consisted of two male puppets, and three novel toys. These toys were externally identical machines, each covered in black construction paper and measuring approximately 5 x 3 x 2.75 in. Toys had three buttons on top: a red button in the middle, and two black buttons flanking the red one (see Figure 1).

Although they all looked the same, the toys worked in different ways. The first toy (called the "training" toy) activated and played music only when the central red button was pressed. Of the remaining toys, the "consistent" one worked the same way. However, the "inconsistent" toy worked differently: only pressing the black button to the participant's far left made it activate. For clarity, we refer to this button as the "correct" black button, and the other as the "incorrect" black button (since it did not activate the toy).

Procedure First, participants were familiarized with the training toy (which turned on when the central red button was pressed). Participants learned that the red button made the toy go, but that the black buttons did nothing. They were then given a chance to press all of the buttons themselves. Next, participants were introduced to two puppets. The experimenter explained that she was going to show the puppets how the toy worked, and told the puppets that while the red button made the toy go, the black buttons did not do anything. Upon the experimenter's request, the puppets pressed the red button together.

Next, the remaining toys were placed on the table (one on either side of the training toy). The experimenter explained that one of the puppets had snuck out from under the table and played with all the toys, and discovered which buttons made the toys play music. The other puppet had stayed underneath the table, and hadn't seen anything. The child's task was to help figure out which puppet had snuck out and played with all the toys.

Each puppet was questioned individually, while the other agent was placed under the table. During his turn, each puppet was asked: "Can you show us how to make one of these toys go?" To make the relation between agents' actions and their experience with the initial toy more explicit, each agent explained himself as he acted. One puppet chose the consistent toy, saying, "Hmm. Well, the red button made this [original] toy go, so the red button makes this toy go too," pointing to the two relevant buttons as he spoke. Finally he pressed the red button, successfully

activating the toy. The other puppet chose the inconsistent toy, saying, "Hmm. Well, the red button made this [original] toy go, but this black button makes this toy go," pointing to the two relevant buttons as he spoke. Finally he pressed the correct black button, successfully activating the toy.

After each puppet demonstrated one of the toys, the experimenter asked the test question: "[Child name], remember how I told you at the beginning of the game that only one of my friends snuck out from underneath the table, and played with all the toys? Can you tell me, which one of my friends snuck out and played with all the toys?" Participants were then asked to explain their answer. The memory check questions (pre-registered as inclusion questions) were asked last, with subjects asked to match each puppet to the toy he had demonstrated: "[Child name], can you remind me, which friend showed us how to make this toy go [both puppets point to a toy]? And which friend showed us how to make this toy go [both puppets point to the other toy]?"

Puppets always demonstrated the toy they were standing closest to. This was to avoid pragmatic concerns that could arise if puppets undertook a cost to demonstrate a particular toy. Therefore, the puppet on the experimenter's left hand demonstrated the leftmost toy, and vice versa. The identity of the puppet whose turn was first, and the toy this agent acted on was always counterbalanced. Additionally, the side each puppet was presented on (left/right) was randomized.

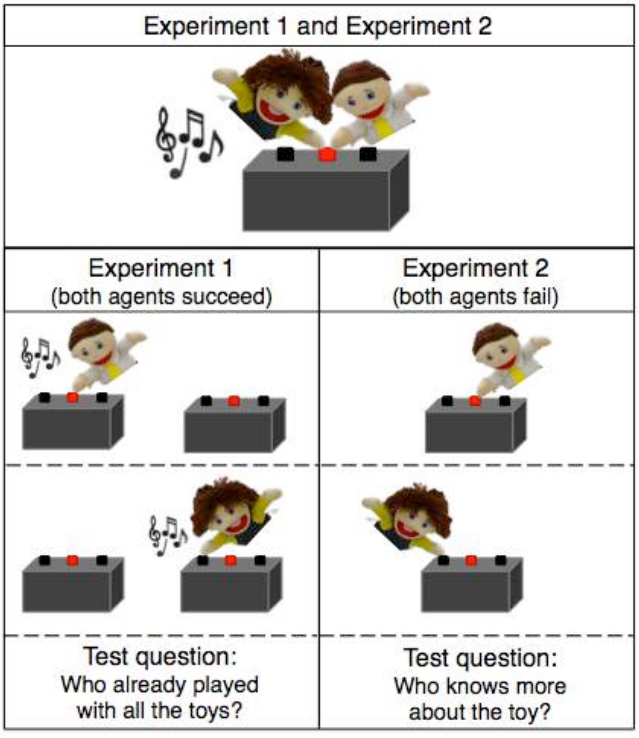

Figure 1: Procedure of both experiments. In Experiment 1 both puppets succeeded in activating the toy. In Experiment 2, both failed. Crucially, one agent's actions were always consistent with his prior experience (pressing the red button); the other agent's were not (he pressed one of the black buttons).

Results and Discussion

Two coders who were not involved in data collection determined exclusions. The first coder determined whether the experiment had been run correctly, blind to children's final answers. The second coder coded only children's answers, unaware of each puppet's role (that is, whether he demonstrated the consistent or inconsistent toy). 22 participants were excluded and replaced (see Participants).

Overall, of 58.3% of children judged that the agent who pressed the black button (and acted inconsistently with his prior experience) was more likely to have had additional knowledge. This proportion is not reliably different from chance (42 of 72; 95% CI: 47.2 – 69.4). However, a logistic regression predicting performance based on age revealed a significant age difference ($\beta = 0.87$, $p = .006$). While only 37.5% of four-year-olds judged that the agent who activated the inconsistent toy had prior knowledge (9 of 24; 95% CI: 16.67 - 58.33), 66.6% of five-year-olds (16 of 24; 95% CI: 50 – 87.5) and 70.8% of six-year-olds (17 of 24; 95% CI: 54.17 - 87.5) selected this agent. And consistent with five- and six-year-olds' success, a logistic regression predicting performance based on age also predicts that children will be more likely to answer the test question correctly (as opposed to incorrectly) by 5.04 years of age.

These results suggest that children do not simply expect ignorant agents to act successfully or unsuccessfully. Rather, by age five, children seem to expect ignorant agents to act reasonably, applying their prior knowledge in novel situations. This is consistent with prior findings that children do not think ignorance means having a false belief (Friedman & Petrashek, 2009; Jara-Ettinger, Floyd, Tenenbaum, & Schulz, 2017). If children assumed that ignorant agents should fail due to a false belief, then participants should have judged that both agents were equally knowledgeable (since both were successful). Our results suggest that by age five, children make principled belief inferences from agents' behavior. Specifically, children expect both knowledgeable and ignorant agents to act consistently with their prior knowledge, and they use these expectations to infer what other people know.

Note, however, that children were only ever taught how the training toy worked. If children (reasonably) assumed all the toys worked in the same way, they may have been surprised to see a puppet activate the inconsistent toy. Perhaps children attributed greater knowledge to this agent not because his actions were inconsistent with his prior knowledge, but because the actions (and their outcome) were inconsistent with children's own beliefs. In other words, children might simply attribute knowledge to agents who teach them something new, or show them something unexpected. We test this possibility in Experiment 2.

Experiment 2

Participants in Experiment 1 learned only how the first (training) toy worked. If participants attributed greater knowledge to the inconsistent actor because he taught them something new or unexpected, teaching children how all the toys work should cause performance to fall to chance because, now, neither agent can provide any novel information.

To address this, Experiment 2 differs in three substantial ways. First, we taught participants how all the toys worked. To reduce concerns about memory load, we used only two machines in this task: the training toy, and the inconsistent toy. Second, when trying to activate the novel toy, both puppets failed. One puppet pressed the red button (consistent with his prior experience), and one pressed the incorrect black button (inconsistent with his prior experience). Finally, we emphasized throughout that one of the puppets knew more, but not all, about the toy, making it plausible that both puppets could fail. Together, these changes allow us to test whether children attribute greater prior knowledge to agents whose actions are not explained by their prior experience, even when the agent fails to achieve their goal.

Method

Participants 72 four-, five- and six-year-olds (mean age: 5.56 years, range: 3.99 – 6.92 years; n = 24 participants per age group) were recruited at a local children's museum. 26 participants were excluded from analyses and replaced because: they did not pass the pre-registered inclusion questions (n = 13), due to experimenter error (n = 5), interruptions or interference with the procedure (n = 3), because the participant did not answer the test question within 30s (n = 3), because the participant had already participated in the past (n = 1), or due to developmental delays (n = 1).

Stimuli Materials were identical to those of Experiment 1, except that now only two machines were used: the training toy, and the inconsistent toy.

Procedure Experiment 2 began identically to Experiment 1. Participants and then puppets were familiarized with the training toy. Next, after placing the puppets underneath the table, the experimenter produced the additional (inconsistent) toy. In contrast to Experiment 1, the experimenter told participants that this toy was "a little bit different." She explained that the red button did not activate this toy, and that only one of the black buttons (the correct black button) made the toy play music. She demonstrated all of the buttons, and then allowed the participant to press each button. Thus, participants were explicitly taught how the toys worked, and experienced for themselves that the toys worked differently.

Next, both puppets returned. The experimenter explained that one of the puppets had seen the toy before, and knew a little bit about it. And she explained that the other puppet had never seen the toy before. The experimenter noted that one of the puppets knew more about the toy, but she didn't know which one. The participant's task was to help the experimenter identify which puppet knew more about the toy.

Each puppet was asked to make the toy go in turn. During each puppet's turn, the other agent was placed underneath the table. One puppet's actions were consistent with his prior knowledge, saying, "Hmm. Well, the red button made this [original] toy go, so the red button makes this toy go too," pointing to the two relevant buttons as he spoke. He pressed the red button. The button did not activate the toy, and the puppet exclaimed "oh!" in surprise when nothing happened. The other puppet's actions were inconsistent with his prior knowledge, saying, "Hmm. Well, the red button made this [original] toy go, but this black button makes this toy go," pointing to the two relevant buttons as he spoke. He pressed the incorrect black button. The button also did not activate the toy, and the puppet exclaimed "oh!" in surprise when nothing happened.

After each puppet pressed a button, the experimenter asked the test question: "[Child name], remember how I told you that one of my friends knows more about this toy? Can you tell me, which friend knows more?" Participants were asked to explain their answer. The inclusion questions were asked last, with children asked to match each puppet to the button he had pressed on the novel (inconsistent) toy: "[Child name], can you remind me, which one of my friends pressed this button [both puppets point to one button]? And which one of my friends pressed this button [both puppets point to the other button]?"

The identity of the puppet whose turn was first, and the button this agent pressed was always counterbalanced. Additionally, the side each puppet was presented on (left/right) was randomized.

Results and Discussion

Results were coded as in Experiment 1, with 26 participants excluded and replaced (see Participants). Overall, 61.1% of participants attributed knowledge to the puppet who pressed the black button, a proportion reliably higher than chance (44 of 72; 95% CI: 50 - 72.2). A logistic regression predicting performance based on age did not reveal a significant age difference ($\beta = 0.42$, $p = .14$). But while participants in all age groups preferred to attribute knowledge to the agent whose actions were inconsistent with his prior experience, only six-year-olds' preferences were robust. While 70.8% of six-year-olds judged that the agent who pressed the black button was more knowledgeable (17 of 24; 95% CI: 54.17 - 87.5), only 54% of four-year-olds (13 of 24; 95% CI: 33.33 - 75) and 58% of five-year-olds (14 of 24; 95% CI: 37.5 - 79.17) also made this judgment. In sum, although no age difference was obtained, only six-year-olds reliably judged that the agent whose failure was inconsistent with his prior experience had greater knowledge.

These findings suggest that children do not simply attribute knowledge to agents who show them something new. If they did, they should have performed at chance, as neither puppet taught children anything new. Instead, our results suggest that, by age six, children not only expect ignorant agents to act based on their prior knowledge, but also understand that knowledge runs along a continuum: agents can know more or less about any given topic. Thus, by age six, children attribute more knowledge to agents whose prior experience cannot explain their actions, even when these actions fail to fulfill their goal.

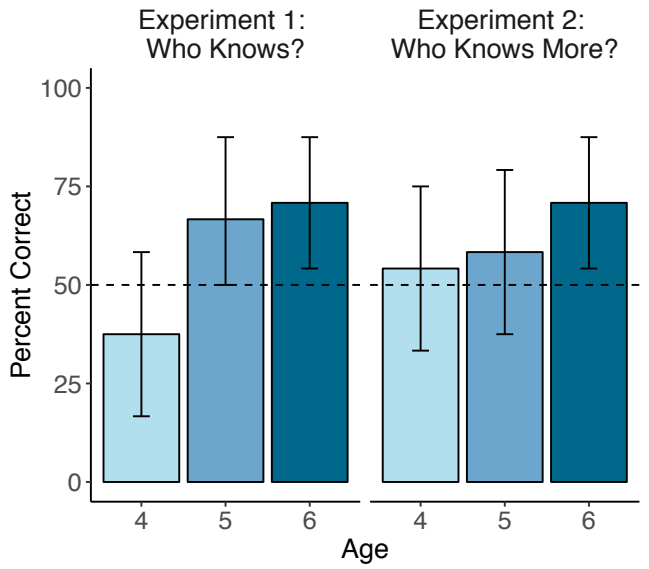

Figure 2: Results from both experiments. The error bars are bootstrapped 95% confidence intervals, and the dotted line indicates chance performance (50%). In Experiment 1, five- and six-year-olds judged that an agent whose success could not be explained by his prior experience had additional knowledge. In Experiment 2, six-year-olds judged that an agent whose failure could not be explained by his prior experience had additional (albeit incomplete) knowledge.

General Discussion

To successfully interact with others, we must understand what they know and believe, what they feel, and what they want. Children understand the link between mind and behavior early in life, inferring goals (Csibra, Gergely, Bíró, Koós & Brockbank, 1999; Jara-Ettinger, Gweon, Schulz & Tenebaum, 2016), beliefs (Onishi & Baillargeon, 2005; Rubio-Fernandez & Geurts, 2013) and desires (Doan, Denison, Lucas & Gopnik, 2015; Repacholi & Gopnik, 1997) from others' actions. Yet, while much work has shown that even young children have expectation about how knowledgeable agents should behave (Surian, Caldi & Sperber, 2007), less work has investigated whether children understand how ignorant agents might apply their prior knowledge to new situations.

Here we found that preschoolers expect ignorant agents to act based on their prior knowledge. When agents' past experience cannot explain their actions, children infer that these agents must have additional knowledge. In Experiment 1, five- and six-year-olds (but not four-year-olds) judged that an agent whose observable past experience could not explain his successful actions must've had additional knowledge. In Experiment 2, four- to six-year-olds (but only six-year-olds reliably) judged that an agent whose observable past experience could not explain his failure must've had some (incomplete) additional knowledge.

Our results show that, by age five, children expect past experiences to shape agents' beliefs and guide their actions in new situations. These results are consistent with related work, which suggests that children do not reliably link ignorance to specific outcomes (Friedman & Petrashek, 2009; German & Leslie, 2001; Ruffman, 1996).

These findings also suggest several broader implications. First, while we often talk about "knowing" or "not knowing," knowledge is not binary. People are rarely completely ignorant or completely knowledgeable. More frequently, knowledge lies along a continuum. In Experiment 2, six-year-olds succeeded in identifying which of two agents knew more, even when both agents were wrong. If children believe that agents can only be fully knowledgeable or fully ignorant, they may not have attributed even partial knowledge in this case (perhaps judging that any agent who is wrong is equally ignorant). The results of this experiment suggest that, by age six, children represent knowledge and ignorance as two poles of the epistemic continuum, leveraging their expectations about how prior experience should affect agents' actions to infer the extent of their knowledge.

Second, these findings provide insight into the development of children's epistemic inferences. While prior work has thoroughly investigated young children's ability to represent others' beliefs (e.g., Onishi & Baillargeon, 2005; Wellman et al., 2001), less research has investigated how children infer belief from action. In our tasks, children had to infer agents' beliefs from their actions. This required understanding that each agent pressed the button they believed would make the toy go, and considering what role their past experiences played in shaping these beliefs. Past work suggests that children infer knowledge from action via a naïve theory of knowledge: a set of expectations about how ignorant and/or knowledgeable agents should act (Aboody, Huey, & Jara-Ettinger, 2018). Our results are consistent with this account, demonstrating that across varied contexts, children can infer what others know or believe by observing their actions.

Our results also open avenues for future work. First, Experiment 2 shows that children do not simply attribute knowledge to agents who show them something new or surprising. However, other simple rules may explain participants' performance. For example, children may expect ignorant agents to act the same way they've acted in the past, without representing their knowledge or beliefs. In our studies, specifically, children may have solved the task by matching agents' current actions to their prior acts,

licensing knowledge any time these acts were inconsistent. Future work can address this possibility by providing agents with knowledge, but not experience (e.g., by telling the puppets in Experiment 1 how the toy works but not allowing them to try it for themselves).

A second possibility is that children expect ignorant agents to try whatever is most reasonable, not in the context of agents' knowledge, but in the context of what children themselves think is reasonable. For example, children in our task could have assumed that the red button was the most obvious thing to try (regardless of agents' past experiences), and attributed prior knowledge to any agent who rejected this obvious solution. While it is unclear whether children in fact find the red button to be the obvious solution in this task, future work can address this possibility by reversing Experiment 1, and introducing children to a training toy that works the same as the inconsistent toy. If children now attribute greater knowledge to the agent who presses the (more visually salient) red button, this would show that children do not just think that ignorance means trying the most perceptually obvious answer.

Third, in both experiments, puppets' actions differed, but so did their explanations of their actions. Namely, one agent said: "Hmm. Well, the red button made this [original] toy go, **so** the red button makes this toy go **too**," and the other said, "Hmm. Well, the red button made this [original] toy go, **but** this black button makes this toy go." Although only two words differed between explanations, it is possible that this could explain children's epistemic attributions in our task. Note, however, that this would be consistent with our account, showing that children attribute knowledge to those who explicitly reject past experience. In addition, if the linguistic cue guides children's inferences, this would be interesting in its own right—the difference between "so too" and "but" is subtle, and to our knowledge, little work has investigated how such words affect children's belief inferences. To identify whether these explanations were critical to children's inferences, future work will leave them out. If children make the same judgments, this would provide evidence that performance in this task did not hinge upon puppets' explanations.

Fourth, in Experiment 2, it is possible that children did not think both puppets were equally wrong. Conceptually, the puppet who pressed the black button may have been closer to being right (since he knew that one of the black buttons made the toy go). It is possible that children didn't consider whether agents' prior knowledge explained their actions, and instead simply attributed greater knowledge to the agent who was closer to being correct. While possible, this account does not explain children's success in Experiment 1. Furthermore, it is unclear how to operationalize what it means to be "closer" to being right in Experiment 2: while one agent was conceptually closer (pressing a black button), the other was physically closer (pressing the red button, which was right next to the correct black button). It is unclear how the magnitude of agents' errors may have guided children's inferences in the current task, but future work should investigate how this factor affects children's epistemic judgments.

Last, across both experiments, children's preferences strengthened with age (significantly in Experiment 1, and non-significantly in Experiment 2). Four-year-olds' failures in both experiments are consistent with prior work, which suggests that the ability to infer knowledge from behavior continues to develop between the ages of four and five (Aboody, Huey & Jara-Ettinger, 2018). But while five-year-olds succeeded in Experiment 1, they were not reliably above chance in Experiment 2. Why might this be?

One possibility is that identifying a completely knowledgeable agent (Experiment 1) is easier than judging which agent has greater (but still incomplete) knowledge (Experiment 2). Furthermore, given that children may equate accuracy with knowledge (Brosseau-Liard & Birch, 2010; Ronfard & Corriveau, 2016), it might be harder for them to attribute knowledge in the face of a failure.

It is also possible that five-year-olds do attribute knowledge based on a rule (for example, attributing knowledge to agents who act in a surprising way). This could explain their weaker performance in Experiment 2, although it is unclear why four-year-olds would not have followed the same rule (which would have led to success in Experiment 1). It is possible that four-year-olds have no rule for inferring belief from knowledge, five-year-olds depend on a rule (e.g., knowledge = rejecting the obvious), and six-year-olds have a deeper understanding of how prior knowledge shapes beliefs. Finally, it is always possible that task demands affected children's performance, although this would fail to explain the difference in five-year-olds' performance across the two studies. Future work will address these possibilities to further clarify how children's epistemic intuitions emerge and develop.

In sum, across two experiments, we find evidence that young children have expectations for how prior knowledge is likely to shape people's beliefs and guide their behavior. We find that children use these expectations to infer what others know (or don't know) from their actions and that, by age five, children do not expect ignorant agents to act as blank slates; rather, they expect ignorant agents to leverage relevant prior knowledge when planning their actions. Altogether, our findings suggest that even young children may understand how ignorance begets belief and action.

Acknowledgments

We thank the Boston Children's Museum, the Peabody Natural History Museum, and the families who participated in this research. We thank Sarah Wong and Ivana Bozic for help with coding, and Lindsay Stoner for help with coding and data collection. Mathematics Skills and Executive Functions Following Preterm Birth: A Longitudinal Study of 5- to 7-Year Old Children

Abstract

Early mathematics skills are an important predictor of later academic, economic and personal success. Children born preterm, about 10% of the US population, have an increased risk of deficits in mathematics. These deficits may be related to lower levels of executive functions and processing speed. We investigated the development of mathematics skills, working memory, inhibitory control and processing speed of healthy children born very preterm (between 25 and 32 weeks gestational age, n=51) and full-term (n=29). Children were tested annually from ages 5 to 7 years. We found persistent lower overall mathematics skills in the preterm group, driven by differences in more informal skills (e.g. counting) at earlier time points, and by differences in more formal skills (e.g. calculation) at later time points. We did not find significant differences between preterm and full-term born children in spatial working memory capacity or processing speed. However, these cognitive measures were significant predictors of mathematics skills in the preterm but not the full-term group, hinting towards the use of different strategies when solving problems.

Keywords: Early Mathematics; Executive Functions; Cognitive Development; Preterm Birth; longitudinal;

Introduction

Mathematics skills are beneficial for success in life. Early mathematics skills at school-entry are predictive of later academic achievement (Duncan et al., 2007; Geary, Hoard, Nugent, & Bailey, 2013), and socioeconomic status (Ritchie & Bates, 2013).

Very preterm birth (before 33 weeks of gestation) has a negative effect on academic achievement in general (Johnson, Wolke, Hennessy, & Marlow, 2011), and mathematical ability in particular (Akshoomoff et al., 2017; Taylor, Espy, & Anderson, 2009). Every year about 15 million children are born preterm, with preterm birth rates ranging from 5-18% (Liu et al., 2016). Recent studies on the effects of preterm birth often examine children born extremely preterm (<28 weeks) and/or with very low birth weight (<1500g). However, these individuals make up a small proportion of the preterm born population. Furthermore, with medical advances, severe complications of preterm birth can be treated, and the rates of preterm born children without severe neurodevelopmental disorders have increased. Yet even in otherwise healthy children, preterm birth is associated with long-term cognitive consequences such as developmental and learning problems (Anderson, 2014).

Mathematical ability is related to executive functions and processing speed in typically developing children (Geary, 2011; Purpura, Schmitt, & Ganley, 2017). The core executive functions are working memory, inhibitory control and shifting (Miyake, Friedman, Emerson, Witzki, & Howerter, 2000). These cognitive skills are affected by preterm birth (Aarnoudse-Moens, Duivenvoorden, Weisglas-Kuperus, Van Goudoever, & Oosterlaan, 2012) and are likely to be related to mathematics deficits. Rose, Feldman, and Jankowski (2011) showed that differences in math and reading skills of 11 year old full-term and preterm children can be explained through preterm deficits in executive function and processing speed. They argue for a cascade of effects: preterm birth leading to lower processing speed, leading to lower executive functions, leading to lower math and reading scores. It is unknown when this cascade of effects begins and how processing speed, executive functions, and mathematics achievement are connected during early childhood.

While we know that preterm birth affects processing speed and executive functions, and that children born preterm exhibit deficits in mathematics achievement, to our knowledge no study has investigated these components longitudinally in preterm born children during childhood.

The Present Study

The present study examines how mathematics ability develops and how it is related to other neuropsychological functions following preterm birth. The children in this study were born between 25 and 32 weeks gestational age. They are considered healthy and do not suffer from any severe medical conditions or neurodevelopmental disorders. However, they make up about 2% of the general population in the US and are thus an important group to study. This longitudinal comprehensive study allows controlling for individual differences and will give insight into the development of the interplay of processing speed, executive functions, motor skills and mathematics ability.

Methods

Participants

Participants were preterm and full-term children who were tested at three time points, each about a year apart. First testing was performed within six months of starting kindergarten, at a mean age of 5.3 years (SD: 0.38). Mean age for the following two time points was 6.4 (SD: 0.37) and 7.3 (SD: 0.35), respectively. A total of 51 preterm and 29 full-term children completed the mathematics, working memory, and inhibition tests at all three time points. Not all of these children completed the other cognitive and behavioral measures; sample size for each of the subtests is stated below.

The preterm sample was primarily recruited from the UC San Diego High-Risk Infant Follow Up Clinic. Inclusion criteria was gestational age at birth of <33 weeks. Out of the 51 children in the preterm group, 10 children were born <28 weeks gestational age, and 41 children between 28 and 32 weeks gestational age. We did not find a correlation between gestational age at birth and mathematics performance within the preterm group, therefore the children were not further divided into subgroups. In the following the term preterm includes both the extremely and very preterm born children of this study.

Exclusion criteria from the preterm sample were a history of severe brain injury (e.g., cystic periventricular leukomalacia), disability (e.g., bilateral deafness or blindness), genetic abnormalities likely to affect development, and acquired neurological disorder unrelated to preterm birth.

Inclusion criteria for the full-term sample was gestational age at birth of >38 weeks and no history of neurological, psychiatric, or developmental disorders. All participants had a score of 80 or higher on the Verbal Comprehension Index of the Wechsler Preschool and Primary Scale of Intelligence (WPPSI-IV) to insure comprehension of tasks (Wechsler, 2012).

Participant characteristics are summarized in Table 1. A social economic status (SES) score was calculated as the sum of rank in maternal education and household income. Maternal education was ranked as 1: high school, 2: 1-3 years of college, 3: four year college, 4: professional/ post-graduate degree. Household income was ranked as 1: less than $50,000, 2: $50,000 - $99,999, 3: $100,000 - $199,999, 4: $200,000 and above.

By definition, the preterm and full-term group differed in gestational age at birth ($F=693.86$, $p<0.0005$) and birth weight ($F=338.96$, $p<0.0005$). They were not significantly different in terms of gender composition, household income or socioeconomic status (SES) composite. Maternal education was significantly higher in full-term compared to preterm children ($F=4.74$, $p=0.033$). They did not differ in age at any testing time.

Table 1: Participants characteristics. GA: gestational age, SES: socioeconomic status

	Preterm (n=51)	Full-term (n=29)
GA at birth (weeks): mean (min-max)	29.5 (25-32)	39.7 (38-41)
Birth weight (g): mean (min-max)	1328 (680-2410)	3411 (2353-4422)
Gender (% female)	47.1	48.3
SES composite: mean (min-max)	5.0 (2-8)	5.43 (2-8)
Maternal education	2.47 (1-4)	2.93 (1-4)
High school	13.7%	10.3%
1-3 years college	35.3%	20.7%
College graduate	41.2%	34.5%
Professional	9.8%	34.5%
Household income	2.52 (1-4)	2.50 (1-4)
Less than $50,000	15.7%	3.4%
$ 50,000 - $99,999	31.4%	44.8%
$100,000 - $199,999	35.3%	44.8%
$200,000 and above	15.7%	3.4%

Cognitive and Behavioral Measures

Measures of mathematics ability, working memory, inhibitory control, processing speed, and motor skills, were examined. A number of tasks were drawn from the Cambridge Neuropsychological Testing Automated Battery (CANTAB). These tasks are well established and standardized computerized non-verbal tasks, administered on a touch screen. They are suitable for children 4 years of age and older. In addition, a more challenging task was administered that can be thought of as a composite measure of executive functions and motor skills, the Head Toes Knees Shoulders (HTKS) Task. To be able to parse apart the effect of motor function on HTKS performance, the Movement Assessment Battery for Children (MABC-2) was administered.

Mathematics Ability was assessed via the Test for Early Mathematics Ability, Third Edition (TEMA-3, Ginsburg & Baroody, 2003). It is designed for children between 3:0-8:11 years of age. It comprises up to 72 items. The items can also be broadly categorized into informal and formal mathematics, and more specifically into seven subcategories: Verbal Counting, Counting Objects, Numerical Comparison, Numeral Literacy, Set Construction, Calculation, and Number Facts (Ryoo, et al. 2015). Measure of overall performance is the TEMA-3 total (raw) score.

Spatial Working Memory was assessed via the CANTAB Spatial Working Memory (SWM) task. The participant's task is to find a token that is hidden under one of several colored boxes. Once found, the token is hidden again, but not under the same box twice. Thus the participant has to remember where the tokens were previously found. The number of trials is gradually increased up to eight boxes. Working memory is measured inversely based on the number of errors made (searching under the same box multiple times).

Inhibitory Control was assessed via the CANTAB Stop Signal Task (SST). The participant has to choose between pressing one of two buttons depending on where an arrow points. If they hear an auditory signal when the arrow appears, the participant has to withhold their response and not press the button. Performance is measured via the stop signal reaction time in the second half of the task, were poor performance is reflected in longer reaction times.

Processing Speed was assessed via the CANTAB Reaction Time Task (RTI). The participant holds a button at the bottom of the touch screen. Above the button are five circles. Once a yellow dot appears in one of the circles, the participant releases the button at the bottom and taps the circle with the dot. Performance is measured via median response time of pressing the circle in which the yellow dot appeared. 10 preterm children from the full sample did not complete the RTI, resulting in a sample size of 41 preterm and 29 full-term children.

The Head Toes Knees Shoulders (HTKS) Task can be seen as a composite measure of executive function and motor skills (Ponitz et al., 2008). It has three rounds: In the first round the participant has to touch their toes when the examiner says to touch their head and vice versa. In the second round the participant has to touch their knees whenever the examiner says to touch their shoulders and vice versa. The third round includes all four body parts and requires remapping of the previously learned instructions. This task requires working memory, as the participant has to keep in mind which body part to touch instead of the one the examiner said; inhibitory control, as the participant has to keep themselves from plainly following the instruction, shifting, as the instructions change; and motor control. The task was added while the study was already ongoing, leading to a relatively small sample of 33 preterm and 13 full-term children who were assessed at all three time points.

Motor Skills were assessed using the Movement Assessment Battery for Children-2 (MABC-2; Henderson, Sugden, & Barnett, 2007). It tests manual dexterity, aiming & catching, and balance. The total test scores were used to compare motor skills. In this analysis, the MABC-2 is used to disentangle wheather performance differences in the HTKS are due to differences in motor or executive function. Thus the MABC-2 was examined on the same sample as the HTKS. It was administered at time point 1 and 3 only.

Results

Executive Functions, Processing Speed & Motor Skills

Group differences in cognitive and behavioral measures other than mathematics ability are summarized in Table 2. Spatial working memory scores did not differ significantly between preterm and full-term children at any time point. The stop signal reaction time in the SST was significantly longer in the preterm group at time 1 and 2, and approached significance at time 3. A longer reaction time indicates more difficulty with inhibitory control. Processing speed as measured via reaction time in the RTI did not differ significantly between groups in the 5 choice version of the RTI. Performance on HTKS was significantly lower in preterm children at all three time points. Preterm children also scored significantly lower on MABC-2 at the two time points in which motor function was measured.

Correlation analysis between performance on these cognitive and behavioral tasks controlled for time point, SES, and group revealed that performance on HTKS was correlated with errors on the SWM ($r=-0.204$, $p=0.035$), SST reaction time ($r=-0.202$, $p=0.036$), and reaction time on RTI ($r=-0.313$, $p=0.001$). Importantly, HTKS and MABC-2 total scores were not correlated ($r=0.097$, $p=0.317$). Thus differences in HTKS reflect differences between participants other than motor function.

Table 2: Group differences in performance on the spatial working memory (SWM), the stop signal task (SST), the reaction time task (RTI), the Head Toes Knees Shoulders (HTKS) task, and the Movement Assessment Battery for Children-2 (MABC-2) as measured via ANOVA. ° no significant difference, ↑ sign. longer in the preterm group, ↓ sign. lower in preterm group. n.d.: no data.

Task	Time point 1		Time point 2		Time point 3	
		F (p)		F (p)		F (p)
SWM	°	0.507 (0.478)	°	3.374 (0.070)	°	0.218 (0.642)
SST	↑	4.627 (0.035)	↑	6.503 (0.013)	°	3.328 (0.072)
RTI	°	0.302 (0.585)	°	2.128 (0.149)	°	1.205 (0.276)
HTKS	↓	7.648 (0.008)	↓	8.628 (0.005)	↓	4.685 (0.008)
MABC-2	↓	14.303 (<0.0005)		n.d.	↓	24.092 (<0.0005)

Mathematics Skills

Preterm born children had lower TEMA-3 total scores compared to full-term born children on all three time points. The difference decreased from time 1 to 2, and increased again at time 3 (figure 1, table 3). Categorization of TEMA-3 test items into subcategories according to Ryoo et al. (2015) revealed that differences between preterm and full-term children did not share a common developmental pattern. Verbal Counting, a more informal skill showed group differences at age 5 and 6 that diminished at age 7 (figure 2). Similarly, other skills such as Numerical Comparison and Counting Objects showed a narrowing of the performance gap between preterm and full-term born children between time point 1 and 3. In contrast, at age 5, preterm children did not score significantly lower on items testing for Set Construction, a more formal, skill. Over time, the a deficit emerged such that preterm born children scored about 15 percent points below full-term children at age 7. Differences in Calculation skills were present at all time points. Notably, the differences show a high increase over time, with about twice the effect size at time point 3, compared to 1 and 2. Performance of both groups on Number Facts was a floor at time point 1, and at time point 2, preterm and full-term children did not score significantly differently. However, by time point 3, large differences emerged, with lower scores in the preterm sample.

In the following Verbal Counting and Calculation skills, as well as the overall TEMA-3 performance are analyzed in more detail. These skills were chosen as they exemplify the differential trajectories of informal and formal skills.

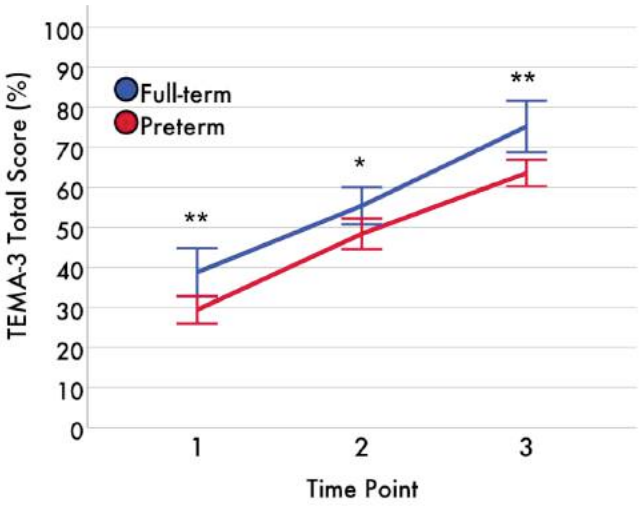

Figure 1: Standardized mathematics ability score of preterm and full-term group. The preterm group has a lower score at all three time points. * $p < 0.05$, ** $p < 0.01$.

Repeated measures ANOVAs showed a significant interaction of time and group for Verbal Counting ($F=4.234$, $p=0.016$, $\eta^2=0.051$) and Calculation ($F=7.079$, $p=0.001$, $\eta^2=0.083$). TEMA-3 total score showed a significant effect of time and group, but not their interaction ($F=1.272$, $p=0.283$, $\eta^2=0.016$). A three-way ANOVA with time and skill (Verbal Counting/Calculation) as within subject repeated measures and group as between subjects factor revealed a significant interaction between time, skill, and group ($F=11.191$, $p<0.005$, $\eta^2=0.125$).

Table 3: Summary of TEMA-3 overall performance (total score) and score of distinct skills as defined by Ryoo, et al. (2015). Scores presented as percentage of total possible score. M: mean, SD: standard deviation, group comparisons via ANOVA.

	Time point 1			Time point 2			Time point 3		
	Full-term	Preterm		Full-term	Preterm		Full-term	Preterm	
Skill	M (SD)	M (SD)	F (p)	M (SD)	M (SD)	F (p)	M (SD)	M (SD)	F (p)
Total score	38.75 (15.89)	29.36 (12.30)	8.689 (0.004)	55.36 (12.26)	48.37 (13.57)	5.265 (0.024)	75.19 (16.92)	63.56 (11.76)	13.065 (0.001)
Verbal Counting	50.49 (26.72)	34.87 (20.24)	8.693 (0.004)	75.86 (18.05)	63.03 (19.68)	8.343 (0.005)	86.95 (13.51)	83.19 (11.32)	1.763 (0.188)
Counting Objects	77.34 (19.66)	64.99 (14.37)	10.403 (0.002)	89.66 (12.01)	85.99 (12.61)	1.611 (0.208)	97.04 (5.89)	92.16 (10.81)	5.056 (0.027)
Numerical Comparison	37.55 (16.38)	27.67 (15.46)	7.234 (0.009)	51.72 (8.54)	43.33 (13.34)	9.186 (0.003)	60.92 (12.46)	54.68 (10.15)	5.904 (0.017)

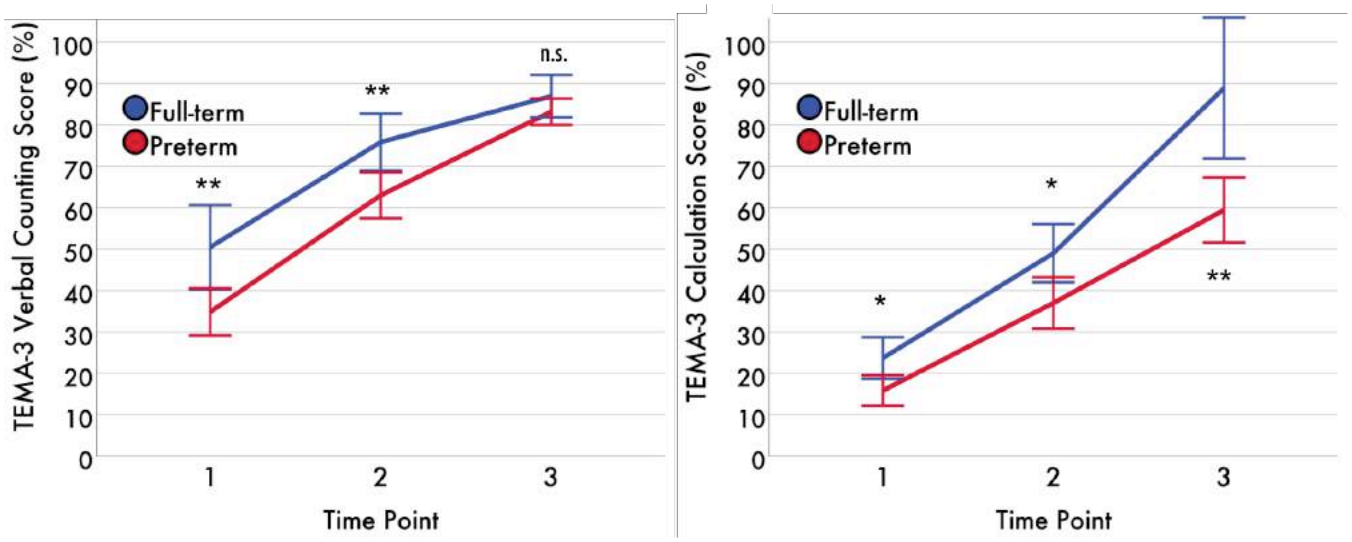

Figure 2: Development of Verbal Counting (left) and Calculation skills (right) as measured via the Test of Early Mathematics Ability – Third Edition (TEMA-3). Error bars: 95% confidence interval. * $p < 0.05$, ** $p < 0.01$, n.s.: $p > 0.05$

Effect of Executive Functions and Processing Speed on Mathematics Skills

Linear models were used to determine which of the cognitive and behavioral measures are predictive of mathematics skills. As the sample size for HTKS is considerably smaller, two separate models were evaluated: Model 1 used SWM, SST and RTI as predictors, while model 2 used HTKS score as predictor (table 4). Time point, SES and gender were included in all models. Time point and SES were significant predictors for both groups, and gender was a significant predictor in the full-term but not the preterm group.

In model 1, SWM and SST were predictive of Verbal Counting and Calculation in the preterm group. RTI was predictive of Verbal Counting but not Calculation. In contrast, SWM was not predictive in the full-term group for either skill, and SST was a significant predictor only for Verbal Counting. RTI did not significantly predict either skill.

Model 1 was a better fit when predicting Verbal Counting (r^2=0.6293) compared to Calculation skills (r^2=0.4580) in the preterm group. Conversely, the model performed slightly better when predicting Calculation (r^2=0.5743) compared to Verbal Counting (r^2=0.5261) skills in full-term children.

Model 2 showed that in both groups performance on HTKS was predictive of Verbal Counting, but not Calculation. Consequently, it was a better fit when predicting Verbal Counting compared to Calculation skills.

Table 4: Summary of linear models predicting Verbal Counting and Calculation Skills in full-term and preterm born children, respectively. Time point, SES and gender are included in all models. Model 1 additionally uses SWM, SST and RTI as predictors, model 2 uses HTKS.

	Verbal Counting		Calculation	
	Full-term	Preterm	Full-term	Preterm
Base Model – predictors: Time point, SES, gender				
Adj. r^2	0.4974	0.5852	0.5275	0.4166
Model 1 – n(preterm)=41, n(full-term)=29				
Adj. r^2	0.5261	0.6293	0.5743	0.4580
Predictors: std. β coeff. (p)				
SWM	-0.0259 (0.2084)	-0.0309 (0.0137)	-0.0376 (0.0522)	-0.0245 (0.0190)
SST	-0.0080 (0.0129)	-0.0037 (0.0309)	-0.0043 (0.1426)	-0.0035 (0.0155)
RTI	0.0003 (0.9025)	-0.0036 (0.0299)	-0.0025 (0.0844)	-0.0009 (0.5056)
Model 2 – n(preterm)=33, n(full-term)=13				
Adj. r^2	0.5549	0.6528	0.4942	0.4061
Predictors: std. β coeff. (p)				
HTKS	0.0570 (0.0316)	0.0559 (0.0008)	0.0473 (0.1607)	0.0233 (0.1351)

Discussion

The present study examined the trajectories of specific mathematics skills and overall mathematics ability in preterm and full-term born children from before starting kindergarten to the end of first grade (age 5 to 7). Consistent with previous studies, we found lower overall mathematics score in the preterm born group at all time points. This observation by itself masks the fact that the differences between preterm and full-term group are not consistent over time. Importantly, one has to distinguish between the developmental trajectory of informal skills (e.g. Verbal Counting) and formal skills (e.g. Calculation).

We found a deficit in Verbal Counting skills in preterm compared to full-term children at time point 1 and 2. However, by time point 3, there were no significant group differences. This type of developmental pattern signals an initial delay of Verbal Counting skills in preterm children, followed by catch up in skill level.

In contrast, the difference in Calculation skills between preterm and full-term group increases over time. This is likely because more formal mathematics skills are commonly introduced in kindergarten, and rapidly develop with schooling. We predict that this deficit in the preterm group will persist over time, and possibly increase further. In line with this, mathematics deficits have been found in pre-teens (Akshoomoff et al., 2017; Rose et al., 2011), and teenagers (Litt et al., 2012) born preterm. The same applies for other aspects of formal mathematics, such as Set Construction and Number Facts.

Differences in mathematics skills might be mediated to some extent by differences in other cognitive functions (Mulder, Pitchford, & Marlow, 2010). We examined measures of spatial working memory, inhibitory control, processing speed, and motor function. Interestingly, while there were no group differences in SWM, we found that it is predictive of both Verbal Counting and Calculation skill in preterm but not full-term children. Similarly, we did not find significant differences in processing speed between preterm and full-term children, and performance on RTI was predictive of Verbal Counting in the preterm group only. This may indicate that the two groups are employing different problem-solving strategies. Children born preterm may rely on different cognitive processes as they develop mathematics skills.

Preterm compared to full-term children show significantly longer reaction times at the SST, an inverse measure of inhibitory control, at time point 1 and 2. While SST is predictive of Verbal Counting in both groups, it is predictive of Calculation in the preterm group only. This may be another hint towards more effortful task completion in the preterm born children, and potentially having to recruit inhibition skills to a greater extent than full-term children.

The HTKS, a task requiring working memory, inhibitory control, shifting, and motor skills, revealed deficits of the preterm compared to the full term group at all time points. Since there was no correlation between performance on the HTKS and the MABC-2, it appears to reflect group differences in composite executive function ability that is not driven by the group differences in motor control.

Performance on the HTKS has previously been shown to be predictive of academic achievement of typically developing children in kindergarten (McClelland et al., 2014). Consistent with this, we found that HTKS scores were a significant predictor for Verbal Counting, but not Calculation for both groups. However, the number of participants who were administered the HTKS was smaller, and it remains to be examined if the results hold up with a larger sample size.

Our study is an important contribution to the existing body of literature as it examines the crucial transition from preschool through the end of first grade, capturing the first formal instruction of mathematics in school. Further follow-up of these children, and their formal mathematics skills in particular, would give valuable insight into the potential differences in developmental trajectory of preterm and full-term born children from childhood through adolescence.

It should be noted that this preterm group had no significant neonatal complications and was considered healthy. Nevertheless, we found deficits in mathematics skills, particularly in formal skills at age 7, that may be heralds of important inequalities later in life (Basten, Jaekel, Johnson, Gilmore, & Wolke, 2015). These differences are important to consider for parents and teachers of preterm born children, and for our society at large.

Abstract

Understanding, predicting, and learning from other people's actions are fundamental human social-cognitive skills. Little is known about how and when we consider other's actions and outcomes when making our own decisions. We developed a novel task to study social influence in decision-making: the social multi-armed bandit task. This task assesses how people learn policies for optimal choices based on their own outcomes and another player's (observed) outcomes. The majority of participants integrated information gained through observation of their partner similarly as information gained through their own actions. This lead to a suboptimal decision-making strategy. Interestingly, event-related potentials time-locked to stimulus onset qualitatively similar but the amplitudes are attenuated in the solo compared to the dyadic version. This might indicate that arousal and attention after receiving a reward are sustained when a second agent is present but not when playing alone.

Keywords: Decision-Making; Uncertainty; Multi-Armed Bandit; Social Interaction; Dyadic EEG

Introduction

For successful social interaction it is useful to represent and predict other people's actions and the consequences of those actions. Joint action is defined as the ability to coordinate one's actions with others to achieve a goal (Vesper et al., 2016). Although it occurs in many sorts of human activities, it can be conveniently studied using the social or two-player versions of standardized cognitive tasks. Such tasks modified for social interactions can reveal complex dynamic in people's use of social information for judgments and action-planning.

For example, the *joint Simon task* (Sebanz, Knoblich, & Prinz, 2003) is a modified, two-player version of the standard Simon task that measures stimulus-response compatibility. Participants learn to respond with left or right button press for visual or auditory cues and show a longer reaction times are shorter when the cue location is compatible with the response hand, than when the cue occurs contralaterally. This *Simon effect* (Simon, 1990), interestingly, remains in the two-player version in which each participant is only responsible for one stimulus-response pair (Sebanz et al., 2003). This can be interpreted as evidence that human action planning is automatic and is elicited by processing another person's actions as well as planning and executing our own actions. The propensity to develop this ability might have evolved to enable efficient social learning (Kilner, Friston, & Frith, 2007; Liao, Acar, Makeig, & Deák, 2015). Particularly under conditions of uncertainty, the capacity to observe, encode, and imitate others' actions can be beneficial (Laland, 2004), permitting a sort of vicarious embodied modeling.

However, it is not always adaptive to generalize from other's actions and outcomes to one's own. The findings from joint Simon and other tasks have shown that representation of other's internal states occurs even when it is unnecessary, or disadvantageous, for optimal task completion. To study the extent to which people use observation of other's actions and outcomes to influence their own choices, even when it is unfavorable, we developed a novel task: the *social multi-armed bandit* task. The standard multi-armed bandit is a single-player paradigm to study decision-making under uncertainty. Named after the 'one-armed bandit' slot machines of casinos that have a fixed reward probability, multi-armed bandit tasks present several different options ('arms') of different, unknown reward probabilities. They manifest a classic exploitation/ exploration problem (Cohen, McClure, & Yu; Gittins, Glazebrook, & Weber, 2011). Commonly, after an initial phase of exploration players employ one of two strategies: maximizing or matching. *Maximizing*, or consistently choosing the most-rewarding arm (based on prior observations), is the optimal strategy for problems with static reward probabilities. By contrast, *matching,* or choosing each arm in proportion to its relative reward probability, is suboptimal but nevertheless seen in humans and other animals (Sugrue, Corrado, & Newsome, 2004).

Notably, although a great deal of problem solving and prediction updating occurs in social or joint tasks, only a few studies have included multiple decision-makers in social versions of prediction tasks such as multi-armed bandit, and even these have not investigated effects of social interaction or observation on decisions (Liu & Zhao, 2010).

In addition to studying behavior, we recorded participants' electroencephalogram (EEG) and pupil size as physiological metrics of cortical and neuromodulatory concomitants of social decision-making. These bio-sensing methods may provide insights into the underlying neural dynamics of decision-making with high temporal resolution. Both of these physiological measures are common in affective computing (Partala, 2003) to measure valence and arousal, and cortical changes (Fink, 2009).

The present study

The present study aims to address a *"key question of today's cognitive science: how and to what extent do individuals mentally represent their own and others' actions, and how do these representations influence, shape, and constrain an individual's own behavior when interacting with others?"* (Dolk et al., 2014).

To do so, we converted a classic three-armed bandit paradigm into a turn taking game. Reward probabilities for the three arms were different for each of two participants, allowing us to estimate the distinct effects of their own and their partner's action and outcome history on their ongoing decision-making. We studied three outcome measures: (1) decision-making behavior, (2) event-related EEG potentials, and (3) pupil dilation. Details are described below.

In the multi-player version, the probabilities remain constant for each player, however, they differ between the two players (see Table 1). This allows us to examine to what extent each participant takes into account their own and their partner's choices and outcomes. We expected to observe two different core strategies:

Egocentric strategy: Participants might make their decisions only based on their own outcome history and ignore information from their partner's outcomes. Players using this strategy should converge on choosing their own highest gaining arm (90% reward probability) most of the time.

Joint strategy: Participants might take into account information from their partner's outcomes to the same extent as information from their own outcomes. Players using this strategy should not converge on choosing one arm, because all arms average the same reward probability if both participants' outcomes are encoded equally. Alternately, in an intermediate strategy, participants might take into account their partner's outcomes but weigh them less than their own outcomes, and then more slowly converge on their own optimal choice.

Table 1: Reward probabilities for the different arms of the social multi-armed bandit

	Arm 1	Arm 2	Arm 3
Player 1	30%	60%	90%
Player 2	90%	60%	30%

Experiment 1

Participants

Participants were 28 female undergraduate students (14 dyads) recruited through the university's SONA system. They received course credit for participation in addition to a small monetary reward based on performance in the social multi-armed bandit (0.05 USD per reward).

One pair was excluded from EEG and eye-tracking analysis due to recording failure; another pair was excluded because one player chose the same arm on every trial. This left behavioral data from 26 participants, EEG data from 12 participants, and pupillometry data from 12 participants.

Experimental Design

The (social) multi-armed bandit was described to participants as 'the ice-fishing game' and presented on a touchscreen. They were shown three 'ice holes' (arms) distinguished by shape, at approximately equal distances from each other (see Figure 2). The arms were associated with discrete and constant reward probabilities (30%, 60%, and 90%) unknown to the players. Upon choosing and touching a hole, participants heard and saw differential reward feedback. Participants had 100 trials each (200 total) to catch as many fish as possible, choosing one ice hole per trial. Each participant played the game once on their own (solo version) and once as a turn-taking game (dyadic version). For each dyad of participants, EEG and pupillometry data were recorded from one player, and behavioral data were recorded from both.

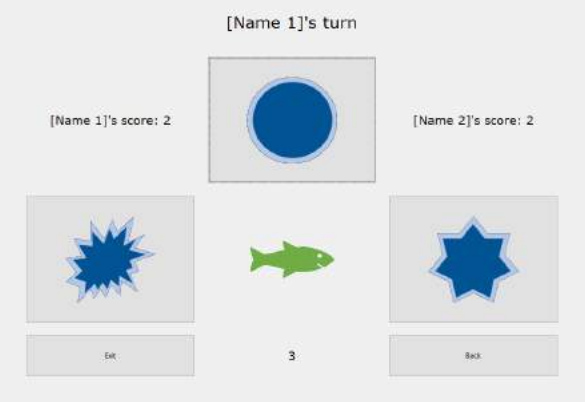

Figure 1: The game screen when a player has won a reward (green fish). The display shows the two players' accumulated rewards as well as which player's turn it is.

Figure 2: Two participants playing the social multi-armed bandit. The player on the left is wearing an Emotiv EEG headset and PupilLabs eye-tracker.

Data Acquisition

The game was presented on a table-mounted capacitive touch screen monitor (diagonal: 66cm). During the dyadic turn-taking game the participants sat facing each other (figure 2). An Emotiv headset (www.emotiv.com) recorded 14-channel EEG data, and a PupilLabs headset (pupil-labs.com/pupil/) captured pupillometry data. These sensors were chosen for participants' comfort and natural movement during a social interaction. EEG was sampled at 128 Hz, and the eye-facing camera sampled at 120 Hz. PupilLabs Software was used to detect the pupil in each frame and calculate its diameter. Lab Streaming Layer (LSL) (Kothe, 2015) was used to synchronize all of the data streams (i.e. EEG, eye-gaze video, and game events) by time stamping each event and each sample.

Synchronized EEG and pupillometry data were locked to participants' game choices in LSL-created XDF files so that behavioral and physiological data were epoched to trials. On each turn the 2 sec of data following the outcome stimulus presentation (win/loss) was used for further analysis.

Data Analysis

The first 20 trials of each game for each player were considered training trials, to teach the participant the game. These trials were not considered in the current analyses.

Decision-Making Behavior Participants' ice hole choice patterns were analyzed via Kullback-Leibler divergence (KLD), a measure of relative entropy.

$$D_{KL}(p,q) = \sum_{i=1}^{N} p(x_i) * log \frac{p(x_i)}{q(x_i)}$$

This quantifies the divergence of one probability distribution to another one. In our experiment we use the KLD to measure the difference between a participant's observed choices, and expected choices according to potential strategies. We hypothesize the employment of four different strategies with the expected choice probabilities as summarized in Table 2. For the egocentric-maximizing strategy, the player chooses the highest gaining arm (arm 3) at every trial. In the egocentric-matching strategy, each arm is chosen in proportion to their reward probability. The joint-equal strategy assumes that the outcomes of both players are weighted equally, resulting in an apparent reward probability of 60% for each arm. In that case each arm is chosen ⅓ of the trials. The joint-social strategy assumes a social value of the arm that has an equal, relatively high reward probability for both of the players (arm 2) and is thus chosen most often.

KLD of observed vs. expected probability distribution for each of the hypothesized strategies was calculated and compared to classify each participant's preferred strategy. As the joint strategy is not applicable in the single-player version, only the two egocentric strategies were compared.

Table 2: Expected choice probabilities for player 1 for each of the four hypothesized strategies. Reward probabilities for

Strategy of player 1		Arm 1	Arm 2	Arm 3
Ego-centric	maximizing	0%	0%	100%
	matching	16.7%	33.3%	50%
Joint	equal	33.3%	33.3%	33.3%
	social	0%	100%	0%

Game Data The game data was an 8 x 200 matrix which included the turn number, player number, reward state, choice, time taken, player 1 reward and player 2 reward. In the single player case the last value was set as -1 and disregarded.

EEG Data The EEG data was cleaned using EEGLAB's Artifact Subspace Reconstruction (ASR) noise removal pipeline (Delorme, 2004; Mullen, 2013). Region of interest was the occipital cortex (channel O1).

Eye-Tracking Data The current analyses only consider a single channel containing pupil diameter information. Samples with abnormally high or zero pupil diameter values (due to detection errors or eye blinks) were ignored and data was interpolated by adjacent values.

After interpolating, the data was normalized to range between 0 and 1 to account for discrepancies in pupil diameter across subjects.

Further Analysis Epochs for each trial containing the response and 2 seconds of subsequent data (including the reward outcome). Our goal was to illustrate the pupil dilation (indicating autonomic response) and cortical dynamics (focusing on updating responses) upon perceiving a reward stimulus after choosing a specific action.

Pupil and EEG data for each type of choice and reward combination were then averaged across all subjects. For EEG data, each channel was averaged independently, to facilitate Event Related Potential (ERP) analyses. The 0.2 sec of data before the event were used as baseline for the normed succeeding EEG data, to control variance in EEG amplitude across subjects.

Results

Decision-Making Behavior Over the course of the game, participants received information through trial and error and could learn that different arms were associated with different probabilities of receiving a reward. In the solo version, participants chose the highest gaining arm more often than the other two. Table 3 summarizes the decision-making behavior via mean total scores and mean number of choices for each arm. Participants distributed their choices more equally and scored lower during the dyadic game.

Table 3: Means (SD) of each decision type in the single- and multi-player games. All measures differ significantly between single and multi-player version ($p<0.001$).

	Reward probability	30%	60%	90%
No. of choices by game version	single	7 (5.0)	17 (10.3)	56 (13.4)
	multi	18 (9.1)	32 (15.1)	30 (19.5)

Mean total score in the single-player game was 76 (SD: 7.0) compared to 63 (SD: 10.1) in the multi-player game ($p<0.001$).

For each version, participants were categorized based on the strategy employed. For each strategy, KLD was calculated between the observed and the expected choices. 70% (18/26) of participants employed a maximizing strategy in the solo version. In the dyadic version, strategies were more varied (see Figure 3). Most common was the joint-social strategy, used by 32% (9/28). There was no correlation between individuals' strategies in the solo and dyadic versions.

Strategy use affected overall scores in the dyadic version ($F=6.083$, $p=0.004$) and had a marginally significant effect in the solo version ($p=0.073$).

Brain Dynamics ERP locked to outcome stimuli for each of the differentially rewarding arms were compared between three conditions: (1) *solo*: a player's responses in the solo version of the game, (2) *dyad (self)*: a player's responses to an outcome of their own action, and (3) *dyad (other)*: a player's responses to an outcome of the partner's action.

Figure 4 illustrates the findings. The ERP displayed a prominent positive potential around 300ms (P3) after dyadic self-reward events in the dyadic version, but not for partner's reward or for reward in the solo game. We also note that the ERP response for partner's rewards as well as for own-reward in the solo game is attenuated but follows the same profile as that of the self-reward condition.

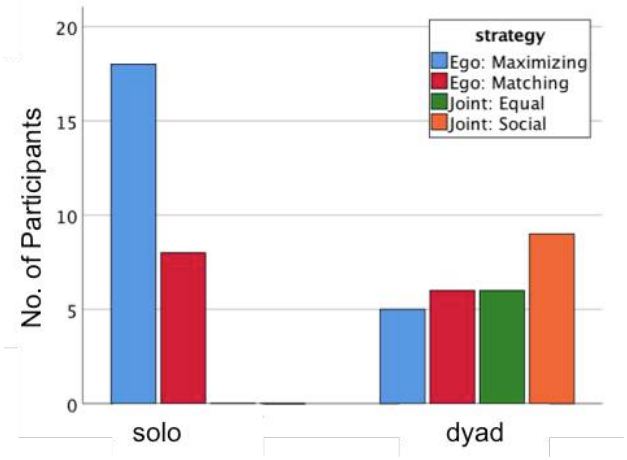

Figure 3: Distribution of strategies being employed by the participants in the single- and multi-player game, as determined via KLD.

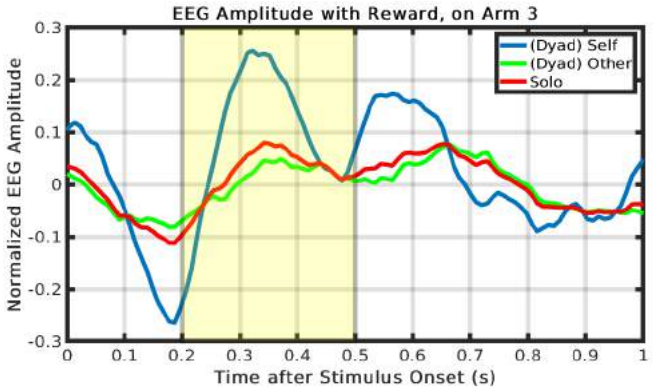

Figure 4: ERP after reward at arm 3 (90%/30%) averaged across participants from channel. Dyad (Self): player receives reward in dyadic version, Dyad (Other): player observes partner receive a reward in dyadic version, Solo: player receives a reward in solo version.

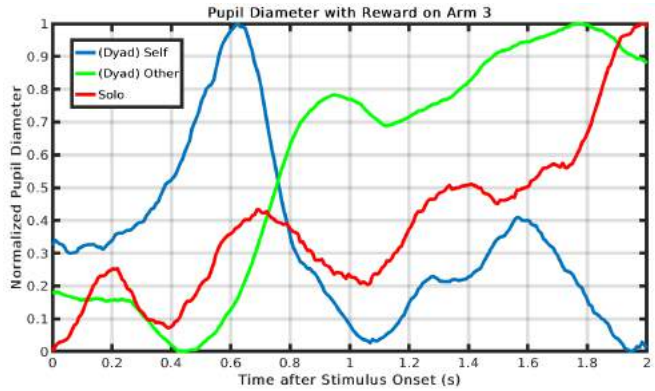

Figure 5: Pupillometry data after reward at arm 3 (90%/30%) averaged across participants from channel. Dyad (Self): player receives reward in dyadic version, Dyad (Other): player observes partner receive a reward in dyadic version, Solo: player receives a reward in solo version.

Pupillometry Pupil dilation significantly increases initially (Figure 5) when a reward is obtained for the player themselves when playing the social multi-armed bandit, but not in the single-player version and not when observing the partner receive a reward. After this initial response, we see that after 0.8 seconds of the reward onset, pupil diameter increases for the Dyad (Other) condition whereas it decreases for the self-reward one.

Discussion

The Social Multi-Armed Bandit revealed that adults take into account information from others' when making decisions. In consistency with previous studies, the majority of participants employed maximizing strategy in the solo version of the task. With this novel paradigm we found that this is not the case when there is a second player present, and when the reward probabilities for the arms are not the same for the two players. Instead, more than half of the participants employed a 'joint'-strategy, in which the actions and outcomes from the other player are integrated with their own when making decisions. One explanation for this phenomenon is a high prior belief of the same underlying probability structure for both players. This is likely the case because the visual representation remains constant throughout the game aside from updating the score count and the display whose turn it currently is. This issue is addressed in Experiment 2.

The ERP time-locked to stimulus onset showed a qualitatively similar pattern after receiving a reward at arm 3 (90%/30% reward probability) for the three conditions analyzed. However, the amplitude is highest when receiving a reward in the dyadic version, and attenuated when observing the partner receive a reward. When receiving a reward in the solo version of the game, the amplitude is also attenuated in comparison to receive a reward in the presence of a second player. We believe that this is due to the higher stakes and reward scenario attached with the dyadic version of the game.

Interestingly, pupil dilation increases drastically at about 0.6 seconds after stimulus onset when receiving a reward in the dyadic version of the game. In contrast, pupil dilation after observing the partner receive a reward has a longer latency of about 0.8 second. This likely reflects differential activation of the parasympathetic nervous system (PNS) for self/other reward scenarios.

Experiment 2

Participants

Participants were 32 undergraduate students (16 dyads, 10 female-female, 4female-male, 2 male-male) recruited through the university's SONA system. They received course credit for participation in addition to a small monetary reward based on performance in the social multi-armed bandit (0.05 USD per reward).

Experimental Design

The experimental design of Experiment 2, is very similar to experiment 1. The modifications of the experiment are:

(1) Whereas in experiment 1, one person in each dyad played the solo version of the game before the dyadic version and the other person played in the reverse order, in experiment 2 both played the solo version either before or after the dyadic version. In other words, game order was randomly assigned by dyad. This ensured that the game process was not driven by prior knowledge of only one of the players.

(2) To reduce the prior belief of a constant underlying reward structure of the game, we changed the background color of the game after each turn, such that there was a distinct visual cue to signal each player's turns.

(3) EEG data was recorded from both participants in Experiment 2 (vs. only one participant per dyad in Exp. 1). Pupillometry data was not recorded.

Data Acquisition

See Experiment 1.

Data Analysis

As in Experiment 1, the first 20 trials were excluded from analysis.

Decision-making behavior

The analysis performed in Experiment 1 is based upon the assumption that participants make use of particular strategies. In this experiment, a different type of analysis was performed, considering choice behavior 'bottom-up' without assumptions of specific strategies.

Participants' choices were analyzed via the Jensen-Shannon Divergence (JSD). The JSD is a distance metric between two probability distributions and based on the KLD:

$$D_{JS}(p,q) = \frac{1}{2}D_{KL}(p,x) + \frac{1}{2}D_{KL}(q,x)$$

with $$x = (p+q)/2$$

The JSD between the relative choice distribution of the last 80 trials of the participants' empirical behavior and the relative choice distribution if all choices were made towards the highest gaining arms (=(0,0,1), maximizing strategy) was used to analyze the data. Hence, the decision-making behavior for each participant could be characterized by their JS divergence in the solo and the dyadic version. As reference, the JS divergence of relative choice distribution between matching behavior (0.17, 0.33, 0.5) and maximizing (0,0,1) is 0.31. This value was used to further cluster participants into 'learners' (JSD < 0.31) and 'non-learners' (JSD ≥ 0.31).

Results

Decision-Making Behavior Participants could be categorized into four groups, depending on if they learned which option was the highest gaining in the solo and/or dyadic version of the game. 50% (16/32) of participants were grouped into 'learners' in the solo version, but into 'non-learners' in the dyadic version. As shown in Figure 6, in the solo version, they choose the 90% reward arm significantly more often than the other two arms ($F = 179.1$, $p < 0.0005$) and significantly more often than in the dyadic version ($F = 59.7$, $p < 0.0005$). 22% (7/32) of participants were clustered into 'learners' in both versions of the game, and 19% (6/32) were clustered into 'non-learners' in both versions of the game. 9% (3/32) were clustered into 'learners' in the dyadic version of the game, but not in the solo version.

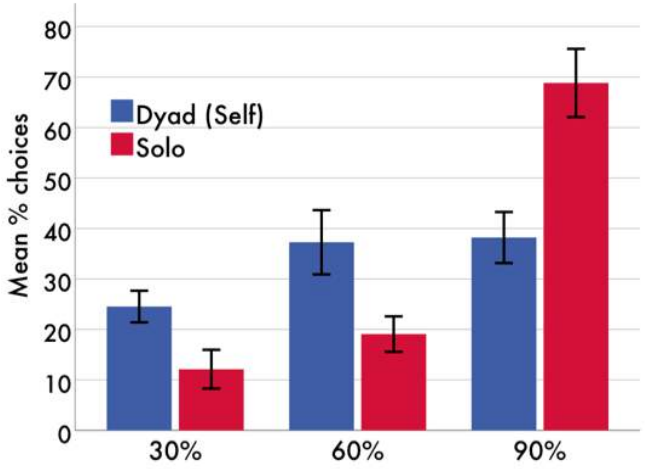

Figure 6: Choice behavior of 50% of participants who learned which arm has the highest reward probability in the solo but not the dyadic version of the multi-armed bandit.

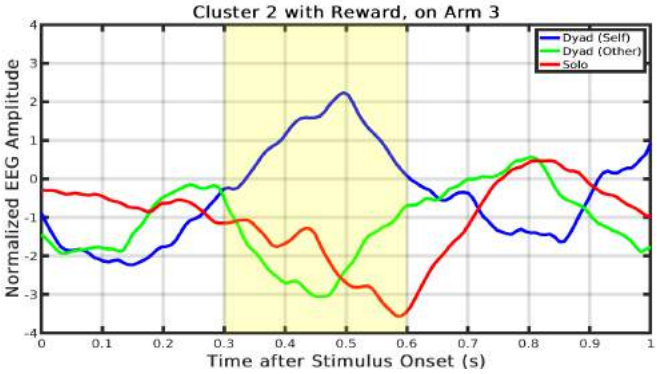

Figure 7: ERP after reward at arm 3 (90%/30%) averaged across participants from channel. Dyad (Self): player receives reward in dyadic version, Dyad (Other): player observes partner receive a reward in dyadic version, Solo: player receives a reward in solo version.

Brain Dynamics ERPs were examined at channel O1 of participants who chose the highest gaining arm most of the time in the solo version, but not in the dyadic version (Figure 7). We observed a high increase in amplitude for the Dyad (Self) condition. In comparison, there was a negative deflection in ERP for the Dyad (Other) and Solo condition.

Discussion

Even when the prior belief of a common underlying reward structure was decreased, half of the participants integrated information gained through observation of their partner similarly as information gained through their own actions.

In Experiment 2, our goal was to combine the subjects' decision-making behavior with their physiology. Similarly as in Experiment 1, the ERP time locked to stimulus onset when receiving a reward at arm 3 showed a high increase in amplitude for the Dyad (Self) condition. In comparison, there was a negative deflection in ERP for the Dyad (Other) and Solo condition. We consider this a good starting point to move towards extracting more high-level features such as EEG power spectrum density, mutual information and pupil diameter-based fixations and saccades in the future.

General Discussion

We developed a Social Multi-Armed Bandit task to examine the influence of social interaction on decision-making. We found that while some individuals do figure out that the other player's information does not apply to them, the majority of participants converged to a suboptimal decision-making strategy. We termed this strategy 'joint' as it most likely emerges through averaging the reward probabilities for both players. Measurement of electrophysiology showed a distinct P3 when the player receives a reward in the dyadic version of the multi-armed bandit but not the solo version. P3 is thought to emerge through stimulus-driven 'top-down' processes when the participant pays focused attention to a task. The distinct presence of the P3 in the dyadic task might thus hint towards heightened attention, particularly towards own rewards, in the presence of another player. Interestingly, the pupillometry data revealed a similar pattern as the ERP.

This task has considerable possibilities for further studies of social interaction. Next steps include a similar experiment with participants are previously acquainted with each other, e.g. friends, and children with their parents. It is likely that having a prior relationship with the other partner will alter the joint strategy for one or both partners. It would also be interesting to test how an asymmetric relationship (e.g., parent-child) would influence decision-making strategies, compared to a more symmetric relationship. It is possible that less-experienced participants (e.g., children) are more likely to follow, or match, the behavior of a 'reliable' person, as is the case in imitation (Poulin-Dubois, Brooker, & Polonia, 2011). Lastly, this task might give interesting insights into decision-making processes of neuro-divergent people, particularly those with potential differences in social behaviors (Montague, 2018).

Abstract

Large-scale behavioral datasets enable researchers to use complex machine learning algorithms to better predict human behavior, yet this increased predictive power does not always lead to a better understanding of the behavior in question. In this paper, we outline a data-driven, iterative procedure that allows cognitive scientists to use machine learning to generate models that are both interpretable and accurate. We demonstrate this method in the domain of moral decision-making, where standard experimental approaches often identify relevant principles that influence human judgments, but fail to generalize these findings to "real world" situations that place these principles in conflict. The recently released Moral Machine dataset allows us to build a powerful model that can predict the outcomes of these conflicts while remaining simple enough to explain the basis behind human decisions.

Keywords: machine learning; moral psychology

Introduction

Explanatory and predictive power are hallmarks of any useful scientific theory. However, in practice, psychology tends to focus more on explanation (Yarkoni & Westfall, 2017), whereas machine learning is almost exclusively aimed at prediction. The necessarily restrictive nature of laboratory experiments often leads psychologists to test competing hypotheses by running highly-controlled studies on tens or hundreds of subjects. Although this procedure gives a better understanding of the specific phenomenon, it can be difficult to generalize the findings and predict behavior in the "real world," where multiple factors are interacting with one another. Conversely, machine learning takes full advantage of complex, nonlinear models that excel in tasks ranging from image classification (Krizhevsky et al., 2012) to video game playing (Mnih et al., 2015). The performance of these models scales with their level of expressiveness (Huang et al., 2018), which results in millions of parameters that are difficult to interpret.

Interestingly, machine learning has long utilized insight from cognitive psychology and neuroscience (Rosenblatt, 1958; Sutton & Barto, 1981; Ackley et al., 1985; Elman, 1990), a trend that continues to this day (Banino et al., 2018; Lzaro-Gredilla et al., 2019). We believe that the reverse direction has been underutilized, but could be just as fruitful. In particular, psychology could leverage machine learning to improve both the predictive and explanatory power of cognitive models. We propose a method (summarized in Figure 1) that enables cognitive scientists to use large-scale behavioral datasets to construct interpretable models that rival the performance of complex, black-box algorithms.

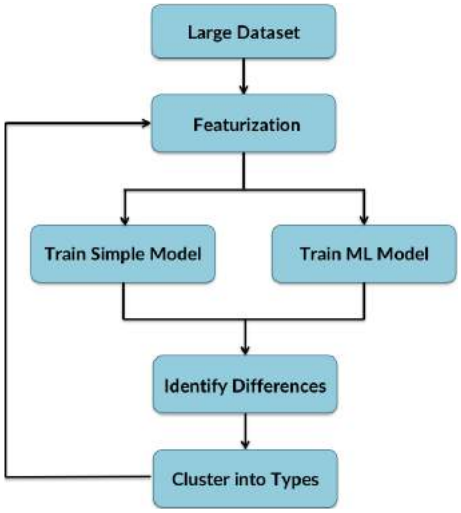

Figure 1: A systematic, data-driven procedure for building interpretable models that rival the predictive power of complex machine learning models.

This methodology is inspired by Box's loop (Box & Hunter, 1962; Blei, 2014; Linderman & Gershman, 2017), a systematic process of integrating the scientific method with exploratory data analysis. Our key insight is that training a black-box algorithm gives a sense of how much variance in a certain type of behavior can be predicted. This predictive power provides a standard for improvement in explicit cognitive models (Khajah et al., 2016). By continuously critiquing an interpretable cognitive model with respect to these black-box algorithms, we can identify and incorporate new features until its performance converges, thereby jointly maximizing our two objectives of explanatory and predictive power.

In this paper, we demonstrate this methodology by building a statistical model of moral decision-making. Philosophers and psychologists have historically conducted thought experiments and laboratory studies isolating individual principles responsible for human moral judgment (e.g. consequentialist ones such as harm aversion or deontological ones such as not using others as a means to an end). However, it can be difficult to predict the outcomes of situations in which these principles conflict (Cushman et al., 2010). The recently released

Moral Machine dataset (Awad et al., 2018) allows us to build a predictive model of how humans navigate these conflicts over a large problem space. We start with a basic rational choice model and iteratively add features until its accuracy rivals that of a neural network, resulting in a model that is both predictive and interpretable.

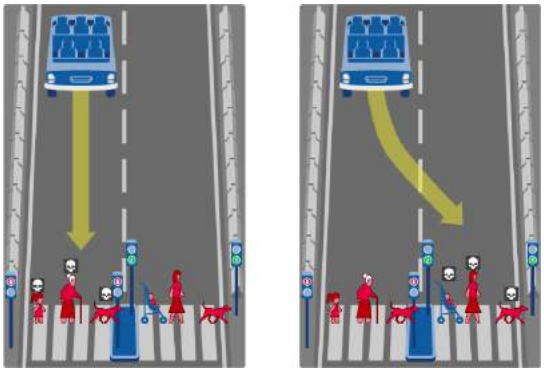
Background

Theories of Moral Decision-Making The two main families of moral philosophy often used to describe human behavior are *consequentialism* and *deontology*. Consequentialist theories posit that moral permissibility is evaluated solely with respect to the outcomes, and that one should choose the outcome with the highest value (Greene, 2007). On the other hand, deontological theories evaluate moral permissibility with respect to actions and whether they correspond to specific rules or rights.

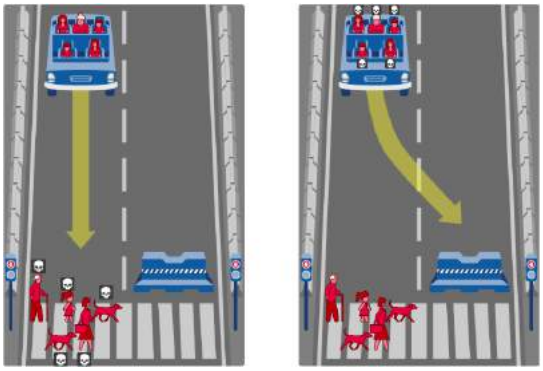
The trolley car dilemma (Foot, 2002; Thomson, 1984) highlights how these two families differ when making moral judgments. Here, participants must determine whether it is morally permissible to sacrifice an innocent bystander in order to prevent a trolley car from killing five railway workers. The "switch" scenario gives the participant the option to redirect the car to a track with one railway worker, whereas the "push" scenario requires the participant to push a large man directly in front of the car to stop it, killing the large man in the process. Given that the outcomes are the same for the "switch" and "push" scenarios (i.e., intervening results in one death, while not intervening results in five deaths), consequentialism prescribes intervention in both scenarios. Deontological theories allow for intervening in the "switch" scenario but not the "push" scenario because pushing a man to his death violates a moral principle, but switching the direction of a train does not.

Empirical studies have found that people are much more willing to "switch" than to "push" (Greene et al., 2001; Cushman et al., 2006), suggesting deontological principles factor heavily in human moral decision-making. Yet, a deontological theory's lack of systematicity makes it difficult to evaluate as a model of moral judgment (Greene, 2017). What are the rules that people invoke, and how do they interact with one another when in conflict? Furthermore, how do they interact with consequentialist concerns? Would people that refuse to push a man to his death to save five railway workers still make the same decision and with the same level of confidence when there are a million railway workers? Any theory of human moral cognition needs to be able to model how participants trade off different consequentialist and deontological factors.

Moral Machine Paradigm As society anticipates autonomous cars roaming its streets in the near future, the trolley car dilemma has left the moral philosophy classroom and entered into national policy conversations. A group of researchers aiming to gauge public opinion created "Moral Machine," an online game that presents users with moral dilemmas (see Figure 2) centered around autonomous cars (Awad et al., 2018). Comprising roughly forty million decisions from users in over two hundred countries, the Moral Machine experiment is the largest public dataset collection on human moral judgment.



(a) An autonomous car is headed towards a group of three pedestrians who are illegally crossing the street. The car can either stay and kill these pedestrians or swerve and kill three other pedestrians crossing legally.



(b) An autonomous car with five human passengers is headed towards a group of pedestrians who are illegally crossing the street. Staying on course will kill the pedestrians but save the passengers, while swerving will kill the passengers but save the pedestrians.

Figure 2: Two sample dilemmas in the Moral Machine dataset. In every scenario, the participant is asked to choose whether to *stay* or *swerve* (Awad et al., 2018).

In addition to the large number of decisions, the experiment operated over a rich problem space. Twenty unique agent types (e.g. man, girl, dog) along with contextual information (e.g. crossing signals) enabled researchers to measure the outcomes of nine manipulations: action versus inaction, passengers versus pedestrians, males versus females, fat versus fit, low status versus high status, lawful versus unlawful, elderly versus young, more lives saved versus less, and humans versus pets. The coverage and density of this problem space provides the opportunity to build a model that predicts how humans make moral judgments when a variety of different principles are at play.

Predicting Moral Decisions

As described earlier, the iterative refinement method we propose begins with both an initial, interpretable model and a more predictive black-box algorithm. In this section, we do exactly this by contrasting rational choice models derived from moral philosophy with multilayer feedforward neural networks.

Model Descriptions

We restricted our analysis to a subset of the dataset ($N = 12,478,340$) where an empty autonomous vehicle must decide between saving the pedestrians on the left or right side of the road (see Figure 2a for an example). The models we consider below are tasked to predict the probability of choosing to save the left side.

Interpretable Models Choice models (CM) are ubiquitous in both psychology and economics, and they form the basis of our interpretable model in this paper (Luce, 1959; McFadden et al., 1973). In particular, we assume that participants construct the values for both sides, i.e., v_{left} and v_{right}, and choose to save the left side when $v_{\text{left}} > v_{\text{right}}$, and vice versa. The value of each side is determined by aggregating the utilities of all its agents:

$$v_{\text{side}} = \sum_i u_i l_i \tag{1}$$

where u_i is the utility given to agent i and l_i is a binary indicator of agent i's presence on the given side.

McFadden et al. (1973) proved that if individual variation around this aggregate utility follows a Weibull distribution, the probability that v_{left} is optimal is consistent with the exponentiated Luce choice rule used in psychology, i.e.,

$$P(v_{\text{left}} > v_{\text{right}}) = P(c = \text{left} | v_{\text{left}}, v_{\text{right}}) = \frac{e^{v_{\text{left}}}}{e^{v_{\text{left}}} + e^{v_{\text{right}}}} \tag{2}$$

In practice, we can implement this formalization by using logistic regression to infer the utility vector $\mathbf{u}$. We built three models, each of which provided top-down different constraints on the utility vector. Our first model, "Equal Weight," required each agent to be equally weighted. At the other extreme, our "Utilitarian" model had no restriction. A third model, "Animals vs. People," was a hybrid: all humans were were weighted equally and all animals were weighted equally, but humans and animals could be weighted differently.

Research in moral psychology and philosophy has found that humans use moral principles in addition to standard utilitarian reasoning when choosing between options (Quinn, 1989; Spranca et al., 1991; Mikhail, 2002; Royzman & Baron, 2002; Baron & Ritov, 2004; Cushman et al., 2006). For example, one principle may be that allowing harm is more permissible than doing harm (Woollard & Howard-Snyder, 2016). In order to incorporate these principles, we moved beyond utilitarian-based choice models by expanding the definition of a side's value:

$$v_{\text{side}} = \sum_i u_i l_i + \sum_m \lambda_m f_m \tag{3}$$

where f_m is an indicator variable of whether principle m is present on the side and λ_m represents the importance of principle m. We built an "Expanded" model that introduces two principles potentially relevant in the Moral Machine dataset. The first is a preference for allowing harm over doing harm, thus penalizing sides that require the car to swerve in order to save them. Another potentially relevant principle is that it is more justified to punish unlawful pedestrians than lawful ones because they knowingly waived their rights when crossing illegally (Nino, 1983). This model was trained on the dataset to infer the values of $\mathbf{u}$ and λ.

Neural Networks We use relatively expressive multilayer feedforward neural networks (NN) to provide an estimate of the level of performance that statistical models can achieve in this domain. These networks were given as inputs the forty-two variables that uniquely defined a dilemma to each participant: twenty for the characters on the left side, twenty for the characters on the right side, one for the side of the car, and one for the crossing signal status. These are the same inputs for the "Expanded" choice model. However, the "Expanded" model had the added restriction that the side did not change an agent's utility (e.g., a girl on the left side has the same utility as a girl on the right side), while the neural network had no such restriction.

The networks were trained to minimize the crossentropy between the model's output and human binary decisions. The final layer of the neural networks is similar to the choice model in that it is constructing the value of each side by weighting different features. However, in these networks, the principles are learned from the nonlinear interactions of multiple layers and the indicators are probabilistic rather than deterministic.

To find the optimal hyperparameters, we conducted a grid search, varying the number of hidden layers, the number of hidden neurons, and the batch size. All networks used the same ReLU activation function and and no dropout. Given that most of these models both performed similarly and showed a clear improvement over simple choice models, we did not conduct a more extensive hyperparameter search. A neural network with three 32-unit hidden layers was used for all the analyses in this paper.

Model Comparisons

Standard Metrics Table 1 displays the results of the four rational choice models and the best performing neural network. All models were trained on eighty percent of the dataset, and the reported results reflect the performance on the held-out twenty percent. We report accuracy and area under the curve (AUC), two standard metrics for evaluating classification models. We also calculate the normalized Akaike information criterion (AIC), a metric for model comparison that integrates a model's predictive power and simplicity. All metrics resulted in the same expected ranking of models: Neural Network, Expanded, Utilitarian, Animals vs. People, Equal Weight.

Table 1: Comparison of Standard Metrics

Model Type	Accuracy	AUC	AIC
Equal Weight	0.571	0.616	1.301
Animals vs. People	0.630	0.702	1.234
Utilitarian	0.732	0.780	1.146
Expanded	0.763	0.826	1.046
Neural Network	0.774	0.845	0.983

Performance as a Function of Dataset Size Table 1 demonstrates that our cognitive models aren't as predictive as a powerful learning algorithm. This result, however, is only observable with larger datasets. Figure 3 plots each metric for each model over a large range of dataset sizes. Choice models performed very well at dataset sizes comparable to that of a large laboratory experiment. Conversely, neural networks improved with larger dataset sizes until reaching an asymptote where $N > 100,000$, at which point they outperform rational choice models. These results suggest that while psychological models are robust in the face of small datasets, they need to be evaluated on much larger ones.

Identifying Explanatory Principles

The neural network gives us an aspirational standard of how our simpler model should perform. Next, our task is to identify the emergent features it constructs and incorporate them into our simple choice model.

Calculating Residuals in Problem Aggregates By aggregating decisions for each dilemma, we can determine the empirical "difficulty" of each dilemma and whether our models predict this difficulty. For example, assume dilemmas A and B have been proposed to one hundred participants. If ninety participants exposed to dilemma A chose to save the left side and sixty participants exposed to dilemma B did, the empirical percentages for A and B would be 0.90 and 0.60, respectively. An accurate model of moral judgment should not only reflect the binary responses but also the confidence behind those responses.

We identified the specific problems where the neural network excelled compared to the "Expanded" rational choice model. Manually inspecting these problems and clustering them into groups revealed useful features beyond those employed in the choice model that the neural network is constructing. We formalized these features as principles and incorporated them into the choice model to improve prediction. Two examples are represented in Table 2.

Table 2a describes a set of scenarios where one human is crossing illegally and one pet is crossing legally. Empirically, users tend to overwhelmingly prefer saving the human, while the choice model predicts the opposite. Our choice model's inferred utilities and importance values reveal a strong penalty (i.e., a large negative coefficient) for (1) humans crossing illegally and (2) requiring the car to swerve. However, the empirical data suggests that these principles are outweighed by the fact that this is a humans-versus-animals dilemma, and that humans should be preferred despite the crossing or intervention status. Thus, the next iteration of our model should incorporate a binary variable signifying whether this is an explicit humans-versus-animals dilemma.

We can conduct a similar analysis for the set of scenarios in Table 2b. Both models output significantly different decision probabilities, the neural network being the more accurate of the two. Most salient to us was an effect of age. Specifically, when the principal difference between the two sides is age, both boys and girls should be saved at a much higher rate, and information about their crossing and intervention status is less relevant. To capture this fact, we can incorporate another binary variable signifying whether the only difference between the agents on each side is age.

Incorporating New Features The two features we identified are a subset of six "problem types" the Moral Machine researchers used in their experiment: humans versus animals, old versus young, more versus less, fat versus fit, male versus female, and high status versus low status. These types were not revealed to the participants, but the residuals we inspected suggest that participants were constructing them from the raw features and then factoring them into their decisions.

Incorporating these six new features as principles resulted in 77.1% accuracy, nearly closing the gap entirely between our choice model and neural network performance reported in Table 1. Figure 4 illustrates the effects of incorporating the problem types into both the choice model and the neural network in details. Importantly, we observe that "Neural Network + Types" outperforms "Neural Network" at smaller dataset sizes, but performs identically at larger dataset sizes. This result suggests that the regular "Neural Network" is constructing the problem types we identified as emergent features given sufficient data to learn them from. More importantly, our augmented choice model now rivals the neural network's predictive power. And yet, by virtue of it being a rational choice model with only a few more parameters than our "Expanded" (and even the "Utilitarian") model, it remains conceptually simple. Thus, we have arrived at an interpretable statistical model that can both quantify the effects of utilitarian calculations and moral principles and predict human moral judgment over a large problem space.

Figure 4b still displays a gap between the AUC curves, suggesting there is more to be gained by repeating the process and potentially identifying new even more principles. For example, the last iteration found that when there was a humans-versus-animals problem, humans should be strongly favored. However, residuals suggest that participants don't honor this principle when all the humans are criminals. Rather, in these cases, participants may favor the animals or prefer the criminal by only a small margin. Thus, our next iteration will include a feature corresponding to whether all the humans are criminals. Our model also underperforms by overweighting

Table 2: Problem Aggregate Comparisons (Left Side Save Percentage)

Left Side Agents	**Right Side Agents**	**Car Side**	**Empirical**	**CM**	**NN**
Pregnant Woman Crossing Illegally	Cat Crossing Legally	Left	0.779	0.411	0.797
Stroller Crossing Illegally	Cat Crossing Legally	Left	0.826	0.425	0.801
Dog Crossing Legally	Male Doctor Crossing Illegally	Right	0.312	0.693	0.293
Cat Crossing Legally	Man Crossing Illegally	Right	0.308	0.692	0.266
Old Woman Crossing Illegally	Cat Crossing Legally	Left	0.670	0.306	0.622

(a) Problems indicating Human vs. Animals Principle

Left Side Agents	**Right Side Agents**	**Car Side**	**Empirical**	**CM**	**NN**
Old Man Crossing Legally	Boy Crossing Illegally	Right	0.350	0.647	0.341
Old Woman Crossing Legally	Girl Crossing Illegally	Right	0.337	0.642	0.321
Man	Boy	Left	0.113	0.417	0.097
Old Woman Crossing Legally	Girl Crossing Illegally	Left	0.268	0.570	0.269
Old Woman	Woman	Right	0.256	0.475	0.269

(b) Problems indicating Old vs. Young Principle

the effects of intervention. In problem types such as male versus female and fat versus fit, the intervention variable is weighted much differently than in young-versus-old dilemmas. The next iteration of the model should also include this interaction. Thus, this methodology allows us to continuously build on top of the new features we identify.

Conclusion

Large-scale behavioral datasets have the potential to revolutionize cognitive science (Griffiths, 2015), and while data science approaches have traditionally used them to predict behavior, they can additionally help cognitive scientists construct explanations of the given behavior.

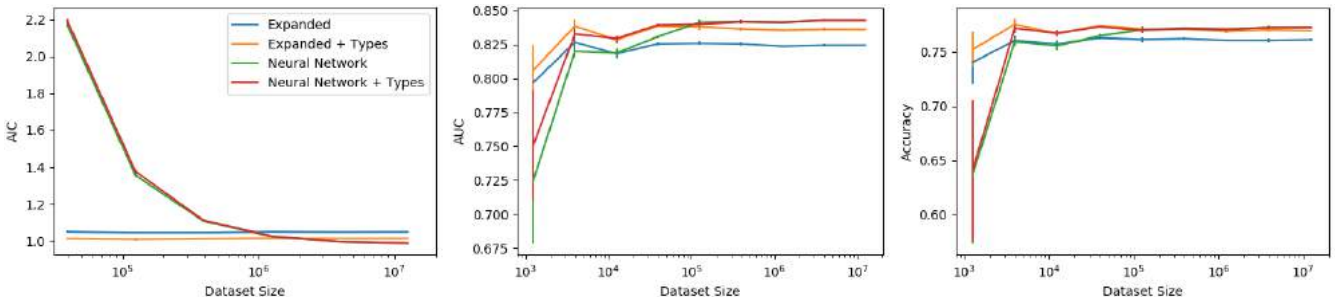
Black-box machine learning algorithms give us a sense of the predictive capabilities of our scientific theories, and we outline a methodology that uses them to help cognitive models reach these capabilities:

1. Amass a large-scale behavioral dataset that encompasses a large problem space
2. Formalize interpretable theories into parameterizable psychological models whose predictions can be evaluated
3. Compare these models to more accurate, but less interpretable black-box models (e.g., deep neural networks, random forests, etc.)
4. Identify types of problems where the black-box models outperform the simpler models
5. Formalize these problem types into features and incorporate them into both the simple and complex models
6. Return to Step 4 and repeat

We applied this procedure to moral decision-making, starting off with a rational choice model and iteratively adding principles until it had a comparable predictive power with black-box algorithms. This model allowed us to quantitatively predict the interactions between different utilitarian concerns and moral principles. Furthermore, our results regarding problem types suggest that moral judgment can be better predicted by incorporating alignable differences in similarity judgments (Tversky & Simonson, 1993), such as whether the dilemma is humans-versus-animals or old-versus-young.

The present case study, while successful, is only a limited application of the methodology we espouse, and further demonstrations are required to illustrate its utility. It will be

[1]While a batch size of 8,192 was used for Table 1, a batch size of 512 was used here because of the smaller dataset sizes.



(a) Dataset Size vs. AIC (b) Dataset Size vs. AUC (c) Dataset Size vs. Accuracy

Figure 4: Test-set performance metrics before and after incorporating new principles. Models were trained on five 80/20 training/test splits. Error bars indicate ± 1 SEM.

particularly interesting to apply our method to problems with even larger gaps between classic theories and data-driven predictive models. It is also likely that transferring insights from data-driven models will require moving beyond the sorts of featurization we consider here (i.e., problem clustering). In any case, we hope the microcosm presented here will inspire similarly synergistic approaches in other areas of psychology.

Acknowledgments. We thank Edmond Awad for providing guidance on navigating the Moral Machine dataset.

Abstract

How do people understand concepts such as *dog*, *aggressive dog*, *dog house* or *house dog*? The meaning of a concept depends crucially on the concepts around it. While this hypothesis has existed for a long time, only recently it has become possible to test it based on neuroimaging and quantify it using computational modeling. In this paper, a neural network is trained with backpropagation to map attribute-based semantic representations to fMRI images of subjects reading everyday sentences. Backpropagation is then extended to the attributes, demonstrating how word meanings change in different contexts. Across a large corpus of sentences, the new attributes are more similar to the attributes of other words in the sentence than they are to the original attributes, demonstrating that the meaning of the context is transferred to a degree to each word in the sentence. Such dynamic conceptual combination effects could be included in natural language processing systems to encode rich contextual embeddings to mirror human performance more accurately.

Keywords: Context Effect; Concept Representations; Conceptual Combination; fMRI Data Analysis; Neural Networks; Embodied Cognition

Introduction

In the embodied cognition approach. (Barsalou, 2008, Binder et al., 2009), the meaning of a concept is not a set of verbal features that people associate with the concept, but rather a set of neural processing modalities that are involved while experiencing instances of the concept. This approach provides a direct correspondence between conceptual content and neural representations, and suggests that concepts can be represented through a number of weighted semantic dimensions that correspond to different brain areas. Recently it has become possible to ground this approach to brain imaging. In particular, Binder et al. (2009) identified a distributed large-scale brain network linked to the storage and retrieval of words. This brain network was used as the foundation for the Concept Attributes Representation (CAR) theory (a.k.a. the experiential attribute representation model). CAR theory proposes that words are represented as a set of weighted attributes stimulated by context.

People weigh concept features differently based on context, i.e., they construct a meaning dynamically according to the combination of concepts that occur in the sentence. Such conceptual combination either uses an attribute of one concept to describe another (in attribute combination) or forms some relation between two concepts to create a new one (in relational combination). In case of attribute combination, the modifier features adapt other concepts in the combination to some degree, and as a result, the words involved are alike (Wisniewski, 1998). For example, listeners must realize that *red apple* could mean just a fruit having a certain color by selecting salient features that dominate in the combination. The noun *apple* is defined by color, size, shape, taste, etc. and one or more of those dimensions will be modified during the attribute combination. In relational combination, the modifier features have nothing to do with the combination. For example *apple basket* or *apple pie* contain a variety of relations that often do not include *apple's* features as in *apple baskets* are not edible, red or a fruit. To help understand that *apple pie* is made of apples but *apple baskets* are not, a thematic relation needs to be built based on world knowledge about plausible combinations. Both attribute and relational combinations play an important role in the construction of new or complex concepts (Gagné & Shoben, 1997; Murphy 1990; Pecher, Zeelenberg, & Barsalou, 2004).

This paper focuses on the attribute combination process. It describes how such a dynamic construction of concepts in the brain can be quantified. This question has been studied in previous work anecdotally, by analyzing a few example cases of how the meaning attributes are weighted differently in various contexts for individual concepts, combinations of concepts, and for sentences (Aguirre-Celis & Miikkulainen, 2017, 2018). The current study expands on this prior work by evaluating the robustness and generality of these conclusions across an entire corpus of sentences and semantic roles. A neural network is trained to map brain-based semantic representations of words (CARs) into fMRI data of subjects reading everyday sentences. Backpropagation is then repeated separately for each sentence, reducing the remaining error by modifying only the CARs at the input of the network. As a result, the strengths of the attributes in the CARs change according to how important each attribute is for that sentence context.

The CAR theory is first reviewed, and the sentence collection, fMRI data, and word representation data described. The computational model is presented, followed by the experiments: an example individual case of how

conceptual combinations affect word meanings, and an aggregate study across a corpus of sentences.

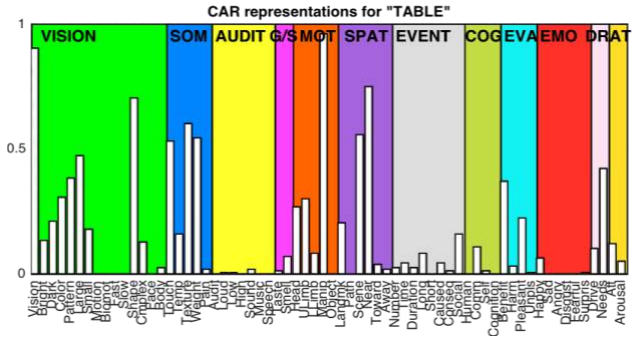

Figure 1: Bar plot of the 66 semantic features for the concept *table*. The values represent average human ratings for each feature. Given that *table* is an object, it gets low weightings on human-related attributes such as Face, Speech, Head, and emotions including Happy, Sad, and Angry, and high weightings on attributes like Vision, Shape, Touch, and Manipulation.

Concept Attribute Representation Theory

CAR theory represents the basic components of meaning defined in terms of observed neural processes and brain systems thereby relating semantic content to systematic modulation of neuroimaging activity (Anderson, et al., 2016; Binder, et al., 2009). They are composed of a list of modalities that correspond to specialized sensory, motor and affective functions, and are therefore not limited to the classical sensory-motor dimensions of most embodied theories.

CARs capture aspects of experience central to the acquisition of event and object concepts, both abstract and concrete. For example, concept ratings on visual and sensory components include brightness, color, size, shape, temperature, weight, pain, etc. These aspects of mental experience model each word as a collection of a 66-dimensional feature vector that captures the strength of association between each neural attribute and the word meaning. For instance, Figure 1 shows the CAR for the concept *table*.

The attributes in CAR theory were selected after an extensive body of physiological evidence based on two assumptions: (1) All aspects of mental experience can contribute to concept acquisition and consequently concept composition; (2) experiential phenomena are grounded on neural processors representing a particular aspect of experience. For a more detailed account of the attribute selection and definition see Binder, et al., (2009, 2011, 2016a, and 2016b). The next section describes how the CAR theory is instantiated by acquiring attribute ratings from human subjects.

Data Preparation

Three data collections were used in this study: A sentence collection prepared by Glasgow et al., (2016), the fMRI images for these sentence by the Medical College of Wisconsin (Anderson, et al., 2016; Binder, et al., 2016), and semantic Vectors (CAR ratings) for words obtained via Mechanical Turk (Anderson, et al., 2016; Binder, et al., 2009). In addition, fMRI representations were synthesized for individual words from the sentence fMRI. Each of these data collections is described in more detail below.

Sentence Collection

The sentence set was prepared for the fMRI study as part of the Knowledge Representation in Neural Systems Program (KRNS). A total of 240 sentences were composed from two to five content words from a set of 242 words (141 nouns, 39 adjectives and 62 verbs). The words were selected toward imaginable and concrete objects, actions, settings, roles, state and emotions, and events. Examples include *couple*, *author*, *boy*, *theatre*, *hospital*, *desk*, *red*, *flood*, *damaged*, *drank*, *gave*, *happy*, *old*, *summer*, *chicken*, *dog*.

The sentence collection is not fully balanced and systematic, but instead aims to be a natural sample. In order to investigate the effect of context, pairs of contrasting sentences were identified in this collection in an early study. This pairs include differences and similarities such as live mouse vs. dead mouse, family celebrated vs. happy family, and playing soccer vs. watching soccer. The resulting collection of 77 such sentences, with different shades of meaning for verbs, nouns and adjectives, as well as different contexts for nouns and adjectives was used to identify anecdotal examples (Table 1). However, the entire colection of sentences was used in the aggregate study described below.

Table 1: Contrasting Sentences. Sentence examples with differences and similarities in meaning. For instance, the role of the verb *flew* is used in two different contexts, bird and duck flying (animate) vs. plane flying (inanimate). Such sentence pairs illustrate the idea of conceptual combination well. However, the entire set of sentences was used in the aggregate study described in this paper.

SEMANTIC CONTRAST		SENTENCES
GOOD	94	*The soldier delivered the medicine.*
AGGRESSIVE	112	*The soldier kicked the door.*
ANIMAL	203	*The yellow bird flew over the field.*
	207	*The duck flew.*
OBJECT	210	*The red plane flew through the cloud.*
BAD PEOPLE	119	*The dangerous criminal stole the television.*
	152	*The mob was dangerous.*
NATURE	99	*The flood was dangerous.*

Neural fMRI Representation of Sentences

To obtain the neural correlates of the 240 sentences, subjects viewed each sentence on a computer screen while in the fMRI scanner. The sentences were presented word-by-word using a rapid serial visual presentation paradigm, with each content word exposed for 400ms followed by a 200ms inter-stimulus interval. Participants were instructed to read the sentences and think about their overall meaning.

Eleven subjects took part in this experiment producing 12 repetitions each. The fMRI data were preprocessed using standard methods, including slice timing and motion correction (AFNI software, Cox 1996). The most stable,

active and discriminative voxels were then selected and Principal Component Analysis and zero mean normalization were performed on them. These transformed brain activation patterns were converted into a single-sentence fMRI representation per participant by taking the voxel-wise mean of all repetitions (Anderson, et al., 2016; Binder, et al., 2016, 2016b). To form the target for the neural network, the most significant 396 voxels per sentence were then chosen (to match six case-role slots of the content words consisting of 66 attributes each) and scaled to [0.2..0.8].

Synthetic fMRI Word Representations

The neural data set did not include fMRI images for words in isolation. Therefore a technique developed by Anderson et al. (2016) was adopted to approximate them. The voxel values for a word were obtained by averaging all fMRI images for the sentences where the word occurs. These vectors, called SynthWords, encode a combination of examples of that word along with other words that appear in the same sentence. Thus, the SynthWord representation for *mouse* contains aspects of running, forest, man, seeing, and dead, from sentence 56:*The mouse ran into the forest* and sentence 60:*The man saw the dead mouse*.

This process of combining contextual information is similar to many semantic models in computational linguistics (Baroni et. al., 2010; Burgess, 1998; Landauer et al., 1997; Mitchell & Lapata, 2010). In other studies, this approach has been used successfully to predict brain activation (Anderson, et al., 2016; Binder, et al., 2016a, 2016b; Just, et al., 2017).

Due to the limited number of combinations, some of SynthWords became identical and were excluded from the dataset. The final collection includes 237 sentences and 236 words (138 nouns, 38 adjectives and 60 verbs).

Semantic CAR Representations for Words

CAR ratings were collected for the original set of 242 words (Glasgow et al., 2016) through Amazon Mechanical Turk. In a scale of 0-6, the participants were asked to assign the degree to which a given concept is associated to a specific type of neural component of experience (e.g., "To what degree do you think of a *table* as having a fixed location, as on a map?"). Approximately 30 ratings were collected for each word. After averaging all ratings and removing outliers, the final attributes were transformed to unit length yielding a 66-dimensional feature vector (Figure 1).

Note that this approach build its representations by directly mapping the conceptual content of a word (expressed in the questions) to the corresponding neural processes and systems for which the CAR dimensions stand. This approach thus contrasts with systems where the features are extracted from text corpora and word co-occurrence (Baroni et. al., 2010; Burgess, 1998; Harris, 1970; Landauer & Dumais, 1997).

Computational Approach

The approach for quantifying the effect of context in the fMRI data is based on the FGREP neural network (Forming Global Representations with Extended BP, Miikkulainen & Dyer, 1991). The idea is to train a neural network to predict what the sentence fMRI should be, based on the CAR representations, and then use FGREP to modify the CARs so that that prediction becomes correct.

Therefore, a simple three-layer neural network is first trained to map the CAR representations to word fMRI (in the left side of Figure 2, the mapping from CARWords, or word attribute ratings, to SynthWords, i.e., fMRI synthetic words).

After training, this network is used to predict what the sentence fMRI would be without the context effects. The SynthWords in the sentence are averaged to form this prediction called SynthSent. The SynthSent is then compared to fMRISent (the original fMRI data) to form an error signal.

That signal is backpropagated through the network (right side of figure 2), but the neural network weights are no longer changed. Instead, the error is used to change the CARWords (which is the FGREP method). This modification can be carried out through multiple iterations until the error goes to zero, or no additional change is possible (because the CAR attributes are already at their max or min limits). Eventually, the revised CARWord represents the word meaning for the current sentence such that when combined with other CARWords in the sentence, the prediction of sentence fMRI is correct.

For the experiments, the FGREP model was trained 20 times with different random seeds for each of the eleven fMRI subjects. A total of 20 different sets of 786 context-based word representations (one word representation for each sentence where the word appear) were thus produced for each subject. Afterwards, the mean of the 20 representations was used to represent each word.

Results

Previous work showed (1) that words in different contexts have different representations, and (2) these differences are determined by context (Aguirre-Celis & Miikkulainen 2017, 2018). These effects were demonstrated by analyzing individual sentence cases across multiple fMRI subjects. This paper verifies these same conclusions in the aggregate through a statistical analysis across an entire corpus of sentences. It measures how the CAR representation of a word changes in different sentences, and correlates these changes to the CAR representations of the other words in the sentence. In other words, it quantifies the conceptual combination effect statistically across sentences and subjects.

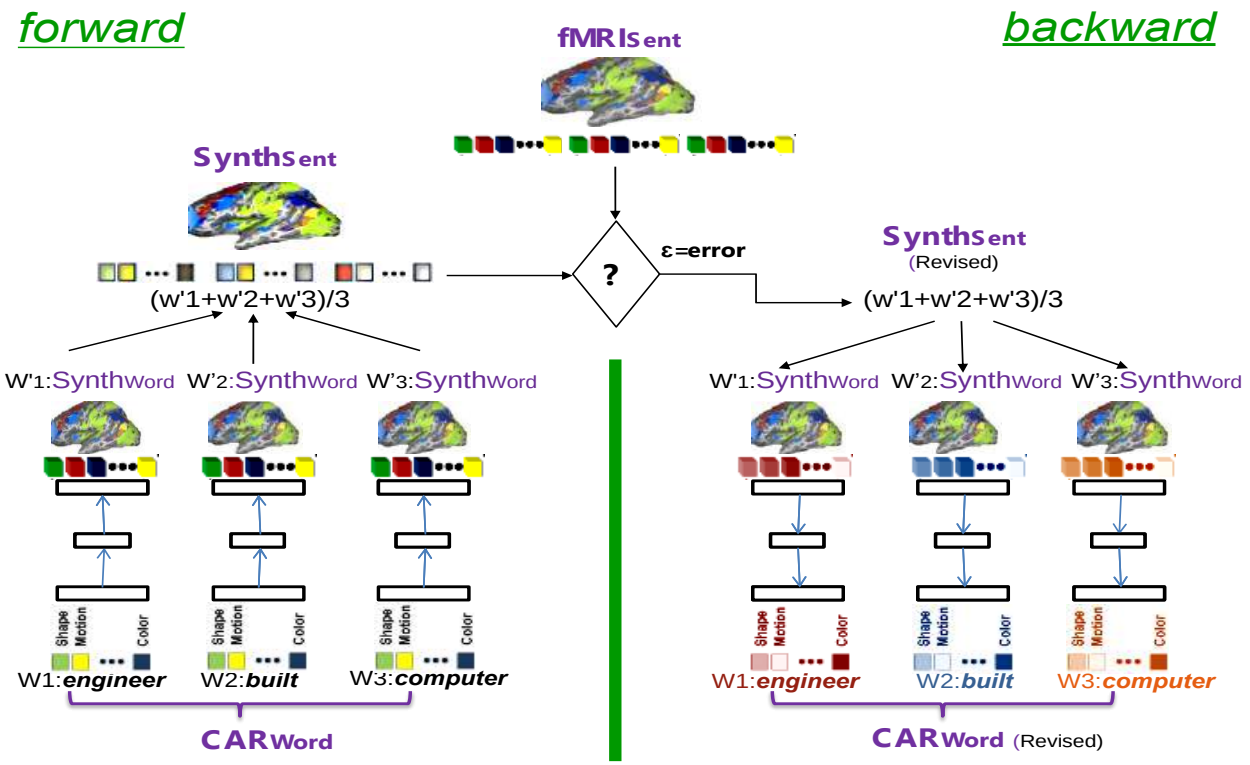

Figure 2: Using FGREP to quantify the effect of context on word meaning. Brain-based semantic representations (CARs) are changed based on a difference of predicted and actual fMRI image for a sentence. (1) Propagate CARWord to SynthWord. (2) Construct SynthSent by averaging the words into a prediction of the sentence. (3) Compare SynthSent against Observed fMRISent. (4) Backpropagate the error with FGREP for each sentence, freezing network weights and changing only CARWord. (5) Repeat until error reaches zero or CARs reach their upper or lower limits. As a result, the changes in CARs illustrate the effect of context on word meaning.

A detailed individual example of the conceptual combination effect is first presented, followed by the aggregate analysis.

The Conceptual Combination Effect

As discussed above, in CAR theory, concepts' interactions arise within multiple brain networks, activating similar brain zones for both concepts. These interactions determine the meaning of the concept combination (Binder, 2016a, 2016b).

As an example, consider the noun-verb interactions in Sentence 200: *The yellow bird flew over the field*, and Sentence 207: *The red plane flew through the cloud*. Since *bird* is a living thing, animate dimensions related to agency such as sensory, gustative, motor, affective, and cognitive experiences are expected to be activated, including potentially attributes like Speech, Taste, and Smell. In contrast, *plane flew* is expected to activate inanimate dimensions related to perceiving an object, as well as possibly Emotion, Cognition, and Attention.

Figure 3 shows the CARs for the word *flew* in the two sentences after they were modified by FGREP as described in Figure 2 and averaged across all 11 subjects. In Sentence 200 there were indeed high activations on animate attributes like Small, Pain, Smell and Taste, Audition, Music, Speech, as well as Communication and Cognition. In contrast, Sentence 207 emphasizes perceptual features like Color, Size, and Shape, Weight, Audition, Loud, Duration, Social, Benefit, and Attention.

These results illustrates the effect of conceptual combination on word meaning. As the context varies, the overlap on neural representations create a mutual enhancement, producing a clear difference between animate and inanimate contexts. The FGREP method then encodes this effect into the CAR representations where it can be measured. In other experiments, a similar effect was observed for several other noun-verb pairs, as well as several adjective-noun pairs. In the next section the effect is quantified statistically across the entire corpus of sentences.

Aggregation Analysis

So far, the conceptual combination effect has been demonstrated in a number of example cases, like the one above, and others in earlier work (Aguirre-Celis & Miikkulainen 2017, 2018). The goal of the aggregation study in this paper is to demonstrate that the effect is robust and general across the entire corpus of sentences and case roles. The hypothesis is that similar sentences have a similar effect, and this effect is consistent across all words in the sentence.

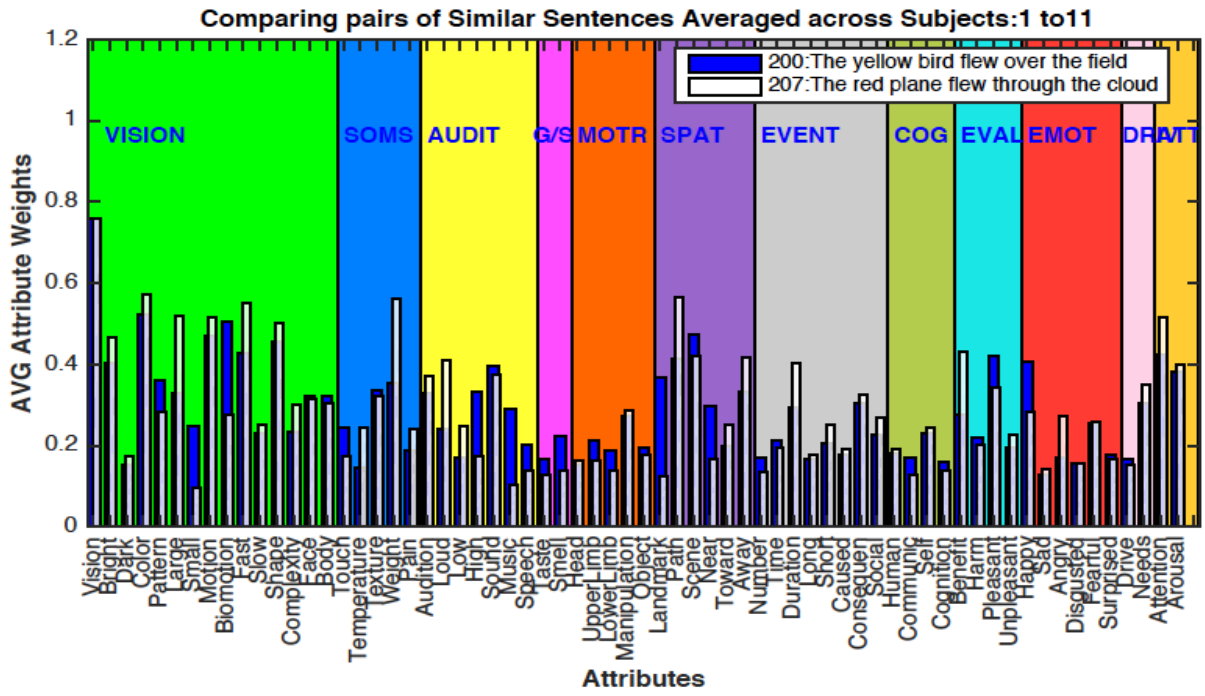

Figure 3: Contrasting the conceptual combination effect in two different sentences. In Sentence 200 (blue bars), the CAR representation modified by FGREP for the word *flew* has salient activations on animate features, presumably denoting *bird* properties like Pain, Small, Smell and Taste, and Communication. In Sentence 207 (white bars), it has high activations on inanimate object features, describing a Loud, Large, and Heavy object such as a *plane*.

This hypothesis was verified in the following process:

1. For each subject, modified CARs for each word in each sentence were formed through FGREP as described in Figure 2.
2. A representation for each sentence, SynthSent, was assembled by averaging the modified CARs.
3. Clusters of sentences were formed by running the Matlab function ***linkage*** on the set of SynthSents. Linkage measure the distance between clusters using the Ward method and the distance between elements with Euclidean distance. It treats each sentence as a single cluster at the beginning and then successively merges pairs of clusters. The process was stopped at 30 clusters, i.e., at the point where the granularity appeared most meaningful (e.g., sentences describing open locations vs. closed locations).
4. For each cluster, CAR representations with similar roles (agent, verb patient) were identified.
5. For each word in each such role, the differences between the modified CAR representations and the original CARs were calculated and averaged, and statistical significance of the difference measured using t-test across the entire set for each CAR dimensions.
6. The CARs of the other words in the sentence were averaged.
7. Pearson's Correlations were then calculated between the modified CARs and the averages CARs of other words across all the dimensions.
8. Similarly, correlations were calculated for the original CARs.
9. These two correlations were then compared. If the modified CARs correlate with the CARs of other words in the sentence better than the original CARs, there is evidence of context effect based on conceptual combination

In other words, this process aims to demonstrate that changes in a word CAR originate from the other words in the sentence. As in the example presented in the previous subsection, the noun-verb combination of *bird flew* and *plane flew* showed how some of the noun properties (animate/inanimate) were transferred to the verb, adapting the combination to the extent that the words share similar features. For example, if the other words in the sentence have high values in the CAR dimension for *Small*, then that dimension in the modified CAR should be higher than in the original CAR for that word. The correlation analysis measures this effect across the entire CAR representation. It measures whether the word meaning changes towards the context meaning.

The results are shown in detail in Table 2. The correlations are significantly higher for new CARs than for the original CARs across all subjects and all roles. As a summary, the average correlation was 0.3201 (STDEV

0.020) for original CAR representations and 0.3918 (STDEV 0.034) for new CAR representations. The results indeed confirm that the conceptual combination effect occurs reliably across subjects and sentences, and it is possible to quantify it by analyzing the fMRI images using the FGREP method on CAR representations.

Table 2: Correlation results. Average correlations analyzed by word class for 11 subjects comparing the original and new CARs vs. the average of the other words in the sentence. A moderate to strong positive correlation was found between new CARs and the other words in the sentence suggesting that features on one word are transferred to other words in the sentence during conceptual combination.

AVERAGE CORRELATIONS PER SUBJECT (3 ROLES)

Discussion and Future Work

This study aimed to verify the hypothesis that during sentence comprehension, people adjust the word meanings according to the combination of the concepts that occur in the sentence. This effect had been demonstrated in individual cases before, and the goal was to demonstrate it more broadly across many subjects, and entire corpus of sentences, and different semantic case roles in the sentence. The correlation results indeed demonstrated that the effect is robust, and can be quantified by analyzing fMRI images through the FGREP mechanism.

These findings are significant considering that the dataset was limited and was not designed to answer the question of dynamic effects in meaning. In the future, it may be possible to extend the data with identical contexts and contrasting contexts, and such fully balanced stimuli could be used to test the hypothesis more systematically.

Similarly, it would be desirable to extend the data with fMRI images of individual words. The current approach of synthetic words (SynthWords) is an approximation often used in computational linguistic (Baroni et. al., 2010; Burgess, 1998; Landauer et al., 1997; Mitchell & Lapata, 2010) and neural activity prediction research (Anderson, et al., 2016; Binder, et al., 2016a, 2016b; Just, et al., 2017). The FGREP process of mapping semantic CARs to SynthWords and further to sentence fMRI, refines the synthetic representations by removing noise. Still, such representations blend the meanings of many words in many sentences, therefore including word fMRI should lead to stronger and clearer results.

One important advantage of CAR theory is that it is grounded on brain representations, and therefore a good choice when mapping semantic representations to fMRI. In the future, it would be interesting to compare whether similar effects can be observed with semantic representations based on co-occurrence in text corpora, or perhaps even a combination of the two. Another important direction of future work is to take advantage of this effect in an artificial natural language processing system. The vector representations for words can be modified dynamically based on context. Such a process should match human behavior better, and result in a more effective and robust system.

Conclusion

This paper shows how word meanings change dynamically depending on context. Using FGREP as a mechanism it was possible to show that the difference between the expected and observed fMRI images can indeed be explained by a change in CARs. Across an entire corpus of sentences, the new CARs are more similar to the other words in the sentence than to the original CARs, demonstrating how features of the context are transferred to each word in the sentence. In the future it may be possible to utilize such dynamic representations in an artificial natural language processing system, by making the word embeddings more sensitive to the semantic meanings that humans actually perceive.

Acknowledgments

We would like to thank Jeffery Binder (Medical College of Wisconsin), Rajeev Raizada and Andrew Anderson (University of Rochester), Mario Aguilar and Patrick Connolly (Teledyne Scientific Company) for their work and valuable help regarding this research. This work was supported in part by IARPA-FA8650-14-C-7357 and by NIH 1U01DC014922 grants.

Numerosity capture of attention

Santiago Alonso-Díaz[a], **Jessica F. Cantlon**[b]

Abstract

Numerosity is informative for living organisms. It can transmit, among many things, amount of food available, heading direction of the troop, which group could win a territorial dispute, the decision of were to build a beehive. Given its ecological importance, we test the hypothesis that numerosity captures visual selection. In five experiments we confirmed that an irrelevant visual stimulus that was numerically large slowed down participants in detecting a task-relevant visual target (Exp. 1 and 2). This capture was not driven by sensory variables that could correlate with numerosity: cumulative area (Exp. 3) and element size (Exp. 4). We also confirmed that the underlying numerosity representations were analogue, not set-based (Exp. 5). In a crowded visual scene numerosity is a relevant cue for visual selection, but represented only in approximate/coarse fashion.

Keywords: Attention; Attention capture; Numerosity

Introduction

Numbers can guide visual selection (Hamilton, Mirkin, & Polk, 2006; Reijnen, Wolfe, & Krummenacher, 2013; Sobel, Puri, & Faulkenberry, 2016; Utochkin, 2013). Imagine going to a crowded town fair for the first time, with different novel attractions. Your decision on where to look will be affected by the number of people around each attraction. Number is a natural and intuitive cue for behavior in uncertain contexts (Arganda, Pérez-Escudero, & de Polavieja, 2012).

A recent review proposed a list of features that could guide attention in visual search and placed them in a scale with five levels of certainty (Wolfe & Horowitz, 2017). The "undoubted guiding attributes" were color, motion, orientation, and size. On the lower side of the scale, the "probably not guiding attributes" were, among others, material type, blur, optic flow, and 3D objects. Importantly, our feature of interest, namely numerosity, was on the third level of certainty: "Possible guiding attributes". This means that even though there are some indications in the literature that it is a guiding feature, more research is required.

A classic task to study attention capture is the additional singleton search task (Theeuwes, 1992). This is a visual search task in which participants have to locate a distinct shape, say a diamond, among many other homogenous shapes present in the visual field, say circles. All the shapes have a line segment inside and subjects must report the orientation of the line in the distinct shape. The main experimental manipulation is that in a set of trials one of the homogenous shapes is turned into a distractor, usually by coloring it differently (e.g. all the shapes are green, including the target, but one is red, the distractor). The notable result is that response times are slower when there is a distractor, suggesting interference in the visual selection of the target. Moreover, the singleton search task is a compound task: participants perceive shape but report line orientation thus the effect is due to perceptual interference not response difficulty.

In a series of experiments we modified the singleton search task and created a distractor by placing more lines inside one of the non-target circles (Fig. 1; Exp. 1) or making the target more numerous while displaying a shape distractor (Exp. 2). A slower response time in the former and no distraction in the latter would indicate spontaneous capture of attention by numerosity.

We further explored whether equating total whiteness inside each of the shapes (Exp 3) (lines were white against a black background) or reducing element size/width could modify the effect (Exp. 4). The overall results indicate that the presence of number capture is robust to those perceptual features and they are consistent with the idea that number is a perceptual dimension guiding visual selection on its own terms (Anobile, Cicchini, & Burr, 2016).

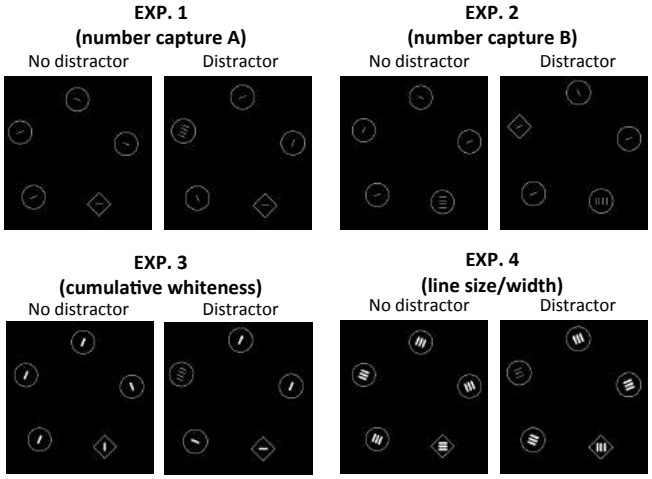

Figure 1: Tasks. In experiments 1,3, and 4 participants had to report the orientation of the line(s) inside the diamond shape (vertical or horizontal). In experiment 2 they reported the orientation of the more numerous one i.e. shape is the distractor. In half of the trials there was a distractor (counterbalanced blocked design). There were 3 different set sizes: 3, 5 (presented here), and 7.

Experiments 1-4: Numerosity Guides Visual Selection

Methods

All experimental procedures adhered to university standards, as approved by the Research Subjects Review Board. For each experiment we aimed to recruit 10 subjects, based on sample sizes of similar attention capture studies (Theeuwes, 2010).

Participants. 42 university students participated in four experiments (26 females, mean age: 21.21 years, s.d.: 3.43. We assigned 10 to each experiment; 2 were dropped due to lack of task enhancement (sleepiness and high error rate). They received $10 as compensation. The task took approximately 60 minutes, including instructions.

Stimuli. Display elements were equally spaced around a fixation point of an imaginary circle (3.4° in radius). Each display element was either a circle (1.4° in diameter) or a diamond (1.4° on each side). Inside each shape there was one or four line segments (0.42° in length) randomly oriented. The orientation inside the target was not random; it could be either vertical or horizontal. Shapes and lines were white on a black background. Participants saw three different set sizes: 3, 5, or 7 shapes equally distributed across trials (Fig. 1 has examples of set size 5).

Procedure. Subjects sat 50 cm from screen and placed their head on a chin rest. Each trial began with a fixation cross and eyes were monitored with an EyeLink 1000 desktop mount system. Images only appeared if fixation was confirmed. After a random fixation time (700 ms – 1700 ms), the fixation-cross disappeared and the shapes became visible. Set size changed randomly on each trial, as well as the position of the target and distractor. The task was to report the orientation of the lines in the target using 'z' and '/' in a qwerty keyboard to indicate vertical or horizontal, respectively. In experiment 1,3, and 4 the target was the diamond shape, and in experiment 2 the shape with more lines inside. Distractors were number (Exp. 1 and 3), a diamond shape (Exp. 2), or line width (Exp 4) (Fig. 1). Instructions emphasized a quick but accurate response. If a response was not detected after 1200 ms., the display images disappeared, the trial aborted, and a reminder text indicated that the response was too slow.

There were 240 training trials and 300 test trials with four resting breaks. Training and test trials were identical but we only analyzed test trials. The objective of training was to make subjects as fast as possible. Trials were blocked. One half had no distractor and the other did. Half of the subjects started with no distractor. Before starting, participants received an explanation of the blocked design and saw example images of each block with the main elements (target and distractor) pointed out. When a new block started, an on-screen instruction reminded participants whether there was going to be a distractor or not.

Data analysis. We analyzed each experiment individually using repeated measures ANOVAs on response times. To statistically compare effect sizes across experiments, we bootstrapped the distribution of effect size differences and compute a 95% confidence interval (samples = 1000) (Kirby & Gerlanc, 2013). For effect size we used the generalized Eta squared of the ANOVAs, suited for repeated measures analysis (Bakeman, 2005). No response time outlier detection was implemented as all trials were forced to last less than 1200 ms (see Procedures above). We report correct trials in the main text (error rates were low). All analysis were done in R.

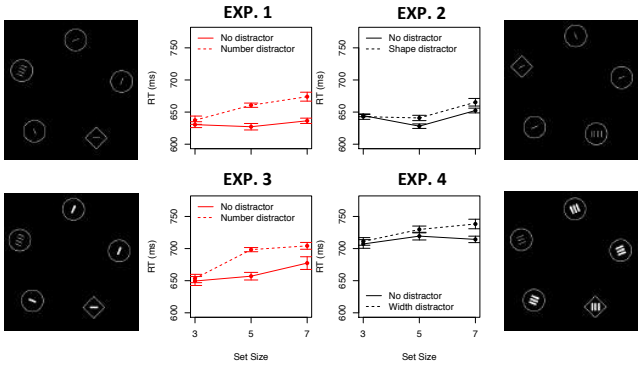

Figure 2: Experiment results. Alongside each plot there is an example image of the corresponding distracting condition (set size 5). Plots are colored red for significant distractor effects ($p < 0.05$). Bars are within subject standard errors (Cousineau et al., 2005).

Results

The presence of a number distractor increased response times in participants of Exp. 1 (Fig. 2). A repeated measures ANOVA on response times found main effects of distractor ($F(1, 9) = 41.138$, $p < 0.001$, $\eta_g^2 = 0.099$), set size ($F(2, 18) = 4.166$, $p = 0.032$, $\eta_g^2 = 0.046$), and their interaction ($F(2, 18) = 4.998$, $p = 0.018$, $\eta_g^2 = 0.029$). The slope of response time in no distractor trials is indistinguishable from zero (1.73 ms per shape; Table 1) and when there is a distractor it increases (9.31 ms/shape) causing the interaction effect. These slopes are really shallow suggesting that the diamond shape can be located in parallel when there is no distractor and even when there is a distractor the detection is much faster than a traditional serial process (Bacon & Egeth, 1994).

In the next experiment we aimed to check if capture occurred due to the generic presence of structured, but irrelevant, information in the visual field. With the same stimulus a different set of participants did the mirror task of Experiment 1: report the line orientations of the circle with more lines and be distracted by the diamond shape (Fig. 1). This time there was no significant attention capture (Fig. 2; distractor: $F(1, 9) = 0.651$, $p =$

0.440, η_g^2 = 0.002, set size: F(2, 18) = 18.914, p > 0.001, η_g^2 = 0.017, interaction: F(2, 18) = 1.038, p = 0.374, η_g^2 = 0.002). Even though not significant, there was still a minimal distraction in Exp. 2 in the same direction as Exp. 1 (Fig. 2) In such cases is important to statistically compare effect sizes (Nieuwenhuis, Forstmann, & Wagenmakers, 2011). We bootstrapped the difference of the effect sizes (η_g^2) of the distractor in both experiments (Exp. 1 minus Exp. 2). The obtained 95% confidence interval is positive [0.037, 0.142], meaning that the effect of distractor is highly unlikely to be larger in Exp. 2., confirming that subjects were at most weakly distracted by shape.

This is not saying that number is uniquely special. In a supplemental experiment we found that a square shape can also capture attention and previous work has established that forms are attractive (Theeuwes, 1992). The unique finding of Exp. 1 and 2 is that sensory stimulation was identical but when human observers are asked to find shape they are distracted by number but not vice versa. This asymmetry is not self-evident as in both versions number and shape are irrelevant for orientation detection.

An alternative explanation for the asymmetry is that in Exp. 2 the distractor was a shape which has nothing to do with the target (lines) and so is less distracting. In Exp. 1, on the other hand, the distractor were lines and the task was to detect orientation of lines, and so is more distracting. However, we selected the Theeuwes task precisely to avoid such confounds. Participants need to detect the relevant feature, shape or number, and then report the orientation. The alternative strategy of trying to directly detect line orientations in this type of task has been shown to be too inefficient (Theeuwes, 2010). That being said, if the alternative explanation holds, our result would implicate that numerosity breaks the strategy of detecting the feature and reporting the orientation; an interesting finding on its own terms that does not invalidate Exp. 1 findings.

In our stimulus capture seems to be driven by a parser that detects more lines. During training and between blocks participants were reminded that the distractor had more segments. And, prefacing the next set of experiments, attention capture was not detectable when numerosity was equal (Exp. 4). It only appeared when there was an increase in the number of lines (Exp. 3).

The next pair of experiments probe with more detail the sensory aspects of the more numerous lines that could have mobilized attention. In Exp. 3 we equated total amount of whiteness in all shapes by making single segments four times thicker (Fig. 1). If the observed number capture in Exp. 1 is due to an overall integration of whiteness (cumulative area/brightness) then distraction should disappear. This was not observed. There were detectable interferences of the irrelevant more numerous location (Fig. 2; distractor: F(1, 9) = 4.137, p = 0.072, η_g^2 = 0.040, set size: F(2, 18) = 8.702, p = 0.002, η_g^2 = 0.071, interaction: F(2, 18) = 4.618, p = 0.024, η_g^2 = 0.016). A direct comparison of effect sizes in Exp. 1 and Exp. 3 actually includes the possibility that the distractor effect is larger when cumulative area is controlled for (95% CI of Exp. 1 minus Exp. 3: [-0.006, 0.116]). The slopes relating set size and RT were again really low (Table 1), lower than a steorotypical serial search (Bacon & Egeth, 1994; Treisman & Gelade, 1980), indicating that the task was done in partially parallel fashion. Number capture is not related in a simple manner to an attraction to overall whiteness.

Table 1. RT slopes

	Exp. 1	Exp. 2	Exp. 3	Exp. 4
No distractor	1.73	1.31	6.79*	1.21
Distractor	9.31*	5.58*	11.56*	6.98*

* p<0.05

It is possible that what drove number capture in Exp. 3 was the width of the lines (Fig. 1). In Exp. 4 we fixed the number of lines inside each of the shapes and made their line width three times bigger than the one in the distractor. If line width is the critical distracting aspect in Exp. 3, then Exp. 4 should reveal attention capture. This was not observed (Fig. 2; distractor: F(1, 9) = 1.332, p = 0.278, η_g^2 = 0.007, set size: F(2, 18) = 2.767, p = 0.089, η_g^2 = 0.011, interaction: F(2, 18) = 1.079, p = 0.360, η_g^2 = 0.003). A comparison of the effect sizes of Exp. 3 and 4 indicates that distraction was more notable in the latter (95% CI of Exp. 3 minus Exp. 4: [0.004, 0.066]). Again, the slopes were really shallow suggesting an efficient search process, close to parallel (Table 1). Line width draws little attention in our visual stimulus.

Discussion

Attention is captured by numerosity, beyond basic perceptual features that could correlate with number: cumulative area/whiteness and element size/width. This was obtained with a compound visual search task that differentiates perception from response difficulty. This is important because distractor effects can be traced back to perceptual interference and not to response interference (Theeuwes, 2010). The overall results are consistent with the idea that numerosity is a basic perceptual feature that guides attention (Anobile et al., 2016; Wolfe & Horowitz, 2017).

Previous reports have demonstrated the importance of number for attentional process. Reijnen et al., 2013 used a task where the target and distractors were numerical. However they used large numerosities and the task of participants actually required numerical estimation. Here we confirmed attentional effects with a much simpler compound visual task with small numerosities.

Utochkin, 2013 found that numerosity guides attention as an aide to find perceptual features, in their case color. Thus, numerosity was actually useful in their task. Our Exp. 1 - 4, numerosity was irrelevant and as such is closer to the notion of attention capture.

Attention capture is usually framed around the conceptual dichotomy of bottom-up or top down sources of the observed distraction (Theeuwes, 2010). However, the notion of priority maps, a working space that integrates current goals, selection history, physical salience, is perhaps more relevant (Awh, Belopolsky, & Theeuwes, 2012). For our purposes, number must induce a priority signal and be a relevant source of information for the nervous system to be able to capture attention. Visual selection would emulate other decision contexts in which numerosity is routinely used, mostly as an heuristic to solve complex uncertain choices (Gigerenzer & Brighton, 2009; Reyna & Brainerd, 2008).

There is great deal of debate on the abstract or sensory nature of number (Anobile et al., 2016; Gebuis, Kadosh, & Gevers, 2016; Leibovich, Katzin, Harel, & Henik, 2017) . We argue that the number capture observed here is consistent with the proposal that number is abstract and a basic perceptual feature. First, the sensory aspects evaluated (cumulative whiteness and element size/width) failed to capture attention. Second, the shallow slopes relating set sizes and response times were not so different from previous attention capture studies using other basic perceptual stimulation (e.g. color) ((Bacon & Egeth, 1994; Theeuwes, 1992). They were not necessarily different from zero to claim any preattentive mechanism, but they are certainly really close to those previous works that demonstrated attention capture from basic features.

There are at least three limitations of our study. First, we did not control for line separation, which may be a feature driving attention in our task. If line separation means frequency then we are not sure how to distinguish frequency from number as they would correlate perfectly. Also, even though we cannot rule out that possibility, a recent review on features that have been found to guide attention did not report line separation (Wolfe & Horowitz, 2017).

The second limitation is that we did not control for overall contrast. We manipulated line width to control for cumulative area effects (Exp. 3 and 4) and the number distractor ended up looking more dim (Fig. 1). We would argue that this actually made our results more robust because it is not about higher contrast. Still, it would have been interesting to determine how much of the effect changes with different contrast levels.

The third and final limitation is that attention may have been driven by the presence of a texture formed by the patch with more lines. However, we would argue that texture is a vague term and we narrowed down on an aspect, namely numerosity. Also, texture is obtained preattentively (Julesz, 1981) and search slopes in Exp. 1-4 were different from zero.

In general, as with most studies of numerosity, it is almost impossible to discard 100% that our results are not influenced by a preattentive sensory features. They may indeed have a role in the underlying effect but we think that there is sufficient evidence in the literature to believe that number is a basic sensory aspect (Anobile et al., 2016); and we think our results add to that line of research.

In many behavioral contexts numerosity is a basic heuristic that hinders or facilitates learning and decision-making (Gigerenzer & Brighton, 2009; Reyna & Brainerd, 2008). Also, the approximate number system seems to influence higher order behavior such as risk attitudes and math scores (Halberda, Mazzocco, & Feigenson, 2008; Schley & Peters, 2014). Our study furthers the link between numerosity and attention which may provide clues on why raw numerosity is such a strong driver of learning and behavior.

Abstract

Probabilities can be described by a numerator and a denominator and students and decision-makers are not indifferent to numerical values of the components. For instance, when people compare two equal ratios their choices gravitate to the option with larger number, even if they know both ratios are equal. To the date, however, it is unclear if whole number biases are present in other cultures. We tested a farming-foraging group living in the Bolivian rain forest in a simple 2AFC ratio comparison task. After appropriate training, the Tsimane were highly accurate in this task, confirming that visual proportional reasoning is present across cultures. Importantly, they had a strong tendency to favor large numbers in equal ratio comparisons, similar to what is found in educated populations. Even though our sample size is moderate (n=76), the whole number bias we found occurred under good proportional reasoning. The bias may be a general feature of cognition, rather than a cultural or education artifact, that may help humans solve ambiguous situations.

Introduction

Detecting differences in discrete visual ratios is useful. They convey a variety of critical information, like how much units of food there is available per competitor or heading direction of a troop by a majority rule (Real, 1993; Strandburg-Peshkin, Farine, Couzin, & Crofoot, 2015). Infants, indigenous population without formal education, and non-human primates can act upon probabilities expressed by visual proportions (Denison & Xu, 2010; Fontanari, Gonzalez, Vallortigara, & Girotto, 2014; Rakoczy et al., 2014). The spontaneous mapping of visual ratios to probabilities in the context of no formal education suggests that this is a core cognitive feature akin to detectors of abstract numerosity and geometry relations found across cultures and species (Carey & Spelke, 1994; Spelke & Lee, 2012)

Discrete probability comparisons, however, suffer from numerosity interferences (Reyna & Brainerd, 2008). It is much easier to compare ratios when the largest one happens to have the larger numerosity. It is unclear if this is caused by cultural characteristics shared by Western, Educated, Industrialized, Rich, and Democratic people (WEIRD) (Henrich, Heine, & Norenzayan, 2010) or if sticking to numerosity is a general feature of how quotients are compared in the mind (Alonso-Diaz, Piantadosi, Hayden, & Cantlon, 2018). The latter option is what we call an intrinsic whole number bias: a pull towards numerical magnitude even though ratio estimates are available. The presence of ratio estimates is critical because it distinguishes it from denominator-neglect or any other strategy used to cover up the inability to compute the value of the fraction.

Previous work probing proportional reasoning in non-WEIRD people, found that the Kaqchikel and K'iche', two indigenous Mayan groups in Guatemala, had refined probabilistic abilities in the absence of formal probability education (Fontanari et al., 2014). Of importance, one of the experiments (Exp. 2) revealed that proportional reasoning was not affected by the numerosity of the options. Participants excelled in comparing 0.25 against 0.75, both when the larger probability had more or fewer number of winners.

Experiment 2 of Fontanari et al., 2014 established probabilistic cognition with no formal education but there were no indications in their study of a whole-number bias, and their analyses nor experimental design tried to uncover one. In fact, to the best of our knowledge, there is no evidence of the whole number bias outside WEIRD populations (perhaps in other species, but not across the WEIRD-NON WEIRD divide). There are at least three hypothesis. Our hypothesis is that it should be similar in NON-WEIRD humans because is a reflection of the inner workings of basic perceptual proportional choice (Alonso-Diaz et al., 2018). A second hypothesis is that the whole-number bias is a mistake caused by deficient education (Reyna & Brainerd, 2008). Under this hypothesis, the whole-number bias should be notably stronger in the NON-WEIRD humans because they lack formal education on probability principles. The third and final hypothesis is that the bias only appears in WEIRD humans because of specific cultural practices (e.g how they learn probabilities and fractions).

We tested a 2AFC ratio comparison task in the Tsimane', a farming-foraging group living in the Bolivian rain forest (Huanca, 2008). A wealth of studies have been done on the Tsimane's cognitive and decision making processes (Apaza et al., 2003; Apaza et al., 2002; Godoy & Jacobson, 1999; Godoy, Jacobson, & Wilkie, 1998; Henrich et al., 2010; Kirby et al., 2002; McDermott, Schultz, Undurraga, & Godoy, 2016; Piantadosi, Kidd, & Aslin, 2014; Reyes-Garcıa et al., 2003). Their aptitude to probabilistic cognition, however, has not been properly researched. The Tsimane are fairly isolated, with low literacy, and no formal instruction on probability principles. We hypothesized the existence of probabilistic reasoning in the Tsimane. Perhaps more important, a detectable bias towards more numerous options in equal ratio trials.

To detect a whole-number bias, we will exploit the fact that when ratios are equal participants should be indifferent to the numerosity of the options and pick randomly; but this is not observed empirically (Denes-Raj, Epstein, & Cole, 1995) even when the proportions are known to be equal (Alonso-Diaz et al., 2018). To be clear, the bias is not exclusive to equal ratio trials. Also, we are not suggesting that only on them probabilistic reasoning fails. The bias towards larger numerosities is intricate and with many explanations (Alonso-Diaz et al., 2018). We are using equal ratio trials as a methodological tool to detect the bias in an indigenous population.

The originality of our work is that we seek an intrinsic whole number bias, one that is detected under appropriate probabilistic reasoning (Alonso-Diaz et al., 2018). To prove good reasoning we will use congruent (the larger probability has larger numerosity), incongruent (the larger probability has smaller numerosity) and equal ratio trials. Congruent and incongruent trials will help us discard illusory Stroop effects by which the irrelevant dimension of numerosity could affect ratio estimates by changing the subjective psychophysical properties of the alternatives (Barth, 2008). In simple words, if the Tsimane are successful in both congruent and incongruent trials we can be sure that they tried to pick the best ratio, not the one with more numerosity.

Their choice on equal ratio trials will be a metric on how intense the bias is. If it is considerably larger or smaller, then we can conclude that cultural practices (e.g. formal education) affect the bias. If it is similar, then it is consistent with being a generic human adaptation (Alonso-Diaz & Penagos, under review).

Methods

The study procedures were approved by the Gran Consejo Tsimane' (Tsimane' grand council), as well as institutional IRBs. Tomás Huanca and the Centro Boliviano de Investigación y de Desarrollo Socio Integral (CBIDSI) provided logistic support (translators, transportation, and general expertise about the Tsimane community).

Participants. We evaluated two groups of Tsimane. This was not an explicit design strategy but rather reflects the dynamics of field-work (details below). The first group received verbal instructions in their native language (n=86, 60 females, M age = 34.13 years, s.d. = 15.09, Education M = 3.18 years, s.d. = 3.28). The second received non-verbal training version (n=78, 53 Females, Age M = 31.884 years; s.d. = 14.528; Education M = 4.012 years, s.d. = 4.037). 76 Tsimane succeed non-verbal training (two subjects failed the training stage). We only present the results for the Tsimane who did non-verbal training (see Alonso-Diaz, 2017 for the verbal-training sample). Each Tsimane did many cognitive tasks sequentially including language, numerosity, color perception, and the probability task reported here.

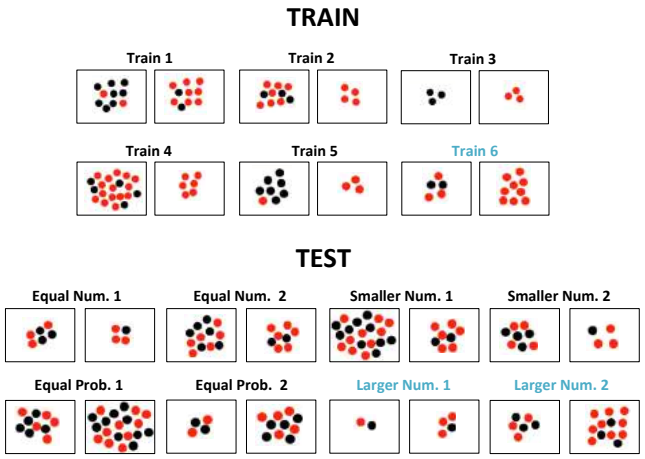

Figure 1: Training and test trials. The ratios of winners (red) to losers (black) in Test trials were 0.5 and 0.75. The titles in the Test images indicate whether the largest ratio had equal, smaller, or larger number of winners or if both options had equal probability. Cyan titles indicate stimulus that just a subsample of Tsimane observed (n=24). If a participant is successful in all control trials (Equal, Smaller, and Larger Num.), we would be more confident that the bias in Equal Prob. trials is intrinsic i.e. it can appear under proper proportional reasoning.

Materials and Procedure. Participants saw two images, one to the left and another to the right side. Each image was presented in individual laminated sheets (legal size) that contained a mix of red and black dots (Fig. 1). Participants had to select the option with best chances of winning (red). The best option was randomly placed on either side. The Tsimane heard a verbal instruction in their native language.

The behavior of the initial 86 Tsimane (those who only received verbal instructions) was hard to classify as either following ratio or numerosity (an analysis of this subsample is provided in Alonso-Diaz, 2017). To make sure it was not related to translation issues, halfway during field research we included non-verbal training with feedback. After verbal instructions we randomly presented six pair of training images until all were correct i.e. we cycled through them until all responses were correct and most Tsimane were quick dispatching training. Training trials were mostly trivial (5 out of 6) in that one side only had winners (Fig. 1), randomly placed to the left or right side. The intention of trivial trials was to deter number-based strategies: the correct option had the same, fewer, or more winners than the wrong side. We presented test trials (Fig. 1) in pseudo-random order with no feedback.

Of the 76 participants with non-verbal training, 52 did three types of test trials: 1) both ratios had equal num-

ber of winners, 2) the best ratio had smaller number of winners, and 3) ratios were identical but one had more winners (Figure 1). To further discard a strategy of low-number of losers (the confound present in Fontanari et al., 2014 Maya's study), the last 24 Tsimane saw the same images as the 52 but also new Test images with identical number of losers (blacks) (and also one more training image, Fig. 1 cyan color).

Data analysis. We will use the following acronyms: EN = both ratios had equal numerator; SN = larger ratio had smaller numerator; LN = larger ratio had larger numerator; EP = both images had equal probability. In EP accuracy reflects the proportion of choices favoring the option with larger numerosity

Binomial tests evaluated if performance was greater than chance. In control trials (EN, SN, and LN), chance means picking the larger ratio more than 50% of the times. In test trials (EP), chance means picking the option with larger numerosity more than 50% of the times. In the binomial tests we used the total number of choices. Because each Tsimane made two choices on each trial type (Fig. 1), n = 2 times sample size.

We classified each Tsimane's behavior according to one of the following potential strategies: consistently picked A) More winners; B) Fewer winners; C) More total number of balls; D) Fewer total number of balls; E) More losers; F) Fewer losers; G) Larger ratio; H) Other. Some behaviors were ambiguous as they could be consistent with more than one strategy. For instance, in the stimuli presented to the subsample of 52 Tsimane (the one similar to Fontanari et al., 2014), being correct in all trials and selecting the option with fewer losers when both ratios were equal will necessarily occur if the agent decides based on fewer losers or the larger ratio. When such coding conflicts occurred, we used the unambiguous behavior. In the example, we would code the Tsimane as following a strategy that picks fewer losers because a strategy of only ratios will be random when both bags have equal ratio.

Results

Tsimane's accuracy in test trials was high (Fig. 2A; EN: 149/152 = 0.98 trials correct, $p < 0.001$; SN: 143/152 = 0.94, $p < 0.001$; LN: 40/48 = 0.83, $p < 0.001$; EP: 66/152 = 0.43, $p = 0.12$). Fig. 2A seems to suggest that in equal probability trials (EP) the Tsimane did not tend to pick the bag with larger numerosity. A closer look reveals that the majority of Tsimane behave in accordance to a ratio-based strategy (n = 36), followed by strategies that follow small number of balls (n = 26), other unidentifiable strategy (n = 8), low number of losers (n = 4), and large number of winners (n = 2) (Fig. 2B). The diversity of strategies is only normal in such unnatural task. Interestingly, we detected a large number bias in equal probability trials in Tsimane' whose performance was flawless in EN, SN, and LN test trials (52/72 = 0.72 trials favored the option with more winners, $p < 0.001$). As a reminder, EN, SN, and LN were control trials for a simple numerosity-based behavior. For instance, a Tsimane who had only followed large numerosities would have failed in both SN trials because in those trials the larger probability had smaller numerosity. This means that the manifestation of the whole number bias in equal ratio trials is hardly explained by a straightforward behavior based on numerical cardinalities in those who did not fail in EN, SN, and LN trials.

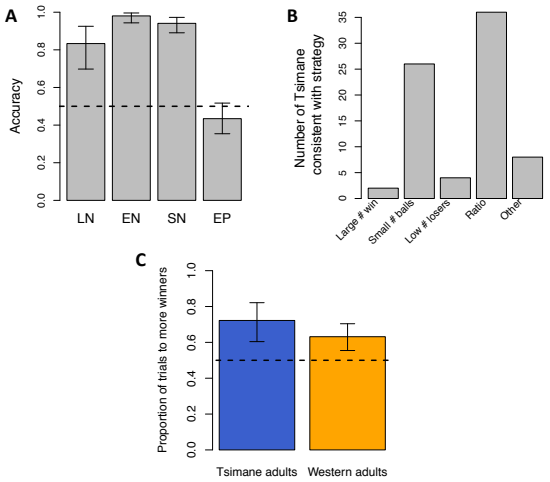

Figure 2: Accuracy (A), distribution of strategies (B), and whole number bias in the Tsimane who were reliably coded as following a ratio-based strategy (C). In A: LN: the best ratio had the large numerator (winners); EN: both ratios had equal numerator; SN: the best ratio had small numerator; EP: both options had equal probability. In EP accuracy reflects the proportion of choices favoring the option with larger numerosity. Dashed line is chance. Error bars are 95% confidence intervals of a binomial test (all $p<0.05$, except EP).

The rate of the bias is comparable to the one found in American adults doing a similar one-shot task. (Fig. 2C; χ^2 (1) = 1.469, p = 0.225; American data in (Alonso-Diaz et al., 2018)). The Tsimane whose behavior is consistent with ratio use (n=36) exhibit the same intuition to favor large numbers in ambiguous contexts. We emphasize that in the other strategies is hard to classify the bias as such because it is baked in the actual definition e.g. in a "large # win" strategy the task is solved following winners. We argue that the theoretically relevant bias is when appropriate proportional reasoning is present.

As it was mentioned in the methods, some participants did additional trials in which both images had identical number of losers. The reason for this was to discard a losers-based behavior. An analysis of these two subsamples reveals a similar pattern. In the subsample that did not see images with identical number of losers

(n=52) they had a behavior above chance in all control trials (chance means picking the larger probability) and in equal probability trials (chance means picking the the image with larger numerosity) (i.e. all binomial tests $p<0.05$) confirming the presence of a whole number bias. Of those 52, 48 had perfect performance in control trials and also revealed a whole number bias in equal probability trials albeit not significant (30/48 = 0.625, p = 0.11). This first subsample was clearly trying to solve the task through ratio-based strategies because they succeeded in SN, LN, and EN trials. However, when faced with equal ratio trials they showed a whole-number bias. This does not necessarily mean that in equal ratio trials their proportional reasoning shuts down (Alonso-Diaz et al., 2018); our experimental design cannot solve that question.

In the second subsample, we can definitely discard a loser-based strategy (n = 24). Their behavior in control trials was different than chance (i.e. all binomial tests $p<0.05$), and revealed a whole number bias in equal probability trials (22/24 = 0.91 trials favored the option with more winners, $p < 0.001$). Thus, the effect was particularly present in those who we can discard any form of number-based strategy in SN, LN, and EN trials.

A caveat of our results is that even though significant, we had a small sample size (n=76), specially the ones that we can confidently discard a number-based strategy (n=24). Future work could increase sample size, but two things make us confident of the results. First, the whole number bias is not a controversial finding (e.g. Alonso-Diaz et al., 2018; Reyna and Brainerd, 2008). Second, the bias we reported was stringent, making sure that it was present under proper proportional reasoning.

Discussion

The Tsimane', similar to other populations (Mayas, human infants, non-human primates), are capable of visual proportional reasoning. Even though the task used was artificial, based on laminated sheets, it was possible to elicit ratio-based responses. Perhaps more relevant, in ambiguous trials, in which both options had equal probability, the intuition of adult Tsimane was in line with that of adult Americans: pick the option with larger numerosity. This was not a number-based strategy induced by lack of proportional abilities as they were very capable of solving congruent (larger prob. has more winners), incongruent (larger prob. has fewer winners), and trials where the large probability had the same number of winners as the wrong alternative.

Perhaps more insightful is that the bias was comparable in size between WEIRD and NON-WEIRD samples (Fig. 2C). Because we obtained the bias under good proportional reasoning and with equal ratio trials, it suggests that numerosity could be a generic cognitive tool to solve ambiguity, not merely a quick heuristic to substitute an inability to compute ratios as previously proposed. In fact, the bias could be a sign of adaptive agents (Alonso-Diaz & Penagos, under review).

The automatic activation and use of numerical values, despite appropriate visual proportional reasoning, is confirmable through more rigorous psychophysics tasks and computational models (Alonso-Diaz et al., 2018). What is suggestive of the Tsimane results is that number intrusions may not be a WEIRD phenomenon of developed economies (Henrich et al., 2010) but the outcome of some generic computation, perhaps influenced by the fact that larger numerosities elicit a greater sense of confidence and capture attention (Alonso-Diaz, 2017; Alonso-Diaz & Cantlon, 2018).

The intuition of relying in numerosities is usually observed during learning and manipulation of symbolic fractions (Ni & Zhou, 2005; Siegler, Fazio, Bailey, & Zhou, 2013). At the same time, there is growing evidence that perceptual and symbolic systems are not independent (Melnick, Harrison, Park, Bennetto, & Tadin, 2013), for instance the approximate number system correlates with formal math tests (Halberda, Mazzocco, & Feigenson, 2008). It is possible, then, that the effects of number in perceptual proportional reasoning transpire to symbolic education and decision-making settings where numerosity should not be employed.

An alternative explanation of our results is that the Tsimane tested were not fully illiterate (mean years of education 4.012) and some negative pedagogical influence in those years may have impacted behavior in our task. The main problem with this interpretation is that the Tsimane succeeded in ratio comparisons with different numerosity manipulations. If anything, the contra argument is also plausible: education might have helped them in solving the task. Rather, we argue that the intuition of relying in larger numerosities is a generic feature of cognition. The human mind is endowed with probabilistic knowledge. However, the mechanisms that lead to overt probabilistic behavior do not necessarily drop the numerical values, even when holistic ratio computations are available. Number intrusions seem to be present across cultures.

Another interesting result is that the Tsimane required non-verbal training to succeed in our task. The first subsample only received verbal instructions in their native language but their performance was lower than those who received non-verbal training (see Methods). It is hard to narrow down the reasons for such difference between verbal and non-verbal instructions but it is relevant for future studies on non-WEIRD populations.

Acknowledgments

We thank the Tsimane people for their gracious help. Also, Tomás Huanca, from the Centro Boliviano de Investigación y de Desarrollo Socio Integral (CBIDSI), and

the translators who were essential to the project success. We want to thank Ted Gibson, Richard Futrell, Julian Jara-Ettinger, and Steve Ferrigno for support and advice in the field.

Abstract

A novel experimental method is motivated and applied in an effort to test for effects of category learning on perceptual discrimination so as to clearly distinguish category boundary effects of expansion and compression from changes in sensitivity to stimulus dimensions. The method includes a control group performing a task that, like category learning, requires attention to one systematically varying stimulus dimension rather than another. Discrimination accuracy is tracked over time and measured using a psychophysical staircase procedure tailored to individual participants that doesn't rely on memory. Initial results suggest improvement in discrimination accuracy over time, particularly on the dimension relevant to the categorization or control task, but no evidence of category boundary effects or effects of category learning on dimension perception stronger than those of the control task. Possible reasons for this and directions for further research are briefly discussed.

Keywords: categorical perception; categorization; learning; expansion; compression; dimensional modulation; selective attention

Introduction

It is well known that various kinds of experience can produce perceptual learning, i.e., improved ability to distinguish objects, features, or values on a dimension (Goldstone, 1998). One of the processes that is claimed to have special effects on the perceptual judgment of stimuli is learning to categorize the items, the phenomenon known as learned categorical perception (CP) (Goldstone & Hendrickson, 2009). Learned CP effects reported in the literature include boundary effects whereby items placed in different categories become more distinguishable, sometimes called expansion, and/or items placed in the same category become less distinguishable, sometimes called compression. However, these are not always clearly distinguished from dimension-wide effects where there is sensitization to the category-relevant dimension(s) and/or desensitization to the category-irrelevant dimension(s).

There are potentially many tasks besides category learning that require or benefit from greater attention to one dimension rather than another whereas only category learning would be expected to produce the boundary effects of expansion and/or compression. It is therefore very important that measures of learned CP carefully distinguish dimensional effects from boundary effects, something that previous research has not necessarily done. An important goal of the work reported here is to develop a method that distinguishes boundary effects of category learning from dimension-wide effects and, if category learning does cause dimension-wide effects, to determine if it does so to a greater extent than a task that doesn't involve category learning.

One reason that learned CP effects are of theoretical interest is that they may provide key evidence of genuine top-down effects on perception, an issue of considerable current controversy (Firestone & Scholl, 2016). But since the vast majority of learned CP evidence is based on measures that rely on memory (e.g., successive judgments of pairs of stimuli for same-different or similarity judgments), it is hard to argue that they are genuinely perceptual effects rather than reflecting higher level cognitive processes. Another purpose of the method adopted here is to eliminate the role of memory and determine if learned CP effects still occur. (Of course, even

if they do, other challenges raised by Firestone and Scholl might still need to be addressed.)

An examination of the existing body of learned CP research also reveals a bewildering pattern of effects and non-effects (compression vs. expansion vs. both, boundary effects with or without accompanying dimensional effects and vice versa, etc.). Researchers rarely have specific predictions regarding which effects will or won't occur and often don't distinguish clearly between them or test for all of them. As noted above, our study will clearly distinguish boundary effects from dimension-wide effects of category learning.

A recent p-curve meta-analysis of this body of research (Andrews, de Leeuw, Larson, & Xu, 2017) found a low level of statistical power, suggesting that it may be unproductive to try to interpret the patterns of effects and non-effects in the existing literature, since low statistical power is likely to produce both false positive and false negative results. Without a firm grasp on which learned CP effects do and don't occur under what conditions, it will be very difficult to make progress understanding the theoretical basis of learned CP or modeling the relevant mechanism(s). In addition to simply running better powered studies, another strategy to increase the informativeness of the data that are collected is to use analysis techniques such as Bayesian statistics that indicate the relative support for different hypotheses regarding learned CP effects, including the null hypothesis of no effects.

Another important methodological feature that renders previous results difficult to interpret is the fact that learned CP experiments almost always use a before-after comparison, a control group that only performs the final task performed by the learning group after category training, or at most, a control group that receives passive exposure to the category training stimuli. The goal of the research reported here is to address this and the other features of learned CP research that render its results ambiguous. Our approach relies on the use of a new method for tracking the effects of learning to categorize a set of patterns *over time* and in *comparison to the effects of performing an appropriate non-category-based control task*. Tracking over time is important for addressing another ambiguity when effects are only measured after training: expansion effects cannot be distinguished from a combination of compression and sensitization to the category-relevant dimension. These could potentially be distinguished if they emerge at different rates or times over the course of training. In order to track effects of learning over time, we test for changes in discrimination ability using a psychophysical staircase procedure throughout the entire experiment, alternating with classification or control task trials.

Because we use *simultaneous* stimulus presentation to avoid memory effects, a standard same-different or XAB task would allow successful performance based on the comparison of meaningless pixel-level features. We therefore developed a stimulus set where the potentially category-relevant dimensions vary both systematically in one respect (e.g., number/density of dots inside a circle) and also randomly (e.g., the exact location of the dots). This means that two stimuli with the same values on the two systematically varying dimensions will not be identical, much in the same way that individual instances of real world categories are usually unique. This allows us to use a variation on same-different judgments that highlights the role of the dimensions and works with simultaneous presentation, as explained in the method section.

The above features of our method make it different from the usual learned CP experiment in a number of ways, but we think it is essential to determine whether learned CP will occur under these more controlled conditions. If it does not, we can systematically re-introduce more traditional methodological features, such as successive presentation on the discrimination test, to determine which are necessary to produce the effects in order to better understand them. While we only report one experiment and acknowledge that our method likely needs adjustment to be fully successful in achieving its goals, our hope is that by sharing our work at this stage we can obtain useful feedback to inform and guide our next steps.

Method

All study materials, data, and analysis scripts are available at this OSF site: https://osf.io/msq57/.

Participants

A total of 101 participants (52 women; mean age 34.8; age range 18-72) were recruited using the online crowdsourcing platform Prolific and paid $4 for participating. Data from 8 participants were missing or incomplete leaving a final total sample size of 93.

Stimuli

Stimuli for this experiment were sunbursts. The number/density of dots and lines was systematically varied across stimuli but the exact placement of the dots and lines and the length of the lines were random (see Figure 1). For each participant in the experimental group (see below), category membership was randomly assigned to be based on either line or dot density. The density of dots or lines in a particular stimulus ranges from 300-2000 dots and 30-550 lines. (Each range is treated as 0.0-1.0 here.)

Procedure

The software jsPsych was used to create the experiment (de Leeuw, 2015). **Phase 1** used a same-different task variant we call the odd-one-out task. Four sunbursts appeared simultaneously: three had the same dot and line densities and one differed on one of those dimensions. Participants had 4 seconds to press a number key (1-4) to indicate the odd one out and receive feedback (see Figure 2).

At the beginning of Phase 1, the dimension that differed in the odd one differed by a large amount from the others. This distance was subsequently adjusted through a staircase

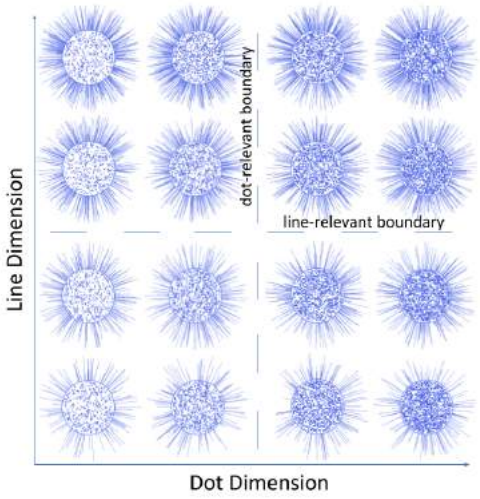

Figure 1. The stimulus space illustrating the two dimensions and the two possible sets of categories.

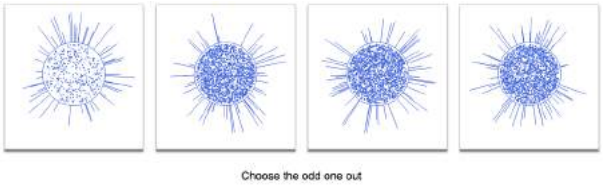

Figure 2. An odd-one-out trial display in Phase 1.

procedure, decreasing or increasing by 15% depending on whether the response was correct or incorrect. Trials continued until at least eight reversals occurred on each dimension. The goal of Phase 1 was to identify an approximation of each individual participant's just noticeable difference (JND) on each dimension, defined as the average of the distances of the last four reversals.

In **Phase 2**, odd-one-out trials alternated with one of two other tasks, classification or number judgment, to which participants were randomly assigned. For both tasks, a single sunburst appears with a question and participants press a key to answer and receive feedback (see Figure 3).

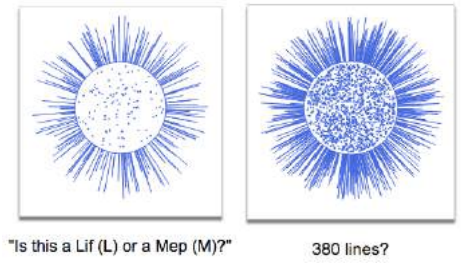

Figure 3. A classification task trial display (left) and a number judgment task trial display (right) in Phase 2.

The number judgment (control) task is to say "more" (M) or "less" (L) in response to a question about the number of dots or lines, where the number varied from trial to trial. For a given participant, the number judgment questions are always about just one of the two dimensions, randomly assigned, so that the control task matches the category learning task in relying on attention to one "relevant" dimension to answer correctly. For the classification ("experimental") group, the randomly assigned relevant dimension defined the category boundary as shown in Figure 1.

The specific stimuli used in Phase 2 odd-one-out trials were initially based on each JND value from Phase 1 for each participant and dimension. The sets of four stimuli (see Figure 2) were of three types as shown below in Figure 4. For both BE (between category) and WI (within category) comparisons, the odd one out differed from the other three only on the relevant dimension while for IRR comparisons, it differed only on the irrelevant dimension. All 48 possible adjacent stimulus pairs were used as the basis for the odd-one-out trials and drawn from the participant's JND-based dimensional space at a given moment.

Phase 2 trials proceeded in 40 blocks each containing six odd-one-out trials (one BE, two WI, and three IRR trials to sample the stimulus space evenly) and six classification or number judgment trials in a random order. The staircase procedure on the odd-one-out task was continued individually for each participant throughout Phase 2 just as in Phase 1, but separately for these six comparison subtypes. This controls for discriminability differences due to stimulus magnitude (e.g., Weber's law). Since adjacent dimensional values were already near JND level, the proportion change from one trial to the next of that subtype was reduced from 15% to 5% and the maximum distance allowed between dimension values was .33.

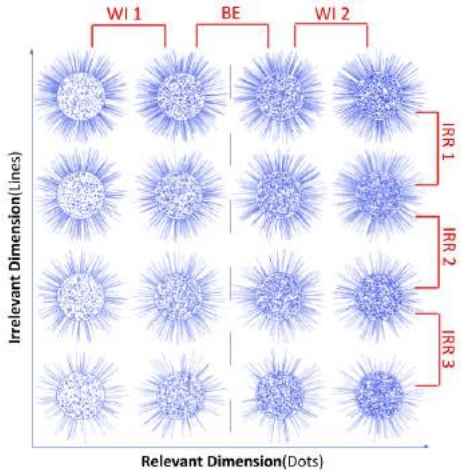

Figure 4. Illustration of the six comparison subtypes for the odd-one-out trials with dots as the relevant dimension.

Analysis Plan

A traditional learned CP analysis takes a behavioral measure such as similarity rating or same-different accuracy and compares the experimental (category learning) and control

groups on that measure for between-category vs. within-category pairs. Our experiment tracked changes in the size of the distance between the two dimensional values used in odd-one-out task trials. Therefore, our learned CP measure was the change in this value for a given dimension from the beginning to the end of Phase 2. If participants improved on the odd-one-out task, their scores will be negative since they will become able to accurately judge smaller differences, and a larger negative score represents more improvement. Because differences in speed of discriminating between-category vs. within-category pairs are sometimes taken as evidence for CP, we also used mean correct reaction time over the last four blocks on odd-one-out trials as an alternate measure. We standardized RTs within subject by converting them to z scores. Note that for both of these measures, a smaller score reflects better performance.

It is traditional for the above types of analysis to adopt some criterion of successful category learning and exclude participants who don't meet it. However, the choice of the criterion is arbitrary, may well influence the results, and is not explicitly motivated in learned CP research. In addition, because our continuous staircasing procedure kept dimensional differences between adjacent stimuli near JND, we expected category learning to be relatively difficult and produce a wide range of performance levels. Since it seems reasonable to predict that learned CP measures should positively correlate with category learning success (see Gureckis & Goldstone, 2008 for a similar approach and positive evidence), we only reported that type of analysis.

Results

Figure 5 shows an example of a result of the Phase 1 staircase procedure for illustrative purposes. Participants whose Phase 1 JND on either dimension exceeded the maximum of .33 allowed in Phase 2 by more than .05 were excluded from subsequent analysis since the Phase 2 staircasing procedure would not apply correctly to them. This produced a final n of 72 (35 control, 37 experimental).

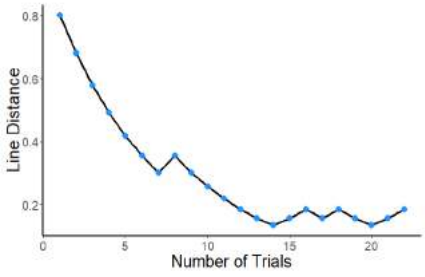

Figure 5. Example outcome of Phase 1 staircase procedure.

The mean proportion correct over Phase 2 on the classification task was .678 (*SD* = .145) and on the number judgment task it was .807 (*SD* = .13).

Phase 2 began with dimensional differences based on each individual participant's Phase 1 JND. Did the staircase procedure continuing throughout Phase 2 (in alternation with the classification or number judgment task) produce further perceptual learning? Figure 6 shows that in general, averaging across all participants, it did, particularly on the relevant dimension comparisons, as one might expect. Using the mean distance change for each participant averaging over the three odd-one-out trials differing on the relevant dimension (BE, WI1, and WI2) in the final block, the mean of the entire sample (M = -2.57) was significantly less than zero ($t(71)$ = -3.547, $p < .0001$). This was not the case for the irrelevant dimension (averaging over IRR1, IRR2, and IRR3 trials) (M = -0.72, $t(71)$ = -0.996, p = .16). A one-tailed paired samples t-test yielded a significant difference between relevant and irrelevant mean distance change ($t(71)$ = -2.014, p = .024).

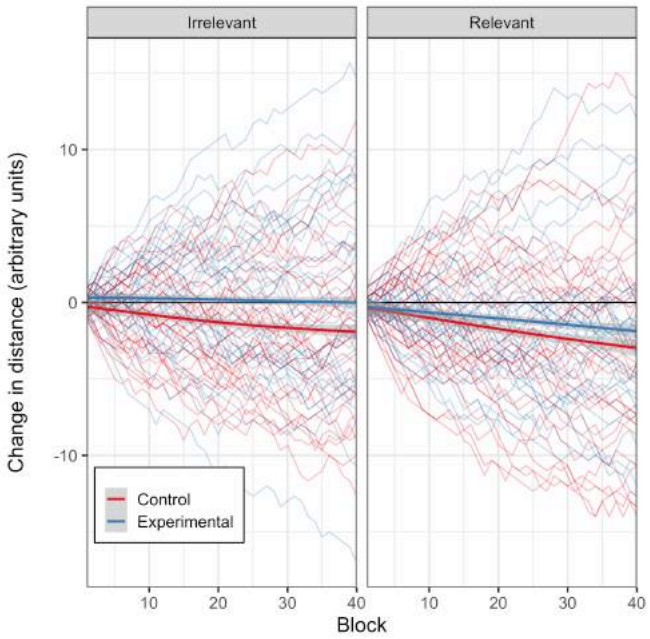

Figure 6. Overall perceptual learning in the experiment; the y axis represents number of staircase steps, e.g., a change in distance of -10 means the staircase has gotten 10 steps more difficult, indicating improved discrimination accuracy.

The left panel in Figure 7 illustrates the pattern that would be expected to hold for the control group, with better performance on the number judgment task coinciding with better performance on the odd-one-out task only (or to a greater degree) for the dimension relevant to the number judgment task, and no difference in the patterns for between and within category comparisons. The right panel shows what the pattern would be if the experimental group showed learned CP boundary effects, with better classification performance associated with better odd-one-out performance on between-category comparisons (expansion) and/or worse odd-one-out performance on within-category comparisons (compression) relative to the control group. If the experimental group were to show stronger sensitization to the relevant dimension or desensitization to the irrelevant

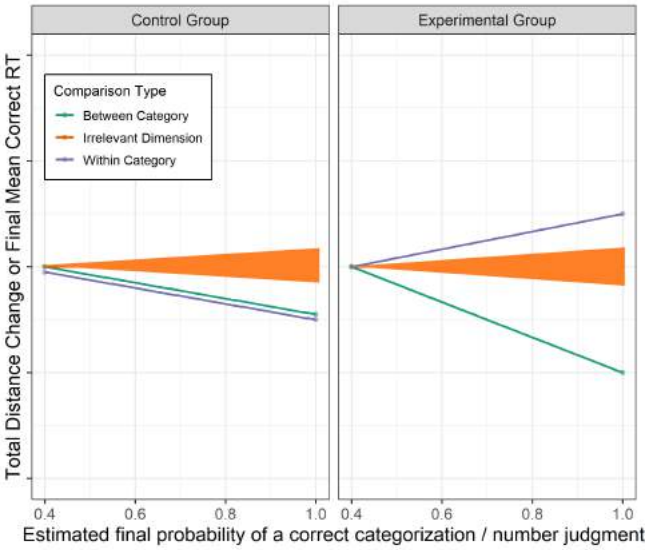

Figure 7. Relationship between classification or number judgment task performance (x axis) and either dependent variable (y axis) predicted by learned CP boundary effects.

dimension relative to the control group, the patterns would be slightly different, but we will focus on the boundary effects that are typically what is meant by learned CP.

Figure 8 shows the actual relationship in our data between total distance change over Phase 2 (y axis) and an estimate of the probability of a correct response at the end of Phase 2 on the number judgment (left) or classification (right) task (x axis) obtained by fitting a logistic regression model for each individual subject.

Overall there is a weak negative relationship such that discrimination performance tended to be better when classification or number judgment was more accurate, perhaps reflecting a general effect of effort. These data were analyzed using a Bayesian linear model to predict total distance change from three variables: comparison type (between, within, or irrelevant), group (control or experimental), and estimated final performance on the number judgment or classification task. The model also included the three-way interaction between these three variables since, as shown in Figure 7, this would have to be present if learned CP effects occurred. The analysis produced a BF_{10} of 119 for the estimated final performance variable, supporting the effort effect mentioned previously. To assess evidence for the critical three-way interaction, we determined the ratio of the BF_{10} for the full model containing the three predictor variables and the three-way interaction (.94) to the BF_{10} for the model containing just the three predictor variables (7.18). This yielded a BF_{10} of .131 indicating moderate support for H0 and therefore no evidence for learned CP.

The same analysis was performed for the RT measure (see Figure 9) and showed only one result favoring the alternative hypothesis and that was for comparison type

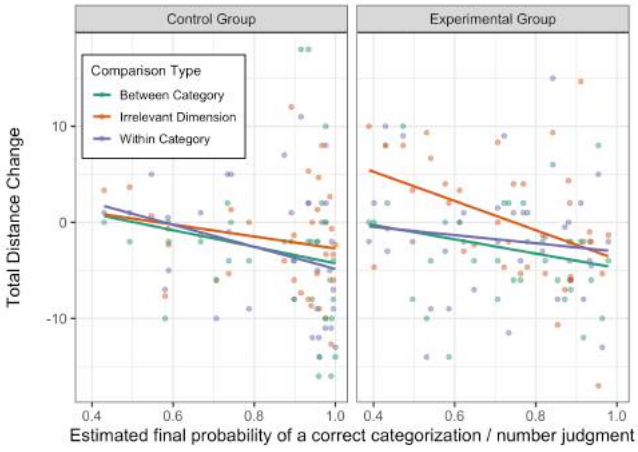

Figure 8. Relationship between estimated final performance on the classification or number judgment task and actual discrimination accuracy improvement over Phase 2 for the three comparison types.

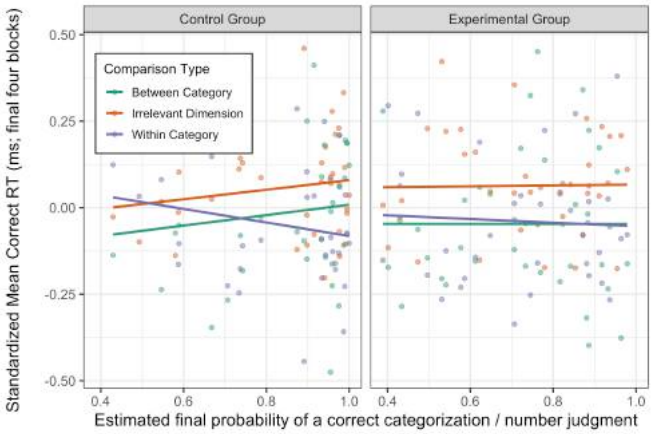

Figure 9. Relationship between estimated final performance on the classification or number judgment task and standardized mean correct RT on the last four blocks of Phase 2 for the three comparison types.

(BF_{10} = 41). The graph shows this to be due to irrelevant dimension odd-one-out trial responses being slower in general than relevant dimension trials of either type. The ratio of the BF_{10} for the full model containing the three predictor variables and the three-way interaction (.095) to the BF_{10} for the model containing just the three predictor variables (.942) yielded a BF_{10} of .101. This constitutes fairly strong support for H0 and thus no learned CP effects.

Discussion

This experiment employed a novel methodology designed to rigorously test for learned CP effects. Stimuli varied systematically on two dimensions, only one of which was relevant for either category learning or a control task. The stimuli also varied in random low-level features to allow for

simultaneous presentation in the discrimination ("odd-one-out") task to eliminate reliance on memory. A staircasing procedure was used to initially determine the JND for each participant on each dimension and this staircasing continued with discrimination trials alternating with classification or control task trials to allow for continuous measurement of discrimination ability on each dimension.

The results provide evidence of sensitization to the relevant dimension for both the classification task and a control task that was comparable in requiring attention to one of the two dimensions. This was seen in significant discrimination performance improvement from the beginning to the end of Phase 2 for the sample as a whole on the relevant but not the irrelevant dimension. The interesting question then is whether there were differences in discrimination performance between the two groups that fit any of the patterns consistent with learned CP.

We did not report traditional analyses of learned CP effects, comparing successful category learners to the control group on our odd-one-out performance measures as a function of comparison type, due to the arbitrariness of setting a criterion for successful learning and the fact that our continuous staircasing procedure kept discrimination across the category boundary difficult. Instead, we examined whether learned CP effects appeared in the form of different *relationships* between category learning performance and discrimination performance as a function of comparison type and in relation to the control group.

The only effects we found were a positive correlation between success on the classification or number judgment task on the one hand and the odd-one-out task on the other, and slower response times by the end of the experiment for odd-one-out trials that required distinguishing stimuli differing on the irrelevant dimension. The critical three-way interaction between group, comparison type, and level of classification or number judgment performance that would be required in order to demonstrate any variety of learned CP effects was lacking for both dependent measures, and the analyses showed more than anecdotal support for its absence.

Note that if learned CP effects had occurred in this experiment, our continuous measurement of discrimination ability on the three types of comparisons would have been valuable for tracking the emergence of different types of effects (e.g., expansion vs. compression) and would have potentially allowed us to distinguish otherwise similar end results (i.e., expansion vs. a combination of compression and relevant dimension sensitization). However, since we did not obtain any learned CP effects overall, we were not able to take advantage of this capability.

There are many possible reasons for these negative results, due to the ways in which our methodology deviated from typical learned CP experiments. Perhaps the constantly changing stimulus set and its randomly varying sub-features below the dimensional level prevented learned CP from occurring. Or it may be that constantly alternating between a classification task and the odd-one-out task interfered with learned CP. If learned CP effects depend on memory and thus require tasks with a delay between stimuli in order to occur, our simultaneous stimulus presentation would be the cause. Or it could be that, previous evidence of boundary effects notwithstanding, so-called learned CP effects are really due to paying attention selectively to one dimension rather than another, and thus also occur as a result of other tasks besides category learning such as the number judgment task used by our control group.

We believe it is very important to determine the conditions under which learned CP effects do and do not occur, which has not been addressed sufficiently in the literature. Our negative results can provide a useful initial reference point. One strategy for building on this would be to next conduct a traditional version of the experiment utilizing a fixed set of the same stimuli and and a successive presentation version of our discrimination task to establish whether learned CP effects do occur under those conditions. If they do, methodological changes can then be incorporated one at a time, such as simultaneous rather than successive discrimination testing and comparison to a control group that performs a task requiring attention to one dimension, to determine which manipulations change and/or eliminate learned CP effects. This would allow us to make real progress in understanding the phenomenon of learned CP and its scope and limits.

Abstract

It is presently unclear how localized, word association network representations compare to distributed, spatial representations in representing distant concepts and accounting for priming effects. We compared and contrasted 4 models of representing semantic knowledge (5018-word directed and undirected step distance networks, an association-correlation network and *word2vec* spatial representations) to predict semantic priming performance for distant concepts. In Experiment 1, response latencies for relatedness judgments for word-pairs followed a quadratic relationship with network path lengths and spatial cosines, replicating and extending a pattern recently reported by Kenett, Levi, Anaki, and Faust (2017) for an 800-word Hebrew network. In Experiment 2, response latencies to identify a word through progressive demasking showed a linear trend for path lengths and cosines, suggesting that simple association networks can capture distant semantic relationships. Further analyses indicated that spatial models and correlation networks are less sensitive to direct associations and likely represent more higher-level relationships between words.

Keywords: neural networks; *word2vec*; semantic priming; semantic space model; word association; network science.

Introduction

Understanding language requires the retrieval of meaning from underlying semantic representations of words. A class of models of semantic memory represent words as nodes in a large memory network, where words with similar meanings are connected to each other via edges (see Kenett, Kenett, Ben-Jacob & Faust, 2011; Steyvers & Tenenbaum, 2005). Semantic network models propose localized word representations, in contrast to feature-based or distributed space models (Smith, Shoben & Rips, 1974; Landauer & Dumais, 1997).

Spatial models of semantic memory represent words in a multi-dimensional space, where words are an aggregate of the individual dimensions of the space. The spatial dimensions are derived from statistical co-occurrences in natural language. For example, Latent Semantic Analysis (LSA; Landauer & Dumais, 1997) is a distributional model that measures semantic similarity by calculating co-occurrences of words in a text corpus. LSA successfully simulates complex human behavior in a variety of cognitive tasks but has had difficulty accounting for semantic priming effects (Hutchison et al., 2008) and power laws (Steyvers & Tenenbaum, 2005), suggesting that spatial models may have some limitations.

A more recent spatial model, *word2vec* (Mikolov, Chen, Corrado & Dean, 2013) has received considerable attention in the fields of computer science and natural language processing. *word2vec* uses neural networks to compute continuous vector representations of words. These semantic representations can then be used to compute an index of semantic similarity between words via vector cosines (higher cosines indicate greater semantic similarity). Interestingly, *word2vec* is able to solve verbal analogy problems (e.g., king: queen::man:?) using simple vector arithmetic, although recent research suggests that *word2vec* successfully captures only certain, simpler types of semantic relationships and not others (Chen, Peterson & Griffiths, 2017). The question of whether individuals use an association-based representation or represent meaning in a high-dimensional space is currently controversial (Griffiths, Steyvers & Tenenbaum, 2007; Jones, Gruenenfelder & Recchia, 2011). Thus, direct comparisons among different types of meaning representations and how they account for more distant semantic relationships is an important next step for the field.

Recently, Kenett, Levi, Anaki and Faust (2017) used a semantic relatedness task to explore the impact of network path length derived from an 800-word Hebrew semantic network. The Hebrew network was created using correlations from continuous free association responses of 60 participants to 800 target words (for complete methodology, see Kenett et al., 2011). The results from the semantic relatedness task indicated that as network path length between word pairs (i.e., shortest distance between two words in the network) increased, fewer word pairs were judged as related. They also reported a quadratic relationship between path length and response latencies to make relatedness judgments, such that response times (RTs) increased for word pairs at shorter path lengths (e.g., BUS-CAR), but after path length 3, RTs systematically decreased for word pairs at longer path lengths (e.g., CHEATER-CARPET). They also showed that this network outperformed LSA and another measure of semantic distance, Positive Pointwise Mutual Information (PPMI) in explaining task performance. However, given that Kenett et

al. used a novel association-correlation methodology based on a Hebrew network, it remains unknown how simpler association networks (e.g., Steyvers & Tenenbaum, 2005) and more recent spatial models (e.g., Mikolov et al., 2013) capture such distant semantic relationships. Moreover, it is important to extend the Kenett et al. network structure to a larger English-based network analysis to examine the generalizability of their findings.

The present set of experiments were designed to compare and contrast the structural differences between three different network-based models and the *word2vec* model, across two behavioral tasks. It is important to note here that we do not claim that association-based networks are a complete account of semantic memory, but the issue we are interested in whether networks created from simple associations can indeed capture distant semantic priming effects, and how they compare to other models of semantic memory, such as spatial models and the association-correlation network. There is a rich tradition of using network-based models to accommodate priming effects (Anderson, 2000; Collins & Loftus, 1975), and we were mainly interested in comparing different types of network-based approaches to each other in accounting for this well-studied task, and also to other spatial representations. In Experiment 1, we extended and replicated the patterns reported by Kenett et al. in the Hebrew semantic relatedness task in three large semantic networks in English along with cosines from the *word2vec* model. We created these networks from a 5018-word database of free association norms collected by Nelson, McEvoy & Schreiber (2004) to examine the extent to which network path lengths would predict performance in the relatedness judgment task.

A potential concern regarding the performance of network models created through human association norms in Experiment 1 is both relatedness judgments and word associations direct attention to the meaning dimension, and thus the patterns observed may just be due to overlap in the type of task. Further, the quadratic pattern observed may just reflect how the semantic "distance" between two words might influence the related/unrelated decision and how a particular individual partitions items into these arbitrary categories. We attempted to address this concern by employing a task that does not require accessing meaning-related information to make the response. Thus, in Experiment 2, participants first viewed a briefly presented prime (120 ms) and then identified targets through a visual demasking task. Hence, we were able to directly compare the different network configurations and spatial representations in accounting for performance in two behavioral tasks.

Semantic Network Construction

To construct the semantic networks, we used a 5018-word database of free-association norms collected by Nelson et al. (2004), in which 150 participants on average wrote down the first word that came to mind in response to approximately 120 word-cues. The cues were selected by Nelson et al. after multiple rounds of data collection, and typically, the most

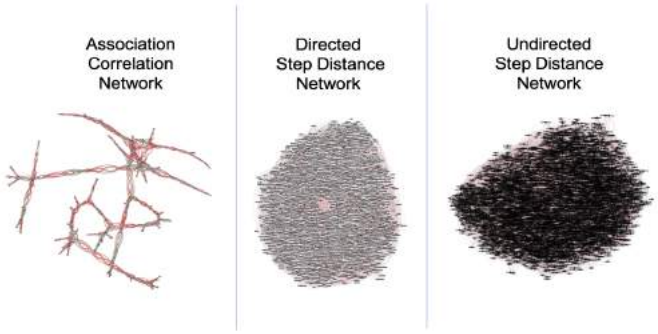

Figure 1: Large-scale visualization of the Association-Correlation Network, Directed and Undirected Step Distance Networks.

frequent responses for each of the cues were contained within the 5018 cues themselves. Responses were included only if at least two participants produced the same response, thus excluding idiosyncratic responses from the database. Responses that were not within the 5018 cues were also excluded during network construction. We constructed three networks from this database: an Association-Correlation Network (ACN), an Undirected Step Distance Network (Undirected SDN) and a Directed Step Distance Network (Directed SDN).

Association-Correlation Network

The ACN was created based on the methodology described by Kenett et al. (2011). Associative responses to 5018 cue words were first converted into a matrix, in which each column represented a cue word, and each row indicated unique associative responses for the target word. This matrix was converted to an association-correlation matrix, where the correlations between two target word profiles (i.e., the words produced to the two targets) was calculated based on the Pearson's formula. This correlation matrix was converted into a weighted, undirected network, such that each target word was a node in the network, and the correlation between two target words represented the weight of the edge between them. This fully-connected network was then reduced to a planar maximally filtered graph, resulting in a smaller planar network (a network in which no edges cross each other) with the same target nodes, but only edges that represent the most relevant associations between target words. Path length between word-pairs was then calculated as the shortest path from one word to another in this smaller network. Figure 1 (Left panel) displays a large-scale visualization of the ACN, and Figure 2 (Left panel) displays the 6-step shortest path from RELEASE to ANCHOR.

Undirected and Directed Step Distance Networks

Following Steyvers and Tenenbaum (2005), in the Directed SDN, two words (*a* and *b*) were connected by an edge if the word *a* evoked the word *b* as an associative response for at least two participants in the Nelson database. In the Undirected SDN, words were connected if *a* evoked *b* or *b*

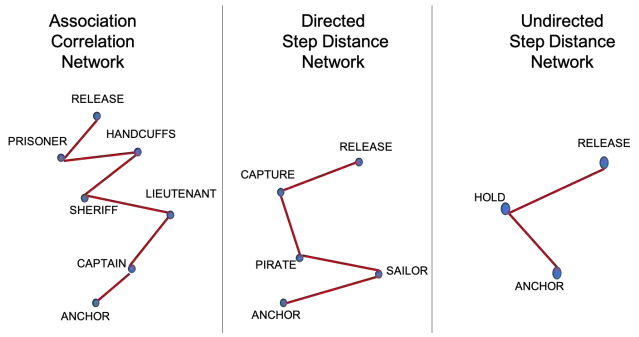

Figure 2: Shortest path from RELEASE to ANCHOR in the Association-Correlation Network, Undirected and Directed Step Distance Networks.

evoked *a*, independent of the associative direction. Path length for each word pair in the network was calculated as the shortest path from one word to another. Figures 1 and 2 (Middle and right panels) display visualizations of the two SDNs, and the shortest path from RELEASE to ANCHOR.

Network Comparisons

Table 1 displays the network parameters for the three networks. As is evident from the large-scale visualizations, ACN is sparser than the SDNs, with a greater clustering coefficient (an index of network connectivity, i.e., the extent to which neighborhoods of neighboring nodes overlap) and longer average path lengths, indicating more distant associations compared to the direct associations captured by SDNs with shorter path lengths overall. Table 2 displays the correlation among the path lengths derived from each of the networks for the sets of words used in our experiments. As is clear, there were considerable differences across the different types of network configurations. As shown in Figure 1, the ACN is a sparsely connected network, in which obscure,

Table 1: Network parameters for the semantic networks

	Simple Step Distance Networks		Association-Correlation Networks	
	Undirected	Directed	English	Hebrew
n	5018	5018	5018	800
<*k*>	22	12.7	5.85	5.94
L	3.04	4.27	23	10
D	5	10	61	25
C	.186	.186	.69	.68
L_{random}	3.03	4.26	1.95	3.94
C_{random}	.004	.004	.05	.005

Note. *n* = the number of nodes; <*k*> = average number of connections; *L* = average shortest path length; *D* = diameter of network; *C* = clustering coefficient; L_{random} = average shortest path length with random graph of same size and density; C_{random} = the clustering coefficient for a random graph of same size and density.

Table 2: Correlation matrix for network path lengths and *word2vec* cosines for word-pairs in Experiments 1 and 2

	ACN	Undirected SDN	Directed SDN	*word2vec* Cosines
ACN	1	-	-	-
Undirected SDN	.49	1	-	-
Directed SDN	.35	.58	1	-
word2vec Cosines	-.42	-.55	-.45	1

Note: All correlations were significant at the $p < .05$ level

higher-level associations are closely represented (e.g., TRAGEDY-REMORSE is 1 step away), whereas several direct (e.g., VOLCANO-ASH is 15 steps away) and mediated associations (e.g., LION-STRIPES is 38 steps away) are exaggerated. Overall, path lengths derived from the two SDNs were very highly correlated, suggesting that the simple associative networks largely overlap in their network structure, and differ from the ACN.

Vector Cosines via word2vec

The *word2vec* model (Mikolov et al., 2013) trains neural networks based on words that naturally co-occur in a text corpus and uses this contextual information to predict a word's immediate contextual neighborhood. Typically, these contextual words have probabilities associated with them, which indicate the likelihood of words co-occurring together in natural language. If two words occur in similar contexts, the model learns similar vector representations for those words. Cosines between these vector representations thus serve as indices of semantic similarity. For all the word pairs used in the current experiments, we obtained *word2vec* cosines from a pre-trained model trained on 100 billion words from a Google News dataset (Mikolov et al., 2013). Table 2 displays the correlations between *word2vec* cosines and path lengths derived from the three networks described above. Note that *word2vec* cosines were negatively correlated with the path lengths, due to the direct cosine similarity measure used. Further, there were considerable differences across the models in the extent to which they captured "semantic similarity", given that the average correlation among all the measures was only .46.

Experiment 1

Methods

Participants Forty Amazon Mechanical Turk users (M_{age}= 37 years, SD = 10.4) and 40 undergraduate students (M_{age}= 20 years, SD = 0.8) recruited from Washington University in St Louis participated in the study. All participants were self-reported native English speakers.

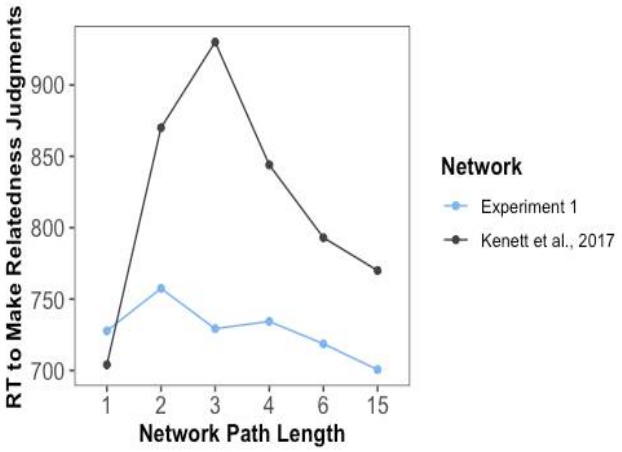

Figure 3: Response times for relatedness judgments in Experiment 1 and Kenett et al. (2017)

Materials In order to extend and replicate the Kenett et al. study, we randomly sampled 40 word-pairs from path lengths 1, 2, 3, 4, 6 and 15 from the ACN. The stimuli consisted of 1200 distinct word-pairs across 5 lists. For each word-pair sampled from the ACN, we also obtained path lengths in the Undirected and Directed SDN and obtained vector cosines from the *word2vec* model. We also obtained lexical characteristics (word length, frequency, lexical decision times and concreteness) for all the words from the English Lexicon Project (ELP; Balota et al., 2007) and used these as covariates in our analyses. All items used in the current study are available at https://github.com/abhilasha-kumar/Distant-Semantic-Connectivity.

Procedure

The relatedness task was developed in JSPsych, an online software for conducting psychological experiments. Each participant completed the experiment online. Following Kennett et al., on each trial, participants saw a fixation cross for 200 ms, followed by a blank screen for 100 ms. Then, the prime was briefly presented for 120 ms, followed by the target for 120 ms. Participants decided whether the prime and target were related or unrelated and responsed by pressing a key (K or L, counterbalanced). After a response, participants saw a blank screen for 500 ms before the next trial.

Results

There were no differences in the overall patterns between the five lists, or the Amazon Mechanical Turk or Washington University sample, thus all analyses included the full sample.

Effect of ACN Path Length on RTs To replicate the analysis procedures reported in Kenett et al. (2017), each path length was first classified as related or unrelated, based on the percentage of related and unrelated responses to specific word pairs. The following were the percentages of "related" responses for the path lengths: 1 (66%), 2 (47%), 3 (29%), 4 (27%), 6 (16%) and 15 (13%). Based on these percentages and the criterion of at least 50% of words producing a related response, only path length 1 was considered related, and the remaining path lengths were considered unrelated. To minimize any effects of slowing and individual differences, all RTs faster than 250 ms and slower than 2000 ms were removed. Second, a mean and standard deviation were calculated from the remaining trials for each participant and any RTs that exceeded 3 standard deviations (SDs) from the participant mean were also removed. This process excluded 5.4% of the total trials. After this trimming procedure, we standardized the remaining trials within each participant and conducted all primary analyses using trial-level standardized RTs. A repeated measures Analysis of Variance (ANOVA) on mean RT revealed a significant main effect of path length, $F_1(5, 395) = 7.42$, $p < .001$, $\eta_p^2 = .09$. RTs significantly increased from path length 1 to 2 ($p = .006$), decreased from path lengths 2 to 3 ($p = .001$) and 4 to 15 ($p = .015$). As shown in Figures 3 and 4, we successfully replicated the pattern reported by Kenett et al. for RTs as a function of path length in the ACN. Importantly, this pattern persisted after including degree of relatedness as a predictor in our analyses, standardizing the RTs and controlling for lexical variables such as word frequency, length, concreteness and standardized lexical decision times, as well as mean degree (i.e., number of direct neighbors of the words) using linear mixed effects models.

Effect of SDN Path Length on RTs In addition to the ACN based on Kenett et al., as noted, we also examined the effect of path lengths derived from two SDNs (Undirected and Directed) based on the method used in Steyvers and Tenenbaum (2005) on standardized RTs in the relatedness task. As shown in Figure 4, both the Undirected and Directed networks also showed a quadratic trend for standardized RTs as a function of path length, with RTs significantly rising from path lengths 1 to 2 ($p<.001$) and then reliably decreasing

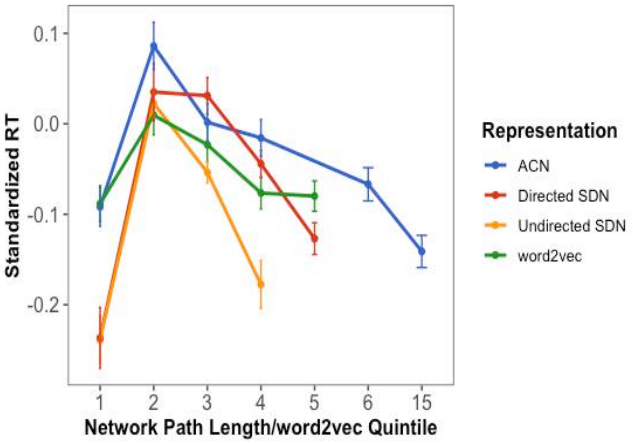

Figure 4: Standardized RTs for relatedness judgments in Experiment 1 as a function of network path lengths and *word2vec* cosine quintiles (reverse-scored)

from path length 2 onwards. We observed a significant decline in RTs from path lengths 3 to 4 in the Undirected ($p < .001$), and from 2 to 5 in the Directed network ($p < .001$).

Effect of word2vec Cosines on RTs We also computed vector cosines derived via *word2vec* for each of the word pairs in Experiment 1. As shown in Figure 4, continuous *word2vec* cosines successfully predicted standardized RTs to make relatedness judgments ($b = -.22$, $t = -3.54$, $p < .001$), and reproduced the quadratic pattern previously observed.

Discussion

The results from Experiment 1 provide strong evidence for multiple-step priming in the relatedness judgment task, and also replicate and extend the quadratic pattern observed by Kenett et al. (2017) for the Hebrew network. In addition, simple directional and nondirectional SDNs also captured distant semantic relationships between concepts. This is noteworthy, as it indicates that the number of "steps" in the ACN do not necessarily reflect *direct* associative strength, at least based on distances captured by simple SDNs. Of course, this does not imply that the ACN distances are unimportant, as the ACN shows comparable performance in the current task. We also found that the *word2vec* model successfully captured the quadratic trend, although there do seem to be differences in the semantic information captured by all the models, based on the relatively low correlations across the networks.

It is important to note that the nature of the relatedness decisions is likely driving the quadratic trend. Specifically, RTs are slowed to make "unrelated" decisions for the more ambiguous items e.g., at path lengths 2 and 3. Interestingly, the RTs for only the "related" decisions continued to increase with greater path lengths, a finding that is more consistent with a spreading-activation account. In addition, the networks in this study were explicitly created from free association norms, and their explanatory power may reflect the high degree of overlap between the base task (free association) and the relatedness judgment task. Thus, in Experiment 2, we explored whether network path length and vector cosines can account for semantic priming in a primed progressive demasking task, which does not explicitly involve explicit semantic retrieval to make a response.

Experiment 2

Methods

Participants Thirty-nine young adults (M_{age} = 20.9 years, SD= 2.8) were recruited from undergraduate courses at Washington University in St Louis. All participants were Native English speakers.

Materials One list of 240 items was randomly chosen from one of the five lists used in Experiment 1. As before, the list contained 40 word-pairs from path lengths 1, 2, 3, 4, 6 and 15 from ACN. Each word pair also had corresponding path lengths in the undirected and Directed SDN, as well as *word2vec* cosines. This list was then used to create two lists counterbalanced across participants, so that each word was a prime as well as a target in the study.

Procedure

The primed progressive demasking task was developed using E-Prime 2.2. Participants saw a black fixation cross on the screen for 500 ms. Next, a blank screen was displayed for 200 ms, followed by the prime word, displayed for 120 ms. Immediately after, the target word was progressively demasked on the screen. During progressive demasking, the display alternated between the target (e.g., XXXX) and a mask (a row of pound signs matching the length of the word, e.g., ######). The total duration of target-mask pair was held constant at 500 ms but the ratio of target display time to target display time progressively increased. The duration of the target increased at each cycle (0, 16, 32,...,500 ms) and the duration of the mask decreased (500, 484, 468,…0 ms). The demasking procedure continued until the target was fully revealed for 500 ms, or until the target was identified by the participants by pressing the spacebar and typing in the target word. The next trial began immediately after typing the target and pressing spacebar.

Results

Effect of ACN Path Length on RTs All trials in which the correct target was not identified were excluded from analyses (2.7%). Next, we standardized the RTs to identify the target as in Experiment 1. A repeated measures ANOVA revealed a significant effect of path length, $F_1(5,190) = 53.85$, $p < 0.001$, $\eta_p^2 = .586$. As shown in Figure 5, we observed a significant increase in RTs from path lengths 1 to 2 ($p <.001$), and 2 to 3 ($p <.001$). Differences between RTs at path length 3 and higher ACN path lengths were not reliable. These effects persisted after controlling for lexical variables & mean degree (i.e., number of direct neighbors of the words).

Effect of SDN Path Length on RTs. We also examined the effect of path lengths from the Undirected and Directed SDNs on standardized RTs. As shown in Figure 5, path lengths from the Undirected SDN significantly predicted RTs to identify the target. RTs increased from path length 1 to 2 ($p = .001$), from path lengths 2 to 3 ($p < .001$), and then marginally from 3 to 4 ($p = .058$). Path lengths from the Directed SDN also predicted RTs to identify the target. RTs increased from path lengths 2 to 3 ($p = .015$) and 4 to 5 ($p = .038$).

Effect of word2vec cosines on RTs We also obtained vector cosines derived via word2vec for each of the word pairs, as in Experiment 1. As shown in Figure 5, continuous word2vec cosines also successfully predicted standardized RTs to identify the target (($b = -1.34$, $t = -9.18$, $p < .001$).

Model Comparisons Because the results from this task were not complicated by the relatedness decision as in Experiment 1 (i.e., RTs should be linearly related to demasking performance), we were able to directly compare the model

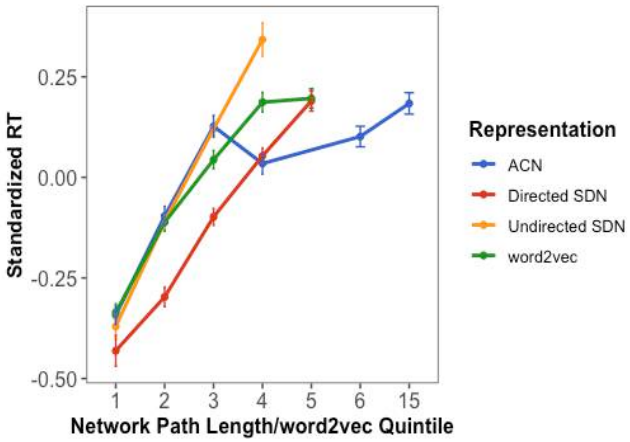

Figure 5: Standardized RTs to identify target word in demasking in Experiment 2 as a function of network path lengths and *word2vec* cosine quintiles (reverse-scored)

estimates. To estimate the unique variance accounted for by each type of network configuration at the item level, we calculated the individual R^2 for each model, as well as estimates of AIC and BIC, after controlling for covariates. As shown in Table 3, the models had overall comparable fits, and explained a significant amount of variance over and above the model with just the covariates, although as discussed before, these models seem to capture somewhat different semantic information.

Discussion

Results from Experiment 2 indicated that network path lengths can indeed account for performance in a progressive demasking task. RTs linearly increased as a function of SDN path lengths and *word2vec* cosines. This is especially interesting as the demasking task does not require any direct retrieval of semantic association to make the response, and yet, we see that path lengths derived from word associations directly predict demasking response latencies. Further, we found reliable differences at relatively distant path lengths in the simple association networks, suggesting that simple association networks are able to capture distant semantic relationships in the memory network, even in tasks that do not necessarily direct attention to semantics. Interestingly, we find that path lengths from the ACN increase linearly only up to 3 steps, after which the network seems to no longer be sensitive to priming effects in this task, suggesting differences in the network structures.

General Discussion

A primary goal of the present study was to compare the extent to which measures of semantic similarity derived from different types of network-based models explained distant semantic priming. In Experiment 1, we replicated and extended a pattern previously reported by Kenett et al. (2017) to a larger 5018-word association network in English and also

Table 3: Model comparison metrics for Experiment 2

Model	R^2 (%)	AIC	BIC	Likelihood ratio test
Covariates	13.33	561.9	586.1	---
ACN	26.99	500.8	545.1	p <.001
U-SDN	22.16	523.3	559.6	p < .001
D-SDN	25.98	506.4	550.8	p <.001
word2vec	28.03	486.8	515	p < .001

compared their graph-theoretical approach of capturing semantic similarity with simpler Undirected and Directed Step Distance Networks (Steyvers & Tenenbaum, 2005). Our results indicated that simple association networks can also capture similar distant relationships between words in the lexicon. Experiment 2 indicated that network models also successfully capture performance in tasks that do not directly rely on word association.

As described earlier, the ACN uses correlations between association responses and a planarity criterion to construct the network, and possibly captures more higher-level associations. This leads to several direct word associations (e.g., TIGER-STRIPES is 37 steps away in the ACN and 1 step away in the SDNs) being dropped, giving rise to more high-level associations (e.g., SUEDE-SERPENT is only 2 steps away in the ACN but farthest, i.e., 4 steps away in the SDNs). The SDNs, on the other hand, capture *direct* associations between words. Importantly, given that all networks had comparable fits, it seems that each network captured different sources of variance in the task.

It is possible that the ACN may be differentially sensitive to semantic relationships if a different criterion for network construction was used, or possibly in a conceptually driven semantic task, which would suggest that different types of stimuli/tasks emphasize different properties of the lexicon. Indeed, Gruenenfelder, Recchia, Rubin and Jones (2015) recently argued for a hybrid representation of semantic memory and suggested that individuals switch between a contextual representation and associative networks when generating free associations. Our results suggest that there may also be differences in how individuals use semantic representations in tasks that do not explicitly involve word association but are still sensitive to semantic relationships.

Another important goal of the current study was to investigate how network-based models of semantic representation compare to a distributed model, *word2vec*, which has been shown to explain human performance in some semantic tasks. Our results indicate that *word2vec* successfully captures similar patterns of behavior as the semantic networks. However, we also observed important differences in the semantic relationships captured by each of the models. For example, the word BOXING is 2 steps away from the word SPLINTER in the Undirected SDN but is very weakly associated in the *word2vec* space with a cosine of -0.022. Thus, there appear to be differences in the type of semantic information the models capture, e.g., the path from

BOXING to SPLINTER is mediated by the word PAIN in the association networks, but it is possible that this particular usage of SPLINTER does not co-occur in the same contexts as BOXING very often, which is the mechanism underlying *word2vec* model. Thus, these findings indicate that the nature of the task as well as the underlying representation are both critical variables that determine the extent to which semantic models explain human performance. Importantly, the tasks in the current study focused on semantic priming, and it is possible that spatial models and correlation networks are most useful in conceptual tasks like verbal analogies.

There were some limitations to the current study. First, the Hebrew network used in Kenett et al. (2017) was based on responses from a continuous free association task, whereas the Nelson et al. norms are based on a discrete free association task. The validity of both continuous and discrete responses has been debated (Hahn, 2008; Nelson, McEvoy & Dennis, 2000) and our use of discrete responses may have produced a different network structure than one based on continuous responses. However, given that the English ACN and SDNs were created from the same norms, we believe that the differences observed between the ACN and the SDNs were not critically influenced by the nature of associative responses per se, although this issue deserves further exploration. Further, the *word2vec* model was trained on a Google News corpus, which is very different from the Nelson et al. database, and the type of corpus can impact how well semantic models account for performance (Recchia & Jones, 2009). Thus, the nature of the task, stimuli and training corpora are all likely to influence the extent to which semantic models explain cognitive task performance.

In conclusion, the current set of experiments investigated the predictive power of path lengths derived from three large semantic networks and cosines derived from a neural network model in two behavioral tasks and provided strong evidence for multiple-step priming. We also demonstrated important structural differences between correlation-based networks and simple association networks and showed that simple association networks are also able to capture relatively distant semantic relationships. Finally, we showed that *word2vec* successfully captures similar behavioral patterns across two tasks. However, based on preliminary analyses, it appears that *word2vec* and the ACN are more likely to capture higher-level semantic representations, whereas simple step networks are more likely to capture direct associations. Clearly, further work is needed to substantiate these observations.

Garnering Support for Number and Area as Integral Dimensions

Lauren Aulet
Emory University, Atlanta, Georgia, United States

Stella Lourenco
Emory, Atlanta, Georgia, United States

Abstract

Non-numerical magnitudes such as cumulative area, element size, and density influence the perception of number. However, it is unclear whether interactions between number and non-numerical magnitudes reflect independent representations that interface vis--vis other systems (e.g., language) or, conversely, reflect holistic perception of number and other magnitudes. In the present work, we found converging evidence that number and cumulative area are perceptually integral dimensions. Whether assessed explicitly (Experiment 1) or implicitly (Experiment 2), perceived similarity for dot arrays that varied parametrically in number and area was best modeled by Euclidean, as opposed to city-block, distance. Critically, we also found that the integrality of number and area is comparable to other integral dimensions (Exp. 1: brightness/saturation; Exp. 2: radial frequency components), but different from separable dimensions (Exp. 1: shape/color; Exp. 2: thickness/curvature). In summary, these findings suggest that non-symbolic number perception is holistic, such that the processing of non-numerical magnitudes is obligatory.

A computational model of feature formation, event prediction, and attention switching

Eman Awad and **Fintan Costello**
School of Computer Science,
University College Dublin,
Belfield, Dublin 6, (eman.awad@ucdconnect.ie,fintan.costello@ucd.ie)

Abstract

In this paper we present a model of three central aspects of probabilistic cognition: event prediction, feature formation, and attention allocation. While most models of probabilistic reasoning take a parameter estimation and error minimisation approach (sometimes referred to as 'predictive coding', and often described in terms of Bayesian updating), our model takes a contrasting frequentist hypothesis-testing approach. This choice is motivated by a series of recent results suggesting that people's probabilistic reasoning follows frequentist probability theory. In simulation tests we demonstrate that this frequentist model, in which predictive features are formed by a process of null hypothesis significance testing, can give a successful account of event prediction and attentional switching behaviour.

Introduction

There are, broadly speaking, two approaches to statistical reasoning: a 'parameter estimation' approach (associated primarily with Bayesian statistics), where some form of generative model is used to predict data and the estimation process involves adjusting parameters of this model so as to reduce errors in prediction; and a 'hypothesis testing' approach (associated primarily with frequentist statistics) where a decision is made to reject a hypothesis (that is, to reject a possible generative model) when the probability of the observed data under that model is less than some significance level. Most current models of probabilistic cognition, learning and attention take the parameter estimation and error minimisation approach, sometimes referred to as 'predictive coding'; this approach is naturally described in terms of Bayesian priors (values of generative model parameters) which are 'updated' by experience, to produce more accurate posterior estimates of those parameters (see e.g. Clark, 2013; Griffiths and Tenenbaum, 2006; Tenenbaum et al., 2011; Miller et al., 1995).

In this paper we present a model of probabilistic cognition based on frequentist hypothesis-testing rather than parameter estimation and error minimisation. We apply this model to the processes of probabilistic learning, feature formation, event prediction, and attention. There are three motivations for this frequentist hypothesis-testing approach to probabilistic cognition. First, the contrasting parameter estimation and hypothesis-testing approaches to statistical reasoning are known to have different strengths and weaknesses: modelling probabilistic cognition via frequentist hypothesis-testing is worthwhile because it allows us to see this type of cognition in a new light.

Second, the hypothesis-testing approach applies very naturally to one core aspect of probabilistic cognition; that of decision making. Decision making is central to feature formation (given observed pattern of co-occurrence between events, how do we decide whether to treat that pattern as representing a single complex event, and so form a feature representing that event?), event prediction (given estimated probabilities of various future events or outcomes, how do we decide which event to predict?) and attention (given multiple sources of information, how do we decide whether to direct our attention to one source rather than another?) The frequentist hypothesis-testing approach was specifically developed to guide decision-making on the basis of data (see e.g. Fisher, 1937), and so provides a natural normative framework for modelling decision making in prediction, feature formation and attention allocation.

Finally, this model is motivated by recent evidence suggesting that people's probabilistic reasoning processes follow the requirements of frequentist probability theory (Costello and Watts, 2018a, 2016), and that a range of well-known biases in probabilistic reasoning can be explained as a consequence of regression produced by random variation or noise in normatively correct frequentist reasoning (Costello and Watts, 2014, 2018b). The model described here represents a computational implementation of this account; in this model random variation arises simply as a consequence of sampling.

We present this model incrementally, focusing first on prediction, feature formation and probabilistic learning for a single 'stream' of input (that is, with fixed attention). We then generalise to learning, feature formation and prediction across multiple simultaneous streams of input (where attention moves from stream to stream). We test the frequentist approach by comparing the effectiveness of an attention switching mechanism derived from frequentist hypothesis testing against the effectiveness of a switching mechanism based on error minimisation (as used in predictive coding), and against a random switching baseline.

The model

At an abstract level, temporal prediction involves taking a temporally ordered stream of categorical events or labels, such as

$$A,B,S,A,B,S,A,-,S,A,-,S,-,A,B,S,A,B,A,B \qquad (1)$$

and predicting the next event in the stream. Our model predicts future events in such sequences by constructing features from observation of a given stream, identifying features which allow statistically reliable predictions, and then combining these 'predictive features' to give an overall predicted probability for the next event in the stream.

Each feature in our model consists of an antecedent event A, a consequent event S, and a time interval t between them. Each feature also holds two counts: k, a count of the number of times A has been followed, after time t, by S; and n, a count of the number of times A has been followed, after time t, by any event. Finally, each feature holds a conditional probability $P(S|A) = k/n$, representing the probability of seeing the consequent S at time t after the occurrence of the antecdent A.

The antecedent A in a given feature may be a single event (e.g. the label A as a predictor of the next event, in our example in (1)), or may be a combination of events occurring over time (e.g the consecutive labels A,B as a predictor of the next event). Our model stores, in 'Short Term Memory' (*STM*), the N most recent events in the stream. Our model stores, in 'Long Term Memory' (*LTM*), a large number of simple or complex features that have been observed, with some features marked as 'reliable', meaning that there is statistically significant evidence supporting the relationship between antecedent A and consequent S in that feature. These reliable features are used to make predictions about the next event in the stream. The model has two free parameters: N, the size of short term memory, which we set by default at 4, and c, the significance criterion, which we set by default at $c = 0.05$.

Reliable features and prediction

To decide whether a given feature describes a statistically reliable relationship between antecedent A and consequent S, our model follows the hypothesis-testing approach of standard frequentist probability theory. We consider two possible cases: one where the antecedent event is a single 'atomic' event; and one where the antecedent is a complex or composite event, made up of multiple subevents.

In the case of a single event as antecedent A, we have two hypotheses: a null hypothesis (that there is no relationship between A and S; under this hypothesis the probability getting S after A is simply the base probability of event S, $P(S)$) and an alternative hypothesis (that there is a reliable relationship between A and S; under this hypothesis the probability seeing S after A is given by $P(S|A)$). The probability of obtaining k instances of S after A in a sample of n occurrences of A, assuming that $P(A) = p$, is given by the binomial

$$Bin(k,x,p) = \binom{n}{k} p^k (1-p)^{n-k} \tag{2}$$

This means that if $Bin(k,n,P(S)) < c$, for some critical significance level c, then we can reject the null hypothesis that $P(A) = P(S)$, and can instead accept the alternative hypothesis, that there is a reliable predictive relationship between A and S. When $Bin(k,n,P(S)) < c$ the model thus marks the feature linking A with S after time t as a statistically reliable predictive feature.

We now consider the situation where we have a complex event made up of sub-events A and B (each of which may itself be made up of further subevents), and where this complex event *AthenB* is itself an antecedent of our consequent S. Here we take k to represent the number of times consequent S has occurred at time t after antecedent *AthenB* in the observed time series, and n to represent the number of times any event at all has occurred at time t after antecedent *AthenB* in the series. In this situation we test against three possible 'null hypotheses': that $P(S|AthenB) = P(S)$, as before; that $P(S) = P(S|A)$ (that the probability getting S after *AthenB* is simply the probability of getting S after A, $P(S|A)$); and that $P(S) = P(S|B)$ (that the probability getting S after *AthenB* is simply the probability of getting S after A, $P(S|B)$). These three 'null hypotheses' are tested using the binomial as before. If all three tests are significant, the model concludes that the complex feature *AthenB* is itself a distinct, statistically reliable predictor of the occurrence of S: given that *AthenB* has occurred, the probability of S is given by $P(S|AthenB)$ (rather than by $P(S), P(S|A)$ or $P(S|B)$). By contrast, if there is no additional relationship between the feature *AthenB* and S beyond that given by A, B, and the base rate $P(S)$ then we can say that A and B (or some combination of their subevents) are independent predictors of the consequence S.

Using this hypothesis-testing procedure our model identifies, for a given sequence of events, the set of independent, statistically reliable, features occurring in that sequence which predict a given event S at the next timestep. Following standard frequentist probability theory the overall predicted probability of S is calculated by 'ORing' these independent predictions

$$Pr(S|A_1,\ldots,A_n) = 1 - \prod_{i=1..n} (1 - P(S|A_i)) \tag{3}$$

to give an overall predicted probability for S occurring next in the sequence.

An example

We can give an example of the model's operation for our example sequence in (1). In that series there are 20 events in total, of which 5 are S (so $P(S) = 0.25$). There are 3 occurrences of B followed one step later by S, and 1 occurrence of B followed one step later by a different event. To test the hypothesis that the occurrence of B predicts the occurrence of S at the next time step, we calculate the probability of seeing 4 occurrences of B, 3 of which are followed by S, if S was occurring at its base rate probability of 0.25: $Bin(3,4,0.25) = 0.0469$. Since this probability is less than our significance criterion of $c = 0.05$ we conclude that there is a statistically reliable relationship between B and S. Similarly, there are 5 occurrences of A followed two steps later by S, and 1 occurrence of A followed two steps later by a different event. To test the hypothesis that the occurrence of A predicts the occurrence of S

two steps later, we calculate the probability of seeing 6 occurrences of A, 5 of which are followed by S, if S was occurring at its base rate probability of 0.25: $Bin(5,6,0.25) = 0.0004$. This probability is also less than our significance criterion of 0.05 and we conclude that there is a statistically reliable relationship between A and S.

We also consider the complex predictive feature *AthenB*. There are 3 occurrences of *AthenB* followed one step later by S, and 1 occurrence of *AthenB* followed one step later by a different event. Since we've seen 4 occurrences of B, 3 of which were immediately followed by S, we estimate $P(S|B) = 3/4 = 0.75$. Testing against the hypothesis that the observed relationship between *AthenB* and S is explained simply be the presence of B we calculate the binomial probability $Bin(3,4,0.75) = 0.42$, and we see that there is no evidence for an additional relationship between the *AthenB* and S beyond that given by B. Since we've seen 5 occurrences of A, 4 of which were immediately followed by S, we estimate $P(S|A) = 4/5 = 0.8$, and since $Bin(3,4,0.8) = 0.41$ we similarly see that there is no evidence for an additional relationship between the *AthenB* and S beyond that given by A. We can thus conclude that the complex event *AthenB* is not a reliable predictor of S; instead, the two simple events A and B are independent predictors of the occurrence of S, with A predicting S after 2 steps with $P(S|A) = 0.8$, and B predicting S after 1 step with $P(S|B) = 0.75$. If events A, B have just occurred, the probability of S occurring next is obtained by ORing the predictions of these two statistically reliable features, giving

$$P(S) = 1 - (1 - P(S|A))(1 - P(S|B)) = 1 - 0.2 \times 0.25 = 0.95$$

as the predicted probability of S occurring at the next timestep in the stream shown in (1).

Switching between multiple streams

In this section we apply this model to feature formation and prediction across multiple different streams of input. We assume a single Long Term Memory (*LTM*), as before. To deal with multiple streams of input we assume multiple separate *STM* stores, one for each stream, and with each *STM* storing the last N events that have occurred in that stream. The model uses the statistically reliable features in *LTM* to calculate predicted probabilities for the next event in each input stream. The predicted next event for input stream i is calculated by finding statistically reliable predictive features in *LTM* whose antecedent event has occurred in STM_i (that is, in the store of recent events from stream i), and then combining the predictions from those features as described above.

Prediction, for each stream, happens in parallel and is computationally cheap (there are typically very few statistically reliable predictive features whose antecedents are present in a given *STM*). Learning and feature formation, however, are computationally 'expensive' and so take place only for one particular stream: the stream that is the current focus of attention. The model forms new features, updates antecedent and consequent occurrence counts, and identifies statistically reliable predictive features just as before, but only for this focal stream.

As the overall goal of the model is to accurately predict its environment (to accurately predict event occurrence in all streams), the model must occasionally switch its focus of attention from one stream to another. Attentional switching is a form of decision making: the model must decide to switch attention away from one stream of input (and so cease any predictive learning from events in that stream) and towards another stream of input (so beginning the process of learning from events in that new stream). The overall goal of the model is to form statistically reliable predictive features; satisfaction of this goal requires a decision process where attention is switched towards streams where statistically reliable predictive features are more likely to be formed, and away from streams where such reliable features are less likely to be formed. As before, frequentist hypothesis testing gives a natural and normatively correct way to make such switching decisions.

Suppose we are considering forming a reliable feature *ApredictsS*, and have observed k instances of A followed by S, out of n occurrences of A overall. This feature will be judged reliable when the observed pattern of co-occurrence between A and S has a low probability of occurrence under the null hypothesis that A does not predict S (when $bin(k,n,P(S)) < c$). This means that the lower the value of this binomial expression $bin(k,n,P(S))$, the more likely it is that the null hypothesis is false and the there is some reliable relationship between A and S. In other words, if we have we have some feature for which $bin(k,n,p) > c$ (some feature which is not yet reliable), then the probability that this feature will become reliable is proportional to $1 - bin(k,n,p)$. More generally, if a given stream i contains a number of not-yet-reliable features with counts k_j and n_j and null hypothesis values p_j, then the overall probability of forming a reliable feature in that stream is obtained by ORing the individual probabilities of each of these features becoming reliable, as given in the expression

$$F(i) = 1 - \sum_{\substack{\text{j= not yet} \\ \text{reliable} \\ \text{feature in} \\ \text{stream i}}} bin(k_j, n_j, p_j) \qquad (4)$$

The greater the value of this expression $F(i)$ for a given stream i, the greater the probability that switching attention to that stream will lead to the formation of a new reliable predictive feature. The model uses these values $F(i)$ to guide switching; at each timestep the model calculates $F(i)$, the probability of constructing a new reliable feature, for all streams i including the current stream x, and identifies the stream *max* with the highest value. If $F(max) - F(x) > s$, where s is a switching decision criterion (if the chance of forming a new feature in stream *max* is s greater than the chance of forming a new feature in the current stream) then the model switches attention to stream *max*; otherwise attention remains in the current stream.

Testing the Model

We test our model via Markov Chain Monte Carlo simulation, as follows.

Any process producing a series of events can be represented by an nth order Markov chain (for some value of n). Such chains thus represent realistic generative models of sequential event occurrence. For each stream of information in our simulation, we construct a generative n-th Markov chain with $m = 4$ (4 distinct categorical events) and $n = 4$ (the current state consists of the last 4 events). There are $4^4 = 256$ distinct states in this chain, each with 4 transition probabilities. For each state these 4 transition probabilities are assigned random values, normalised so their sum for that state equals 1. Each stream thus represents a (randomly constructed) Markov chain process.

We use the Markov chain to generate a large sequence of categorical events from that stream. We first pick an 4 initial events at random, representing the initial state of the Markov Chain. We identify the 4 transition probabilities associated with that state, and choose one transition (one new event) at random, proportional to its transition probability from the current state in the Markov Chain. The selected event is added to our sequence of generated events. The new state of our Markov model now consists of the 4 most recent events (three previous events and the event that was just added to the series), and the cycle repeats.

The events for each stream are fed in parallel to our model, which forms statistically reliable predictive features, makes predictions for the next event to occur at each time step in each stream, and switches attention between streams as described above.

After an initial training phase we continue running the model and the Markov Chain generators for an additional test phase. We gather, at each time step of this phase, the model's predicted probability for each event in each stream, and whether or not that event actually occurred. We assess the model by gathering together all cases where the model predicts that an event will occur with probability in some range R. If the model is accurate, the proportion of those predicted events that did actually occur should be in or near the range R. For example: we gather together all cases where the model predicted some event with probability in the range $0.1 - 0.15$. If the model's predictions are accurate, then the predicted event should have actually occurred around $10\% - 15\%$ of the time; the probability (or proportion) of actual occurrence of the predicted event should be close to the range $0.1 - 0.15$.

Test 1: Learning from a single stream

Table 1 shows results obtained when running the model with a single stream of input (no switching between streams), for a 5000 timestep training phase (during which the model formed predictive features) followed by a 5000 timestep test phase (during which we gathered the model's predicted probabilities for the next event, at each timestep). This table gives the proportion of times the model's predicted event occurred, for prediction ranges from $0.05 - 0.10$ to $0.55 - 0.60$. As the table demonstrates, the model's predicted probabilities corresponded closely with the actual probability (or proportion) of occurrence of the predicted event.

Table 1: This table shows the number of times our model predicted that an event would occur with a probability that fell into a given range **R** (column 2), and of those predictions, the number of times when the predicted event actually occurred (column 3). If the model is making accurate predictions, the proportion of occurrence of the predicted event (the observed probability, column 4) should follow the range value R. The two values are highly correlated ($r = 0.99$) indicating that the model is predicting event probabilities accurately.

Predicted probability range **R**	Number of predictions in **R**	Predicted event occurred	Observed probability of predicted event
0.05 - 0.10	1393	193	0.14
0.10 - 0.15	2268	401	0.18
0.15 - 0.20	2600	516	0.19
0.20 - 0.25	3016	6463	0.21
0.25 - 0.30	3901	1094	0.28
0.30 - 0.35	3341	1005	0.3
0.35 - 0.40	1806	597	0.33
0.40 - 0.45	788	272	0.35
0.45 - 0.50	307	117	0.38
0.50 - 0.55	171	64	0.47
correlation with probability range **R**			0.99

As Table 1 also demonstrates, there is regression in the model's predictions: for low predicted probability ranges, observed event probabilities tend to be significantly higher than the probability range, while for high predicted probability ranges, observed event probabilities tend to be significantly lower than the probability range. This pattern of regression in turn implies that the models predicted probabilities are regressive towards the center of the probability scale, relative to true event probabilities Erev et al. (1994). This pattern of regression is just as assumed in Costello & Watts frequentist account of probabilistic reasoning (Costello and Watts, 2014, 2016, 2018a,b). This model thus provides a mechanistic implementation of that account, in which regression arises as a consequence of random sampling variation.

Test 2: Learning from a multiple streams

To test the hypothesis-testing model of switching given above, we test the model in the same Random Markov chain regime, but with 5 parallel streams of input, each with its own randomly initialised Markov Chain generator. Specifically, we compare learning under this model against learning under random switching, and learning under an alternative 'predic-

Table 2: Average observed probability of occurrence of predicted event for prediction range *R*, across all streams. Observed probabilities are calculated as in Table 1. Data is given for each switching mechanism, running the model for 5000 times/steps in each case. Both the 'Switch to max error' and the 'switch to form reliable features' switching methods gave predictions closely correlated with observed probability.

Range **R**	Observed probability of predicted event for predictions in range **R** (by Switching method)		
	Random switching	Switch to max. error	Form reliable features
0.05 - 0.10	0.17	0.00	0.14
0.10 - 0.15	0.18	0.16	0.17
0.15 - 0.20	0.17	0.17	0.19
0.20 - 0.25	0.17	0.19	0.21
0.25 - 0.30	0.2	0.22	0.25
0.30 - 0.35	0.34	0.32	0.3
0.35 - 0.40	0.41	0.39	0.34
0.40 - 0.45	0.48	0.45	0.39
0.45 - 0.50	0.56	0.49	0.39
0.50 - 0.55	0.49	0.61	0.42
correlation	0.90	0.98	0.99

tive coding' model of attentional switching, where we switch attention to the stream where errors in event prediction are highest.

Random switching As a baseline for comparison, we run the model with a fixed-length random-choice method for switching between streams. Under this switching method, the model will remain in a certain stream for 100 timesteps at a stretch; after each sequence of 100 timesteps has passed, the model will switch to a randomly selected other stream. Given that the learning model performs well in learning to predict events in a single stream, we expect that the model will perform relatively well in predicting events across multiple streams under this random switching regime.

Switching to minimise predictive error As an alternative for comparison, we run the model with a switching method designed to minimise predictive error. In the predictive coding view, a learning model makes predictions which are compared with outcomes: attention is driven towards locations where those predictions are incorrect (and so more learning is required) and away from locations where predictions are accurate (and so less learning is needed). In our model, predictive error in a given stream at a given time is simply equal to the predicted probability of the event that actually occurred in that time: if S is the event that actually occurs and the model's prediction probability for S was high, then there is little predictive error; if S occurs and the model's prediction probability of S was low, there is significant predictive error.

Table 3: Average correlation between observed and predicted event probability, obtained after learning with each switching method, for runs of different length (500,1000,5000,10000 and 50000 times/steps). Both the 'Switch to max error' and the 'switch to form reliable features' switching methods gave predictions that were more closely correlated with observed even occurrence rates, with the 'switch to form reliable features' approach giving the highest average correlation between observed and predicted probability.

Run size	Correlation between observed and predicted probability (by Switching method)		
	Random switching	Switch to max. error	Form reliable features
500	0.85	0.96	0.88
1000	0.89	0.97	0.96
5000	0.9	0.98	0.99
10000	0.9	0.98	0.99
50000	0.9	0.96	0.99

To implement a switching mechanism based on predictive error, we give a method which calculates, for each stream i, the average predicted probability of the last N events that occurred in this stream. The lower this average, the more prediction error in stream i. Letting $G(i)$ be equal to 1 minus the average prediction probability for stream i, the model uses a decision criterion s to guide switching; at each timestep the model calculates $G(i)$ for all streams i including the current stream x, and identifies the stream *max* with the highest value. If $G_{max} - G(x) > s$ (if prediction error in stream *max* is s greater than that in the current stream) then the model switches attention to stream *max*; otherwise attention remains in the current stream.

Results

We ran the model separately with each of the three different switching mechanisms described above, and with different number of training and test timesteps (500, 1000, 5000, 10000 and 50000 timesteps: in each case the training phase was the same length as the test phase). As before, we grouped the model's predictive probabilities into a series of 'buckets' or ranges **R** (so one bucket would hold all cases where the model predicted some event with a probability between 0.05 and 0.1, another would hold all cases where the model predicted some event with a probability between 0.1 and 0.15, and so on). For each bucket we counted the number of times the predicted event actually occurred. If the model is accurate, the proportion of those predicted events that did actually occur (the observed probability of occurrence of predicted events), for a given range R should be in or near the range R (the predicted probability for those events).

Table 2 shows the results of this analysis of model prediction for the 5000 timestep run with each of the three switching methods. This table gives the observed probability of events whose predicted probability fell in range R, in runs of the model with each of the 3 possible switching methods. The observed probabilities shown here are averages across predictions made in all 5 parallel streams of input, in a single run of the model (observed probabilities in each stream closely follow the pattern seen here, and closely follow the pattern seen in Table 1). As this table shows, there was a reliable correlation between the range in which the model predicted an event will occur and the actual rate or ratio of occurrence of that event, for all switching methods. This is expected: as we saw in the earlier 'single-stream' simulation tests, the model does well in learning to predict events accurately from observed event sequences, and so we would expect the model to learn to predict all streams relatively well no matter what attentional switching mechanism was being used.

The table also shows that both the 'switch to form reliable features' and the 'switch to maximum error' methods give results that matched observed probabilities much more closely than those given by the 'random switching' mechanism. These results demonstrate the contribution that effective attentional switching can make to prediction accuracy.

Table 3 shows the correlation between model predicted probabilities and observed event probabilities for each switching method, across increasing training and test time. As this table shows, correlation between predicted and observed probabilities increased with learning to some degree for all switching methods, but increased to very high correlation values for both the 'switch to max error' and the 'switch to form reliable features' methods. Taken together, these results demonstrate that this hypothesis-testing model forms features which reliably predict future events, and switches attention in a way that maximises formation of such features.

Conclusions

We have described a computational model of prediction, feature formation, and attentional switching. This model is interesting because it is based on the frequentist, hypothesis-testing approach to statistical reasoning, as opposed to the parameter-estimation approach currently popular in models of these cognitive processes. This model represents a computational implementation of a general account of probabilistic reasoning, also based on frequentist probability (Costello and Watts, 2014, 2016, 2018a). That account sees human probabilistic reasoning as being based on normatively correct processes, but subject to random variation or 'noise': that noise has systematic regressive effects, producing a range of biases in people's probabilistic judgement. The computational model implemented here demonstrates just the pattern of regression assumed in that more general account, and so inherits its account for those biases.

The frequentist, hypothesis-testing approach described here may usefully address two problems with the standard parameter-estimation approach to probabilistic prediction. These problems arise because the Bayesian approach to learning and prediction often require the specification of initial priors, in two separate ways. First, such models require initial assumptions as to the form of the generative model being used to predict data (assumptions which specify which features are 'available' for use in prediction, for example, and which features are not). The hypothesis-testing approach described here in some ways avoids this requirement, by providing a mechanism whereby predictive features are 'built' out of observed event. Second, such models require assumptions as to the initial values of parameters in that generative model (assumptions about the initial, prior, probability distribution associated with features in the generative model). The hypothesis-testing approach described here avoids this requirement also, because features are not identified as 'reliable' (and so do not contribute to predictions) until the events making up those features have been repeatedly observed (that is, until any initial 'prior' has been made irrelevant by repeated experience with the events in question). These points suggest that an integrated approach, combining the parameter-estimation and the hypothesis-testing perspectives, may prove insightful. Understanding the interplay between hypothesis testing and parameter estimation in human probabilistic reasoning is an important aim for future work.

Abstract

Many industry professionals are poorly calibrated, overestimating their ability to make accurate forecasts. Previous research has demonstrated that an individual's calibration in a specific domain can be improved through calibration training in that domain; however devising a training program for each specific domain within a field is laborious. A more efficient method would be if individuals from different disciplines could undertake the same general training and transfer the skills learnt to their respective, specific domains. This study investigated whether calibration training in a general domain was transferable to the specific domain of petroleum engineering. The results showed that, whilst the feedback training was effective within the general domain, there was only limited transfer to the specific domain. This is argued to be due to recognition failure, where the participants failed to recognise that the skill learnt through training in the general domain could be transferred to the specific domain.

Keywords: calibration; overconfidence; training; skill transfer.

Introduction

In technical disciplines and industries, individuals are required to provide range estimates, such as 80 percent confidence intervals, for uncertain parameters used in modeling and decision making (see, e.g., Capen, 1976). The accuracy of the individual's estimates can greatly influence decisions, with significant impacts on company bottom lines (see, e.g., Welsh, Begg & Bratvold, 2007). Calibration is the measure of how well individuals' estimates match real world outcomes (Lichtenstein, Fischhoff & Phillips, 1982). For example, if a weather forecaster makes multiple predictions of an 80% chance of rain, and on 80% of those occasions it does rain, they are well calibrated (for 80%), meaning they have a higher likelihood of providing more accurate estimates, which lead to more informed decisions.

Poor calibration in range estimation tasks can result from cognitive biases (e.g., biases from the anchoring and availability heuristics; Tversky & Kahneman, 1974) and is described as overprecision - one type of overconfidence bias (Moore & Healy, 2008). Overprecision describes the observation that individuals provide overly narrow ranges that do not represent their true degree of knowledge (Moore, 2008). The tendency for individuals to be over-precise in estimation has been demonstrated repeatedly (e.g., Soll & Klayman, 2004; Lichtenstein *et al.,* 1982) and seems to affect experts similarly to novices (McKenzie, Lierch & Yaniv, 2008). (NB, many studies use the term 'overconfidence' rather than overprecision and, in order to stay consistent with past literature, this will be done hereafter.)

Calibration Training

Past research has shown calibration can be improved through debiasing techniques, the most effective being domain-specific performance feedback training, wherein a subject receives timely feedback on the accuracy of their estimates within a particular area of knowledge (e.g., a field like petroleum engineering or meteorology; see, e.g.: Adams & Adams, 1958; Fischhoff, 1981) or learns this over an extended period in an amenable environment (see, e.g., Tetlock & Gardner, 2016). Whilst domain-specific training may be effective, devising training programs for numerous specific domains within a wider field or industry is laborious. For example, oil industry personnel include engineers and geoscientists across various specialties and a generalised training program, with calibration training learnt in a general domain and learnings transferred to specific domains, would be a more efficient method of improving calibration for a company employing these people.

Despite this previous research on domain-specific performance feedback training, it has seldom extended to the idea of creating generalised performance feedback training. Adams and Adams (1961) showed that training a subject's calibration in a series of tasks lead to an improvement in calibration in a separate task, an idea termed "generalisation"; although the degree of improvement in the untrained task was lower than in the trained task. Lichtenstein & Fischhoff (1980) showed that calibration training in a base task improved calibration in other, similar, tasks but not on dissimilar tasks, which was attributed to the subjects' inability to spontaneously relate the new task to the base task.

Similarly, Bornstein & Zickafoose (1999) demonstrated that individuals' confidence and accuracy were stable across domains of general knowledge and eyewitness memory, and that training using general knowledge questions reduced overconfidence in eyewitness memory. Improvements in calibration and resolution, however, were not observed, implying no improvement in accuracy. Thus, the above studies suggest that generalised training could be effective but, given inconsistent results and the fact that this was not their primary focus, the question of whether generalised training transfers to specific domains remains open.

An argument supporting the plausibility of the generalizable calibration training is analogical transfer,

where studies have shown transfer of knowledge (although not calibration training) across domains. Analogical transfer involves the use of a familiar problem to solve a novel problem of the same structure (Reeves, 1994). By identifying similarities in the structure of base and target problems, a subject can transfer the principles of the base problem to solve the target problem (Glick & Holyoak, 1983). Analogical transfer is argued to be the main method used to solve novel problems in all domains (Rumelhart, 1989). Given this, if the process of improving calibration training can be stripped down to its base structure, analogical transfer may facilitate transfer of calibration training across domains.

Whilst the structural similarities of the base and analogue problems are essential to facilitate transfer, they do not guarantee *recognition* of the relationship, which would prevent spontaneous transfer from one problem to the next without instructions or help (Day & Goldstone, 2012). Recognition failure is argued to occur largely as a result of dissimilar surface elements in the respective problems (Day, 2012) – for example, questions drawn from different domains - but may be improved by providing multiple base problems, as this will allow the subject to derive a more general analogy (Glick & Holyoak, 1983). Recognition failure may provide an explanation for the limitations in generalisation seen in Lichtenstein & Fischoff (1980), and Bornstein & Zickafoose (1999). Conversely, Adams and Adams (1958) achieved moderate generalization - using training in multiple, different tasks.

Given the paucity of research into the generalization of calibration training and the apparent absence of research connecting transferability of calibration training to analogical transfer, this paper has the opportunity to fill a distinct research gap. The research is further warranted by the paper's focus on the practical issue of how best to provide training. That is, seeing whether analogical transfer facilitates calibration training transferring to a new domain is both practically and theoretically interesting.

Aims

Given the unclear evidence in the literature, this paper's primary aim is to see whether generalised training in calibration can be developed to enable transfer of improved calibration to problems in a different, specific knowledge domain – specifically, petroleum engineering. This leads to two main hypotheses, as shown below:

H1: Calibration training will improve calibration within the domain in which the training is given.
H2: Improvements in calibration training will transfer to a new, specific domain.

It is important to highlight that the term "general domain" is used to describe a domain, unrelated to the specific domain, in which training will be given. The term generalized training thus refers to training applied in the general domain. In the context of a real world application it makes sense for the general domain selected to be general knowledge, as this domain is accessible to all, and is clearly separate from a subject's specific domain of expertise. A general domain in this context could, however, be any domain other than the participant's specific domain.

Methodology

Participants

Participants were 54 (15F and 39M) recent (n=7) and current (n=47) students of the Australian School of Petroleum, University of Adelaide, ranging in age from 18 to 35 (M=22, SD=3.0). Previous experience with calibration varied amongst the participants, with 31 participants having previously undertaken a course that taught calibration, and 15 who had not undertaken the course but who indicated (prior to the study) that they understood what calibration was and how it affects decision making. Participants entered a draw (1 in 6 chance) to win one of several $200 gift cards.

Materials

Testing materials consisted of three questionnaires - two general knowledge, and one in the domain of petroleum engineering - and a feedback/training package (described below). In this scenario, petroleum engineering is the specific domain, and general knowledge the general domain. Petroleum engineering was chosen to be specific domain due to the higher level of expertise in this field (compared to the general populace) shared by all participants. This higher level of experience is expected to elevate their knowledge of this domain above the participant's understanding of more general knowledge; separating it from the general domain. In terms of knowledge transfer, the assumption is that participants may think differently about their area of specialty than general knowledge questions and, thus, that recognition failure across the two domains may be more likely.

The first general knowledge test – designated "Pre-Training" - contained 30 questions; however, the number of questions in the remaining tests (designated "Post-Training" and "Domain Specific") were reduced to 20 each following participant feedback. The tests consisted of questions that had definite numerical answers and were sufficiently difficulty for participants not to simply know the true answer. An example of a question used in the general knowledge domain (i.e., the Pre-Training and Post-Training questionnaires) was "How many countries does the Nile River cross over?" For comparison, an example question used in the Domain Specific questionnaire was "How many times greater is the Young's Modulus of a stiff sandstone compared to the Young's Modulus of coal?"

In all cases, participants were asked to provide a low and a high value such that they were 80% confident their range would contain the true value. (The initial page of each test provided information about how to answer the questions, including an example question.)

While the second test is designated "Post-Training",

feedback materials were provided only to the Experimental Group. This was a pdf document, consisting of: information about calibration and overconfidence, a calibration curve illustrating the subject's under/overconfidence, a histogram showing the subject's calibration score relative to other participants, and a graphical depiction of the subject's confidence intervals, plotted against the corresponding true answers. These figures were intended to help participants understand the degree of overconfidence they had shown in the Pre-Training test. Each figure was accompanied by a short explanation, and information on methods for improving calibration on the remaining tests – including recognition of their current calibration in order to prompt them to give wider ranges.

Procedure

After registering their interest, participants were provided with links to access the Pre-Training questionnaire online (on SurveyMonkey) with instructions to complete each question by providing 80% confidence interval estimates. Based on the results of the Pre-Training questionnaire, participants were divided into two groups with similar levels of calibration. Feedback training was then distributed to the Experimental Group via email, at most two weeks after completing the test, with instructions to read and understand the material completely before continuing to the general knowledge Post-Training questionnaire). To test whether participants understood the feedback, a four-question quiz was given on the material covered in the training package. Participants who scored less than 3 out of 4 (2 participants) were moved from the Experimental Group to the control group, as it was adjudged they had not read the material and hence not received the feedback (NB – while recognizing that removing the participants may have been a more appropriate, this choice was made in light of the already small sample). Links to the Post-Training and the Domain Specific questionnaires were then provided to participants straight after the feedback training was distributed.

Improvements in calibration due to the feedback training were measured by comparing the Experimental Group's Post-Training and Domain Specific questionnaires to baselines of the Experimental Group's Pre-Training questionnaire and the Control Group's Post-Training and Domain Specific questionnaires. Comparisons were made under the assumption that the tests were of equal hardness and both groups were equally well calibrated. This yields measures of both the effectiveness of the feedback training and the transferability of the training across domains.

Results

Descriptive Statistics

Table 1 shows the demographics for the experimental and control groups while Figure 1 shows the mean calibration achieved by each group under each condition (with 95% CIs - recalling that questions asked for 80% ranges meaning numbers under 80% reflect overconfidence). Prior experience refers to the knowledge the participants had acquired regarding calibration and overconfidence prior to this experiment's start. Participants who answered 'Yes' indicated they had received prior training or learning regarding calibration and overconfidence. 'Partial' referred to participants who believed they understood the concepts at least vaguely. 'No' referred to the participants believing they had no understanding of calibration or overconfidence.

Table 1. Descriptive statistics for demographic variables including prior knowledge of calibration by group

	Overall	Control	Experimental
N	54	29	25
Gender (%)	M: 72 F:28	M: 72 F: 28	M: 72 F: 28
Age (SD)	22.0 (3.0)	22.7 (1.3)	22.3(4.2)
Prior Experience (%)	Yes: 57 Partial:28 No:15	Yes: 72 Partial:24 No: 4	Yes: 40 Partial:28 No:32

Looking at the figure, ones sees clear evidence of overconfidence across both groups and tests with none of the 95% CIs containing the 'expected' 0.8 proportion correct. The two groups seem to show similar levels of calibration on the Pre-Training questionnaire and Domain Specific Test but differ on the Post-Training questionnaire.

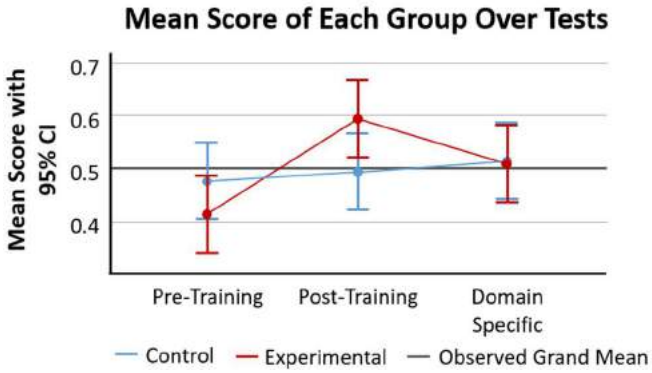

Figure 1. Calibration by group and condition.

Repeated Measures ANOVA

A Repeated Measures ANOVA was used in SPSS to test the two hypotheses simultaneously. Table 2 summarises the significant results from this.

As shown in Table 2, participant's calibration scores differ across the three tests and there is also an interaction between test and group – supporting the observations made above. Independent samples t-tests were used, post-hoc, to compare the mean calibration scores of the Control Group and Experimental Group for each of the three tests as shown in Table 3. The tests indicated that, for both the Pre-Training questionnaire and Domain Specific questionnaire, the difference observed in mean calibration score between the Experimental and Control Group was not significant. However, there was a significant difference in the means of the Experimental and Control Groups on the Post-Training

questionnaire with the mean calibration score of the Experimental Group noticeably higher. This supports Hypothesis 1 – that the feedback training improved the experimental group's Post-Training questionnaire results.

Table 2: Significant results of RM ANOVA

Comparison	F(df)	F-value	P-value
Questionnaire	F(2,104)	10.4	<0.001
Questionnaire*Group	F(2,104)	6.1	0.003

Table 3: Independent t-tests between Experimental and Control Group for each questionnaire.

Questionnaire	t(52)	p
Pre-Training	0.925	.359
Post-Training	-2.189	.033
Domain Specific	0.164	.871

Paired samples t-tests were used, post-hoc, to compare the relative difficulty of the tests, and to verify improvements in calibration observed in the independent samples t-tests. The tests, shown in Table 4, indicated that differences in the means between all the Control Group's tests were non-significant. That is, the tests were equally difficult for the Control group. Conversely, the tests indicated that differences in the means between all Experimental Group tests were significant – as shown in Table 5.

Table 4: Paired t-tests between each questionnaire for the Control Group.

Comparison	t(28)	P
Pre-Training– Post-Training	0.852	.402
Post-Training– Domain Specific	0.627	.536
Domain Specific– Pre-Training	1.315	.199

Table 5: Paired t-tests between each questionnaire for the Experimental Group.

Comparison	t(24)	p
Pre-Training– Post-Training	-5.368	0.000
Post-Training– Domain Specific	3.633	0.001
Domain Specific– Pre-Training	-2.439	0.023

The results of the ANOVA and t-tests, along with observation of Figure 1, suggest no significant difference in calibration scores in the Control Group – as would be expected. However, the figure and analyses show that calibration score for the Post-Training questionnaire of the Experimental Group is significantly higher than both the Experimental Group's Pre-Training questionnaire, and the Control Group's Post-Training questionnaire, which is taken as evidence that feedback training improved calibration.

The near-identical scores of the Control and Experimental groups on the Domain Specific questionnaire, however, suggests this benefit did not transfer to the new domain. That is, despite all tests using the same question format (80% confidence intervals), the change in domain was seemingly sufficient to prevent the training transferring, meaning Hypothesis 2 was not supported. A caution to this interpretation, however, is the observation that the Experimental Group's calibration in the Domain-Specific questionnaire was significantly higher than in the Pre-Training questionnaire, but statistically no different to Control Group's calibration in the Domain-Specific questionnaire. This discrepancy is explored further, below.

Discussion

Experimental Findings

Baseline Measure

The performance on the Pre-Training questionnaire between the Experimental Group and the Control Group suggested both groups were similarly calibrated, indicating that the method for dividing participants into two groups was successful and that the control group can, justifiably, be compared to the experimental group as a baseline.

The consistent results of the Control Group across all tests similarly showed that each test was of similar difficulty, justifying comparisons between tests within a group.

Feedback Effectiveness

The comparison between the mean calibration scores of the Pre-Training questionnaire and Post-Training questionnaire of the Experimental Group shows that the feedback was effective - to a degree. This was reinforced through the comparison of the Experimental Group and the Control Group for the Post-Training questionnaire, which also found a significant result. Between the Pre-Training questionnaire and the Post-Training questionnaire for the Experimental Group, calibration scores improved by 17% (from 42% to 59%). This improvement in calibration was expected, as a wealth of previous research has shown that performance feedback training improves a subject's calibration (Adams & Adams, 1961; Lichtenstein & Fischhoff, 1980; Moore et al., 2017; Stone & Opel, 2000).

Transfer

As noted above, the comparison of the Experimental and the Control Groups on the Domain-Specific Test showed no significant difference, suggesting the Experimental Group was *not* able to transfer their knowledge of calibration to a different domain and thus arguing for recognition failure.

Comparing the Experimental Group's Pre-Training and Domain Specific results, however, showed a significant result driven by an approximately 8% increase (from 42% to 50%) in the Experimental group's mean calibration score. Considering the two tests were of similar difficulty – according to the baseline measure from the Control group - the significant increase in calibration suggests participants *were* able to, at least partially, transfer their skills from the general knowledge domain to the specific domain of petroleum engineering and that this is being obscured in the analyses above by the Experimental Group's slightly lower scores on the Pre-Training questionnaire.

To quantify the extent of the transfer, the Post-Training

questionnaire was compared to the Domain-Specific for the Experimental Group. This showed an ~10% decrease in mean calibration score from the Post-Training questionnaire to the Domain-Specific Test (60% compared to 50%, respectively). This significant difference suggests participants were not able to transfer all of what they had learnt about improving calibration to the new domain. Looking solely at the Experimental group's results in Figure 1 suggests that about half of the improvement seen following training transferred to the Domain Specific Test.

This, of course, contradicts the previous results and the discrepancy between these means that no strong conclusion can be drawn regarding whether the transfer of knowledge between domains did or did not occur. However, one conclusion that can be drawn is that, if the transfer occurred, it is well under 100%, in agreement with Adams & Adams (1961). This is also reminiscent of Glick & Holyoak's (1983) work on analogical transfer, where they argue that incomplete transfer may be due to recognition failure; that is, a failure to recognise the similarities in the problem structure and, hence, to recognise that the skills used successfully in one problem are applicable to the other.

While the question formats used in the three tests herein were identical – asking for 80% confidence intervals - it is possible that having experience in a domain evokes a different thought process to that which may be used to solve general knowledge type questions - reminiscent of knowledge partitioning (Lewandowsky & Kirsner, 2000) - and suggesting that individuals' domain specific knowledge could be separated from their general knowledge and thus processes used to access one may not work for another.

This may have caused the participants to not recognise the similar structure between the general knowledge and specific domain type questions. That is, participants may have simply not recognised that their calibration training should also be applied to the specific-domain questions.

External Factors

Initial Calibration and prior knowledge

Simple comparisons showed participants, regardless of their stated prior experience with calibration (trained, aware or unaware) had similar calibration, and similar improvement after feedback. This is likely due to participants with prior knowledge not being able to apply the knowledge they learnt previously when setting confidence intervals. These results suggest that participants with previous experience with calibration were unsuccessful in reducing their overconfidence long-term, likely due to the fact they did not receive frequent calibration training or regularly practice calibration – as has been observed in previous research (see, e.g., Welsh, Bratvold & Begg, 2005).

Caveats

Sample Size

The sample size was smaller than hoped, as a result of strict time constraints for the project, meaning that statistical power is low. A larger sample might, for example, have helped determine to what extent transfer was actually occurring or whether the effect is an artefact of differences between groups and tests aligning coincidentally. As noted above, the low sample size also resulted in the decision to move participants from the experimental group and control group.

Expertise

The type of questions asked throughout the Domain-Specific Test were designed to relate to the expertise of the participants. As petroleum engineering students, participants have increased knowledge about the petroleum engineering field, but would not be classified as 'experts'. This is doubly true, as the sample includes student participants from different year levels and thus with differing amounts of learning within the field. This concern is somewhat alleviated by the fact that the majority of participants were final year students or recent graduates, who could be expected to have similar levels of understanding of the field (which might, in fact, be less true of professionals further into their careers who tend to specialise into a sub-field). The selection of students of all year levels as the sample, however, meant that, despite all of the questions being related to the oil and gas industry, they had to be kept general enough that all participants could reasonably understand what they referred to – rather than being specific, technical questions that only a fully trained petroleum engineer could understand. That is, while the questions were *about* petroleum engineering, they did not truly test fundamental skills learnt by the participants. Questions more central to the petroleum engineering domain would provide a more accurate measure of knowledge transfer across domains but would require an expert sample.

Testing Conditions

As noted, all tests were online, meaning participants were unable to ask clarifying questions if they did not understand the point of the test - or may have approached the test in unanticipated ways. Although instructions indicated that questions should take no longer than 30 seconds, many participants spent much longer than that on some questions, which may have repercussions on the consistency of the answers. Future work could, therefore, be conducted face to face, or more time be spent explaining the purpose of the test, possibly with the aid of a video. This would make it easier to see if participants are engaged in the test and answering the questions as expected. Conducting training feedback sessions in person could also be beneficial in ensuring that the main points of the training session are highlighted to the participant, so that they can better learn how to improve their calibration for future tests.

Questions

Another concern related to the amount of time available to pilot the general knowledge questions with people similar to the expected participants. As noted elsewhere, the study was conducted as part of the student authors' coursework and, as

such, had to be completed within semester, meaning that time for piloting was limited. While efforts were made to include a wide variety of questions participant feedback indicated there were several questions where some participants did not understand what the question was asking, and hence had no point of reference.

Future Research

As noted in the acknowledgements, this experiment was conducted as part of the first three authors' final-year, undergraduate, research project. As such, there were strict time and budgetary constraints which dictated the approach taken and resulted in unavoidable limitations. Given this, and the equivocal evidence observed herein, larger, more rigorous follow-ups are warranted.

Analogical Transfer

The results from this paper could be extended to determine the true extent at which analogical transfer of calibration training can occur. As shown by Glick & Holyoak(1983), one method to overcome recognition failure and improve transfer is to provide hints about applying the solution of the base problem to solve the analogue problem. In terms of this study, providing hints could simply entail telling participants to apply the training to the specific domain. The purpose of these hints is to remind the participants to use the knowledge and skills learnt from the training on the Post-Training questionnaires, in order to improve calibration. Directly reminding them to incorporate these skills when providing their ranges, would show how much of the training could be transferred in optimal conditions.

Individual Differences

An interesting approach would be to examine responses to a larger study of this type at an individual level – in order to determine whether the group-level improvements are driven by the majority of people improving a small amount or a smaller number of people showing a large improvement in calibration. Which of these better represents the true state of nature has implications for how to improve training processes. If the first, one might consider that better, or more intensive training is required to get participants closer to optimal calibration. If some participants are reaching optimal calibration with the current training, by comparison, the characteristics of or explanations provided by those participants might help improve current training to assist others in achieving similar benefits.

Initial Calibration

The results from this experiment suggested that having prior knowledge of calibration did not influence the participants calibration estimates at any point during the test (in line with previous research from Welsh et al, 2005). An extension to the research could thus conduct a second, Post-Training questionnaire at a later date to determine if the effectiveness of the feedback training remained over time for participants who either had or had not been provided continuing feedback aimed at maintaining better calibration. This could assist in determining how durable any benefits of training are and, thus, how often they need to be reinforced.

Conclusion

Participants in this experiment showed levels of miscalibration in the form of overconfidence (overprecision) consistent with previous literature. The Control group, who received no feedback on their performance, showed very similar levels of overconfidence across the three tests with around half of their (theoretically) 80% interval estimates containing the true value on each test – suggesting that they were appropriately matched for difficulty and that the participants degree of expertise within a specific domain did not alter their degree of calibration relative to the general knowledge domain. Additionally, no benefit was seen for participants who reported having prior experience or knowledge of calibration and overconfidence.

The feedback training provided to participants in the Experimental group proved effective, increasing the number of their ranges containing the true value from 42% to 60%. Whether this benefit transferred to the Domain-Specific Test, however, was less clear, with different analyses pointing in different directions. The Experimental group did not significantly outperform the control group on the Domain Specific Test (in fact, they performed very slightly but not significantly worse). This may, however, reflect their having started from a somewhat lower base – as their Domain Specific Test results *were* significantly better than their own Pre-Training questionnaire results.

Given this conflict, the strongest conclusion that can be drawn is that, while it seems that transfer may have occurred, it was less than complete and that future research is needed to more accurately determine the bounds on the efficiency of transfer of expertise in calibration across domains.

Efficient Data Compression Leads to Categorical Bias in Perception and Perceptual Memory

Christopher J. Bates (cjbates@ur.rochester.edu)

Robert A. Jacobs (rjacobs@ur.rochester.edu)
Department of Brain and Cognitive Sciences, University of Rochester
Rochester, NY

Abstract

Efficient data compression is essential for capacity-limited systems, such as biological memory. We hypothesize that the need for efficient data compression shapes biological perception and perceptual memory in many of the same ways that it shapes engineered systems. If true, then the tools that engineers use to analyze and design systems, namely rate-distortion theory (RDT), can profitably be used to understand perception and memory. To date, researchers have used deep neural networks to approximately implement RDT in high-dimensional spaces, but these implementations have been limited to tasks in which the sole goal is compression with respect to reconstruction error. Here, we introduce a new deep neural network architecture that approximately implements RDT in a task-general manner. An important property of our architecture is that it is trained "end-to-end", operating on raw perceptual input (e.g., pixels) rather than an intermediate level of abstraction, as is the case with most psychological models. We demonstrate that our framework can mimick categorical biases in perception and perceptual memory in several ways, and thus generates specific hypotheses that can be tested empirically in future work.

Keywords: Perception; memory; deep neural networks; rate-distortion theory; categorical bias

Introduction

Biological cognitive systems are not infinite. For instance, it is commonly hypothesized that people have finite attentional and memory resources, and that these constraints limit what people can process and remember. In this regard, biological systems resemble engineered systems which are also capacity-limited. For any capacity-limited system, biological or engineered, efficient data compression is paramount. After all, a capacity-limited system attempting to achieve its goals should maximize the amount of information that it processes and stores, and this can be accomplished through efficient data compression. Of course, this raises the question of what one means by "efficient".

In engineered systems, resources (e.g., bandwidth, finite memory) are limited, and thus system designers allocate these resources so as to maximize a system's performance, a process referred to as "bit allocation" (Gersho & Gray, 1992). Consider the design of digital compression algorithms. For example, file sizes can be reduced by a substantial factor using JPEG (image) or MP3 (audio) compression while still maintaining enough fidelity for most applications. When thinking about how to best perform bit-allocation, engineers must consider several questions. Which data items are frequent, and thus should be encoded with short digital codes, and which data items are infrequent, and thus can be assigned longer codes? Which aspects of data items are important to task performance, and thus should be encoded with high fidelity via long codes, and which aspects are less task relevant, and thus can be encoded with lower fidelity via short codes? For example, frequencies beyond the range of the human ear are less important when compressing audio waveforms with MP3, and can be stored with less fidelity. To address these questions, engineers have developed rate-distortion theory (RDT), a sophisticated mathematical formalism based on information theory (Cover & Thomas, 1991).

Our goal in this paper is two-fold. First, although exact methods already exist for RDT analysis in low-dimensional spaces, approximate methods are needed for high-dimensional spaces. To date, researchers have used deep neural networks to approximately implement RDT in high-dimensional spaces, but these implementations have been limited to tasks in which the sole goal is data compression with respect to reconstruction error (e.g. Ballé, Laparra, & Simoncelli, 2016). An innovation of the research presented here is that we introduce a new deep neural network architecture that approximately implements RDT in a task-general manner. That is, our architecture discovers good data compressions even when the data will be used for regression, classification, recognition, or other tasks. An important property of our model is that it is trained "end-to-end", operating on raw perceptual input (e.g., pixels) rather than intermediate levels of abstraction (e.g., orientation, texture, shape), as is the case with most psychological models. In this way, our framework represents an early step toward scaling up models of perception and perceptual memory toward levels of complexity faced in real-world situations.

Our second goal is to present one important and previously uninvestigated implication of efficient data compression which can be compared against empirical phenomena in perception and perceptual memory. While in this paper we present only a qualitative comparison, future work can focus on more rigorous, empirical evaluations of the hypotheses that our modeling framework generates. Specifically, we examine the phenomenon of categorical bias, which we explain in more detail below.

Principles of Efficient Data Compression and their Implications for Perception and Memory

This section examines important principles and implications of efficient data compression. We focus on one implication in particular, categorical bias, and draw a connection between

categorical bias in efficient compression and that found in perceptual memory.

All physically-realized systems are finite, and thus have finite limits on processing and storage capacities. For people, this implies that faulty perception and memory—what engineers refer to as "lossy compression"—is inevitable. If perception and memory cannot be perfect, can they at least be as good as possible given their capacity limits? This question has been explored in the context of low-level perception ("efficient coding"; see Barlow, 1961; Simoncelli & Olshausen, 2001), and researchers have found that low-level perceptual representations tend to be highly efficient with respect to the statistics of the environment.

Here, we focus on explaining higher-level sensory perception from the standpoint of efficient data compression. As we show in our results and analyses below, abstraction and categorization may be data-efficient strategies in many capacity-limited situations. There is strong empirical evidence that people employ these strategies in memory. For instance, research suggests visual working memory (VWM) avails of a wide array of summary statistics (e.g. Brady & Tenenbaum, 2013; Brady, Konkle, & Alvarez, 2009; Sims, 2016; Mathy & Feldman, 2012). In addition, various forms of abstract conceptual structures have been studied extensively in the context of long-term memory (LTM), such as schemas and scripts (Bartlett & Burt, 1933; Schank & Abelson, 1977).

A central assumption for our analysis below on categorical bias is that memory traces decay. Evidence for decay can be found in many experiments, including iconic visual memory and VWM (e.g. Sperling, 1960; Luck, 2008). We account for the decay of individual memory traces by hypothesizing that memory is biased toward representing recent information because recent information tends to be more task-relevant (Anderson, 1991). Consequently, memory engages in a form of adaptive bit-allocation in which fewer resources are devoted to older perceptual traces (suggesting that these traces are recoded in more compact and abstract ways over time) until so few resources are devoted to a trace that, effectively, the trace has fully decayed. This process frees up resources that can then be used to encode new information.

We propose that this reallocation happens both across and within memory subsystems. Within a subsystem (e.g. visual short-term memory), an individual trace tends to lose information over time to decay. Across systems, decay rates for individual traces vary. First, at stimulus offset, highly-detailed sensory information decays very rapidly. Next, sensory (e.g. iconic) memory representations are less detailed (more categorical) and decay more slowly. Short-term or working memory representations contain still less detail about the stimulus, are even more categorical and abstract, and decay more slowly than those of sensory memory. Finally, LTM contains the least amount of detail about the originally-observed stimulus, is the most categorical and abstract, and decays slowest.

For a well-designed system with limited storage, making decay rates proportional to information content is an efficient strategy—abstract representations (e.g those found in LTM) have low information content, and therefore can be retained "cheaply". As an analogy, imagine you are trying to make room on a full hard drive. It would be efficient to first remove large video files, before worrying about much smaller text files. Because highly abstract traces can be retained cheaply, LTM can accrue and store a large amount of traces over time. By contrast, working or sensory memory subsystems contain more detailed representations, and therefore cannot keep as many traces concurrently.

Consistent with our theory, experimental findings indicate that nearly all subsystems are influenced by a mix of perceptual and conceptual factors, but that the balance tilts more in favor of the conceptual the longer something is held in memory. Irwin (1991, 1992) demonstrated that iconic memory maintained more visual detail about an array of dots than VWM, whereas VWM representations seemed to be more abstract, coding information in a way that was robust to spatial translations. Brady and Alvarez (2011) found that observers' memories for the size of an object are systematically biased toward the mean of the object's category (see also Hemmer & Steyvers, 2009). Several experiments also indicate that memories for spatial location are biased toward spatial "prototypes" (Huttenlocher, Hedges, Corrigan, & Crawford, 2004; Huttenlocher, Hedges, & Duncan, 1991; Huttenlocher, Newcombe, & Sandberg, 1994). VWM representations not only encode "gist" or summary statistics (Oliva, 2005) over low-level visual features and textures, they also summarize high-level constructs such as the emotion of a face (Haberman & Whitney, 2007, 2009).

Visual LTM representations appear to be even more abstract. Konkle, Brady, Alvarez, and Oliva (2010) performed a visual LTM experiment in which subjects studied images of real-world objects drawn from different categories. Subjects studied between one and 16 exemplars per category, and later performed memory recognition test trials. It was found that as the number of exemplars from a category increased during study, memory performance decreased. Further analysis revealed that the conceptual distinctiveness of a category—low when category exemplars belong to the same subcategories and high when exemplars belong to different subcategories—is correlated with visual LTM performance but perceptual distinctiveness is not. The authors concluded that "observers' capacity to remember visual information in long-term memory depends more on conceptual structure than perceptual distinctiveness" (Konkle et al., 2010, p. 558).

To understand how abstraction results from efficient compression, it is important to understand the two central principles of RDT, which we name the "Prior Knowledge Principle" and the "Task-Dependency Principle". Now, we will briefly explain each principle and intuitively how each one can give rise independently to categorical representations.

Prior Knowledge Principle: Prior or domain knowledge is crucial to designing information-efficient systems. Accurate knowledge of stimulus statistics allows an agent to form

efficient representational codes given a limited capacity. To code a stimulus efficiently, a code must be designed using knowledge of the statistics of the to-be-coded items. Consider Morse code which is an algorithm for encoding letters of the alphabet as binary signals ("dots" and "dashes"). The designers of this code realized that they could increase its efficiency (i.e., decrease average code length) using knowledge of letter frequencies by assigning the shortest binary sequences to the most frequently transmitted letters. The more "peaky" the frequency of letters, the less information messages convey, and the shorter codes can be on average. For example, if 90% of the English language consisted of the letter 'e', then messages could be coded much more compactly on average than with real English in which e's are not nearly so frequent.

In many domains, the stimulus prior (i.e. distribution over stimuli) is highly peaked around several values. For example, if the set of stimuli consists of many photographs of various apples and bananas, this would constitute two different peaks (or modes) in the space of images around apples and bananas respectively. Efficient data compression predicts that these types of "modal" stimulus distributions will result in categorical bias. Specifically, as memory capacity is decreased (e.g. when decaying from short-term to LTM), representations should be attracted to one of the two modes, resulting in categorical bias.

Task-Dependency Principle: In addition to prior knowledge, for a code to be optimal, it must also take into account the current behavioral goals (or task) of an agent. Codes should allocate resources according to how an agent will use the encoded information. In particular, if it is costly to an agent to confuse stimulus values x and y, then codes should be designed so that these values are easily discriminated, even if this means a loss of precision for other discriminations.

As was the case with prior knowledge, efficient data compression predicts that certain behavioral goals will result in categorical bias. Namely, if effective behavior depends on making category distinctions, then when capacity is decreased, efficient codes should become more biased toward category prototypes, even when the stimulus prior is uniform. Thus, efficient data compression produces two distinct hypotheses for the existence of categorical bias. Either it results from modalities in the stimulus prior or from behavioral goals. These hypotheses may be evaluated in future work.

In the next section, we present the RDT formalism in order to make the prior knowledge and task-dependency principles mathematically precise. Then, we will demonstrate in simulation that each principle can indeed give rise to categorical bias.

Overview of Rate-Distortion Theory

Information theory addresses the problem of how to send a message over a noisy channel (e.g., a telephone wire) as quickly as possible without losing too much information. How much information can be sent per unit time (or per symbol) is the information 'rate' of a channel. Rate-distortion theory focuses on the case when the capacity (or rate) is too low to send the signal perfectly for a particular application (e.g., trying to hold a video conference with a slow internet connection). In this situation, one's goal is to design a channel that minimizes the average cost-weighted error (or distortion) in transmission, subject to the capacity limitation. Crucially, the optimization depends on two factors: (i) the prior distribution over inputs to the channel, and (ii) how the transmitted signal will be used after transmission. The first factor is important because common inputs should be transmitted with greater fidelity than uncommon inputs. The second factor is important because, depending on the application, some kinds of errors may be more costly than others.

Whereas much of the cognitive science literature uses the number of remembered "items" as a measure of memory capacity, information theory defines channel capacity as the mutual information between the input distribution and the output distribution. That is, if you know what comes out of a channel, how much information does that give you about what was inserted into the channel? If mutual information is high (high capacity), then the outputs tell you a lot about the inputs, but if it is low (low capacity), then the channel does not transmit as much information. The mutual information $I(x;y)$ for discrete random variables x and y is given by:

$$I(x;y) = \sum_{x,y} p(x,y) \log \frac{p(x,y)}{p(x)\ p(y)}. \tag{1}$$

In the case of memory, sensory stimuli (e.g., pixel values) can be regarded as inputs to a channel, and neural codes are the channel's outputs (e.g., firing rates, changes to synaptic weights). The capacity of memory is the mutual information between the stimulus distribution and the neural code.

RDT seeks to find the conditional probability distribution of channel outputs (neural codes, denoted $\hat{x}$) given inputs (sensory stimuli, denoted x) that minimizes an error or distortion function $d(x,\hat{x})$ without exceeding an upper limit C on mutual information. For example, the distortion could be defined as the squared difference between the channel input and output, $(x-\hat{x})^2$. Mathematically, this minimization is the following constrained optimization problem:

$$\begin{aligned} Q^* = \underset{p(\hat{x}|x)}{\arg\min} & \sum_{x,\hat{x}} p(x)\ p(\hat{x}|x)\ d(x,\hat{x}) \\ & \text{subject to } I(x;\hat{x}) \leq C \end{aligned} \tag{2}$$

where Q^* is the optimal channel distribution.

Rate-Distortion Theory and Categorical Bias

Above, we described abstract or categorical representations as being an efficient strategy for compression, and pointed to evidence that human cognition makes use of this strategy. Furthermore, we noted that as the average information-content of memory traces decreases, the degree of categorical bias increases. We suggested that LTM might be viewed as using highly-compressed and categorical compressions, whereas perception uses less-compressed, less-categorical

compressions. For example, suppose you view an image of an apple. At short delays, you may remember that it was a red apple, at a longer delay, you may only remember that it was an apple, and perhaps at still longer delays, you may only remember that you saw a fruit. At long delays, categorical bias is large, because your memory for one apple is very similar to your memory for a different apple. Here, we demonstrate this phenomenon in simulation. We use a toy, one-dimensional domain in which it is possible to find the optimal lossy compression. In experiments below, we use approximate methods to extend this result to high-dimensional spaces, closer to the level of complexity that real brains must cope with.

As mentioned above, lossy compression can produce categorical bias when the stimulus prior is modal or when the loss function penalizes miscategorizations. Figure 1 demonstrates categorical bias effects in each case for unidimensional stimuli. The top panel (A) shows the case of a modal prior and squared error loss for d, while the bottom panel (B) shows the case of a uniform prior and categorical loss for d. According to the categorical loss, there is high cost to misremembering a stimulus that belongs to category A as one that belongs to category B, but low cost to misremembering a stimulus as another member of the same category. For example, consider plants that can be grouped as edible or poisonous. Misremembering a poisonous plant as an edible plant has high cost, whereas misremembering an edible plant as a different edible plant has low cost.

Figure 1A and B illustrate that channels optimized for a modal prior or a categorical loss, respectively, yield strong categorical bias at low capacity, but little at higher capacity. In the top rows of each (low capacity), $p(\hat{x}|x)$ is nearly identical for all values of $x = x_0$ within a category, but differs for two x_0 from different categories. In both A and B, categorical bias arises because values closer to the modes are "safer" when capacity is low and transmission errors are likely. On the other hand, at high capacity (bottom rows), $p(\hat{x}|x)$ is tightly peaked around the true input x_0 in both cases. In experiments below, for brevity we only elicit categorical bias via the distortion function (panel B).

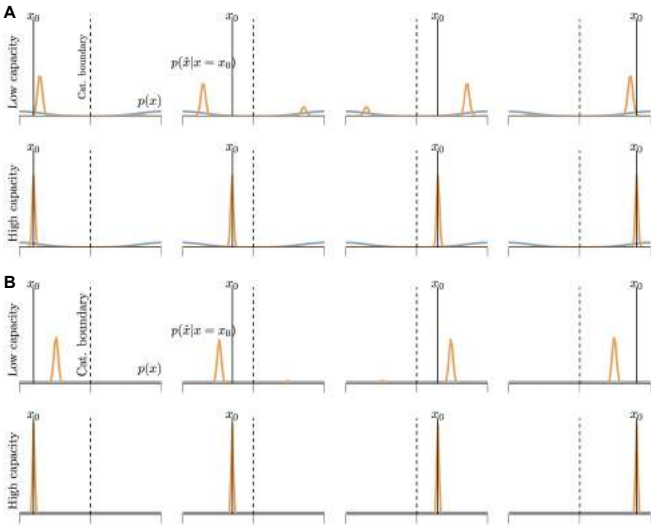

Figure 1: Illustration of how categorical bias can be explained via the prior (A) or the distortion function d (B). Horizontal axes plot stimulus space, vertical axes plot probability, dotted vertical line is the category boundary, solid vertical line marks the true stimulus value ($x = x_0$), and orange line plots output distribution $p(\hat{x}|x)$. Input distribution $p(x)$ is given by the blue line. Top and bottom rows in A and B show results for low and high capacity channels, respectively. In A, distortion function was squared error and $p(x)$ was bimodal. In B, distortion function was a weighted sum between a pure categorical loss and a square-error loss with weights of 1 and 0.001, respectively, and $p(x)$ was uniform.

RDT Neural Networks

Although RDT can be implemented exactly to find optimal compressions for problems using low-dimensional stimuli, it is too computationally expensive to be used with high-dimensional stimuli. Therefore, researchers have considered approximate implementations based on deep neural networks. To date, however, these implementations have been limited to tasks in which the sole goal is data (e.g., image) compression (e.g. Ballé et al., 2016). In this section, we introduce a new deep neural network architecture that approximately implements RDT in a task-general manner. In other words, our architecture discovers good data compressions even when the data will be used for regression, classification, recognition, or other tasks. Like previous RDT neural network implementations, our architecture is trained "end-to-end", meaning that it operates on raw sensory input (e.g., pixel values) rather than intermediate levels of abstraction (e.g., orientation, texture, shape), as is the case with most psychological models. The combination of end-to-end operation and task generality represents an important step toward scaling up models of perception and perceptual memory toward levels of complexity faced in real-world situations.

Rate-distortion (RD) Autoencoders: A key component of our models is the "autoencoder", parameterized models (e.g., neural networks) that map inputs to themselves subject to an information bottleneck. This bottleneck "forces" a model to find a more abstract, latent representation of the data. These abstract representations can then be used in subsequent tasks. Conventional neural network autoencoders consist of one or more 'encoder' layers, a middle 'latent' layer, and one or more 'decoder' layers. The latent layer typically has many fewer units than there are input dimensions, effectively reducing the dimensionality of the representation.

RD autoencoders differ from traditional autoencoders in that (i) they have a stochastic latent layer, and therefore a clear probabilistic interpretation, and (ii) a regularization term is added to the training objective function which acts to constrain how much information is represented in the latent units. If the coefficient on this term is high, then the network will seek a highly compressed latent representation. In our experiments, the latent unit activations are our models' "memory" of an input. Several variants of the rate-distortion autoencoder have been proposed, but here we choose the β-

Variational Autoencoder (β-VAE; Alemi et al., 2018).

Architecture: The models for all experiments presented here are defined by deep feedforward neural networks. Our general architecture (see Figure 2) consists of two modules: a β-VAE autoencoder and a decision module. The decision module takes as input the memory code (i.e., the activations of the latent units in the autoencoder) and optionally a task-related "probe" image, and outputs a decision variable. For example, in a change-detection task, the input to the autoencoder would be a target image, the input to the decision module would be a probe image and memory representation of the target, and the output of the decision module would be the probability that the probe is different than the target. Correspondingly, the training objective function has three terms, which can all be weighted differently to achieve different tradeoffs, corresponding to: (1) the distortion (or error) of the autoencoder's image reconstruction, (2) the information capacity of the memory representation, and (3) the decision error. Crucially, we can manipulate what kind of information is encoded in memory by varying how much reconstruction error is weighted relative to decision error during training, as well as how one kind of decision error is weighted relative to others (e.g., up-weighting errors along one stimulus dimension relative to other dimensions).

Implementation Details: Specific architectural choices for both experiments discussed below were standard within the neural network literature, and no specific fine-tuning was required to produce our results. In Experiment 1, we chose standard fully-connected layers with 'tanh' activation functions. The encoder and decoder both had two hidden layers, and the decision module had one. The latent layer and all hidden layers had 500 units. However, results were relatively insensitive to the choices of number of hidden units and layers, as long as the number of units was large. In Experiment 2, the encoder was composed of four 3×3 convolutional layers (32, 64, 64, and 64 filters for each layer, respectively), followed by a fully-connected layer with 1000 units. There were 1000 latent (memory) units. The decoder mirrored the encoder, except that convolutional layers were replaced with standard convolution-transpose layers. All hidden units used rectified-linear activations (ReLU). Again, a range of architectural choices can produce similar results. Finally, the decision module output was a single sigmoidal unit in Experiment 1, while in Experiment 2, the output was a softmax layer with one output unit for each of the three categories. All networks were trained with the "Adam" optimization algorithm.

Training sets: For Experiment 1, the dataset consists of images of an artificial plant-like object which we varied along two dimensions: leaf width and leaf angle. Images were converted to gray scale, down-sampled, and cropped to a size of 120×120 pixels. The space was discretized to 100 values along each dimension, for a total of 10,000 unique stimuli.

For Experiment 2, we used the Fruits-360 database[1]. We chose a subset of the classes to train on, specifically apples, tomatoes, and bananas. We augmented the dataset during training by randomly zooming and cropping inputs, as well as flipping the inputs horizontally at random. All images were resized to 112×112 pixels.

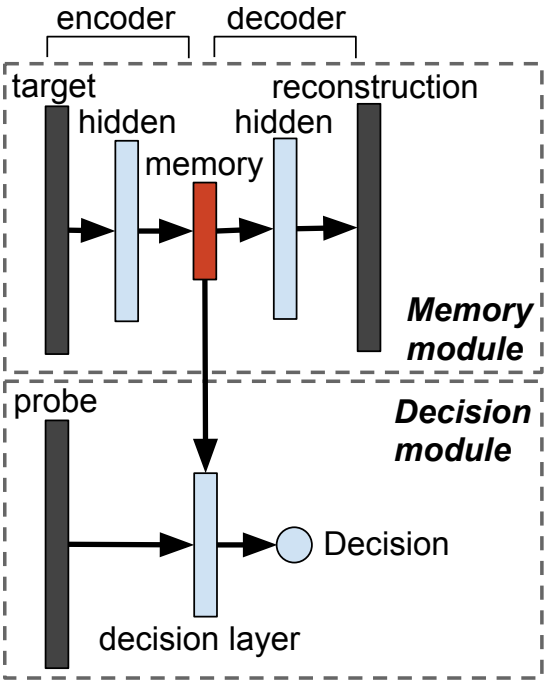

Figure 2: Schematic of the general model architecture. Dark gray boxes represent a vector of pixel values, while other boxes represent layers (or a set of layers) in the network. Layer that represents the memory code is in red.

Experiment 1: Artificial Images: Experiment 1 used the artificial plants dataset to demonstrate that the categorical bias effect depicted in Figure 1 extends to models operating in high-dimensional pixel-space. We show that, as expected, when a limited-capacity network is highly penalized for miscategorizing a stimulus, its memories exhibit categorical bias.

We trained the architecture on the full plants dataset. Following panel B in Figure 1, the training objective function was a mixture of pixel reconstruction error and categorical error, with a high relative coefficient on the latter. Specifically, the decision module was tasked with deciding whether the target image (input into the autoencoder) was the same category as a subsequent randomly-chosen probe image (input to the decision module). Given the high penalty for miscategorization, the optimal strategy for a model with very little capacity is to store little more than the category label. Figure 3 demonstrates this outcome by plotting target image reconstructions (outputs from the decoder) corresponding to a range of possible inputs. At low capacity (top panel), reconstructions of exemplars to the left of the category boundary are all nearly identical, and reconstructions of exemplars to the right of the boundary are also nearly identical. However, reconstructions on one side of the boundary are quite different from those on the other. In other words, there is a strong bias in the reconstructions to the appropriate category means, and thus a

sharp discontinuity at the category boundary. These results imply that at low capacity, the memory representation is a code that simply indicates which category the input belonged to. The best the autoecoder can do in this case is to produce the mean or prototype of that category. At higher capacities, the memory code contains more perceptual details beyond the category membership.

Experiment 2: Natural Images Experiment 2 used the Fruits-360 dataset to show that our approach scales to natural images. Again, we show that our models have increasing categorical bias as capacity decreases. However, our analyses in this experiment differ in a few ways. First, because natural image datasets do not contain a clear set of dimensions along which stimuli vary (like leaf width and leaf angle in Experiment 1), we indirectly measure the categorical bias in the trained models using autoencoder reconstructions and principle components analysis (PCA). An additional difference is that the decision module was trained to categorize each image, rather than to detect a change between target and probe.

Figure 4 (top panel) shows image reconstructions from the autoencoder at high, medium, and low capacity. These images demonstrate that the amount of detail that is retained in memory decreases as capacity decreases. At low capacity, the reconstructions are clearly categorical: each type of fruit corresponds to a unique output, which is the average of all images in that category. At medium capacity, different varieties within each species of fruit can begin to be distinguished. The figure's bottom panel demonstrates that the model's memory codes become more categorical at lower capacities. We performed PCA on memory vector activations and plotted stimuli in the space defined by the first two principle components. At medium or low capacity, memory codes for stimuli that belong to the same class are very similar, whereas at high capacity, memories of stimuli within a category are quite distinguishable from each other, and thus more perceptual details may be recovered[2].

Conclusion

We have argued, from both theoretical and empirical standpoints, that efficient data compression may be a central goal of perceptual and memory subsystems. In future work, we will discuss the extensive empirical evidence that efficient data compression is implemented in biological perception and memory, beyond the limited examples given here. In the current work, we highlighted one interesting piece of evidence that neural systems follow these principles, specifically that categorical representations are prevalent in memory. In simulation, we showed how categorical representations can be a natural outgrowth of efficient compression. These mechanisms for categorical bias generate hypotheses that can be tested in future empirical work. Because our modeling framework operates in an end-to-end and task-general manner, we believe that it shows promise for being scalable in ways that most psychological models are not.

[2]Note that even though the principle-components space appears to scale with capacity, this does not imply that the degree of categorical bias stays constant. For example, if the magnitude of noise that is added to the latent activations is fixed, more separation between two points in principle-components space implies that the decoder can more easily distinguish between them despite the noisiness. In fact, as network capacity is increased, the magnitude of noise added to the latents tends to *decrease* (because this allow more information to be stored), and thus two points that are a distance d apart in principle-components space are at least as distinguishable at high capacity compared to low capacity.

Abstract

We show, contrary to some recent claims in the literature, that prototype distributional semantic models (DSMs) are capable of representing multiple senses of ambiguous words, including infrequent meanings. We propose that word2vec contains a natural, model-internal way of operationalizing the disambiguation process by leveraging the two sets of representations word2vec learns, instead of just one as most work on this model does. We evaluate our approach on artificial language simulations where other prototype DSMs have been shown to fail. We furthermore assess whether these results scale to the disambiguation of naturalistic corpus examples. We do so by replacing all instances of sampled pairs of words in a corpus with pseudo-homonym tokens, and testing whether models, after being trained on one half of the corpus, were able to disambiguate pseudo-homonyms on the basis of their linguistic contexts in the second half of the corpus. We observe that word2vec well surpasses the baseline of always guessing the most frequent meaning to be the right one. Moreover, it degrades gracefully: As words are more unbalanced, the baseline is higher, and it is harder to surpass it; nonetheless, Word2vec succeeds at surpassing the baseline, even for pseudo-homonyms whose most frequent meaning is much more frequent than the other.

Keywords: distributed semantic models; word meaning; ambiguity; prototype models; exemplar models; word2vec

Introduction

A central question for the cognitive science of language is how word meanings are represented in the minds of language users. Distributional semantic models (DSMs) represent word meanings as vectors in a high-dimensional space (Landauer & Dumais, 1997; Erk, 2012). The location of these points is based on the words in the neighbouring linguistic context (e.g., a window of words around the target word, or the document the word occurs in). DSMs have been successful in simulating diverse facets of human cognition, such as similarity judgments and analogy completion (e.g., McNamara, 2011; Pereira, Gershman, Ritter, & Botvinick, 2016).

Given that a vast majority of the words in English (and presumably most languages) are ambiguous (Klein & Murphy, 2001), the question arises whether a single vector, which functions as a 'prototype' of the word's meaning, can adequately represent the multiple meanings of an ambiguous word. Several researchers have argued that this is indeed the case. Schütze (1998), Burgess (2001), and Kintsch (2001) each show, using different models and set-ups, how aggregate representations of the context words can disambiguate ambiguous words. Arora, Li, Liang, Ma, and Risteski (2018) propose that word vectors are combinations of the vectors of the component meanings, and that these meaning vectors can be recovered from the 'compact' representation. Further circumstantial evidence for the adequacy of prototype representations comes from the fact that the DSMs successfully model various aspects of cognition even when representing a massively ambiguous vocabulary (Pereira et al., 2016).

Other work, however, suggests that single vector representations are inadequate for the representation of word meaning ambiguity. In the computational linguistics literature, this consideration has led to approaches in which multiple vector representations are learned for a word, each serving as the prototype of *one* of its senses (Reisinger & Mooney, 2010; Li & Jurafsky, 2015). In cognitive science, this assumption has led to the proposal of exemplar-based models, in which a word meaning is represented not as one or more prototype vectors, but as a weighted trace of the memorized contexts that a word occurred in. Jamieson, Avery, Johns, and Jones (2018), for instance, demonstrate that their exemplar-based model of word meaning representation succeeds where two widely-used DSMs (LSA; Landauer & Dumais, 1997 and BEAGLE; Jones & Mewhort, 2007) fail: While the prototype DSMs are able to represent the dominant (most frequent) meaning of a word, subordinate meanings are poorly captured by a single vector, suggesting that these models cannot reliably identify the intended meaning of an ambiguous word in context.

Given the general success of prototype DSMs, such a failure to simulate a key cognitive behaviour would indeed be worrisome if it applied to the entire class of approaches. However, Beekhuizen, Milić, Armstrong, and Stevenson (2018) show in a series of corpus experiments that not all prototype DSMs behave alike in representing ambiguous meanings. In this paper, we will argue that claims concerning the inadequacy of prototype DSMs are not justified. We will do so by showing that another prototype DSM, the CBOW algorithm of word2vec, has model-internal properties that enable it to disambiguate word meaning, and to succeed at accurately representing the infrequent meaning of ambiguous words. Crucially, we believe that this success in disambiguating infrequent meanings is driven by the fact that word meaning interpretation is distributed over two sets of representations in word2vec.

Our Approach

Word2vec (Mikolov, Sutskever, Chen, Corrado, & Dean, 2013) is a word embedding model that learns a distributed semantic space that enables it to best predict words from their contexts. Figure 1 illustrates the process graphically, when using the continuous bag-of-words (CBOW) algorithm of word2vec. Each word in the vocabulary is represented as a row vector in the context matrix C and as a column vector in the target word matrix T. At every training step, the model is given a target word t as well as a window of k context words on either side of the target word. The model then learns to best predict the target word from the context words.

To determine its prediction, word2vec first takes the vector representations in C of the k context words and averages them, forming the aggregate context vector a. The context vector a is then compared with the current word representations in T to predict which word is most likely the target in that context. Intuitively, the more similar the context a is to the current vector representation of a word in T, the higher the predicted probability of observing that word. In training, after making a prediction for an example context, the model checks how far it is off from the desired probability distribution – that is, a probability of 1 for observing the given target word t and 0 for all other words – and proportionally updates the vectors in both C and T to minimize this error.

Although word2vec trains both a context matrix C and target matrix T, researchers typically just use one set of the trained representations (those of the context matrix C) as the resulting DSM of word meaning. Then, for disambiguating a word, a natural approach is to combine the vector representations (from that matrix) for the ambiguous word and its (presumably disambiguating) context words, and then to compare the resulting vector to other representations – for instance, synonyms of the two possible meaning of the ambiguous word – from the same matrix, under the assumption that the aggregate vector will be closest to the appropriate synonym (i.e., the one corresponding to the intended meaning of the ambiguous word). This approach has been explored in computational linguistics by Iacobacci, Pilehvar, and Navigli (2016).

In contrast, we propose a novel approach to using word2vec representations in modeling the disambiguation process, by drawing on its *training procedure* to derive the contextual interpretation of a word. Our insight is that both the context matrix C and the target matrix T contain learned knowledge that is important in disambiguation, just as they work together in the training process to form compatible representations of the context and target words (cf. Mitra, Nalisnick, Craswell, & Caruana, 2016). Rather than throwing away this important information and using representations from just one of the matrices, we use both the C and T matrices: We form an aggregate context vector a using C as a representation of the context of a word to be disambiguated, and compare that aggregate vector to representations of synonyms of its possible meanings embedded in the target word matrix T.

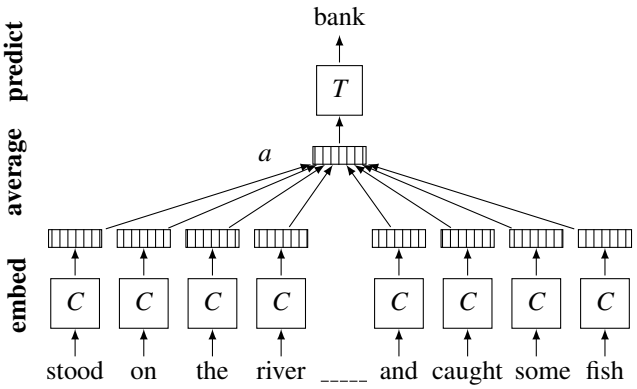

Figure 1: Word2vec model, using the CBOW algorithm

The use of a part of the training procedure is desirable, as it addresses an issue Jamieson et al. (2018) raise, namely that the prototype DSMs that have been shown to work use ad-hoc patches that are added to the models in order to represent word meanings in context. For word2vec, the aggregate context vector a is a representation of the context that is native to the model, as is the process of comparing a to representations in the T embedding space.

On a conceptual level, we believe that word2vec reflects an important property of word meaning interpretations, namely that they are not completely represented 'in' the word itself (cf. Elman, 2009). The word can be thought to provide a 'sketch' of the meaning (Levinson, 2000) that is completed through inferential processes by the linguistic and extralinguistic context in which it is embedded (e.g. Sperber & Wilson, 1986). This consideration is in fact one of the motivations of an exemplar-based approach. However, in word2vec too, ambiguous meanings are similarly not fully 'represented' in the word vectors of C or T. Rather, C and T, along with the algorithm that compares them, share the responsibility for predicting the target words from the context.

With regard to interpretation of infrequent meanings of a word, this approach gives word2vec an advantage. Given that word2vec's objective is to predict the target word, it suffices to optimize the representations in T so that the vector of the ambiguous target word represents just enough of the infrequent meaning to enable the appropriate context words to predict it (cf. the notion of 'good enough semantic processing' in Ferreira, Bailey, & Ferraro, 2002; Frisson, 2009). In the experiments below, we will illustrate how using the context and target matrix together allows word2vec to represent infrequent word meanings and identitfy them in context.

Artificial Language Simulations

As a first proof of concept, we replicate the artificial language simulation of Jamieson et al. (2018), which compared disambiguation in an exemplar-based model of word meaning to two prototype DSMs, and found the latter less successful.

An artificial corpus was generated in which the homophone sound form /breɪk/ (i.e., the sound of *break* or *brake*) was used in three contexts corresponding to three different meanings (to brake a car, to break the news, or to break a plate; henceforth all referred to as *break*). The models were tested to see whether they could identify each of the three meanings of *break* used in various disambiguating contexts (e.g., *man break car*, *woman break news*, *woman break plate*). Aside from sentences containing *break*, sentences with verbs that are synonymous to one of the three meanings were generated as well (e.g., *woman stop car*, *man report news*, *man smash glass*). These unambiguous verbs enabled evaluation of whether disambiguation models were able to identify the correct meaning of *break* in the context. Crucially, the corpus was generated either so that all meanings of *break* were equally frequent (balanced), or so that one meaning was 4 times as frequent as the other two meanings (unbalanced). For further details, see Jamieson et al. (2018).

We replicate this experiment for word2vec by generating the corpus in the same way as outlined above and training word2vec on it.[1] We then apply our approach using word2vec (described in the previous section) to see if it can correctly disambiguate the different meanings of *break*. To do so, we see whether the prediction of *break* in a sample context (e.g., *woman+car*) is as strong as the prediction of the appropriate unambiguous word (in this case, *stop*), and much stronger than the inappropriate unambiguous words (those corresponding to the other meanings of *break*). Importantly, the approach follows the flow of the learning procedure of word2vec: we average the representations of the context words in C to create an aggregate context vector a, and then compare a to the representation in T of each of the four different words (*break*, *stop*, *smash*, *report*) to determine the strength of prediction.

As Figure 2 shows, word2vec successfully predicts both *break* and its contextually appropriate synonym, both for the balanced corpus (where the three meanings of *break* are equally frequent) and the unbalanced corpus (where one meaning is more frequent than the others). Note that in all cases, the aggregate context vector is about as similar to the correct unambiguous verb as it is to *break*. For example, the model has learned that in the context of *woman* and *news*, both *report* and *break* are similarly predicted, and thus are similar to each other *in this context*.

Interestingly, we found that this behaviour is only present when both C and T are used; when aggregating context word vectors in C and then comparing them to the vectors of the unambiguous words in C again, the appropriate disambiguation behaviour was not achieved.[2] This means that word2vec is able to represent the contextually disambiguated meaning of a verb through the interaction of its context matrix C with its target matrix T. This behaviour can be expected, as the training algorithm of word2vec optimizes the similarity of the aggregate representations in C (i.e., the vector a) to that of the target word in T. That is: a and the vector of the target word in T are (by design) embedded in the same space, whereas an *aggregate* representation of the context words in T (as opposed to the individual words' representations in T) and the vector of the target word in T are not.

Our successful results contrast with those in Jamieson et al. (2018), who found that, while their exemplar-based word meaning model (Instance Theory of Semantics, henceforth ITS) performed well in this task, the two prototype DSMs – LSA and BEAGLE – were not as successful. In particular, in the balanced condition, all three models show the desirable disambiguation behaviour, but in the unbalanced condition, ITS can successfully disambiguate, but LSA and BEAGLE cannot. For these prototype models, only the most frequent meaning (the *stop* sense of *break*) is activated correctly, whereas the contexts of infrequent meanings (the *report* and *smash* senses) also activate (incorrectly) the most frequent meaning.

While our approach using word2vec demonstrates that a prototype DSM *can* successfully disambiguate infrequent meanings, a potential point of criticism is that our approach may work in an artificial setting like this, but not when the model is trained on a corpus with a realistic vocabulary size and many more unique contexts. After all, a realistic set-up necessitates a far greater degree of compression to allow for a maximally accurate prediction given only 200 dimensions to store all information in — and thereby a greater chance of having infrequent meanings being pushed out by the more frequent ones. Furthermore, the artificial language set-up tests the disambiguation on the data it was trained on, and so we are not directly addressing whether the model can carry out disambiguation in a generalizable way. These issues led to the design of the next experiment.

Disambiguation in a Naturalistic Setting

While the artificial language experiment provides a proof-of-concept of contextual disambiguation, it cannot test whether models have *generalizable* knowledge that scales to *naturalistic* contexts. The obstacle to larger-scale, more realistic scenarios is that testing disambiguation requires knowing the "correct" answer – that is, for any given instance of an ambiguous word in context, we need to know which meaning was intended in order to judge whether a model is performing appropriately. This requires a natural corpus that has the instances of homonyms annotated with the correct meaning in each case.

Since no such corpora of substantial size exist, we follow Arora et al. (2018) in adopting a method of using "pseudo-

[1] In all experiments reported, we used the implementation of word2vec in gensim (Řehůřek & Sojka, 2010), using CBOW with 200 vector dimensions, a window size of 5, a minimum frequency of 1, and otherwise default parameter settings. All software used is available as supplementary material at `https://tinyurl.com/w2vcogsci`.

[2] We also tried other ways to use word2vec, including its Skip-Gram variant, but CBOW with both C and T matrices was the most robust with unbalanced homonyms.

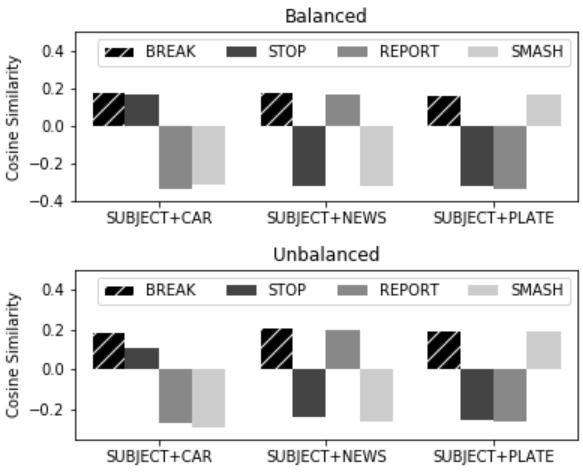

Figure 2: Cosine similarities between the word2vec representations of the context words (on x-axis) and the representations of the target words (in legend), for the balanced corpus and the unbalanced corpus.

homonyms" – pairs of words that are considered as if they were a single word. For example, if we consider the set of usages of *pizza* and *water* as if they were a single word with meanings PIZZA and WATER, then we would have a corpus in which all the instances in context of `pizza_water` are known to be disambiguated as either PIZZA or WATER (corresponding to the original word in that instance).

This set-up allows us to present our word2vec-based disambiguation approach with test cases (contexts containing a pseudo-homonym), and see whether it can identify which component meaning of the pseudo-homonym was intended in that context. We similarly evaluate the performance of ITS (Jamieson et al., 2018) on the same data, to see how our approach, based on a prototype DSM, compares to an exemplar-based approach to word meaning.

We use the TASA corpus of Landauer, Foltz, and Laham (1998), with the first half of the corpus as training data, and the second half as test data. Using a training-test split of the data, we made sure the models were actually tested on their capacity to disambiguate target words in novel, unseen contexts. We sampled 100 pairs of non-homonymous words that were similar to one of the real homonyms listed in Armstrong, Tokowicz, and Plaut (2012) in their length, frequency, and relative frequency of the two component meanings. This was done to make sure the pseudo-homonyms displayed similar relevant properties as real homonyms (Piantadosi, Tily, & Gibson, 2012).[3] We next explain how we can test each model under this approach.

Pseudo-homonym set-up for word2vec. For word2vec, we need to modify the corpus to enable training on a set of pseudo-homonyms, which were created by merging two non-homonymous words – e.g., replacing all instances of the words *pizza* and *water* with the single token `pizza_water`. The context and target matrices of word2vec were trained once on the original version of the training data, yielding C and T, and again on the version with pseudo-homonyms, yielding C' and T'. In this way, we have representations both for the pseudo-homonyms and for their component words individually. Then, for each instance of a pseudo-homonym in the test data, say `pizza_water`, we tested whether its aggregate context vector a from C' (based on the pseudo-homonym version of the corpus) was more similar to the correct or incorrect component meaning representation in T – *pizza* or *water* – whichever occurred in the original corpus).[4]

Pseudo-homonym set-up for ITS. ITS (Jamieson et al., 2018) follows the intuition that an accurate representation of word meaning is derived from all previously encountered instances of the word. Starting with words represented as high-dimensional random vectors, ITS represents the *memory trace* of each document in a corpus as the sum of the random vectors of all the words in that document. Word meanings in context are then derived from the matrix of memory traces by presenting the model with a *probe* in the form of a set of words, and retrieving its *echo*: an aggregate of all memory traces, weighted by how similar they are to the probe. Figure 3 presents a graphical representation of the echo retrieval process.

In our ITS set-up, we constructed a matrix of 20K-dimensional memory traces for the training portion of the original TASA corpus. Then, for each instance of either of the component words of a pseudo-homonym in the test data, a context probe was constructed out of the five words to the left and to the right of the word (excluding stopwords and punctuation), plus the two component words of the pseudo-homonym themselves. The echo of this aggregate probe was retrieved and compared to the echo of each component word individually. The component word whose echo had the highest cosine similarity to the echo of the aggregate context probe was selected as the disambiguated meaning.[5]

Results This approach gives us 91,703 ambiguous pseudo-homonym tokens in the test data, aggregated over the 3 simulations (on average 306 per pseudo-homonym). We find that word2vec scores an overall accuracy (proportion of correctly disambiguated test items) of .85 versus .69 for ITS. This means that overall, word2vec is better able to disambiguate words in their naturalistic contexts.

It is important to also consider how these accuracies compare to a chance baseline – is either model doing better than random guessing? Assuming there is some way to know which is the most frequent (dominant) meaning, a model that always guessed the dominant meaning would achieve a score

[3]Due to the random sampling, we ran three simulations, each with a new set of 100 pseudo-homonyms, and report aggregate findings of the three simulations.

[4]To compare vectors from C' to those from T, we use Orthogonal Procrustes, a standard method, to rotate T to T' so the vectors are all in a compatible vector space.

[5]This set-up was found to yield the best results for ITS compared to other set-ups we tried.

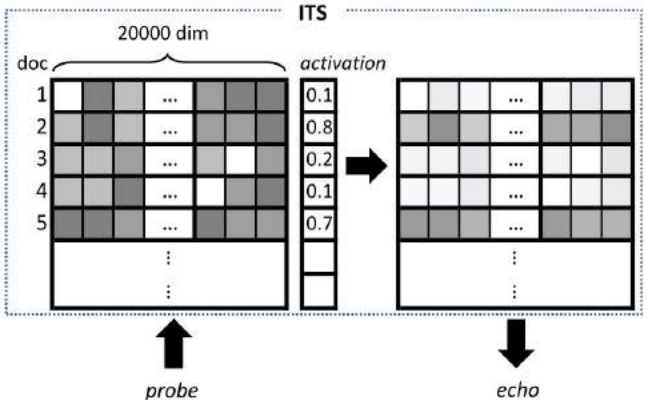

Figure 3: A visual example of the retrieval of an echo in ITS through the selective activation of memory traces when presented with a probe.

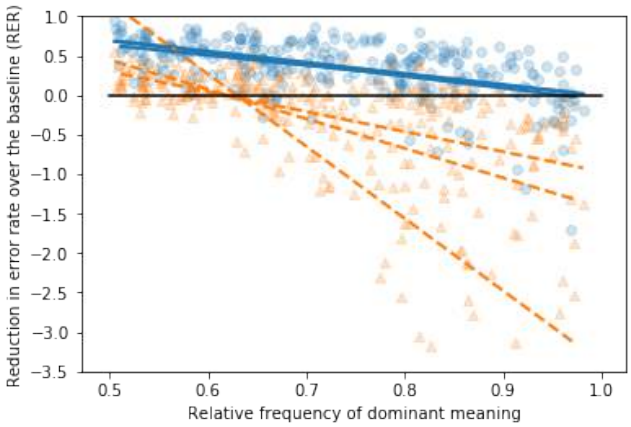

Figure 4: Reduction in error rate over the baseline (RER), aggregated over the three simulations. Dots (orange triangles for ITS, blue circles for word2vec) represent pseudo-homonyms. Regression lines are given for each simulation (orange dashed lines for ITS, blue solid lines (all overlapping) for word2vec). The black line represents zero error rate reduction; values below 0 are error rate increase, above 0 error rate reduction.

of .73 for our pseudo-homonyms – i.e., the average relative frequency of the dominant meaning. This seems like a reasonable baseline to assume, since we are interested in whether a model can learn the non-dominant meanings of ambiguous words. For each simulation, a two-tailed paired-samples t-test compared the accuracy per pseudohomonym for the model predictions and the dominant meaning baseline. In all simulations, word2vec did significantly better than the baseline (Sim. 1: $T = 9.71, p < 0.001$ / Sim. 2: $T = 11.96, p < 0.001$ / Sim. 3: $T = 10.01, p < 0.001$). ITS, however, performed significantly worse than the baseline (Sim. 1: $T = 3.32, p < 0.01$ / Sim. 2: $T = 2.34, p < 0.05$ / Sim. 3: $T = 2.74, p < 0.01$).[6]

Critical for our purposes is whether each model not just performed accurately for words with balanced meanings, but also was able to accurately disambiguate cases where one of the meanings is much more dominant. To assess this, we look at each pseudo-homonym individually. To compare fairly across pseudo-homonyms with different baselines (different degrees of dominance of meanings), we need a measure which looks at the amount by which each model surpasses (or falls short of) that baseline. A common measure to do so is the so-called reduction in error rate over the baseline (RER), defined as the amount by which the model improves over the baseline, divided by the error rate of the baseline.[7]

Figure 4 plots the RER for each pseudo-homonym as a function of its baseline (the relative frequency of its dominant meaning). The lines indicate the best linear fit between the two per simulation (all linear fits with Pearson's r are significant at $p < .001$). Both models display a downward slope across all simulations. This is unsurprising, since we would expect for any model that it is more difficult to disambiguate a very unbalanced homonym toward the infrequent meaning.

However, as can be gleaned from Figure 4, the slopes for word2vec are less negative than those of ITS, a difference that is significant across all three simulations (Sim. 1: $T = 3.03, p < .01$ / Sim. 2: $T = 4.83, p < .001$ / Sim. 3: $T = 2.90, p < .01$). This means that word2vec degrades more gracefully as homonyms become more unbalanced than ITS. Indeed, ITS only surpasses the baseline for relatively balanced items, and is unable to do better than the baseline for items whose most frequent meaning has a relative meaning frequency of around .66 or more. By contrast, the regression lines for word2vec only touch the null line (meaning always guessing the most frequent meaning) for the most unbalanced pseudo-homonyms (right end of the x-axis).

This means that, contrary to the predictions of Jamieson et al. (2018), and arguments raised in the computational linguistics literature (Reisinger & Mooney, 2010; Li & Jurafsky, 2015), not all prototype DSMs are unable to represent a contextually-resolved meaning of an unbalanced ambiguous word: word2vec performs adequately on such disambiguation tasks. Scaling up the disambiguation experiment to a more naturalistic corpus size and set of contexts, our approach using word2vec consistently surpasses the most-frequent sense baseline, and can thus be said to robustly resolve lexical ambiguities on the basis of the context words. Furthermore, word2vec degrades gracefully: it is harder to do better than chance for very unbalanced items than it is for balanced ones, but word2vec nonetheless on average surpasses the baseline even for very unbalanced pseudo-homonyms.

General Discussion

In this paper, we set out to show that, contrary to claims in the literature (Griffiths, Steyvers, & Tenenbaum, 2007; Reisinger & Mooney, 2010; Jamieson et al., 2018), proto-

[6] By virtue of transitivity, this also means that word2vec performs better than ITS (Sim. 1: $T = 12.13, p < 0.001$ / Sim. 2: $T = 11.82, p < 0.001$ / Sim. 3: $T = 11.23, p < 0.001$).

[7] That is, $RER = (model\_acc - baseline\_acc)/(1 - baseline\_acc)$

type distributed semantic models are capable of representing infrequent meanings of ambiguous words. We proposed that word2vec contains a natural, model-internal way of operationalizing the disambiguation process, and tested this approach successfully on the artificial language simulations for which Jamieson et al. (2018) showed that other prototype DSMs failed.

Importantly, we further assessed whether these results scaled to the disambiguation of naturalistic corpus examples. We generated a pseudo-homonym corpus by replacing all instances of sampled pairs of words in a corpus with pseudo-homonym tokens. We then trained word2vec on one half of the corpus, and assessed if the model was able to disambiguate pseudo-homonyms on the basis of their linguistic contexts in the second half of the corpus. We observed that our disambiguation approach using word2vec well surpasses the baseline of always guessing the most frequent meaning to be the right one, in contrast to an exemplar-based model (Jamieson et al., 2018). Word2vec moreover degrades gracefully: as words are more unbalanced (i.e., as the most frequent meaning has a higher relative frequency), the baseline is higher, and it is harder to surpass it. Word2vec nonetheless succeeds at surpassing the baseline, even for very unbalanced pseudo-homonyms.

A follow-up question is why Word2vec can represent infrequent meanings while LSA and BEAGLE cannot. It is tempting to speculate that this is due to the fact that word2vec vectors are trained to *predict* words, whereas LSA and BEAGLE vectors reflect the *counting* of words, and prediction-based DSMs have been found to outperform count-based DSMs (Baroni, Dinu, & Kruszewski, 2014). However, Levy and Goldberg (2014) argue the skipgram variant of word2vec performs implicit factorization of a count-based matrix in its objective function, so the actual differences between count-based and prediction-based models are not completely clear. This is an open area of research to which our findings contribute an important data point – i.e., that our approach to using the prediction mechanism of word2vec in semantic disambiguation outperforms a non-predictive approach using count-based DSMs (BEAGLE and LSA, as shown in Jamieson et al., 2018). A relevant future step is the comparison of our approach using the CBOW algorithm of word2vec to other prediction-based models or variants such as skipgram (Mikolov et al., 2013), as well as other contemporary approaches such as GloVe (Pennington, Socher, & Manning, 2014) and ELMo (Peters et al., 2018).

Another option is that it is the use of both the context word and target word matrices that allows us to achieve these results. Whereas off-the-shelf vectors have been used extensively in cognitive modeling experiments, our paper proposes to use a model-internal approach that leverages the fact that word2vec represents meaning as context word vectors *and* as target word vectors. This approach addresses the concern of Jamieson et al. (2018) that many prototype models only have ad hoc ways of carrying out the disambiguation procedure. It furthermore instantiates two critical points of the perspective on lexical semantics put forward by Elman (2009), namely: (1) that the drive to predict upcoming (linguistic) behaviour has sizable impact on the kinds of representations learned, and (2) that the interpretation of a word is always a function of some prior knowledge of the word as well as its context. It is effectively this idea that, combined with high-parametric representations and an abundance of data to train on, has led to the success of contemporary NLP word-meaning models such as ELMo (Peters et al., 2018).

We would like to argue that because of this distributed way in which word2vec learns to predict words, its representations reflect the important point that not all of a word meaning representation needs to be stored 'inside of' the word itself, but also by how word meanings relate to other word meanings (i.e., the 'oppositions' with other lexical items they have; Trubetzkoy, 1969 (1939)), as well as by rich pragmatic interpretive processes (Sperber & Wilson, 1986; Levinson, 2000). An important goal for the cognitive sciences of word meaning is to develop computationally precise models of how these processes work and interact. The present paper constitutes a stepping stone towards that goal.

Are all Remote Associates Test equal?
An overview and comparison of the Remote Associates Test in different languages

Abstract

The Remote Associates Test (RAT, CRA) is a classical creativity test used to measure creativity as a function of associative ability. The RAT has been administered in different languages. Nonetheless, because of how embedded in the language the test is, only a few items are directly translatable, and most of the time the RAT is created anew in each language. This process of manual (and in two cases computational) creation of RAT items is guided by the researchers' understanding of the task. However, are the RAT items in different languages comparable? In this paper, different RAT stimuli datasets are analyzed qualitatively and quantitatively. Significant differences are observed between certain datasets in terms of solver performance. The potential sources of these differences are discussed, together with what this means for creativity psychometrics and computational vs. manual creation of stimuli.

Keywords: Remote Associates Test; RAT; CRA; Creativity; Creativity evaluation and metrics; Creativity Test

Introduction

The Remote Associates Test is a creativity test often used in the literature (Ansburg & Hill, 2003; Cunningham, MacGregor, Gibb, & Haar, 2009; Mednick & Mednick, 1971; Cai, Mednick, Harrison, Kanady, & Mednick, 2009; Ward, Thompson-Lake, Ely, & Kaminski, 2008).
A RAT problem given to a participant contains three words, for example FISH, MINE, RUSH; the participant has to come up with a fourth word related to all of the three given words. In this case, GOLD is an answer, because the compounds GOLD FISH, GOLD MINE, GOLD RUSH can be built with it. For a human or a machine (Olteţeanu & Falomir, 2015) to solve the RAT, knowledge about the compound words of a language is needed.

Because solving the RAT relies on knowing various expressions and compound words from a language, native speakers have an advantage and are generally the target population when deploying the RAT. This raises the need for various RAT stimuli sets in different languages.

As the RAT relies on knowledge and expressions which are language specific, the RAT is, in most part, not translatable between languages. An exception to this are the rare cases in which all compounds required as knowledge by a RAT item in a specific language also exist in another language - for example GOLDFISCH, GOLDMINE, GOLDRAUSCH as the German counterpart of the above mentioned query.

As only a few items are translatable, RAT sets of items are created anew by researchers in each language. This entails that RAT queries are probably impacted by the language itself, and quite likely by the preferences and knowledge of compound words of the stimuli dataset authors. The Remote Associates Test (RAT) is administered in many creativity studies, in the native language of the participants. Results reported in these studies are therefore impacted by the quality and difficulty of RAT items in each language. How can this impact be assessed?

No overview exists of the human performance in the RAT / CRA in the different languages. Such an overview would help us understand whether significant differences exist between performance on different RAT problem sets in the various languages in which it is employed. If no significant differences exist, this may indicate that results reported on creativity studies which use the RAT in different languages are, indeed, cross-comparable. If a significant difference however does exist, the comparability of the RAT across languages may require more nuance, and the development of an understanding of the sources of this difference.

This paper sets out to construct an overview of the RAT across eight languages and two types of the RAT (compound and functional), and provide an initial analysis between RAT sets across all these languages.

The RAT and languages

Sets of RAT / CRA problems of the following languages were analyzed - please note that some languages come with multiple datasets (D):

- German (Landmann et al., 2014)
- Chinese (Shen, Yuan, Liu, Yi, & Dou, 2016)
- Italian (Salvi, Costantini, Bricolo, Perugini, & Beeman, 2016)
- Romanian (Olteţeanu, Taranu, & Ionescu, n.d.)
- Polish (Sobków, Połeć, & Nosal, 2016)
- English D1 (Bowden & Jung-Beeman, 2003)
- English D2 (Olteţeanu, Schultheis, & Dyer, 2017)
- English D3 (Olteţeanu, Schöttner, & Schuberth, 2019)

– Finnish (Toivainen, Olteţeanu, Repeykova, Likhanov, & Kovas, 2019)

– Russian (Toivainen et al., 2019)

RAT comparison

A qualitative and quantitative comparison of the RAT datasets above is provided in the next sections.

Qualitative comparison

English datasets D2 and D3 contain different types of items: *compound* versus *functional*. For compound items, the relationship between the three given words and the answer word is a relationship manifested in language – for example, GOLD FISH, GOLD MINE and GOLD RUSH are compounds which all appear in language. By contrast, the relationship between functional query words and the answer reflects a functional relationship between the two, but may or may not be a compound linguistic relationship. For example, the relationship between CLOCKWISE and RIGHT or WRONG and RIGHT is a functional relationship. Of the above datasets, English D3 is functional.

Independent of the compound/functional classification, RAT problems have also been divided into two types based on the order of the words: homogeneous and heterogeneous items. RAT items are homogeneous if the solution word is either a prefix or a suffix to all the three words of the problem (like in the query FISH, MINE, RUSH, where GOLD acts as a prefix to each of the query items). Problems are heterogeneous, if the solution word is the prefix for some of the words and a suffix to other words of the problem (e.g. in the query RIVER, NOTE, ACCOUNT, the answer BANK is a suffix for the first word, and a prefix for the other two).

Of the above datasets, the German, Italian and English D1 ones distinguished between the heterogenous and homogeneous type of the queries. ANOVA with task type as a factor were run by the authors on these sets. The task type factor showed no significant effect on Accuracy (the number of queries solved by the participants). In the German version, a significant effect of the task type factor was observed on reaction times.

Finally, of the dataset items above, most are manually created. An exception to this are items from the English D2 and English D3 datasets. English D2 (Olteţeanu et al., 2017) successfully attempts the computational creation of RAT items, and compares results with an existing (English D1) normative dataset. English D3 (Olteţeanu et al., 2019) applies the computational approach using a new type of language knowledge to the creation of functional items, thus resurrecting an older idea of Worthen and Clark (Worthen & Clark, 1971) regarding the existence of such items, and their differences to compound items. These items are compared to compound items in the paper.

Quantitative comparison

In the following, a descriptive statistics overview of the different datasets is provided. To answer the question whether differences exist between RAT datasets in the various languages, Welch's unequal variances t-test is used on each two language pairs to determine the effect of language on the Remote Associates Test.

Descriptive data

The various RAT datasets contained varying numbers of items, between 17 (Polish) and 144 (English D1). Furthermore, the various items were deployed either (a) giving participants different timeframes to solve each query, between 2s and 60s, or (b) without setting a time limit. Since 2s, 5s and 7s timeframes were only used once across these datasets, only items between 15s and 60s are analysed in this paper. The stimuli were deployed on populations of various sizes, with n ranging between 26 and 317 participants. The Accuracy (number of correct answers given by the participants) fluctuated between .31 and .58. The response times ranged between $7.26s$ and $37.34s$. Please note that means and standard deviations were calculated for this paper from the given data, where they were not provided by the initial dataset. Table 4 gives an overview of all the datasets and various descriptive metrics across all languages.

Cronbach's alpha

Cronbach's alpha is the most commonly used method for estimating the reliability of a test, as reflected by its internal consistency between items. Scores below 0.5 indicate an unacceptable internal consistency, whereas higher scores indicate a better one. Generally scores above 0.7 are considered to reflect an acceptable amount of reliability, and an α above 0.9 is excellent. The Cronbach α scores were calculated by authors for some of the intial papers (see Table 4) and vary between .73 and .99.

Differences between languages

In order to measure differences between languages, heterogenous and homogeneous items were combined and Welch's unequal variances t-test was conducted to measure the difference between means on two existing performance metrics: Accuracy and Response Times.

Accuracy in 15s timeframe

As shown in Table 1, there were significant differences of means between:

- Italian ($M = .39$; $SD = .23$) and German ($M = .30$; $SD = .27$); $t(250) = 2.86$, $p = .0046$
- Italian and English D1 ($M = .31$; $SD = .22$); $t(253.88) = 2.95$, $p = .0035$

Table 1: Welch test results for accuracy in a 15s timeframe

accuracy	GER			ITA		
15s	t	df	p	t	df	p
ITA	2.86	249.99	.005**	-	-	-
ENG D1	0.13	260.92	.89	2.95	253.88	.004**

Accuracy in 30s timeframe

Like displayed in Table 5, there were significant differences of means between:

- Chinese ($M = .58$; $SD = .25$) and Polish ($M = .41$; $SD = .23$); $t(38.29) = 4.92$, $p < .0001$
- Chinese and German ($M = .30$; $SD = .27$); $t(254.28) = 5.92$, $p < .0001$
- Chinese and English D1 ($M = .31$; $SD = .22$); $t(265.86) = 3.47$, $p = .0006$
- English D1 and German; $t(262.27) = 2.72$, $p = .007$

Accuracy without timeframe

As reported in Table 6, there were significant differences of means between:

- English D2 ($M = .52$; $SD = .14$) and Finnish ($M = .46$; $SD = .11$); $t(93.95) = 2.1$, $p.038$
- English D3 ($M = .33$; $SD = .16$) and Romanian ($M = .54$; $SD = .43$); $t(83.26) = 3.98$, $p = .0002$
- English D3 and Russian ($M = .55$; $SD = .14$); $t(92.87) = 3.73$, $p = .0003$
- English D3 and English D2; $t(93.46) = 3.83$, $p = .0002$

RT in 15s timeframe

As presented in Table 2, there was a significant difference of means between:

- English D1 ($M = 7.26$; $SD = 1.65$) and Italian ($M = 6.52$; $SD = 1.46$); $t(258.86) = 3.87$, $p = .0001$.

RT in 30s timeframe

As shown in Table 3, there were significant differences of means between:

- English D1 ($M = 10.45$; $SD = 3.47$) and Polish ($M = 14.03$; $SD = 3.06$); $t(21.38) = 4.48$, $p = .0002$
- Chinese ($M = 9.74$; $SD = 3.13$) and Polish; $t(20.7) = 5.42$, $p < .0001$

RT without timeframe

As stated in Table 7, there were significant differences of means between:

- Finnish ($M = 37.34$; $SD = 17.36$) and Romanian ($M = 15.37$; $SD = 10.53$); $t(52.72) = 6.67$, $p < .0001$
- Finnish and Russian ($M = 23.53$; $SD = 10.38$); $t(58.18) = 5.05$, $p < .0001$
- Finnish and English D2 ($M = 14.52$; $SD = 9.89$); $t(76.07) = 4.79$, $p < .0001$
- Finnish and English D3 ($M = 11.68$; $SD = 10.96$); $t(67.26) = 6.48$, $p < .0001$
- Russian and English D3; $t(83.71) = 2.99$, $p = .004$
- Russian and Romanian; $t(91.38) = 3.37$, $p = .001$
- English D2 and English D3; $t(91.92) = 2.09$, $p = .04$

Discussion and further work

The hardest sets to solve seem to be the English D3 set of items from Study 2, with a an average accuracy of .30, and the Finnish dataset in terms of response times, with a mean 37.34 seconds. The response times of the Russian RAT were also noticeably higher (23.53s).

This paper set out to compare the RAT in different languages, and across different datasets. Significant differences were observed between multiple languages and datasets, on both the Accuracy and Response Times performance metrics.

The significant difference observed between the English D2 and English D3 sets may have as a source the difference between types of items (compound versus functional).

In the cases in which a significant difference exists between different language datasets, various causes could act as the source:

(a) different population samples are more creative (or at least better at the associative factor in creativity);

(b) the RAT is more difficult in some languages, because of the language itself and the cognitive factors resulting from encoding linguistic knowledge and solving the RAT in that language and/or

(c) sets of RAT queries vary in difficulty, because they are created without using standardized methods, thus depend on the inspiration and knowledge base of the researchers creating them.

This initial investigation shows that differences between the RAT in various languages need to be addressed in more detail. Before cross-comparison of creativity results can be declared, the source of these differences needs to be found. Experimental or analytical setups need to be designed in order to establish which one of (a), (b) and (c), or combination thereof, is the source of the differences.

An initial thought on establishing comparability could be to attempt to find translatable items across the various languages. By keeping stimuli items constant, differences of creativity pertaining to the population or use of language could be established.

However, even if translatable, the same RAT items may not be the same difficulty in different languages. Some light on this is shed by computational models like comRAT-C (Olteţeanu & Falomir, 2015), essentially models of memory search, which can solve the RAT by organizing their knowledge in a semantic net-like structure and propagating activation through word associations. The comRAT-C's probability

of solving a query correlates with human performance. This model entails that, even if different RAT queries can be translated in different languages, equivalence does not necessarily exist between them: the number of word associates and the strength of association may not be the same in different languages. Different tools may thus need to be used to try to establish query equivalence.

A potential solution may be to establish a stronger item equivalence in computational terms: for example by using computational RAT query generators like comRAT-G (Olteţeanu et al., 2017), to create sets of items where a high degree of control can be maintained over the number of associates and the association strength of the query words. Such approaches have already proven fruitful in the deployment of more precise empirical designs (Olteţeanu & Schultheis, 2017), and in the creation of other types of items (Olteţeanu et al., 2019).

Another direction of future work would be to establish a creative association measure which transcends the constraints of language like a visual Remote Associates Test - some work in this direction has already been done by (Olteţeanu, Gautam, & Falomir, 2015; Toivainen et al., 2019).

This paper gives an overview of RAT datasets in multiple languages, and shows that cross-linguistic comparability should not be taken for granted in the case of this broadly used creativity test.

Abstract

Narrative processing is an important skill to model both from a cognitive science perspective and a computational modeling perspective which applies to intelligent agents. Communication between humans often involves storytelling patterns that make the mundane exchange of information more interesting and with proper emphasis on important communicative goals. Current narrative generation models evaluate their generations based on either a priori domain semantics (e.g. game state for an in-game conversation with player agents) or generic text quality measures (e.g. coherence). However, in utilizing storytelling as a communicative tool for real-world interactions, domain-specific approaches fail to generalize and text quality measures fail to ensure that the narrative is perceived as *interesting*. Hence, such generation needs to consider the cognitive processes involved in the perception of narrative. Using theories of cognitive interest, we present results of an investigation of whether word embeddings (e.g. GloVe (Pennington, Socher, & Manning, 2014)) could be used to model and estimate cognitive interestingness in stories.

Introduction and Background

In computational narrative generation, the communication context for which the narratives are generated plays an integral role in determining both the method constraints during the generation and the evaluation metrics for the resulting narratives. Not all approaches to narrative generation are compatible with all narrative communication paradigms, because they result in vastly different qualities in the generated narratives and also differ in their assumptions and constraints.

Moreover, no single set of evaluation or optimization metrics can ensure the success of a narrative generator across multiple paradigms. Such "success" is usually dependent upon being received positively by the audience and achieving any potential communicative or social goals. In simpler terms, a "good" narrative has to be interesting to the audience.

Entertainment, and games in particular, have been a prominent context for narrative generation and communication. Many games change the events that are not (at least directly) in control of the player, or affect what the players say (in voice or text), in order to create the "best" storyline possible with a goal of maximal immersion and character believability (Mateas & Stern, 2003; McCoy, Treanor, Samuel, Mateas, & Wardrip-Fruin, 2011; Ryan, Mateas, & Wardrip-Fruin, 2016). Other games can involve an interactive settings, where the player can influence the progression of the story through making choices (Riedl & Bulitko, 2012).

In such game-related use cases, it is often possible to infer the quality or interestingness of the generated story using known domain semantics. For instance, if a simple generator is making a story about chess, it is easy to know which sequence of events or moves are worthy of being recited as a story, since we know the significance of every move, or sequence of moves, to the game progression or to the winning chances of each side. Similar inferences about event sequences can be made about more complex games as well, given that some game semantics are available. Moreover, even when games are not involved, many story modeling and narrative generation approaches rely on a semantic model of a particular domain (e.g. characters, goals, entity relationships, etc.) which allows the derivation of a sequence of events and ultimately a narrative, such as in (Elson, 2012a). The same is true about classic story generation systems that while inspiring, rely on a bank of previous stories and their assumed structures to generate new ones with a measure of interestingness or success, such as Minstrel (Turner, 1994) and Mexica (PÉrez & Sharples, 2001).

Other narrative generation approaches are less dependent on a particular context of communication and use case, and consequently, do not depend on a priori semantic models. Instead, they attempt to generate narrative of stories that make general sense (as a sequence of events) and contain correct sentences (if presented in text). Thus, in order to assess the quality of the generated story, such approaches often focus on the general properties and qualities of the generated text, such as coherence or the causal plausibility of the sentence ordering (Papineni, Roukos, Ward, & Zhu, 2002). This way of generating narrative is sometimes referred to as *open story generation* (Martin et al., 2017; Swanson & Gordon, 2008).

Improving on generic text-based evaluation metrics, in (Purdy, Wang, He, & Riedl, 2018), a set of proxy measures are introduced to assess the "story quality" in an open story generation task. These measures are shown in (Purdy et al., 2018) to correlate with human judgment of story quality; hence, they can be used towards a better evaluation of the generated narrative and an easier and faster fine-tuning of many generative models, such as Recurrent Neural Networks (RNNs). They include:

- Correct grammar use ("grammaticality"),
- Complexity of used language ("narrative productivity"),
- Similarity of adjacent sentences ("local contextuality"),
- Level of adherence to the usual ordering of events in most

stories, e.g. "eat" comes after "order" ("temporal ordering").

Humans possess an intuitive evaluation metric for stories, one that goes beyond linguistic measures. Expert human storytellers are not considered experts merely because of the quality of their use of language (however sophisticated it may be), but also because of their ability to tell stories that seem interesting to a large number of audience. Such experts master narrative authorship techniques and can recognize the processes involved in human's cognitive perception of narrative. In other words, they tell stories in ways that are informed by their understanding of how human perception of narrative works.

To that end, proxy measures introduced above are a useful start to assessing narrative quality when it is not tied to a specific domain of semantics. However, an important aspect of story quality, i.e. "how good a story is", depends on more complex evaluations metrics than language use, local contextuality, or the normality of the event orderings. While those measures are relevant, they do not inform the generation process about the perception of narrative. Ideally, a generator should also optimize for its generated narratives to be perceived as interesting. Moreover, as mentioned above, a computational generation of narrative heavily depends on the communication context in which it operates. A particular reason why a focus on narrative perception is imperative is the rapid evolution of such contexts, which will increasingly include interactive and sociable agents (e.g. embodied or virtual agents (Goodrich, Schultz, et al., 2008; Fong, Nourbakhsh, & Dautenhahn, 2003) or conversational agents (NPR, 2017)).

Story Interestingness

Storytelling, as an intuitive, natural and commonplace human behavior, seems deceptively simple to judge in terms of "interestingness". However, similar to some other intuitive and natural behaviors, such as nodding and gazing, it is extremely complicated to predict or reconstruct a story's interestingness. This perceived interest can be subjective, is often cultural and it can also change over time (e.g. a popular movie's narrative becomes less popular among a new generation). Moreover, the subtleties and arts of authorship makes the ways in which a narrative can seem interesting incredibly diverse, subtle and nuanced. Despite such difficulties, there are ways in which we can start understanding this phenomenon and begin developing proxy measures for perceived story interestingness, to be used in generative models. To this end, the related work in the field of cognitive science is a great resource to draw from.

While various types of interest can be established in a story, many researchers have broadly categorized these interests in two main groups. Under various names, such as *individual* and *situational* (Hidi & Baird, 1986), or *cognitive* and *emotional* (Kintsch, 1980), researchers have focused on the source of interest to make such categorization. "Cognitive" interests are largely the properties of the narrative (or authorship techniques) and "emotional" interests are largely rooted in an audience's predispositions. The latter group is more subjective, and can consist of instinctive "absolute" (Schank, 1979) interests (e.g. danger, power, sex), or "topic interests" (Campion, Martins, & Wilhelm, 2009).

While it is plausible to assume that all kinds of interest affect each other when it comes to perception, cognitive interests are categorized as the less subjective factors, ones that have a larger focus on the stimuli: the properties of the narrative. Many researchers have developed theories of the mechanisms that lead to the establishment of cognitive interest in stories. Notable theories include: unexpectedness (Schank, 1979), the interaction between background knowledge, uncertainty and postdictability (Kintsch, 1980), incongruity (Mandler, 1982), change in one's belief (Frick, 1992), generation of inference (Kim, 1999), and the generation of predictive inference (Campion et al., 2009).

Many of these theories above are conceptually close to and can overlap with each other. In this paper, we focus on two of these theories that represent familiar notions: **unexpectedness** (closely related to surprise) and **predictive inference** (closely related to foreshadowing).

A detailed overview of the theories of story interestingness is provided in (Behrooz, Mobramaein, Jhala, & Whitehead, 2018).

Search for Specificities

Another reason for creating proxy measures for story interestingness is the potential roles of such measures in choosing an appropriate set of specificities in a narrative.

Picking the Right Specificity in a Situated Context If a narrative generation system, for instance one used by an agent operating in the real world, attempts to build a narrative from events that have previously happened, there would be a search problem involved to choose which observations, details or specificities (if any) should be included in the story. At a minimum, a sequence of events can be described as a mundane narrative that minimally describes the story's events. However, the inclusion of certain specificities about the elements in the story is usually what allows for authorship skills.

The "Chekhov's Gun" principle says: "every element in a story must be necessary, and irrelevant elements should be removed." On the other hand, many seemingly unnecessary parts of a telling of a story serve the particular purpose of making the narrative more interesting (e.g. through foreshadowing or red herring techniques). For instance, specifying that "the moon was shining bright" a few events before two characters (that the audience may suspect are in love) kiss for the first time, asserts a property of the moon that is (most likely) inconsequential to what happens in the story, but is nonetheless a part of what makes the telling of it interesting.

Thus, while completely irrelevant details and specificities

can violate Chekhov's Gun principle, some details and specificities, when chosen and employed in an informed and artistic way, can contribute to the interestingness of narrative when perceived by an audience.

Complementing Approaches That Involve Generalization of Concepts This search problem can also arise when generative neural networks (such as RNNs) are used to generate stories. In order to increase the chances of convergence in such models, researchers sometimes replace verbs and words in a story corpus that is used to train the model with generalized concepts (Martin et al., 2017) using semantic word networks such as VerbNet and WordNet (Schuler, 2005; Miller, 1995). This would result in the replacement of both of the words "car" and "automobile"with the semantic label "self-propelled vehicle.n.01", and consequently, it becomes easier for the model to find event patterns involving either of these words. However, the narratives generated using such models would then also include the generalized concepts, and hence, they can be more mundane and less specific as a result. Having proxy measures to find the more interesting specificities may offer a solution to this problem. In particular, word vectors can help with choosing a specific instance of a semantic label. This lack of specificity can occur in any generative method for open story generation that involves generalization of concepts or events, and consequently results in mundane generated stories, such as in (Li, Lee-Urban, Johnston, & Riedl, 2013).

Cognitive Interest as a Proxy Measure

In the absence of a domain's semantic model (as explained in previous sections), we explore the idea of using word embedding vectors with the goal of developing proxy measures for story interestingness. Word vectors introduce a way to estimate the semantic similarity and relationships between words, largely based on co-occurrence. The rapid improvements in deep learning have greatly contributed to the quality of word embeddings and they have seen much success in many computational linguistic tasks. In this paper, we investigate the use of word embeddings to estimate the cognitive interest in stories.

Foreshadowing

As briefly reviewed before, one of the main causes of the establishment of cognitive interest in stories is predictive inference by the audience (Campion et al., 2009). Among the diverse set of reasons why and ways in which a reader may try to infer what will occur in the continuation of a story, we focus on a common way in which authors attempt to intentionally cause such inference in the reader. Commonly known as *foreshadowing* (Chatman, 1980), this authorship techniques involves giving readers implicit hints that can, in various ways, provide clues about the upcoming noteworthy events in the story. Foreshadowing can have various degrees of subtly. In some cases, it can create a vivid question mark in user's mind about why a particular point is mentioned in the story (e.g. "the road seemed scary and dark, with no barriers in the middle of it"). In such cases, foreshadowing is more likely to lead to predictive inference. At other times, what is also recognized as foreshadowing may be too subtle of a hint to drive predictive inference and may not pose a question mark to the user until a later event reveals a rather cryptic connection. In both cases, the goal is for the reader to realize this connection and make sense of a "coherent macrostructure" of the story in retrospect; a notion called postdictability by Kintsch (Kintsch, 1980).

There have been a few notable attempts to generate foreshadowing in stories. Minstrel (Turner, 1994), relying on a bank of stories that it has seen before and knows about, attempts to foreshadow those upcoming events that are uncommon and hence unexpected. In (Bae & Young, 2008), another planning-based system provides solutions for generating foreshadowing and flashbacks for events that are found to be surprising. Suspenser (Cheong & Young, 2006) uses similar approaches to generate suspense in a planning-based story generation system. While our focus on cognitive interest and foreshadowing is not part of a story generation system, it can be used in one and the aforementioned system are a great source of inspiration for our work. However, as explained earlier, our focus is on systems that cannot assume the levels of semantics needed for use in planning-based systems.

Using Word Vectors to Find Foreshadowing

Estimating the presence of foreshadowing, without a semantic model of the domain, is a complicated task. Foreshadowing can take many different shapes, be causal or non-causal, and can depend on domain-specific clues. However, certain cases of foreshadowing involve usage of words that co-occur in many contexts and hence, are likely to have similar word vectors in an embedding space. This is the main intuition behind our approach.

Obtaining the Story Keywords Consider the example story in Table. 1. It contains a case of foreshadowing with a potential to cause predictive inference in the reader: event 5 (waiter is distracted and tired) foreshadows event 7 (food is wrong, waiter apologizes). Treating all the words in the story as a bag-of-words, we first remove stop words (e.g. "the", "is"), and then further narrow down our selection of words using part-of-speech tags. In order to focus on the words that capture most of the events and descriptions in the story, we select verbs, nouns and adjectives. Specifically, for verbs we use verb roots extracted via VerbNet (Schuler, 2005) and for nouns we exclude named-entities such as "Sam". It is worth noting that the current target for state-of-the-art open story generation approaches is short stories that are 6-10 sentences (Purdy et al., 2018).

Table 1: An example story which contains a case of foreshadowing. The numbers on the left are story event indexes.

1	Sam and Judy went out for dinner at their favorite restaurant.
2	While driving to the restaurant, Judy's favorite song played on the radio.
3	Sam found a parking space at the very front of the restaurant.
4	Sam and Judy were seated immediately and ordered their favorite food to the waiter.
5	The waiter looked distracted and tired but was polite while taking their order.
6	Sam's favorite song played on the radio while they waited for their food.
7	When the waiter returned with their food it was all wrong! The waiter apologized and returned a few minutes later with the correct order.
8	Sam and Judy enjoyed their meal.
9	They paid their tab, left a tip for the waiter, and drove back home.

Table 2 shows the keywords extracted as above for the story in Table. 1 (using Stanford CoreNLP (Manning et al., 2014) for part-of-speech tags).

Table 2: Extracted keywords from the story in Table. 1.

waiter, return, pay, song, seat, order, radio, look, go, apologize, dinner, take, home, wrong, favorite, find, space, leave, minutes, restaurant, food, enjoy, parking, tired, drive, distracted, front, correct, meal, tip, tab, play, wait

Vectorizing and Visualizing the Story Keywords We used GloVe embeddings, pre-trained on Wikipedia articles, in order to obtain a set of vectors that represent the words in Table 2. Hence, this set of vectors represent the major occurrences and descriptions in the story, as they map onto the embedding space at use. Moreover, by extension, these vectors can also represent major groups of concepts that are perceived by the audience when reading the story.

The original embedding space used is 300-dimensional. In order to visualize the word vectors, we used the T-SNE algorithm (Maaten & Hinton, 2008) to yield a 2-D representation of them. The results can be seen in Fig. 1.

Interpreting the Vector Space The T-SNE visualization shows to us that certain clusters of words can be distinguishable from others. These clusters can semantically categorize the contents of the story without any semantic models of the domain, such that each focus on a particular aspect of the story, involving its own events, objects and specificities. Attempting to extract some of the clusters seen in Fig. 1, we notice the following by grouping the words that are reasonably close to each other:

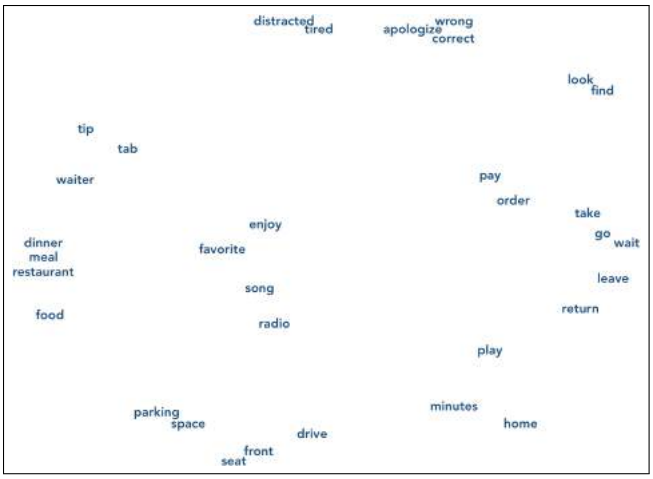

Figure 1: 2-dimensional T-SNE visualization of the GloVe vectors representing the keywords in Table 2.

- **dining:** waiter, restaurant, dinner, meal, food, tip, tab
- **car:** parking, front, seat, space, drive
- **logistics:** return, take, wait, go, leave
- **music:** song, radio, enjoy, favorite
- **cashier:** pay, order
- **searching:** look, find
- **mistake-recovery:** distracted, tired, apologize, wrong, correct
- **play-minute-home:** play, minute, home

It is also worth noting that other unsupervised clustering approaches, such as K-means, would lead to very similar clusters. We used T-SNE for this analysis because K-means proved less deterministic and could yield less predictable results depending on its starting state; however, the distance between two given pairs of word vectors is constant, hence, T-SNE depicts an appropriate representation of those constant distances.

Finding the "Key Event" Usually, a key event in a short story (or a segment of a long one) is the target of foreshadowing. In classic dramatic structures, such event can play the role of the story "climax" (Elson, 2012b). Alternatively, an "inciting incident" in the story (McKee, 1997) can become the subject of foreshadowing. Such events are often followed by a resolution (e.g. the correct food order is then brought, in our example story). Usually, this key event is unexpected,

surprising, or otherwise interesting to the audience, such that it would justify the telling of the story in the first place. Finding this key event without semantic models of the story's domain is not an easy task. Most techniques employed for this purpose depend on irregularities and unexpectedness in a story. In order to find irregularities, one would need to first develop an understanding of regular progressions of the story first (without relying on a priori semantics about them). In (Behrooz, Swanson, & Jhala, 2015), for instance, sequence modeling is employed to build a model of regular event sequence in a domain, and subsequently, irregular progressions of the story and the events that cause them are identified.

In this paper, we use the *cosine similarity* of vectors representing all of the verbs in the story in order to find the most anomalous verb. Based on the above, this verb has the highest chance of being part of the key event. In Table 3, all of the roots of the verbs in the story in Table 1 are listed along with the cosine similarity metric between *each verb root vector* and the *mean of all verb root vector* in the story. This measure can indicate how close or far each verb vector is from the rest of the verbs in the story, and hence, how semantically related or unrelated.

Table 3: Verb roots of all of the verbs in the story in Table 1 (excluding stop words), along with a cosine similarity distance between each verb root vector and the mean of all verb root vectors. Verb roots are obtained using VerbNet (Schuler, 2005), and word vectors using a pre-trained GloVe model (Pennington et al., 2014).

Verb root	Cosine similarity
go	0.838
drive	0.517
play	0.609
find	0.734
seat	0.416
order	0.566
look	0.698
take	0.839
favorite	0.458
wait	0.697
return	0.697
apologize	**0.335**
enjoy	0.57
pay	0.631
leave	0.744

As we can see in the Table 3, the verb `apologize` is the most anomalous verb in our example story, since it has the lowest cosine similarity score with the mean of all verb root vectors. We identify this verb as the *key verb* in the story, and since the key verb is mentioned in event 7 (in Table 1), we also identify that event as the *key event* in the story.

Finding the Foreshadowing Cluster Given the key event and key verb, as described above, we can use the keyword clustering of the story, seen in 1, to find out if there exists a cluster whose constituent keywords:

1. play a role in the key event and include the key verb, and,
2. play a role in one other preceding event (or sentence) in the story.

With such constraints considered, we can see that the **mistake-recovery** can be the *foreshadowing cluster*; a cluster that includes the words involving the foreshadowing in the story.

Finding the Foreshadowing The preceding event or sentence in the story in Table 1, in which the foreshadowing cluster plays a role, is event 5. Hence, we can guess that event 5 has a chance of foreshadowing our key event, 7. Moreover, as a whole, these steps can result in an estimate of the presence of foreshadowing in the story.

Unexpectedness

As mentioned before, many approaches to open story generation focus on finding the usual progressions of events in the story. Among such approaches are story scripts (Schank & Abelson, 2013) which argue that plots about many domains of storytelling usually follow a similar general pattern. Another example are Plot Graphs (Li et al., 2013), which use crowdsourcing to build networks of usual progressions and precedence rules of events (e.g. a graph covering many of the usual paths that a "dining at a restaurant" story would cover). In (Purdy et al., 2018), using a corpus of movie plot summaries, a temporal ordering network is created to capture the common ordering of verbs in stories. The resulting proxy measure, introduced earlier as "temporal ordering", is then used to find the extent to which a new sequence of events adheres to the common ordering of events in stories.

While such adherence would help estimate a correct causal chain of events or logical precedence between them, it is noteworthy that one of main reasons for cognitive interest in stories is the *unexpectedness* of events (Schank, 1979). Hence, as a story generator would benefit from a proxy measure for correct temporal ordering of events, it may also benefit from one that rewards it for having some unexpected event.

"The Inverted-U Function" Kintsch (Kintsch, 1980) argues that cognitive interest can be an "inverted-U" function of knowledge and uncertainty about the story. Simply described, this view argues that if a story creates too many or too few question marks in user's mind, it is less likely to be perceived as interesting. This guides us towards a proxy measure that can have a higher value if a story deviates in small amounts from the usual ordering of events, and a lower

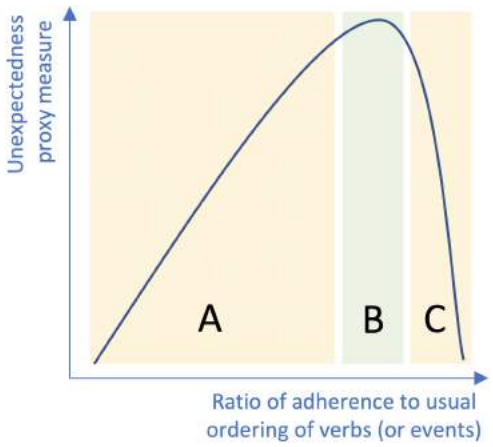

Figure 2: An illustration of a cognitive interest proxy measure based on unexpectedness and inspired by Kintsch arguments (Kintsch, 1980). The area marked as *A* denotes a story that does not sufficiently adhere to the usual ordering of verbs (or events). *C* shows an area where there is no or too little deviation from the usual ordering for the story to cause cognitive interest. *B* shows an area indicating that the story generally adheres to the usual ordering, but contains enough deviations and hence may cause cognitive interest.

value if it deviates too much from (or does adheres at all to) the usual ordering. Using a temporal ordering network, for instance, an unexpectedness proxy measure can have its highest value if most but not all (e.g. 90%) of the pairs of verbs in the story adhere to the network's order. The proxy measure would sharply decrease if this adherence ratio is much less, or approaches 1. An illustration of such proxy measure function can be seen in Fig. 2.

Unexpectedness and Word Vectors Using a vector space that represents verbs (or sentences (Pagliardini, Gupta, & Jaggi, 2017)) in a story, the distance between each vector and the average of all vectors belonging to a story (similar to Table 3) can estimate how unexpectedly each verb is perceived compared to the rest of the story. Hence, in order to follow an inverted-U pattern, a proxy measure of unexpectedness can have the highest value when most entries in Table 3 have large values, but at least one entry has a much lower value than others.

Conclusion

Communication context is a consequential factor in narrative generation, in terms of approach, constraints, and evaluation criteria. Certain narrative generation approaches are tied to a specific communication context (e.g. games) and depend on that context's a priori semantics to evaluate how good a generated story is. Other approaches are not bound to a specific context (called *open story generation*) and often use generic text quality measures to assess the quality of the story. Given the importance of narrative perception in real-world use cases of such story generation (e.g. by an intelligent agent), we draw from theories of cognitive interest and investigate the use of word embeddings vectors to find how interesting a generated narrative is. Specifically, we assess the existence of predictive inference (through foreshadowing) and unexpectedness in stories, using GloVe word vectors (Pennington et al., 2014). We plan to evaluate this approach in a situated scenario and seek to find correlations between proxy measures of cognitive interest and judgments of human subjects.

Abstract

People predict incoming words during online sentence comprehension based on their knowledge of real-world events that is cued by preceding linguistic contexts. We used the visual world paradigm to investigate how event knowledge activated by an agent-verb pair is integrated with perceptual information about the referent that fits the patient role. During the verb time window participants looked significantly more at the referents that are expected given the agent-verb pair. Results are consistent with the assumption that event-based knowledge involves perceptual properties of typical participants. The knowledge activated by the agent is compositionally integrated with knowledge cued by the verb to drive anticipatory eye movements during sentence comprehension based on the expectations associated not only with the incoming word, but also with the visual features of its referent.

Keywords: event knowledge; anticipatory eye movements; visual perception; prediction.

Introduction

People use their experiences of events in the world to organize their semantic knowledge about objects and actions (Radvansky & Zacks, 2014). For example, the event of "going to a restaurant" implies the presence of waiters, tables, food, and money as well as actions of cooking, serving, and eating. Several studies have illustrated the central role of knowledge about events in online sentence comprehension. Event knowledge is cued by lexical items, integrated to form a coherent representation of the situation being described, and used to generate expectations about incoming input. (Tanenhaus et al., 1995; Altmann, 1999; Altmann & Kamide, 1999, 2004, 2007; Kamide et al., 2003; Knoeferle, Crocker, Scheepers, & Pickering, 2005; Knoeferle & Crocker, 2006, 2007; Bicknell et al. 2010; Matsuki et al. 2011; Metusalem et al., 2012). In this paper, we present an eye-tracking experiment that investigates the hypothesis that event knowledge activated during sentence comprehension is inherently multimodal, because it derives from people's sensori-motor (i.e., watching and performing events) and linguistic experiences (i.e. talking and reading about events), and allows people to generate expectations not only about the most likely noun filler of a verb's thematic role (e.g., *ball* as a typical patient of *throw*), but also about the visual properties of the noun referent (e.g., oval ball vs. round ball).

We used the visual world paradigm to investigate how event knowledge activated by an agent-verb pair is integrated with perceptual information about the referent that fits the patient role. For instance, the noun *ball* can refer to a small white baseball, to a large orange basketball, or to a large oval (American) football. We call these nouns *perceptually underspecified*, because the noun in isolation does not entail a specific type of perceptual referent. This affects the kind of predictions that people will generate. Compare for instance the following sentences:

(1) a. *The man threw the ball*.
b. *The quarterback threw the ball.*

In (1a), we cannot anticipate which type of ball was thrown, without further contextual information. Conversely, in (1b) we can predict that the ball is likely to be an oval football. Our hypothesis is that this prediction about the patient in (1b) depends on the integration of event-based knowledge cued by the agent and the verb. In particular, *quarterback* activates knowledge about football, including

that the ball is oval. Once this information is integrated with *throw*, predictions are generated that make *ball* a highly expected patient noun and allow comprehenders to anticipate the specific object to which it refers.

In the present experiment, participants read sentences such as *The doctor/bartender uncaps the bottle*, in which agent-verb pairs denote events that activate knowledge about plausible noun fillers of the patient role. The visual scenes contained two objects that may fit the event expressed by the verb (a pill bottle and a beer bottle). The patient role was filled by a perceptually-underspecified noun that can denote both objects (*bottle*). Anticipatory eye movements on the predicted object mirror the integration of the event-based knowledge activated by the agent-verb pair and perceptual information coming from the visual input during online sentence comprehension.

Related Studies

Words encode mutual expectations between events and their typical participants (McRae et al., 1998; Ferrettti et al., 2001; McRae et al., 2005; Hare et al., 2009). McRae, et al. (2005) found that agents, patients and instruments prime verbs that describe events in which they typically are involved (*waiter*, *chainsaw* and *guitar* prime verbs like *serving*, *cutting* and *strummed*). Bicknell et al. (2010) conducted an Event Related Potential (ERP) experiment to investigate whether an already filled role affects how another role can be filled. They found that typical agent-patient pairs such as *journalist-spelling* and *mechanic-brakes* in *The journalist checks the spelling* and *The mechanic checks brakes* elicited reduced N400s as compared to *The journalist checked the brakes* and *The mechanic checked the spelling*. The effects on N400 amplitudes show both generalization across input modalities and regularity between N400 properties and sensory, conceptual and linguistic factors, suggesting that the effects are modality sensitive but not modality specific (Kutas & Federmier, 2011). According to Kuperberg and Jaeger (2016), "prediction" concerns a change in the state of the language processing system based on the context prior to the availability of new input. The context involves both linguistic and extralinguistic information, that can facilitate the processing of new information at multiple levels of representation, which interact and communicate during language processing. Contextual information includes semantic knowledge about specific events, event structures, event sequences, and general schemas (Altmann & Mirković, 2009; Radvansky & Zacks, 2014). According to Knoeferle and Guerra (2016), during sentence comprehension visual perceptual information interacts with word knowledge. Some eye tracking studies have manipulated argument-verb combinations to investigate anticipatory eye movements (Altmann & Kamide, 1999; Kamide, et al., 2003; Knoeferle & Crocker, 2006, 2007).

Altmann and Kamide (1999) investigated the hypothesis that people tend to predict which object will fit the patient role after hearing the verb. They used sentences like *The boy will eat the cake* in combination with pictures of a boy, a birthday cake, a toy car, a toy train and a ball. Subjects fixated the single edible object in the scene (birthday cake) more often than the other depicted objects before hearing *cake*. By contrast, when subjects heard *The boy will move the cake* with the same visual scene they looked equiprobably at all of the movable objects. This shows that verb selectional preferences constrain the set of possible objects that follow the verb. Kamide, Altmann and Haywood (2003) investigated whether agent-verb pairs elicit anticipatory eye movements toward entities that fit the patient role. Sentences such *as The man will ride the motor bike* and *The girl will ride the carousel* were combined with pictures of a motorbike, a carousel, a beer and a sweet. The same visual scene was presented while participants listened to *The man will taste the beer* and *The girl will taste the sweet*. Anticipatory eye movements on the predicted objects (motorbike and carousel; beer and sweet) were triggered by the verb. The results are consistent with the assumption that expectations associated with agent-verb pairs help people to predict which entity fills the incoming patient role.

Knoeferle and Crocker (2006, 2007) performed an eye tracking experiment to investigate the interplay between current visual context and event knowledge during sentence comprehension. Sentences such as *The detective will soon spy on the pilot* and *The wizard will soon spy on the pilot* (in German) were combined with pictures of a wizard looking a pilot through the telescope, a detective serving the pilot some food, a pilot and a tree. In the verb time window (*spy*) when listening to *The wizard will soon spy on the pilot* (which corresponds to the event occurring in the visual scene) participants often looked more at the wizard, though spying is a detective's typical action. Since the visual scenes provided information that conflicts with typical event knowledge (wizard spies vs. detective spies), the outcomes are consistent with the assumption that listeners exploit information coming from current visual context during online comprehension. These studies suggest that contextual information includes multiple types of knowledge such as event structures and sensory input. Predictions are strongly associated with the interplay among words, event contingencies and conceptually combined knowledge (Altmann & Mirković, 2009; Altmann & Kamide, 2004, 2007; Barsalou, 2008; Hagoort et al., 2004).

Experiment

We investigated how event knowledge activated by an agent-verb pair influences pre-activation of multimodal information about the referent that fits the patient role. Sentences like *The doctor uncaps the bottle* were combined with four pictures such as a pill bottle (target), a beer bottle

(action related object), a syringes (agent related object) and a comb (unrelated object), as shown in Figure 1:

1. **target objects** fit the patient role given the agent-verb combination. Since doctors prescribe and sometimes administer medication, typically they open pill bottles rather than beer bottles;
2. **action related objects** fit the verb (a beer bottle can be uncapped), but not the agent-verb combination
3. **agent related objects** corresponded to objects that commonly occur in situations together with the agents, such as doctors and syringes;
4. **unrelated objects** were not congruent with the agent, verb, or agent-verb combination.

Figure 1. Combination of visual and linguistic stimuli.

The sentence stimuli were divided into two lists and the targets of the first list became the action related objects in the second list, which contained the same verb but a different agent. In *The bartender uncaps the bottle*, for example, the beer bottle was the predicted object (target), and the pill bottle was the action related object. Since the verb-patient pairs co-occur with different agents in the two lists, the agent related objects changed as well. The noun *bartender* cues situations that involve objects such as taps and mug, while *doctor* triggers situations involving surgical scalpels and stethoscopes. The agents activate knowledge about objects that commonly occur in the events performed by them (targets and agent related objects).

Method

Norming

We measured the strength of the association between the agents and the predicted object (target) images. We used the Figure Eight crowdsourcing platform[1] to create a task in which participants evaluated how likely it was that the agent and the object appeared in the same situation, using a scale that ranged from 1 (not very likely) to 7 (very likely). Participants read the name of the agent, such as *doctor*, opened the link for the object picture (pill bottle), and rated "How likely is it that the person and the object appear in the same situation?". The mean ratings were 6.3 and the 95% confidence interval was 0.1. Thus, the agents and the objects were judged to co-occur strongly in the same real-world situations.

Participants

Twenty-four University of Western Ontario undergraduate students were compensated $10 for their participation. They ranged in age from 19 to 28 years. All participants had normal or corrected to normal visual acuity and self-reported English as their native language. Self-reportedly, participants had never endured a traumatic brain injury or illness and were not currently diagnosed with any major psychiatric illness.

Sentences

There were 60 trials consisting of 30 experimental and 30 filler trials. In the experimental trials, participants heard sentences in which the agent performs an action that could be associated with two pictures in the visual scene, the target and the action related object. The patient role was filled by a perceptually underspecified noun that could refer to both objects. The sentences were split into two lists to present only one type of verb-patient pair to each participant. Fifteen filler trials consisted of two pictures of objects that could be denoted by the same word but the sentence did not refer to either of them. It referred instead to a third object. For example, *The man does not like candies* was combined with pictures of a candy, a fishing hook, a coat hook and a candelabra. An additional 15 filler sentences had various syntactic structures and one word referred to one of the pictures (e.g., *Karen made the tea with her new pot* with pictures of a teapot, a marble, a picture frame, a mitten). We used four practice trials to familiarize participants with the experiment.

Auditory Stimuli

A female native English speaker recorded all sentences. They were recorded using Audacity Cross-Platform Sound Editor 2.2.2 (released February 20 2018), and annotated by marking relevant points of the sentence using a customized script in Praat 6.0.37 (retrieved February 3 2018). For each sentence we set a pointer at: agent onset, agent offset/verb onset, verb offset/second article onset, second article offset/patient onset and patient offset as well as the start and end of the sentence. The agent offset/verb onset was normalized in all auditory files (1200 ms).

[1] https://www.figure-eight.com/

Visual Stimuli
All images were presented at 300x300 pixels in colour. Each picture was placed in a different quadrant of the screen at a 45-degree angle from the center. The location of the four images was randomized across trials and participants. The pictures were selected from BOSS[2], KONKLAB[3] and COGPSY Image Corpora.

Eye Tracker
We used a desktop mounted Eyelink 1000 and Experiment Builder, Version 1.10.1241 software (SR Research Ltd.). The camera lens was positioned approximately 60 cm from the participant's head at an approximately 35-degree angle to the participant's eyes. Participants were positioned 70 cm away from a 16-inch monitor displaying the visual stimuli (resolution set to 1024 x 768 dpi). Calibration was performed prior to the start of the experiment, as well as at any time the equipment registered significant head movement.

Procedure
During the first ten seconds of each trial a fixation cross was presented. The participant was then redirected to calibration. After three seconds during which the participant fixated the cross, this was replaced by the four trial images. Participants had one second to become familiar with the images before the auditory stimulus began. A series of red circles were flashed in the center of the screen to bring the participant's attention back to the fixation cross. The sentence began when participants fixated the cross. The four pictures remained on the screen while the sentence was presented and participants' eye movements were recorded. An additional 300 ms of silence followed the end of the sentence. When the images disappeared, the next trial began. Before starting the session, participants were assigned to a list. Each list contained three trial blocks. At the start of the experiment, participants received the following instructions: "You will see a display with four pictures while hearing a sentence. There is no task involved; just look at the pictures and listen to the sentences. We'll start with some practice trials to see how it works." The first block contained four practice trials. Thereafter, participants saw: "This is the end of the practice sessions for part one. Do you have any questions before the experiment begins?" The other two trial blocks contained the experimental and filler trials randomly presented for each participant. Instructions were repeated at the start of each block. An equal number of experimental and filler items were presented in each list. Participants were given a short break between blocks to rest their eyes.

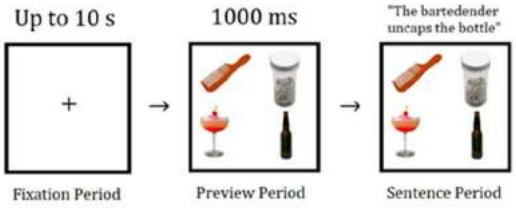

Figure 2. Example of the procedure for one trial.

Results

We recorded the proportion of fixations on the target pictures and compared them to the proportions of fixations on the other pictures (agent related, action related and unrelated) in specific time windows (agent, verb and patient). We analyzed three time windows: the agent (*bartender*); the verb + article (*uncaps the*), which is the anticipatory time window, and the patient (*bottle*). The Area Of Interest (AOI) for each picture consisted of each screen quadrant. The analyses were conducted with RStudio Version 1.1.463 (2009-2018). We fit one Linear Effects Mixed Model (LMER) for each time window using the lmer() function from the linear mixed effects package lme4 (Bates et al., 2015; Baayen et al., 2008; Barr et al., 2013). The four AOIs and the two lists are the fixed effects. We calculated two random slopes accounting for random effects (subjects and trials). Fixed and random effects remain stable for each model and during all the analyses conducted on the dataset. For each time window, we calculated estimated means of proportions, Standard Errors, *t*-values, and *p*-values of AOIs comparisons (Table 1).

Agent window
The agent time window extended from agent onset (610 ms) to verb onset (1200 ms). The duration was 590 ms. The onsets of the spoken sentences were preceded by a silence to normalize the verb onset (457 ms). There were no significant differences in proportions of fixations. Moreover, there were no significant differences in proportions of fixations between the action, agent related and unrelated objects (Table 1).

	List1-List2	0.03	0.02	1.73	0.1

Verb window

The verb time window extended from verb onset (1200 ms) to the second article offset/patient onset (1899 ms). The duration was 699 ms. Participants fixated the object that fit the agent-verb combination more often than the objects that were associated with the verb only, the agent only or the unrelated object. Furthermore, the agent-related and action-related objects were fixated significantly more often than the

unrelated object. Finally, participants fixated the agent-related object more often than the action related object.

Patient window

The patient time window extended from the patient onset (1899 ms) and to end of sentence (2524 ms). Again, participants fixated the object that fit the agent-verb combination more often than each of the other objects. Both the agent-related and action-related objects were fixated more often than the unrelated object.

Discussion

Our results support the hypothesis that the knowledge activated by the agent concerning events in which it typically appears is compositionally integrated with knowledge cued by the verb, so as to drive anticipatory eye movements during online sentence comprehension. This is consistent with the assumption that during language comprehension people generate expectations using their multimodal knowledge about experienced situations in the world (Zwaan & Radvansky 1998; Barsalou 2008; Radvansky & Zacks 2014). Such integrated multimodal event knowledge allows comprehenders to resolve the perceptual underspecification of the patient noun and to anticipate the appropriate type of referent in the situation triggered by the agent-verb combination. According to Huettig and McQueen (2007), there is an interplay during the comprehension between the stored knowledge of visual properties of referents elicited by the spoken words and perceptual information in the current visual input. Our results suggest that the information in the current visual context was integrated with event knowledge cued by agent-verb pairs, eliciting the knowledge of the correct referent of the unfolding patient role. This is also consistent with Altmann and Kamide (1999), Kamide, Altmann and Haywood (2003), and Knoeferle and Crocker (2006, 2007), who demonstrated that word meaning combines with visual perceptual information to contribute to predictive processes involving event-based knowledge. This supports the hypothesis that the stored event knowledge is associated with perceptually based information that can be elicited by the current visual context and by specific agents. These cue information about particular referents that could fit the unfolding patient. What distinguishes this study from Kamide et al. (2003) is the use of very specific agents (doctor/bartender vs. girl/man) and referents (pill bottle/beer bottle vs. sweet/beer) in linguistic and visual stimuli respectively. Their combinations allowed us to investigate the hypothesis that comprehenders make extremely fine-grained predictions about referents of patient roles exploiting the event knowledge cued by agent-verb combinations and the visual context.

From a computational linguistic perspective, predicate-argument expectations have been modeled using distributional semantics (Erk, Padò and Padò 2010; Erk & Padò 2008; Lenci 2011; Santus et al. 2017). Distributional Semantic Models collect corpus-based co-occurrence statistics and encode them in vectors (also known as *word embedding*) that represent word meaning according to the so-called Distributional Hypothesis (Lenci 2018). Since these models represent the meaning exclusively in terms of connections between words, several recent studies have focused their attention on the combination of textual and visual information extracted from pictures, yielding Multimodal Distributional Semantic Models (Bruni, Tran, Baroni 2014; Lazaridou, Pham & Baroni 2015; Kiela 2016).

We plan to use multimodal distributional semantics to model the behavioral data we have collected in our experiment. We expect this computational model should be able to predict that a quarterback throws an oval ball while a pitcher throws a small white ball based on the integration of multimodal distributional information cued by lexical items.

Abstract

Human decision-making deviates from the optimal solution, i.e. the one maximizing cumulative rewards, in many situations. Here we approach this discrepancy from the perspective of computational rationality and our goal is to provide justification for such seemingly sub-optimal strategies. More specifically we investigate the hypothesis, that humans do not know optimal decision-making algorithms in advance, but instead employ a learned, resource-constrained approximation. The idea is formalized through combining a recently proposed meta-learning model based on Recurrent Neural Networks with a resource-rational objective. The resulting approach is closely connected to variational inference and the Minimum Description Length principle. Empirical evidence is obtained from a two-armed bandit task. Here we observe patterns in our family of models that resemble differences between individual human participants.

Keywords: Bounded rationality; computational rationality; variational inference; reinforcement learning; meta-learning; individual differences; multi-armed bandit

Introduction

In this work we study human decision-making strategies on a stationary multi-armed bandit task. These are among the simplest sequential decision-making problems, that require reasoning about trade-offs between exploration and exploitation. In the special case of an infinite horizon and geometric discounting their Bayes-optimal solution is the Gittins index strategy (Gittins, 1979), while in general it is defined as the result of a planning process in an augmented Markov Decision Process (Duff & Barto, 2002). Prior work however suggests, that several heuristics appear to be favourable as a model of human decision-making, when compared to the Bayes-optimal solution (Steyvers, Lee, & Wagenmakers, 2009; Zhang & Angela, 2013).

Understanding human cognition in terms of heuristics has been a major theme in cognitive science over the past decades (Tversky & Kahneman, 1974; Simon, 1990; Gigerenzer & Todd, 1999). They can be viewed as crude, but realizable, approximations of optimal behavior. Heuristics are thus connected to the idea of rationality under resource constraints, which is commonly referred to as bounded rationality (Simon, 1972), computational rationality (Gershman, Horvitz, & Tenenbaum, 2015), or resource-rationality (Griffiths, Lieder, & Goodman, 2015). Examples for resource constraints include related prior experience on a given task, limited capacity of our brain or restricted deliberation times. For a more general overview of computational rationality we refer the reader to Gershman et al. (2015). Here we are interested in the hypothesis, that humans employ a learned, resourced-constrained approximation of an optimal decision-making strategy. More specifically we show, that different, potentially sub-optimal, human strategies emerge naturally in artificial learning systems when varying the strength of the constraints placed upon them. For a realization of this principle, we rely on information-theoretic concepts, similar to the approach of Ortega and Braun (2013).

We instantiate a particular kind of such resource-rational agents using recent advances from the meta-learning literature (Wang et al., 2016; Duan et al., 2016). In this framework the algorithm to be learned is parametrized by a Recurrent Neural Network (RNN). RNNs are known to be Turing-complete and hence are in theory able to realize any algorithm (Siegelmann & Sontag, 1991). The RNN is trained on a set of related tasks to act as an independent Reinforcement Learning algorithm for solving the original problem. We treat all parameters of the RNN as random variables and infer approximate posterior distributions by solving a regularized optimization problem. Varying the regularization factor leads to a spectrum of resource-rational algorithms, each possessing different properties. Models with large constraints need to rely more on prior assumptions and thus prefer simple strategies, while models with weaker constraints will approach the optimal solution (up to the representational capabilities of the RNN and the limitations of the meta-learning procedure).

The resulting approach is closely related to the Minimum Description Length (MDL) principle (Hinton & Van Camp, 1993; Grunwald, 2004), which asserts that the best model is the one, that leads to the best compression of the data, including a cost for describing the model. The bits-back argument establishes a link between the MDL principle and Bayesian learning (Honkela & Valpola, 2004), opening up connections to Bayesian theories of cognition (Griffiths, Kemp, & Tenenbaum, 2008). Indeed several heuristics have been recently interpreted as Bayesian models under strong priors (Parpart, Jones, & Love, 2018).

Our hypothesis is validated on a classical two-armed bandit task. However we view multi-armed bandits merely as

the first step towards investigating more complex tasks and the proposed algorithm is not limited to any specific problem class. The following section first introduces the framework in more general terms, before considering multi-armed bandits as a special case. We then identify different strategies of human participants and subsequently show how the proposed class of models captures important characteristics of human behavior on both a qualitative and quantitative level. Our results indicate, that the seemingly sub-optimal decision strategies used by humans might be a consequence of the constraints under which these very strategies are learned.

Methods

Reinforcement Learning

Let $M = (\mathcal{S}, \mathcal{A}, p, \gamma)$ be a Markov Decision Process (MDP), with a set of states $\mathcal{S}$, a set of actions $\mathcal{A}$, a joint distribution over the next state and a scalar reward signal, describing the dynamics of the environment, $p(s_{t+1}, r_t | s_t, a_t)$ and a discount factor $\gamma \in [0,1]$. The objective of a Reinforcement Learning (RL) agent is to find a policy $\pi(a_t|\cdot)$, that maximizes the discounted, expected return $\mathbb{E}_{p,\pi}\left[\sum_{t=0}^{\infty} \gamma^t r_t\right]$ without having direct access to the true underlying dynamics p.

Learning Reinforcement Learning Algorithms

Following the approach of Wang et al. (2016); Duan et al. (2016) we want to *learn* a RL algorithm for solving a MDP sampled from a distribution over MDPs. We parametrize the algorithm to be learned with a Recurrent Neural Network (RNN), in form of a Gated Recurrent Unit (Cho et al., 2014), followed by a linear layer. The set of all model parameters is denoted with θ in the following. The RNN takes previous actions and rewards as inputs in addition to the current state, making the output a function of the entire history $X_t = (s_0, a_0, r_0, s_1 \ldots, a_{t-1}, r_{t-1}, s_t)$. A good algorithm has to integrate information from the history in order to identify the currently active MDP, based on which it subsequently has to select the appropriate strategy. The RNN is trained to accomplish this using standard model-free RL techniques. In this work we utilize n-step Q-Learning (Mnih et al., 2016), although in theory any other algorithm could be applied as well. The RNN implements a freestanding RL algorithm through its recurrent activations after training is completed (the parameters of the RNN are held constant during evaluation). Throughout this work we use the abbreviation LRLA – for learned Reinforcement Learning algorithm – to refer to this kind of model. Alternatively we can view this procedure as a model-free algorithm for partially observable MDPs, where the hidden information consists of the currently active task.

Resource-Rational Decision-Making

We consider maximizing the following regularized objective for inferring a distribution q_ϕ over parameters θ of LRLAs:

$$\mathcal{L}(\phi, \mathbf{X}, \mathbf{y}) = \mathbb{E}_{q_\phi(\theta)}\left[\log p(\mathbf{y}|\mathbf{X}, \theta)\right] - \beta \mathrm{KL}(q_\phi(\theta)||p(\theta)) \quad (1)$$

where the hyperparameter β controls how much the posterior is allowed to deviate from the prior in terms of the Kullback-Leibler (KL) divergence. We assume a likelihood $p(\mathbf{y}|\mathbf{X}, \theta)$, that factorizes over data points $\prod_{i=1}^{N} p(y_i|X_i, \theta)$ and we approximate each factor with a normal distribution of fixed scale σ_y: $\mathcal{N}(y_t; Q_\theta(X_t, a), \sigma_y)$. In our setting $Q_\theta(X_t, a)$ corresponds to the RNN output after seeing history X_t and y_t corresponds to the n-step return $\sum_{k=0}^{n-1} \gamma^k r_{t+k} + \gamma^n \max_a Q_\theta(X_{t+n}, a)$. The corresponding policy is derived as follows:

$$\pi(a_t|X_t) = \begin{cases} 1 & \text{if } a_t = \arg\max_{a \in \mathcal{A}} Q_\theta(X_t, a) \\ 0 & \text{else} \end{cases} \quad (2)$$

Setting β to a specific value can be interpreted as implicitly defining a constraint on $\mathrm{KL}(q_\phi(\theta)||p(\theta))$. Importantly the KL term determines how much the model parameters can be compressed in theory (Hinton & Van Camp, 1993). Hence our models are resource-constrained with regard to a hypothetical lower bound on their storage capacity. Intuitively, if the regularization factor β is large, parameters are forced to match the prior closely. In this work we employ priors favoring simple functions, hence models are only allowed to realize more complex functions as $\beta \to 0$.

Bayesian Interpretation

If we set $\beta = 1$, we recover the evidence lower bound (ELBO) as an objective for performing variational inference. In the setting of large data-sets subsampling techniques are often employed to approximate Equation 1 using mini-batches $\mathcal{B}$ of size M with an appropriately scaled log-likelihood term:

$$\log p(\mathbf{y}|\mathbf{X}, \theta) \approx \frac{N}{M} \sum_{i \in \mathcal{B}} \log p(y_i|X_i, \theta) \quad (3)$$

If data arrives in sequential fashion, as it does in the RL setting, the data-set size N is not known in advance and has to be treated as an additional hyperparameter. This leads to a Bayesian interpretation of Equation 1 even for $\beta \neq 1$. For any values of β and N maximizing Equation 1 is equivalent to performing stochastic variational inference with an assumed data-set size of $\hat{N} = \frac{N}{\beta}$. In practice we optimize a by N^{-1} scaled version of Equation 1, which leads to $\hat{N}^{-1}$ as a factor for the KL term.

In the following section we investigate whether we can understand individual differences in human decision-making in terms of optimal solutions to Equation 1 for varying values of β. It is worth clarifying, that we are only interested in the computational aspects of this hypothesis, i.e. we want to test, whether human decision-making can be characterized through resource-rational strategies. We do not attempt to answer how this objective is realized on an algorithmic or implementational level.

Technical Details

We maximize Equation 1 using standard gradient-based optimization techniques. For this we simulate k environments in

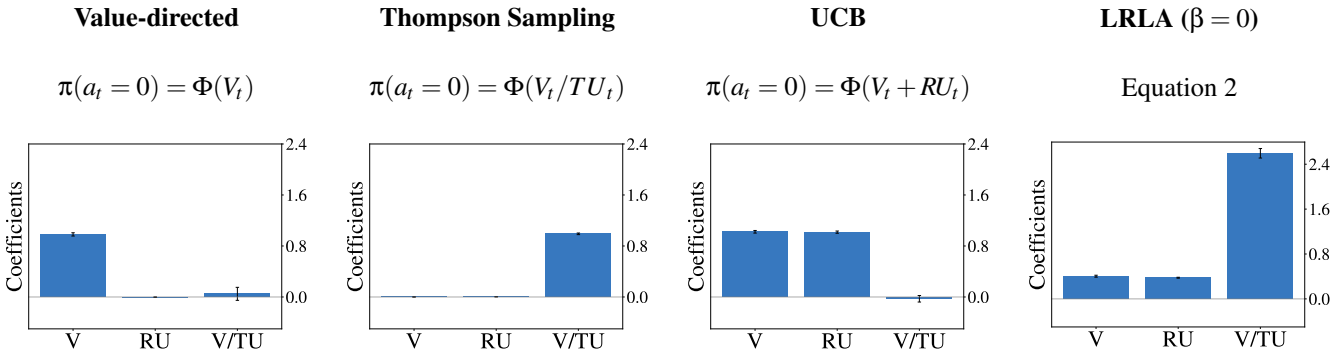

Figure 1: Illustration of different algorithms for two-armed bandits. **Middle**: Definitions of the respective policy. **Bottom**: Coefficients obtained from fitting the probit regression (Equation 5) to corresponding trajectories. Error bars indicate the uncertainty (one standard deviation) in the coefficients estimated through a Laplace approximation. Note, that for LRLAs the coefficients are task-dependent. For this plot we use the set of two-armed bandits described in the later sections to compute the coefficients. Φ denotes the cumulative distribution function of a standard normal distribution.

parallel and update the model at the end of each episode. All models in this work employ a group horseshoe prior, which can be viewed as a continuous relaxation of a spike-and-slab prior (Mitchell & Beauchamp, 1988), over their weights:

$$s \sim \mathcal{C}^+(0, \tau_0); \quad \tilde{z}_i \sim \mathcal{C}^+(0,1);$$
$$\tilde{\theta}_{ij} \sim \mathcal{N}(0,1); \quad \theta_{ij} = \tilde{\theta}_{ij}\tilde{z}_i s$$

and we represent the approximate posterior $q_\phi(\theta)$ through a fully factorized distribution as proposed in (Louizos, Ullrich, & Welling, 2017). The hyperparameter of the horseshoe prior is fixed to $\tau_0 = 10^{-5}$. The horseshoe prior is a sparsity-inducing prior, which causes our models to implement simple functions in absence of any experience. During training we approximate the expectation of the log-likelihood term with a single sample from $q_\phi(\theta)$ and make use of the reparametrization trick (Kingma & Welling, 2013). Resampling of weight matrices is done only at the beginning of an episode as proposed in Gal and Ghahramani (2016); Fortunato, Blundell, and Vinyals (2017). Target values y_t are computed using the maximum a posteriori estimate of a separate target network (Mnih et al., 2013; Lipton et al., 2017). For additional details we refer the reader to the publicly available implementation[1].

Multi-Armed Bandits

Experiments in the following section involve a multi-armed bandit task. These are MDPs consisting of a single state. At each step t an agent selects one out of multiple actions and is rewarded according to an unknown, stationary distribution based on its choice. This interaction is repeated T times.

The trade-off between exploiting good options and exploring yet unknown ones is the central theme in multi-armed bandits (and in RL in general). Methods for resolving this exploration-exploitation dilemma can be categorized in two major groups: directed and random exploration strategies. Directed exploration attempts to gather information about uncertain, but learnable, parts of the environment, while random exploration injects stochasticity of some form into the policy. Gershman (2018) showed, that these two principles can be distinguished exactly under certain conditions. For this we consider a two-armed bandit task with normal distributions over both the mean of rewards for each arm and their reward noise at each time-step. Let $\mathcal{N}(r_a; \mu_{0,a}, \sigma_{0,a})$ be an independent normal prior over expected rewards for each action a and $\mathcal{N}(r_a; \mu_{t,a}, \sigma_{t,a})$ be the posterior after t interactions. Many popular strategies can be formulated using the parameters of these distributions. Define:

$$\begin{aligned} V_t &= \mu_{t,0} - \mu_{t,1} \\ RU_t &= \sigma_{t,0} - \sigma_{t,1} \\ TU_t &= \sqrt{\sigma_{t,0}^2 + \sigma_{t,1}^2} \end{aligned} \tag{4}$$

V_t constitutes the estimated difference in value, while RU_t and TU_t describe relative and total uncertainty respectively. Choice probability in Thompson sampling (an example for random exploration) is only a function of V_t and TU_t, while it is a function of V_t and RU_t for the UCB algorithm (an example of directed exploration). Figure 1 (middle row) shows definitions of all strategies under consideration. For a given set of observed trajectories $\mathcal{D}$ one can fit a probit regression model to infer the importance of factors from Equation 4:

$$p(a_t = 0 | \mathcal{D}, \mathbf{w}) = \Phi(w_1 V_t + w_2 RU_t + w_3 V_t/TU_t) \tag{5}$$

Analyzing the resulting coefficients $\mathbf{w}$ can reveal, which exploration strategy generated the observations, as shown in Figure 1 (bottom row). We utilize this form of analysis throughout the following sections.

Empirical Analysis

Human Participants

We initially inspect human exploration strategies on a two-armed bandit task with episode length $T = 10$. The mean

Prototypes were obtained from a mean-shift clustering, shown in the middle plot. Colors correspond to clusters. Error bars indicate the uncertainty (one standard deviation) in the coefficients estimated through a Laplace approximation. **Middle**: UMAP (McInnes & Healy, 2018) embedding of coefficients for all participants. **Right**: Joint UMAP embedding of coefficients for human participants and LRLAs $\in \mathcal{H}_{\text{LRLA}}$.

reward for each action is drawn from $\mathcal{N}(\mu_a; 0, \sqrt{100})$ at the beginning of an episode and the reward in each step from $\mathcal{N}(r_t; \mu_{a_t}, \sqrt{10})$. Intuitively we expect some participants to be more proficient at the task, for example because they have more experience at related problems (higher $\hat{N}$), while the opposite is true for others. We rely on data gathered by Gershman (2018), which contains records of 44 participants, each playing 20 of the aforementioned two-armed bandit problems. Figure 2 (middle) shows the result of fitted probit regression coefficients for individual participants. This analysis reveals three major subgroups within the population, each using a different set of strategies. We visualize coefficients of three example participants (Figure 2, left) and observe, that a large fraction is well-described through Thompson sampling (clusters 2 and 3), while other participants have tendencies towards a mixture of strategies (cluster 1).

Learned Reinforcement Learning Algorithms

Next we show, that optimizing LRLAs with different regularization factors leads to the emergence of diverse exploration pattern. We train otherwise identical models for $\hat{N} \in \mathcal{H}_{\text{LRLA}} = \{256, 512, 1024, 2048, 4096, 8192\}$ on the same two-armed bandit task until convergence and report average results over 10 random seeds unless otherwise noted. Equation 1 is approximated with a batch of samples from complete episodes of 16 parallel simulations and gradient-based optimization is performed using Adam (Kingma & Ba, 2014). Figure 3 (left) shows, that performances continuously improves as $\hat{N}$ increases, confirming our expectation that models become more sophisticated for large $\hat{N}$. Fitting the aforementioned probit regression model to the resulting policies (Figure 3, right) reveals value-based characteristics at one end of the spectrum. Towards the other end we observe coefficients, that slowly transition to those of the unconstrained ($\beta = 0$) model.

Modelling Human Behavior

We are mainly interested in whether the set of resource-constrained LRLAs can help us to understand human behavior on an individual level. To answer this question, we compare the optimized models to human decision-making strategies in terms of the probit regression analysis. We visualize the regression coefficients for 50 models (10 for each value of $\hat{N} \in \mathcal{H}_{\text{LRLA}}$, excluding $\hat{N} = 256$) alongside those of the human participants in Figure 2 (right). Although some parts of the low-dimensional embedding are over- and underrepresented, the overall variation of human exploration strategies is captured by the resource-constrained LRLAs.

Model Comparison

The regression analysis performed so far provides only qualitative indicators for our hypothesis. In order to obtain a quantitative measure for the explanatory power of the proposed hypothesis, we performed a Bayesian model comparison. Figure 4 (left) shows log-likelihoods for each participant and model. We observe, that different participants are modelled best with different values of $\hat{N}$.

To verify that the class of resource-constrained LRLAs $\mathcal{H}_{\text{LRLA}}$ contains a good model, we compute Bayes factors (BF) between the marginal probability of the resource-

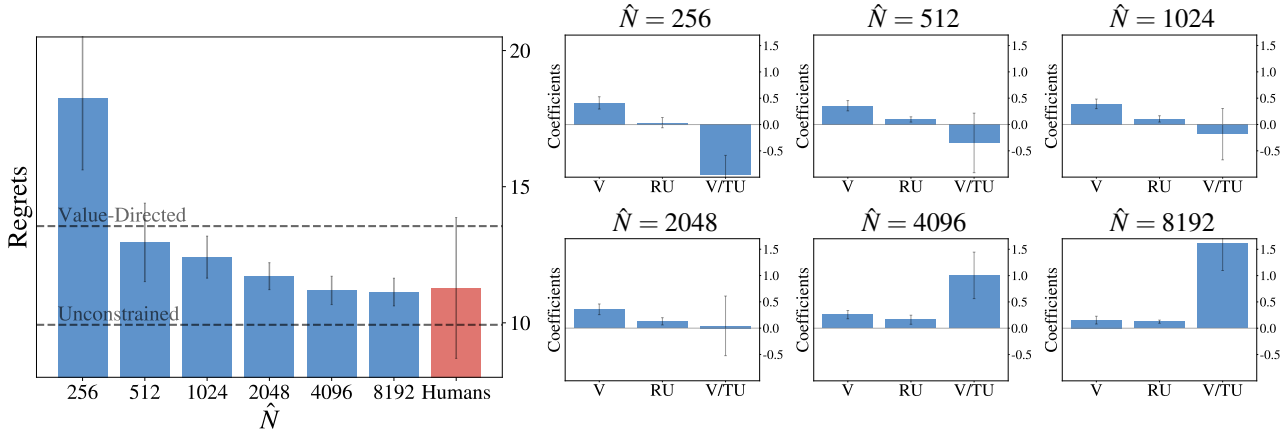

Figure 3: Results for optimized LRLAs with different $\hat{N}$. **Left**: Visualization of per episode regret averaged over 10 models and 1000 episodes. Horizontal lines correspond to the performance of a value-directed policy and an unconstrained LRLA. **Right**: Coefficients of the probit regression from Equation 5. Error bars indicate standard deviations across the 10 models.

constrained LRLAs and a value-directed policy:

$$\log BF_i = \log p(\mathcal{D}_i|\mathcal{H}_{\text{LRLA}}) - \log p(\mathcal{D}_i|H_{\text{value-directed}})$$
$$p(\mathcal{D}_i|\mathcal{H}_{\text{LRLA}}) = \frac{1}{|\mathcal{H}_{\text{LRLA}}|} \sum_{H \in \mathcal{H}_{\text{LRLA}}} p(\mathcal{D}_i|H) \tag{6}$$

where $\mathcal{D}_i$ refers to all actions taken by a specific participant and $\frac{1}{|\mathcal{H}_{\text{LRLA}}|}$ is a prior that corrects for multiple comparisons across different values of $\hat{N}$. The resulting $\log BF$s (see Figure 4, right) reveal strong evidence for 42 of the 44 participants in favor of the class of resource-constrained LRLAs, when compared with the baseline. This indicates, that one of the models in $\mathcal{H}_{\text{LRLA}}$ explains the participant's behavior much better than the value-directed policy. There are nine participants best described by letting $\hat{N} = 512$, nine by $\hat{N} = 1024$, 20 by $\hat{N} = 4096$ and six by $\hat{N} = 8192$. This heterogeneity highlights, that the model class is able to accomodate individual differences between human participants.

Finally we want to show, that the proposed class of models captures exploration strategies across all participants better than any standard exploration strategy alone. To verify this, we computed Bayes factors between $\prod_i p(\mathcal{D}_i|\mathcal{H}_{\text{LRLA}})$ and two baseline exploration strategies: $\prod_i p(\mathcal{D}_i|H_{\text{Thompson}})$ and $\prod_i p(\mathcal{D}_i|H_{\text{UCB}})$. We find $2\log BF = 72.8$ against Thompson sampling and 5391.4 against UCB, indicating that our class of models is overall better at representing exploration strategies for all participants in comparison to any single, fixed strategy.

Discussion

In this work we proposed a justification for seemingly sub-optimal human strategies in sequential decision-making problems based on the idea of computational rationality. We view human decision-making as an instance of a learned, resource-constrained RL algorithm. This is formalized through learning distributions over parameters of a meta-learning model with a regularized, resource-rational objective. The emerging spectrum of strategies resembles characteristics of human decision-making without being explicitly trained to do so. Additional model comparison suggests, that the resulting resource-constrained LRLAs describe human policies well on a quantitative level. However, the correspondence between human behavior and the LRLA model class is not perfect. Looking at Figure 2 (right) we observe, that some clusters are not represented exactly. Furthermore it remains open, why none of the participants is best described through the model with $\hat{N} = 2048$. Accounting for these observations remains a question for future work.

The analysis on the two-armed bandit task presented in this work can be extended in several ways. Relating deliberation times to regularization factors could, for example, provide additional evidence for our hypothesis. It also remains to be seen whether our conclusions transfer to other sequential decision-making problems beyond the bandit setting. In this context we are especially interested in tasks, where descriptive models of individual human behavior consist of a set of different heuristics. We are also interested in methods, that allow us to disentangle resource-rational behavior from the Bayesian interpretation.

Recent work on model-free meta-learning methods, similar to the one employed in this work, indicates an emergence of model-based behavior (Wang et al., 2016) and causal reasoning (Dasgupta et al., 2019) as well as the ability for few-shot learning (Santoro, Bartunov, Botvinick, Wierstra, & Lillicrap, 2016), properties supposedly absent in artificial systems. Having systems capable of such feats, opens the possibility for interesting studies on human cognition.

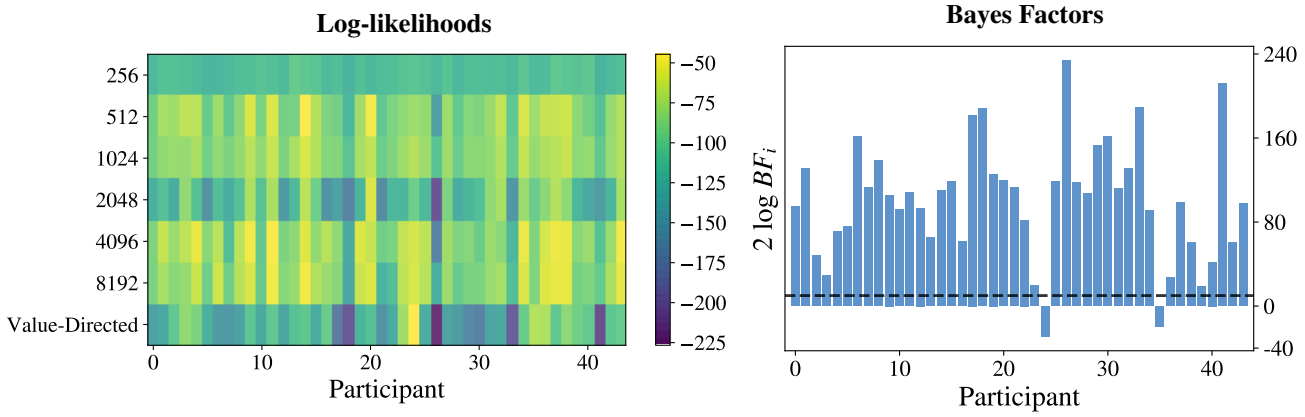

Figure 4: Model comparison of the set of resource-constrained LRLAs with a value-directed baseline. **Left**: Log-likelihoods for each participant and model. Higher values indicate a better fit. **Right**: Bayes factors (see Equation 6) for each participant i. The dotted horizontal line (equal to 10) corresponds to the threshold for very strong evidence (Kass & Raftery, 1995) in favour of $\mathcal{H}_{\text{LRLA}}$.

Predicting Learned Inattention from Attentional Selectivity and Optimization

Abstract

Although selective attention is useful in many situations, it also has costs. In addition to ignoring information that may become useful later, it can have long term costs, such as learned inattention – difficulty in learning from formerly irrelevant sources of information in novel situations. In the current study we tracked participants' gaze while they completed a category learning task designed to elicit learned inattention. During learning an unannounced shift occurred such that information that was most relevant became irrelevant, whereas formerly irrelevant information became relevant. We assessed looking patterns during initial learning to understand how different aspects of attention allocation contribute to learned inattention. Our results indicate that learned inattention depends on both the overall level of selectivity (measured as entropy of proportion of looking to each feature) and the extent to which participants optimized attention (becoming more selective over time).

Keywords: selective attention; categorization; learning; attention

Introduction

Category learning is a critical cognitive process that enables abstract thought and allows for generalization of knowledge to novel situations. Since the early work by Shepard, Hovland, and Jenkings (1961) selective attention has been considered a critical component of categorization and category learning. Selective attention refers to the ability to prioritize task-relevant information and filter out task irrelevant information (Desimone & Duncan, 1995; Hanania & Smith, 2010; Plude, Enns, & Brodeur, 1994; Pashler, Johnston, & Ruthruff, 2001; Yantis, 2000).

Most models of categorization and category learning adopt the Shepard et al. (1961) view and consider selective attention a critical contributor to human categorization. Exemplar models (Hampton, 1995; Medin & Schaffer, 1978; Nosofsky, 1986), prototype models (Smith & Minda, 1998), clustering models (Love, Medin, & Gureckis, 2004), and dual process models (Ashby, Alfonso-Reese, Turken, & Waldron, 1998) all include some form of selective attention as a factor determining the influence (or weight) of stimulus dimensions on categorization. According to some of these models, as participants learn categories, they tend to shift attention to features that are more likely to predict category membership, while attending less to less predictive features, the idea known as attention optimization. This idea has been confirmed empirically: there is eye-tracking evidence indicating that when learning categories, people indeed tend to optimize their attention over time, increasing fixating at the features most predictive of a category and decreasing fixating at irrelevant features (Rehder & Hoffman, 2005; Blair, Watson & Meier, 2009).

Costs and Benefits of Selectivity

Although selective attention is often beneficial in many learning scenarios (e.g. faster, efficient processing of attended information), selective attention also has costs (Best, Yim, & Sloutsky, 2013; Hoffman & Rehder, 2010; Plebanek & Sloutsky, 2017; Rich & Gureckis, 2018). Some of the costs are relatively short-term: people miss non-selected information. Other costs are longer term in that they affect future learning. One such short-term cost is that non-selected information is filtered out. Focusing attention is a tradeoff in that it results in efficient learning and performance, but it also results in missing information that could be used later.

While short-term costs of selectivity affect only the task at hand, longer term costs also affect performance on future tasks. One type of long-term cost has been recently discussed by Rich & Gureckis (2018), who referred to it as a "learning trap". The authors demonstrate that under certain circumstances selective attention can be a trap in that it can result in getting stuck on inaccurate representations of the to-be-learned structure and preventing the exploration needed to discover the correct structure. This happens particularly when there are possible negative outcomes to exploring, in which case selective attention results in overgeneralizing which things should be avoided.

A more general long-term cost is that selective attention may result in learned inattention (see Hoffman & Rehder, 2010, for a review) – difficulty in learning from sources of information that were uninformative in a previous situation. Optimizing one's attention to the currently most relevant sources of information can result in not only learning to ignore currently irrelevant sources of information, but continuing to ignore these sources in novel situations in the future (Kruschke & Blair, 2000). As a result, if those sources of information become relevant later, learning is more difficult than it would have been if one had not first learned to ignore them. Learned inattention can be detrimental when task demands change, or when a new classification contrast depends on previously irrelevant features.

For example, Hoffman & Rehder (2010) had participants learn to classify stimuli consisting of three dimensions. Learning occurred in either a classification condition or a feature inference condition. In classification, participants predict the category label from all of the stimulus' features. In inference they predict one missing feature from the label and the remaining features.

In the first phase of the experiment only dimension 1 was relevant to distinguish two categories, while the other two were irrelevant. In a second phase, only dimension 2 was relevant for distinguishing two new categories, while in a third phase dimension 3 was relevant for a novel contrast between categories. Classification encourages selective

attention since only a single feature predicts category membership. Inference, on the other, encourages distributed attention, since participants may need to predict any of the three features.

Participants performing the classification task were impaired at learning the new contrast when the relevant dimension changed compared to participants doing the feature inference task. Additionally, eye-tracking showed that the classification participants were much less likely to fixate the relevant dimension after learning it was irrelevant in a prior phase of the experiment compared to baseline levels at the start of the experiment. These costs occurred because learners selectively attended the relevant feature while classifying the stimuli—optimizing their attention to ignore (or inhibit) the other features.

The Current Study

The goal of this study is to further investigate learned inattention during category learning by examining how different aspects of attention allocation contribute to learned inattention. This study also serves as a first step toward a larger investigation of developmental differences in attention allocation and optimization and their consequences. The current study investigates only adults, but developmental implications and predictions for children are touched on in the Discussion.

In our experiment, we presented participants with a category learning task while tracking their gaze. The to-be-learned categories had a rule-plus-similarity structure, with one deterministic feature perfectly predicting category membership and multiple probabilistic features, providing good, but imperfect prediction (see Deng & Sloutsky, 2016, for a similar structure). In addition, one feature was completely irrelevant to categorization.

Given the structure, participants could either form a rule-based representation (by relying on the deterministic feature) or a similarity-based representation (by relying on all features). So, either selective or distributed attention could lead to effective learning. Once participants mastered the categories in this initial phase, there was an unannounced shift in the category learning task. After the shift, feature dimensions that had been deterministically predictive in became irrelevant, and features that had been irrelevant in became deterministically predictive.

Learned inattention was expected to produce costs on learning in Phase 2, making participants less likely to attend to and learn to use the new deterministic feature. We examined what aspects of attention during initial learning were most likely to manifest these costs. In particular we investigated the effects of overall selectivity and of attention optimization (increase in selectivity over time).

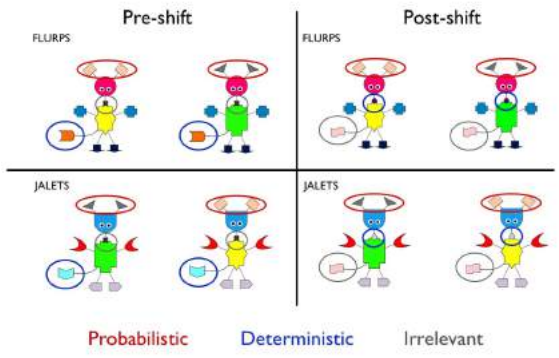

Figure 1. Examples of stimuli. The stimuli were creatures composed of seven discrete-valued dimensions differing in shape and color. One Deterministic feature perfectly predicted category membership (the tail in this example). One Irrelevant feature was the same across both categories (the button on the neck here). Five Probabilistic features predicted category membership with 80% accuracy. After an unexpected shift occurred, the Deterministic became Irrelevant, and the Irrelevant feature became Deterministic Probabilistic features were unchanged by the shift.

Method

Participants

A total of 38 adults (26 women) participated in the experiment. Participants were undergraduate students participating for course credit.

Materials and Design

Stimuli were colorful images of creatures composed of seven discrete-valued dimensions (see Figure 1). The creatures were divided into two categories, referred to as Flurps and Jalets. Of the seven features (antenna, head, body, button, hands, feet, and tail), one feature deterministically predicted category membership (henceforth the Deterministic feature), five features were probabilistically predictive with 80% accuracy (the Probabilistic features), and one feature was non-predictive—having the same value across all exemplars of both categories and therefore irrelevant to classification (i.e., the Irrelevant feature). Table 1 shows the stimulus structure used in the task.

Stimuli were organized into pairs of complementary sets. Each set in a pair was identical to its counterpart except that the Deterministic and Irrelevant features swapped roles. Probabilistic feature values and the category labels remained the same. As discussed below, participants learned one set in Phase 1 of the experiment (i.e., before the shift), and then the stimuli were unexpectedly replaced with the complimentary set for Phase 2 (i.e., after the shift). There were two pairs: one where feet and hands were the Deterministic/Irrelevant features, one where tail and neck button were the Deterministic/Irrelevant features. Which pair was presented and which set in that pair was learned in Phase 1 were counterbalanced between participants.

Stimulus sets also contained Ambiguous items. These were hybrid items having the Probabilistic features from one category and the Deterministic feature from the other category. These items were presented only during the testing sessions and were designed to test which features controlled categorization. There were 10 Ambiguous items total per set—one corresponding to each exemplar seen during training (i.e. with identical Probabilistic features but with the Deterministic feature from the opposite category). These items allow us to determine whether participants' category judgments were based more on the single Deterministic feature or on one or more of the Probabilistic features.

Note: D/I is the feature that is Deterministic prior to the shift and Irrelevant after the shift. I/D is the feature that is Irrelevant pre-shift and Deterministic post-shift. P1-P5 are the probabilistic features.

Procedure

Adult participants conducted a classification procedure while their gaze was monitored with an EyeLink 1000 hydraulic-arm eyetracker at 500Hz (SR research, Ontario, Canada). The experiment was divided into two phases. Both phases contained a training section (with feedback) followed by a testing section (no feedback). In Phase 1 participants learned to classify two categories of creatures (and then were tested), and then in Phase 2 an unannounced shift occurred wherein the previously Deterministic feature and the previously Irrelevant feature swapped roles.

The formerly Deterministic dimension took on a new, previously unseen, value that was fixed across all stimuli of both categories, while the formerly Irrelevant dimension now had two new potential values that perfectly predicted category membership. Participants were given no warning that this shift would occur at any point. Like Phase 1, Phase 2 consisted of training followed by testing.

At the beginning of the experiment participants were given information about the Deterministic and Probabilistic features. For Probabilistic features they were told that most of the members of the category had that particular feature value. For the Deterministic feature they were told that all members of category A have one value while those of category B have another value, while being shown both. The Irrelevant feature was never mentioned in the instructions. These informative instructions were included to ensure good learning in Phase 1, since any expected costs due to the shift rely on the categories initially being learned well. Additionally, as noted above we plan to eventually investigate developmental differences, and young children require this type of informative instructions and feedback in order to learn well within the timeframe of the experiment.

Training Training in each phase consisted of 30 trials (in 3 blocks of 10 trials). In each block of 10 trials the ten training exemplars, five from each category, were presented in random order, so participants saw each exemplar three times throughout training (see Table 1 and Figure 1).

On each training trial, one stimulus was presented in the middle of the screen and participants indicated which category they thought it belonged to. Corrective feedback was then given which tried to equally encourage attention to general appearance (similarity-based responding) and to the Deterministic feature (rule-based responding). For example feedback would be "Correct this is a Flurp. It looks like a Flurp and has the Flurp hands.", or "Oops this is actually a Jalet. It looks like a Jalet and has the Jalet hands.", in the case where hands were the Deterministic feature.

In Phase 2, after the unannounced shift, feedback was simplified to mention only the correct category without drawing attention to the features (e.g. "Correct this is a Flurp."). While this change in feedback may have given participants some indication that a change had occurred, it was necessary so that participants would need to figure out on their own the new contingencies between features and categories. That learning process in Phase 2, discovering what is informative, is the critical area of interest, while parity between Phase 1 and 2 is not critical.

Testing Testing in each phase consisted of 20 trials. Again, participants saw the stimuli one at a time and classified each one, but no feedback was provided during the test. The 10 items seen during training (henceforth the High Match items) and 10 Ambiguous items were each presented once, in random order. These two types of items, respectively, were the basis for the behavioral measures of general shift costs and shift costs due to learned inattention.

Accuracy on High Match items indicates how well each participant learned during the immediately prior training session. A decrease in accuracy from Phase 1 to Phase 2 on these items would indicate a general cost (in terms of poorer learning) due to the unexpected shift, which may occur for a number of reasons.

Responses to the Ambiguous items, in contrast, provide the cornerstone of our behavioral analyses related to learned inattention. Prior to the shift they provide the baseline level that each participant tended to categorize based on the single Deterministic feature. After the shift responses to the Ambiguous items tell us whether participants learned and used the rule on the new Deterministic (formerly Irrelevant) feature. Low deterministic responses indicate learned inattention since it suggests that the participant had difficulty finding the new rule on the feature that was previously irrelevant.

Results

Behavioral Results

Initial learning in Phase 1 was good overall (see Figure 2). Mean accuracy was 92.1% correct. A repeated measures ANOVA found a main effect of block [F(1,75) =. 14.74, p = 0.0003, partial η^2 = 0.164] suggesting that participants learned well during training. Categorization accuracy on High Match items during the test was also high (M = 93.9% correct).

Responses to the Ambiguous items provide insight into which features controlled participants' categorization: Responding based on the Deterministic feature points to rule-based categorization, whereas responding based on the Probabilistic features suggests similarity-based (or at least non-rule-based) categorization. Distributing attention during training could lead to either type of responding (since all features were attended), but selective attention to the Deterministic feature should only result in rule-based categorization. Participants were overwhelmingly deterministic in their categorization of the Ambiguous items: 88.4% deterministic responses, which was well above chance, $t(37) = 9.69$, $p < 0.001$, $d = 1.57$.

Post-shift Learning Participants learned well in Phase 2 after the shift (77.0% correct), which was above chance, $t(37) = 19.09$, $p < 0.001$, $d = 3.10$, but accuracy was lower than prior to the shift, $t(37) = 6.91$, $p < 0.001$, $d = 1.12$, which is expected—even in the absence of learned inattention—due to less informative feedback in Phase 2 compared to Phase 1 and any general costs of adapting to the shift. A repeated measures ANOVA on Phase 2 training accuracy found a main effect of block [F(1,75) = 7.192, p = 0.009, partial η^2 = 0.087], suggesting accuracy increased over time. Accuracy on High Match items during the test was significantly higher than chance (M = 81.3% correct), $t(37) = 10.06$, $p < 0.001$, d = 1.63, but was also lower than in Phase 1, $t(37) = 3.52$, p = 0.001, d = 0.571, suggesting a learning cost due to the unexpected shift. This represents a general shift cost which may be due to a variety of factors including learned inattention. We assess costs specific to learned inattention in the next section.

Shift Costs Due to Learned Inattention We assessed effects of learned inattention by examining responses to the Ambiguous items in the Phase 2 test (Figure 3). Learned inattention would result in relatively low levels of deterministic responses on the post-shift test, since participants would be less likely to attend to the previously Irrelevant (now Deterministic) feature, and thus would have difficulty learning the new rule on that feature. This would result in participants relying primarily on the Probabilistic features instead when making category judgments after the shift. Participants were significantly below chance, M =36.6%, $t(37) = 2.53$, $p = 0.016$, $d = 0.41$, suggesting that they primarily relied on Probabilistic features to categorize after the shift, in contrast to their behavior prior to the shift.

Figure 3 shows individual participants proportion of classifying Ambiguous items based on the Deterministic feature in the post-shift test.

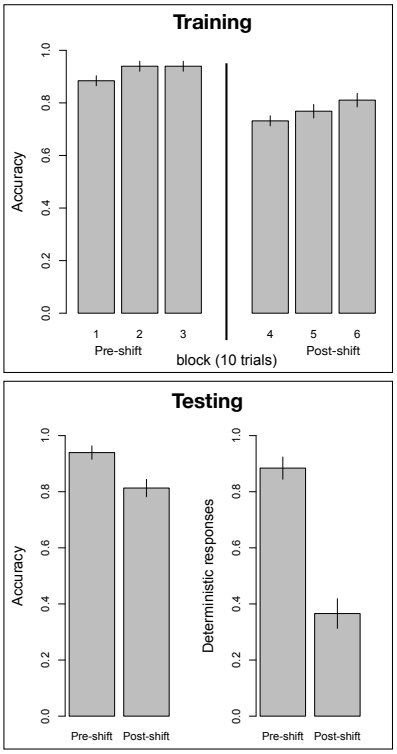

Figure 2. Behavioral results. During initial training participants learned well and achieved high accuracy. A substantial drop occurred after the shift. Accuracy during test was high for old (High Match) items, and was lower after the shift, displaying a general cost of the shift. Responding based on the Deterministic feature was very high prior to the shift, but dropped substantially in the post-shift test, suggesting effects of learned inattention. Error bars represent standard error of the mean.

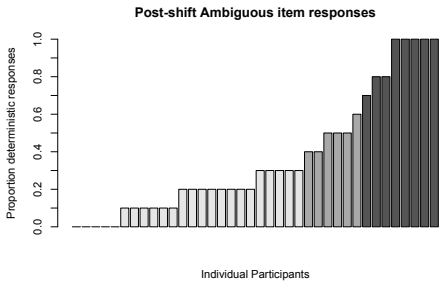

Figure 3. Individual participants' post-shift deterministic responding. Responses to Ambiguous items on the post-shift test varied widely between individuals. The majority classified based on the Probabilistic features, with some intermediate, and less than one-quarter of participants classifying based on the new Deterministic feature.

Eye-Tracking

Regions of interest isolating each feature were used to calculate the proportion of each trial spent looking at each feature for each subject. Timepoints where participants were not looking at any of the features were removed. Figure 4 shows the average proportion of looking at each feature type during training. Prior to the shift the proportion of the trial spent looking at the Deterministic feature increased over trials, while time spent looking at Probabilistic features decreased. Looking at the Irrelevant feature was extremely low throughout all of training (M = 2.82% of total looking time), but did decrease over the course of training—as measured by comparing block 1 (M = 3.60%) to block 3 (M = 1.52%), $t(37) = 3.39$, $p = 0.002$, $d = 0.161$.

After the shift, looking at the previously Deterministic (now Irrelevant) feature dropped off rapidly, while looking to the Probabilistic features shot up. Critically, looking at the newly Deterministic feature (that was previously Irrelevant) did not increase from block 1 to block 3, $t(37) = 0.53$, p = 0.600, demonstrating the effects of learned inattention. They continued to ignore this feature despite the high level of information it now contained.

We assessed attentional patterns during initial learning by calculating the entropy (Shannon, 1948) for each trial. Entropy was defined as,

$$S = -\sum_{i=1}^{n} p_i * \log(p_i)$$

where p_i is the proportion of the trial spent looking at feature i. Higher entropy indicates more distributed attention, where maximum entropy is produced by looking at all seven features equally, and lower entropy indicates more selective attention—focusing on a smaller number of features. We use entropy as a measure of selectivity rather proportion of looking at the Deterministic feature since some participants may have optimized their attention to one of the Probabilistic features, and that selectivity should still produce learned inattention despite being suboptimal. Entropy for each trial was normalized by dividing by maximum possible entropy, such that all values were between 0 and 1.

Drop in entropy was calculated as average entropy per trial in block 1 minus average entropy in block 3. This served as a measure of attention optimization, since greater drops indicate an increase in selectivity of attention.

We performed a logistic regression predicting classification of Ambiguous items on the post-shift test from average entropy during pre-shift training, the drop in entropy over training, and their interaction. This analysis revealed a significant interaction, $z = 3.318$, $p = 0.001$. To better understand the interaction, we divided participants into low and high entropy groups based on a median split. We then performed a logistic regression on Ambiguous item responses predicted from the drop in entropy for each group. For the low entropy group, there was a significant negative relationship between entropy drop and Ambiguous item responses, $z = -3.153$, $p = 0.002$, indicating that those who optimized their attention in the initial training were less likely to use the new Deterministic feature to categorize items after the shift (see Figure 5). In contrast, participants in the high entropy group did not show a relationship between the drop in entropy and responses to Ambiguous items, $z = 1.899$, p = 0.0575.

In other words, attention optimization was associated with greater learned inattention in the low entropy (selective attention) group, but not in the high entropy (distributed attention) group. This interesting interaction has important implications. It implies, not surprisingly, that a certain level of selectivity is necessary to produce learned inattention. But more importantly, this high level of selectivity is not enough. Learned inattention seems to also require that attention allocation be incrementally learned over time. This suggests that it occurs when people initially consider multiple features, but learn through experience to ignore them (in contrast to a top-down strategy implemented from the beginning to focus on one or few features).

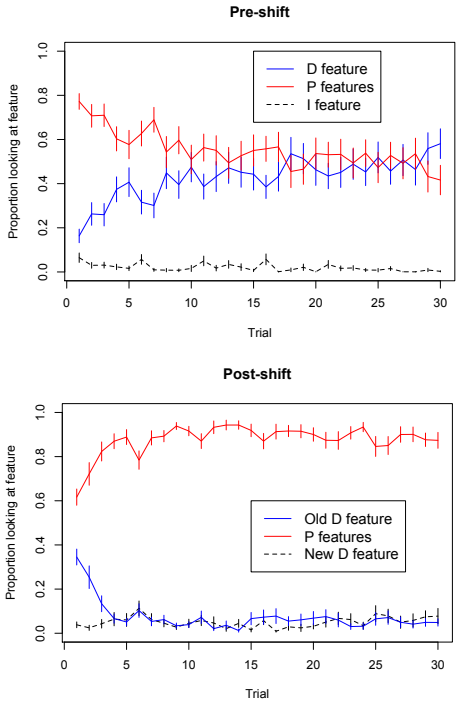

Figure 4. Proportion looking at each feature type during training. Note that the proportion for Probabilistic features is summed across all five Probabilistic features. During initial training looking to the Deterministic feature increased, while looking to the other features decreased (i.e. attention optimization occurred). Post-shift looking to the previously Deterministic feature quickly dropped and was replaced by increased looking to the Probabilistic features, while the previously Irrelevant (now Deterministic feature) remained low. Error bars represent standard error of the mean.

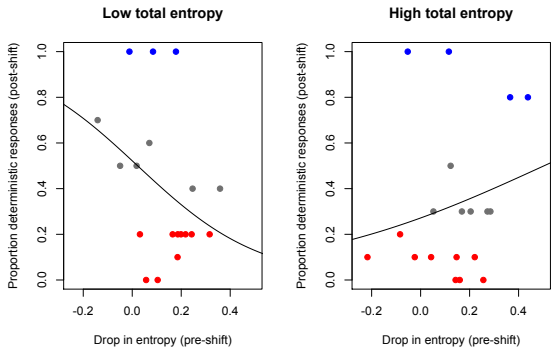

Figure 5. The role of selectivity and attention optimization. Overall entropy (how distributed attention was) interacted with the change in entropy (attention optimization) to produce costs consistent with learned inattention. Participants who were both highly selective (low entropy) and who optimized (large drop in entropy) were the least likely to categorize based on the new deterministic feature after the shift. Line shown the fit line of logistic regression. Dot color indicates deterministic responders (blue), probabilistic responders (red), intermediate (grey).

Discussion

Although selective attention is often effective and efficient, there are potential costs. One particular (longer-term) cost is that selective attention can result in learned inattention to non-selected information, which in turn affects future learning. In the current study, participants performed a category learning task designed to induce learned inattention while we tracked their gaze. Both behavioral and eye-tracking measures showed evidence of learned inattention. When making category judgments after the unexpected shift, participants were less likely to use a stimulus dimension that was previously irrelevant, but was now highly informative. Eye-tracking showed that after the shift occurred, participants quickly shifted attention away from the previously informative (and now irrelevant) feature. Their attention instead shifted to probabilistically predictive features, but they continued to ignore the previously irrelevant, now perfectly predictive, feature—with looking to that feature remaining low and not increasing over the course post-shift training. Participants simply ignored this feature despite its potential usefulness in their task.

The level of learned inattention that was exhibited varied across individuals, though. We used measures of selectivity and attention optimization for each individual to determine what aspects of initial learning best predicted the level of learned inattention that occurred. Our results suggest an interaction between these two measures, such that learned inattention was most likely for participants who were overall highly selective, but importantly, who optimized their attention over time. Participants who were highly selective from the beginning, and so did not optimize attention over time, did not show high levels of learned inattention (see Figure 5). These results suggest that learned inattention crucially depends on incremental learning over time, and is not simply an effect of ignoring sources of information, but of *learning* to inhibit them after initially considering them.

Participants who did optimize attention over time, but whose attention was overall relatively distributed (having high entropy), also did not show high levels of learned inattention. One possibility is that these participants needed more time to optimize attention before reaching the level required for substantial learned inattention to occur, and that with more training trials they would reach that level.

That both the level of selectivity and attention optimization predict individual differences in learned attention has important implications for cognitive development. Young children tend to distribute their attention broadly and do not optimize attention as much as adults do (Best, Yim, & Sloutsky, 2013; Deng & Sloutsky, 2016), so they may be largely protected against the adverse effects of learned inattention.

Allocating attention is always a tradeoff: selective attention results in more efficient processing of attended information, but has several potential pitfalls, including learned inattention. In contrast, if attention is distributed, processing is less efficient, but these traps are avoided. Therefore, to allocate attention effectively estimations must be made about information's potential future relevance. With less general knowledge, children have less basis to make solid conclusions about what might and might not be useful to know later. Additionally, these types of costs could be particularly damaging early in the learning process, and so perhaps children's tendency to distribute attention may be not only a result of immature control, but also adaptive for their particular situation. Understanding the developmental differences in this process is an important direction for future research.

Translation Tolerance in Vision

Anonymous CogSci submission

Abstract

A fundamental challenge in object recognition is to recognize an image when it is projected across different retinal locations, an ability known as translation tolerance. Although the human visual system can overcome this challenge, the mechanisms responsible remain largely unexplained. The 'trained-tolerance' approach holds that an object must be experienced across different retinal locations to achieve translation tolerance. Previous studies have supported this approach by showing that the visual system struggles to generalize recognition of novel objects to translations as small as 2° of visual angle. The present paper outlines a series of eyetracking studies that show novel objects can be recognized at translations as far as 18° from the trained retinal location, challenging the standard account of translation tolerance in neuroscience and psychology.

Keywords: Translation Tolerance; Translation Invariance; Object Recognition; Vision

Introduction.

We can identify familiar objects despite the variable images they project on our retina, including variation in image size, orientation, illumination, and position on retina. How the visual system succeeds under these conditions is still poorly understood. Here we focus on our ability to identify objects despite variations in retinal location and consider the extent to which the visual system relies on "on-line" vs. "trained" translation tolerance. In the case of on-line tolerance, learning to identify an object at one location immediately affords the capacity to identify that object at multiple retinal locations. At one extreme, the visual system can immediately generalize to all locations (to the limit of visual acuity), what might be called on-line translation invariance; at the other extreme, generalization is limited to a few degrees of visual angle. Trained tolerance, by contrast, refers to the hypothesis that we learn to identify familiar objects across locations by explicitly training the visual system to identify each object across a broad range of retinal locations. On this view, one of the functions of eye-movements is to ensure that objects are projected to multiple locations. These two accounts trade-off on one another: the more restricted on-line translation tolerance is the more trained tolerance is required to support the ability to identify objects across a wide range of retinal locations.

As detailed below, most of the empirical research in psychology and neuroscience suggests that on-line tolerance is restricted to a few degrees of visual angle, and to date, all neural network models of object identification show the same restriction. As a consequence, most theories of vision assume that trained tolerance plays an important role in our ability to identify objects across a range of retinal locations.

Early long-term priming studies by Biederman and colleagues (Biederman & Cooper, 1991; Cooper, Biederman, & Hummel, 1992; Fiser & Biederman, 2001) provided evidence for extensive on-line translation tolerance, and indeed, in some cases, translation invariance. For example, Fiser and Biederman (2001) asked participants to name line-drawings of objects as fast and accurately as possible in a study phase. In a later test block, participants were faster and more accurate to name repeated images compared to a set of control objects (same name, different exemplar) regardless of whether retinal position was the same at study and test or displaced by 10 degrees (°) of viewing angle. A limitation of all these studies, however, is that they assessed priming for familiar objects, and accordingly, participants had seen the same type of objects in a wide variety of retinal locations prior to the experiment. This leaves open the possibility that the findings reflected trained rather than on-line translation tolerance within the visual system, or indeed, trained tolerance outside the visual system with priming effects occurring within semantic or verbal systems (Kravitz, Vinson, & Baker, 2008).

In contrast with the Biederman studies, a number of authors have failed to observe robust translation tolerance for novel objects that participants had not seen prior to the experiment (e.g., Afraz & Cavanagh, 2008; Cox & DiCarlo, 2008; Dill & Fahle, 1997; Dill & Fahle, 1998; Newell, Sheppard, Edelman, & Shapiro, 2005). *Figure 1* outlines a selection of studies that used different experimental paradigms and found highly limited (in one case no) translation tolerance (adapted from Kravitz, Vinson, & Baker, 2008). Based on the outcome of such studies, Chen et al. (2017) state that "the translation-invariance of the human visual system is limited to shifts on the order of a few degrees - almost certainly less than 8°" (p.5). In line with this, Kravitz et al.'s (2008) review of behavioral studies found that "most of the training and matching studies found a significant decrement in discrimination performance with translations varying from 0.5° to 2°" (p. 118).

Neural data are also consistent with the idea that on-line translation tolerance is highly limited. Researchers have identified neurons in inferior-temporal cortex (IT) with a range of receptive fields (ranging from 2.8° to 26°; for review see Kravitz et al., 2008). The larger receptive fields are thought to provide the neural underpinning of translation tolerance, but it is important to note that these receptive fields have only been observed for familiar or newly-trained stimuli that have been seen at multiple

retinal locations (e.g., Gross et al., 1972; Ito, Tamura, Fujita, & Tanaka, 1995; Tovee, Rolls, & Azzopardi, 1994). Accordingly, these large receptive fields could reflect trained or on-line translation tolerance. Consistent with the former hypothesis, Cox and DiCarlo (2008) only observed small receptive fields for their novel stimuli that were trained in one location, as shown in *Figure 1C*. That is the neural data appear to mirror the behavioral data: robust translation tolerance and large receptive fields are found for familiar stimuli, limited generalization and small receptive fields are observed for unfamiliar stimuli. Indeed, Cox and DiCarlo reach a similar conclusion to Kravitz et al. (2008), writing "...the computational machinery of the ventral visual stream is not constructed in a manner that automatically produces position tolerance in IT, even across relatively small changes in retinal position. Instead, the creation and/or maintenance of IT position tolerance might require experience".

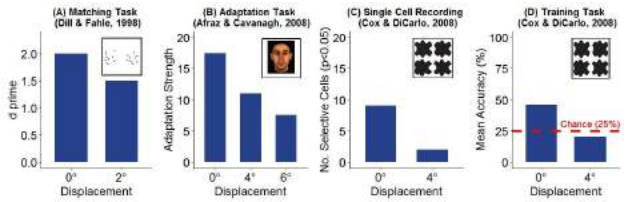

Figure 1. Behavioral studies of translation tolerance.

Similarly, work with artificial neural network models has reported robust translation tolerance for words and objects at trained locations, but highly limited generalization to untrained locations. For example, Dandarund et al. (2013) and DiBono & Zorzi (2013) showed that that their models of visual word identification supported translation invariance, but the models were trained with each word at each location. Elliffe, Rolls and Stringer (2002) showed that a biologically inspired neural network model called VisNet supported on-line translation tolerance to untrained locations for simple stimuli, but each stimuli had to be trained at multiple spatial locations (after training in 7 locations the model generalized to an 8th and 9th location), and the authors tested small translations (translations of 8 pixels in a 128x128 retina). The above behavioral, neural, and computational above findings have led most theorists in psychology and neuroscience to endorse the 'trained' account of translation tolerance.

Despite empirical and computational results, there are still reasons to question the trained tolerance hypothesis. Behavioural studies that failed to observe on-line translation (e.g., *Figure 1*) suffer from a number of limitations. For example, stimuli are typically unlike real objects (e.g., Dill & Fahle, 1997; see *Figure 1a*), and/or are very similar to each other (e.g., Cox & DiCarlo, 2008; see *Figure 1c*). Differentiating between highly similar items may rely on low-level visual representations that are retinotopically constrained (Kravitz et al., 2008). Additionally, stimuli in these experiments were typically trained at a given location for just 100ms (contrary to everyday visual experiences in which stimuli can be encoded for longer intervals). More extended studying time may be required for robust online translation tolerance. Consistent with the first possibility, Dill and Edelman (2001) observed much more extensive translation tolerance for unfamiliar objects that were more object-like and discriminable from one another. Indeed, they reported no significant reduction in performance in five of six experiments when images were displaced by 8 degrees. And consistent with both possibilities, Bowers, Vankov and Ludwig (2016) reported more robust translation tolerance still when participants trained to identify more discriminable stimuli novel stimuli that were studied at one retinal location for longer periods of time. Indeed, in their Experiment 3, participants were ~80 % accurate in naming novel objects following a shift of 13° (when chance was 16.7 %).

In this article we explore on-line translation tolerance in humans given the conflicting empirical evidence regarding on-line translation tolerance and the theoretical implications for theories of vision in psychology and neuroscience. Two gaze-contingent eye-tracking studies are reported and include the following critical design features. First, in all studies, 24 novel objects were used, each of which was a member of a pair of objects built from similar parts but in a different global configuration (see Method). Using a large set of stimuli of this sort should encourage participants to learn the complete objects rather than just the parts. Previous studies have rarely matched items on the basis of their parts (but see Dill & Edelman, 2001), and have typically included far fewer stimuli. Second, the novel three-dimensional objects we included were designed to be more naturalistic compared to the novel stimuli used in previous experiments, such as those depicted in *Figure 1a* and *1c*. This makes it more likely that the visual system will process these new stimuli in a manner more similar to everyday recognition. Third, we included study conditions in which stimuli were presented for unlimited time at study as opposed to the brief display conditions in previous studies that may have artificially reduced on-line translation tolerance. Fourth, we included test conditions in which objects were presented for 100ms durations, reducing the likelihood that participants adopted artificial strategies at test. Note that the Bowers et al. (2016) experiments reporting robust on-line translation invariance included a smaller number of less realistic objects that were displayed for an extended time at test. Accordingly, the current studies provide a much stronger test of the on-line translation tolerance hypothesis.

Experiment 1.

Method

Participants and Equipment. Fifteen participants (Experiment 1a=6, 1b=9) were recruited from the University of Bristol's course credit scheme for Psychology students. Eye-movements were monitored using the Eyelink 1000 plus system (SR Research). Stimuli were presented using Psychopy v1.85.3 (platform: Linux-Ubuntu), and on a 120Hz monitor with a spatial resolution of 1920 x 1080 pixels (screen width = 53cm), at a distance of 70cm.

Stimuli. Twenty-four novel objects were taken from Leek, Roberts, Oliver, Cristino, and Pegna (2016). Each object was part of a pair that had similar local features but a different global configuration (see *Figure 2*). For each participant, one member of each pair was randomly assigned the label 'A' and the other was assigned 'B'.

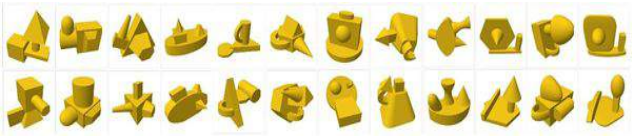

Figure 2. Twenty-four novel objects. Each column contains a pair of objects that are matched for similar local features, but which differ in global configuration.

Procedure. In the learning phase of the experiment participants were trained to categorize the 24 objects as 'A' or 'B'. Each object was presented one-by-one in the centre of the screen and occupied 5°x5° of visual angle. Participants were required to maintain their gaze on a centrally located fixation-cross for 1000ms for an object to appear. If gaze moved 1.5° beyond the fixation-cross, a mask replaced the object. The learning task was split into two phases: (i) *Familiarization*. The familiarization phase consisted of two presentations of each object. Each object was presented for an unlimited time and was accompanied by a sound-file indicating its category (A or B). (ii) *Training*. Each object was displayed at the same location without the sound file and for unlimited time until the participant pressed a button to indicate the image's category. Audio feedback was then provided. The training phase continued until the participant correctly identified each object consecutively (i.e., 24/24 consecutive correct answers). After completing the first training phase (Block 1), participants completed two additional training phases - Block 2 and Block 3 - which were identical except for their shorter presentation times of 500ms and 100ms respectively.

After the learning phase, participants completed seven test-blocks, each consisting of 24 presentations (one of each object); each test-block differed in terms of horizontal eccentricity from the centre of the object to the central fixation cross (i.e., displacement from training location). Test blocks 1, 2, 3, 4, 5, 6 and 7 presented images at 0° (i.e, trained-position), 3°, 3°, 6°, 6°, 9°, and 9° displacement from the centrally trained position, respectively. Test-blocks with the same displacement (e.g., block 2 and 3 were both 3°) differed in terms of presentation side (left or right). Within each test-block, order of presentation was randomised and no feedback was provided. In Experiment 1a images remained on the screen until participants responded. Experiment 1b was the same as Experiment 1a except that images were presented for 100ms at test in order to reduce possible response strategies. These final presentation durations are similar to previous studies that have failed to find online translation tolerance (see *Figure 1*).

Results.

Table 1. Mean (+/- 95% CI range) Accuracy in Experiment 1. *Columns show displacement of the test presentation from the trained location.*

	Mean (+/- 95% CI range) Accuracy			
	0°	**3°**	**6°**	**9°**
Exp 1a (N = 6)	98% (5%)	98% (3%)	95% (9%)	94% (9%)
Exp 1b (N = 9)	98% (2%)	95% (3%)	91% (4%)	84% (7%)

As shown in *Table 1*, novel objects were recognised with high accuracy at untrained retinal-positions (chance is 50%). Even at the most distal untrained position (9°), objects were recognised with a mean accuracy of 94% when unlimited time was afforded at test (Experiment 1a), and although translation tolerance was reduced when stimuli were presented for 100ms at test (Experiments 1b), accuracy was still 84% when at 9° displacement.

Experiment 2.

Experiment 2 served two purposes. (i) Although we observe near complete translation invariance for newly acquired objects displaced by 9° when objects were presented for an unlimited amount of time, there was a significant reduction when stimuli were presented for 100 ms at test. In an attempt to reduce any effects of retinal specificity, Experiment 2a adopted a learning condition known as 'location-training' (i.e., training at the test location - see below). (ii) Experiment 2b also used location training to examine whether the robust on-line translation reported in our experiments (1a to 2a) could be extended to an even more distal untrained location, 18° from the trained location.

Location training has been used by previous studies to show that participants can overcome retinal-specificity for low-level visual discrimination tasks. Xiao et al. (2008) demonstrated that participants who had been trained to discriminate contrasts at location 1 showed complete transfer of this ability to location 2 only when they had also been trained to discriminate different stimuli on a different dimension (orientation) at location 2 (otherwise, learned contrast discrimination was location specific). Xiao et al. concluded that training at location 2 trained participants to overcome stimulus-nonspecific factors like local noise at the stimulus location, and this enabled complete location transfer. Our Experiment 2 investigated whether location training may also reduce retinal specificity in high-level visual recognition tasks (Experiments 2a and 2b investigated this at displacements of 9° and 18°, respectively).

Participants, Equipment and Stimuli. Experiment 2 used identical equipment, stimuli and recruitment methods as Experiment 1. Ten participants were used in Experiment 2a, and 10 different participants in Experiment 2b.

Experiment 2a: Learning and Test Phase. During learning blocks 1 and 2, objects were trained for unlimited time and 100ms duration respectively, at the centre of the screen (at fixation). In block 3, 'location training' took place: twelve objects were trained at one peripheral location, 9° from the central fixation-cross and the remaining 12 objects were trained at a contralateral peripheral location, 9° to the other side of the fixation-cross (all presentations were 100ms). Participants were trained until they got 12/12 consecutive correct answers at each peripheral location. In the test phase, objects were tested at three test locations: 9° left, 9° right, and centre of fixation, giving three test conditions: "trained-central" (0° displacement from central training location), "trained-peripheral" (0° displacement from peripheral training location) and "novel-peripheral" locations (9° displacement from central training location, on the opposite side to the trained peripheral location). To control for possible order effects, the three test locations were randomly interleaved within each test-block.

Experiment 2b: Learning and Test Phase. Experiment 2b examined whether the robust on-line translation reported in Experiment 2a could be extended to an even more distal untrained location, 18° from the trained location. In order to displace presentations by 18° at test, images were presented at one peripheral location only (and never at central fixation): 12 images were presented 9° to the right, and the remaining 12 were presented 9° to the left of central fixation (images were presented for unlimited time in block 1, and for 100ms duration in blocks 2 and 3). In an attempt to boost performance compared to Experiment 2a, participants were required to get 24/24 consecutive correct answers in each block. At test, objects were tested at two test locations: 9° left, and 9° right of fixation, giving two test conditions: "trained-peripheral" (0° displacement from peripheral trained location) and "novel-peripheral" locations (9° displacement from central fixation, and thus 18° displacement from the opposite peripheral location).

Results.

Table 2. **Mean (+/- 95% CI range) Accuracy scores in Experiment 2a and 2b.** Columns show degrees by which the test presentation was displaced from the nearest training location and the screen position of that test presentation.

	Mean (+/- 95% CI range) Accuracy			
Displacement	**0°**	**0°**	**9°**	**18°**
Screen Position	**Centre (trained)**	**Peripheral (trained)**	**Peripheral (novel)**	**Peripheral (novel)**
Exp 2a (N=10)	93% (5%)	83% (5%)	81% (6%)	not tested
Exp 2b (N=10)	not tested	97% (3%)	not tested	89% (7%)

The results of Experiment 2a and 2b are summarised in *Table 2*. In Experiment 2a, mean accuracy scores at the *novel-peripheral* position (9°) were significantly above chance and were nearly equivalent to those yielded in the *trained-peripheral* position (0° Peripheral). Thus, Experiment 2a provided strong evidence for robust online translation tolerance over 9° displacement even when objects are presented for just 100ms at test.

In Experiment 2b, objects were recognised with a very high degree of accuracy even when the trained location was displaced by 18°. Moreover, 5 of the 10 participants scored above 90% on mean accuracy at 18°. As illustrated in *Figure 3*, the findings from Experiment 2b, show on-line translation tolerance for novel stimuli over much more distal displacements compared to all previous work.

Discussion

The present paper has provided evidence of robust on-line translation tolerance in the human visual system. Participants trained to recognise novel objects at one retinal position could recognise the same objects at untrained distal retinal-locations (up to 18°) with high accuracy.

The findings are contrary to previous studies that demonstrate much more limited generalization over translations as small as 2 and 4° (e.g., Cox & DiCarlo, 2008; Dill & Fahle, 1998) and that have been used to support trained theories of translation tolerance. Indeed,

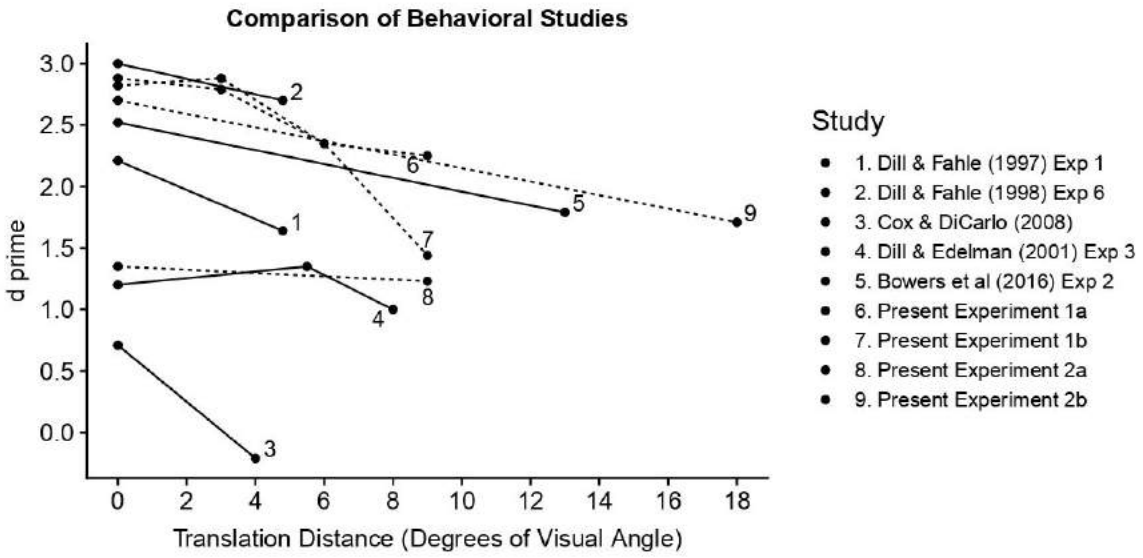

Figure 3. Comparison of d-prime scores for previous and present experiments as a function of translation distance. For each study, the experiment with the best performance at the largest displacement is illustrated. The present experiments (dashed lines) show more robust on-line translation tolerance than the majority of previous experiments. Experiment 2b showed robust on-line translation tolerance over a larger translation distance (18°) than any previous experiment. d-prime scores were calculated using the psyphy package (Knoblauch, 2014) for R (R Development Core Team, 2018).

advocates of the approach have recently claimed "the translation-invariance of the human visual system is limited to shifts on the order of a few degrees - almost certainly less than 8°" (Chen et al., 2017; p. 5). Rather, the present findings indicate that novel object recognition can be generalized on-line to more distal untrained retinal positions than previously demonstrated (see *Figure 3*): objects were recognised over translations as large as 18° with performance near 90%.

Why was robust on-line translation tolerance demonstrated in the present experiments whereas most previous experiments demonstrated highly limited generalization? As described above, previous studies typically used stimuli that are unlike real objects and/or are very similar to each other. Differentiating such stimuli may rely on low-level visual processes that are highly retinotopically constrained. High-level visual processes may also be more retinotopically constrained under these conditions. Indeed, there is some physiological evidence that receptive field (RF) sizes of neurons in the infero-temporal cortex (IT) are a function of stimuli size (DiCarlo & Maunsell, 2003). The present study used more naturalistic stimuli and included a number of variations in the procedure used by most psychophysical studies, including extended sampling times and, in Experiment 2, 'location training'. The more naturalistic conditions may have encouraged recruitment of IT neurons with larger RFs. Other studies that have also observed robust translation tolerance have also used more naturalistic, easily discriminable stimuli (Dill & Edelman, 2001) and extended sampling times (Bowers et al., 2016), but our findings go beyond this work by showing that robust translation tolerance extends to 18° under conditions in which strategic processing is minimized (by flashing items at test for 100 ms and by including a large set of novel objects that differed in the configuration of similar parts).

The findings are also relevant to computational modelling of the visual system. As noted in the Introduction, previous attempts to achieve on-line translation tolerance with artificial neural networks have reported highly limited tolerance. Such demonstrations may have been considered a strength given similarly limited tolerance reported in humans (e.g., Dill & Fahle, 1997; 1998). The present results show the need for these models to capture the robust on-line translation tolerance we have reported in humans. There is reason to believe that at least one class of artificial neural network can achieve this. Deep convolutional neural networks (CNNs) are designed to support translation tolerance by including convolutional layers and global pooling layers. Convolutions involve copying learning that occurs at one retinal location to other locations (the premise that information learned at one location is relevant at others), whilst pooling layers aggregate information from multiple

spatially organized units to a single unit in order to down-size the image. Both of these inbuilt ("innate") mechanisms are widely claimed to support translation tolerance, but there is surprisingly little evidence as to whether these mechanisms can support robust on-line translation tolerance as we have observed. We are in the process of running simulations to assess whether CNNs can support our empirical results.

Overall, the evidence outlined above is a clear demonstration that the human visual system can support recognition of novel objects at untrained distal retinal positions. Since the standard approach within psychology and neuroscience is to deny such robust generalization, there is a need for the field to more widely acknowledge an on-line generalization mechanism that can account for these results.

Abstract

Using the prepositions *in* and *on*, Jamrozik and Gentner (2015; 2014; 2011) explored a particular factor of meaning that was hypothesized to serve as a metaphorical link between spatial and abstract concepts. Across several studies, these researchers have provided evidence for the idea that there is a "continuum of control" that exists for both spatial and abstract uses of *in* and *on*. Our research explores other potential meaning factors that might play a role in non-spatial uses of *in* and *on*. Our results replicate and extend Jamrozik and Gentner's (2011) findings. We advocate using a multi-componential approach as research involving indirect metaphors continues moving forward.

Keywords: prepositions; spatial language; abstract language; metaphor; language understanding; semantics

Introduction

A popular assumption in cognitive linguistics is that metaphors are extremely common in both language and thought (e.g., Lakoff & Johnson, 1980). Historically, the evidence provided for this assumption has been primarily linguistic in nature. For example, a conceptual metaphor such as LOVE IS A CONTAINER is proposed to exist in the minds of speakers because it is natural to talk about people being in love or people falling out of love regardless of containment being a spatial concept and love being an abstract concept. One question, which arises from this assumption, is the nature of the connection between the spatial and the abstract. In other words, how might the spatial and abstract concepts activated by a conceptual metaphor be connected?

The potential for this type of metaphorical connection is most apparent when people talk about abstract concepts, such as time, thoughts, and emotions, using terms drawn from physically-based domains, such as space, force, and motion. Jamrozik and Gentner (2015; 2014; 2011) have explored the possibility of such connections using the prepositions *in* and *on*. Steen (2010) refers to these as indirect metaphors. Across several studies, these researchers present evidence suggesting that control is an important concept not only for spatial uses of *in* and *on* but also for abstract uses of *in* and *on*. For example, consider the scenario of a marble in a jar that has been secured with a lid. The marble is considered the figure and the jar is the ground. Even if you were to shake the jar or turn it upside down, the marble has very little control over where it can be at any given moment in time. In other words, the ground has more control than the figure in this situation. Alternatively, consider the scenario of a marble on a plate. The marble is still the figure, but this time the plate is the ground. If you were to move the plate, the marble might easily roll right off. In this example, the figure has more control than the figure. Borrowing from Beitel, Gibbs, and Sanders' (2001) terminology, the plate does not constrain the movement of the marble as well as the closed jar.

Jamrozik and Gentner's (2015) research suggests that this difference in the amount of control associated with *in* as compared to *on*—what they refer to as a "continuum of control"—also exists for abstract uses of *in* and *on*. Again, consider an example. If someone was described as being *in trouble*, participants in Jamrozik and Gentner's (2015) studies thought that the figure had a low degree of control over their situation. If someone was described as being *on a roll*, participants in Jamrozik and Gentner's (2013) studies thought that the figure had a higher degree of control over their situation.

Jamrozik and Gentner (2015) selected control as their factor of interest because previous researchers (Coventry, Carmichael, & Garrod, 1994) have considered control to be the most likely candidate for extension to abstract contexts. Our goal is to extend Jamrozik and Gentner's (2015) research by considering other factors that might be useful in differentiating between abstract uses of *in* and *on*. If control is not the only candidate for extension, then one place to look for other potential candidates is in literature involving the spatial semantics of the locative prepositions *in* and *on*.

Early research on the spatial meaning of *in* and *on* tended to focus on the role of geometric constructs such as inclusion and contact (e.g., Bennett, 1975; Herskovits, 1986; Leech, 1969; Miller & Johnson-Laird, 1976); however, these approaches cannot account for cases in which the necessary geometric constructs are present but the lexical item in question is dispreferred (e.g., a pear on a counter that is being covered by an overturned bowl is not considered *in* the bowl) as well as cases in which the necessary geometric constructs are not present but the lexical item in question is preferred (e.g., describing a book that is on top of another book as being *on* a table even though it is not directly in contact with or being supported by the table). In response to these inadequacies, researchers have developed more multi-

componential approaches in which they propose that a variety of different factors feed into the meanings of spatial relational terms (Coventry & Garrod, 2004; Feist, 2000, 2010). These factors include geometric contact and geometric inclusion, which are factors less likely to extend to abstract concepts, as well as factors such as location control that are more likely to extend to abstract concepts. One example of a factor that may extend to abstract concepts is object association. More specifically, research by Coventry and Prat-Sala (2001) revealed a complex interaction between the factors of control and object association such that when figure control was high, acceptability of *on* was higher when the figure-ground combination was unusual (e.g., a brick on a plate) and lower when the figure-ground combination was expected (e.g., a fish on a plate). Whether or not this spatial factor of expectedness plays a significant semantic role in non-spatial uses of *in* and *on* and whether it has the same complex interaction with figure control has yet to be explored.

Interestingly, Jamrozik and Gentner's (2015) research on the abstract uses of *in* and *on* suggests another factor that should be taken into consideration. It is a factor that has not previously been considered as a spatial meaning component: valence. Throughout their studies, Jamrozik and Gentner (2011; 2014; 2015) provide a variety of stimulus examples. More often than not, these examples are indicative of a particular relationship between control and valence: Statements associated with higher figure control are often more positive (e.g., *Jordan is on a roll*) than statements associated with lower figure control (e.g., *Casey is in a depression*). Jamrozik and Gentner (2015) explain that this is evidence of a natural correlation between control and positive valence. They point out that the correlation is not perfect, and there are certainly examples for which the relationship does not hold (e.g., *on thin ice*; *in shape*).

Given all of this, we first set out to explore the potential relationships between control, valence, and the comprehension of *in* and *on* in non-spatial contexts. We then set out to explore the potential relationships between control, valence, and expectedness and how these factors might influence the production of *in* and *on* in non-spatial contexts.

Experiment 1

In line with previous results (cf. Jamrozik and Gentner, 2015), we predicted that participants would rate the figures of conventional *on* phrases as having more control than the figures of conventional *in* phrases. We also predicted that participants would rate conventional *on* phrases as more positive than conventional *in* phrases.

Method

Participants A total of 47 college students participated in exchange for course credit: 24 in Version 1 and 23 in Version 2. The mean age of participants was approximately 19 (M = 18.8, SD = 1.7). Forty were female (85%) and seven were male (15%). Only one participant reported being a non-native English speaker.

Materials and Design Participants in this experiment were presented with 160 sentences. Each sentence consisted of a human figure and either a prepositional phrase or verb phrase. Of these sentences 89 were the target stimuli used by Jamrozik and Gentner (2015): 44 *in* sentences and 45 *on* sentences. We developed the remaining 71 filler sentences by following a procedure similar to the one described by Jamrozik and Gentner (2015) in which we selected conventional abstract uses of prepositions (other than *in* and *on*) and verbs from online idiom dictionaries and randomly assigned them common gender ambiguous names. Using a procedure similar to that described by Jamrozik and Gentner (2015), names were selected for use if they appeared in the top 1,000 names given to both males and females in social security records of American children born between 1990 and 2000. Of the 71 filler sentences, 21 were prepositional phrases (e.g., *Peyton is at ease*; *Bailey is under the weather*), 26 were verb + preposition phrases (e.g., *Quinn is letting the cat out of the bag*; *Alex is beating around the bush*), and 24 were verb phrases (e.g., *Noel is taking it easy*; *Taylor is jumping the gun*).

Procedure Participants took part in this study via SurveyMonkey.com. After consenting, participants were asked to answer a standard set of demographic questions: their age, gender, native language, and other languages they are able to speak, write, read, or understand.

Participants then read and rated the 160 sentences described previously. Following from Jamrozik and Gentner (2015), the sentences were presented one at a time on the screen and in a pseudo-randomized order such that there were never two *in* sentences, *on* sentences, or target sentences presented back-to-back. Participants were instructed to "imagine the scenario each sentence describes and think about how much the person controls or is controlled by the situation" as well as "the degree to which the situation being described is likely to be a positive or negative event in that person's life." For each sentence, participants were presented with a figure-control question (i.e., "To what degree does the person have control of the situation?") to which they would respond on a scale ranging from "1-extremely low control of the situation by the person" to "5-extremely high control of the situation by the person." On the same page participants were presented with a valence question (i.e., "To what degree is the situation being described likely to be a positive or negative event in their life?)" to which they would respond on a scale from "1-extremely negative" to "5-extremely positive." We also developed 19[1] catchtrials that were presented in a pseudo-randomized order such that there was only ever one catchtrial per sentence and never more than two

[1]There were originally 20 catchtrials; however, due to experimenter error, one catchtrial in which the response was five was not included in the final version of the study.

catchtrials appearing back-to-back. Catchtrials involved asking participants to provide a specific numerical rating from one to five on the scale provided.

At the end of the experiment, participants were then presented with an electronic debriefing form. Two versions of the experiment were developed due to concerns that participants might simply provide the same response to both the figure control and valence questions. Participants were assigned to one version, and the only difference between them being that the valence scale response options were flipped such that "extremely positive outcome" was associated with one and "extremely negative outcome" was associated with five. These responses were reversed scored before analysis.

Results

Of the 47 participants described previously, 12 were removed from further data analysis: one for reporting a native language other than English, two for responding incorrectly to three or more of the catchtrials, and nine for not finishing the study. Thus, data for 35 participants were used in the following analyses.

To determine whether the mean figure-control ratings produced by participants in the current study were aligned with the mean figure-control ratings produced by participants in Jamrozik and Gentner's (2015) Experiment 1a, we conducted a pairwise correlation, $r(88) = .94$, $p < .001$.

It should not be surprising, then, that when we conducted a mixed-model ANOVA with preposition as a within-subjects variable and version as a between-subjects variable that we found the same significant effect of preposition on ratings of figure-control reported by Jamrozik and Gentner (2015): Participants in the current study rated figures *on* ground as having more control ($M = 3.6$, $SD = .48$) than figures *in* ground ($M = 3.1$, $SD = .47$), $F(1, 33) = 132.81$, $p < .001$, $\eta p^2 = .801$. As expected, there was no significant main effect or interaction involving version.

To determine the proportion of stimuli that fit with our predictions, we conducted a median-split analysis using the control ratings. The results showed that our predictions held for 64% of the *on* sentences (ratings falling above the median) and 66% of the *in* sentences (ratings falling below the median).

When we conducted a mixed-model ANOVA with preposition as a within-subjects variable and version as a between-subjects variable using valence scores, we found that participants rated figures *on* ground as more positive ($M = 3.26$, $SD = .28$) than figures *in* ground ($M = 2.92$, $SD = .24$), $F(1, 33) = 103.97$, $p < .001$, $\eta p^2 = .759$. We also expected that if participants were simply providing the same response to the control and valence questions that we would see significant difference across versions when the anchoring of the valence question was reverse. No significant main effect or interaction involving version was observed.[2]

To determine the proportion of stimuli that fit with our predictions, we conducted a median-split analysis using the valence ratings. The results showed that our predictions held for 42% of the *on* sentences (ratings falling above the median) and 57% of the *in* sentences (ratings falling below the median).

Discussion

As predicted, we were able to replicate the results of Jamrozik and Gentner's (2015) Experiment 1a using their set of conventional phrases. In addition to finding that *on* is associated with more figure-control than *in*, we also observed that *on* phrases were rated as more positive than *in* phrases. This evidence suggests that, in addition to control, valence may serve as a meaning component that can be used to differentiate between abstract uses of *in* and *on*. That being said, our median-split analyses revealed that control might play a more predictable role than valence across a variety of different contexts. We argue that these patterns are consistent with a multi-componential approach, meaning that consideration of a variety of different semantic factors might be useful when investigating the non-spatial semantics of *in* and *on*.

A significant limitation of Experiment 1 is that these findings might also be due to a lack of counterbalancing because participants were always presented with the same order of ratings: control followed by valence. It could be that a significant effect of valence was found only because valence ratings were always considered through the lens of control. It is also possible that these findings might simply be the result of characteristics particular to the sentences that were used as stimuli. Furthermore, even though using conventional phrases served to enhance the ecological validity of Experiment 1, it also limited the degree to which we were able to explore the potential interaction between control and valence.

Experiment 2

With mounting evidence that control is an important factor in distinguishing between the meanings of *in* and *on* in non-spatial contexts, we wanted to take a multi-componential perspective and explore the potential relationships between control, valence, and expectedness and how these factors

[2]Due to experimenter error, the *in* sentence *Noel is in the know* was absent from the stimuli presented to the participants. Instead the filler phrase *out of practice* was inadvertently presented twice, once with the name Avery and once with the name Noel. Because the missing phrase would have likely been rated by our participants as positive and a situation in which there was low control of the situation by the person, this could be viewed as a confound since we may have inadvertently eliminated data that could have served to refute our hypothesis. To address this possibility, we eliminated from analysis the *on* phrase with the most positive valence rating (*Adrian is on task*; $M = 4.71$) and conducted the same set of analyses described in the main text. Even without this sentence, the pattern of results and the significance tests outcomes were the same: A significant main effect of preposition was found for both control and valence ratings.

might influence the production of *in* and *on* in non-spatial contexts.

Method

Participants A total of 122 college students participated in exchange for course credit. The mean age of participants was approximately 18 (M = 18.1, SD = 1.8). Nineteen were male (16%) and 103 were female (84%). Only three participants reported being non-native English speakers.

Materials and Design We developed 64 stories for this experiment. Eight base stories were created. The stories averaged 3 sentences (or 45 words) in length. Each base story was associated with a general theme and a fictitious person name that was gender ambiguous. Eight story types were developed from each base story by fully crossing the following factors: control of the figure (high vs. low), valence of the outcome (positive vs. negative), and expectedness of the scenario (expected vs. unexpected). Eight versions of the experiment were then created, each containing only one story from each base and only one of each story type. Each participant was randomly assigned to a particular version of the experiment, and the order in which the stories were presented to participants was completely randomized.

We also selected eight nonwords to serve as novel prepositional objects for the production portion of this experiment. Using a procedure similar to the one described by Jamrozik and Gentner (2015), we generated these eight nonwords using the ARC Nonword Database (Rastle, Harrington, & Coltheart, 2002: https://www.cogsci.mq.edu.au/research/resources/nwdb/nwdb.html): *vight*, *slief*, *thwom*, *yease*, *prach*, *gwinn*, *malse*, and *zaiff*. The eight nonwords were assigned in a pseudo-randomized fashion such that each participant saw each nonword only once during the experiment and that each nonword appeared with a different story type across each of the eight versions.

Procedure Participants took part in this study via SurveyMonkey.com. After consenting, participants were asked to answer a standard set of demographic questions: their age, gender, native language, and other languages they are able to speak, write, read, or understand.

We then asked participants to read and respond to eight short stories (see Table 1 for examples). Four catch trials were also included in each version of the experiment. Catchtrials involved asking participants to provide a specific numerical rating from one to five on the scale provided.

After reading each story, participants were presented with three questions and their respective scales: a figure-control question (i.e., "To what degree does the person have control of the situation?") to which they would respond on a scale ranging from "1-extremely low control of the situation by the person" to "5-extremely high control of the situation by the person;" a scenario expectedness question (i.e., "To what degree is the situation natural and expected?") to which they would respond on a scale ranging from "1-extremely unnatural and unexpected" to "5-extremely natural and expected;" and an outcome valence question (i.e., "To what degree is the situation being described likely to be a positive or negative event in their life?)" to which they would respond on a scale from "1-extremely negative" to "5-extremely positive." Participants were then asked to imagine that they overheard someone talking about the fictitious person they just read about in the story and to decide whether *in* or *on* was more likely to appear in the novel statement that they overheard (e.g., "Adrian is ____ a gwinn").

After reading eight stories and responding to the four questions following each story, participants were then presented with an electronic debriefing form.

Table 1: Example of two story types developed from one base story.

Figure-control	Valence outcome	Scenario expectedness
High	Positive	Expected
Lee works at a local pizza place and has spent lots of time developing their customer service skills. Because of what they learned, Lee always wears a clean uniform to work. Lee just found out that they are going to be promoted.		
Low	Negative	Unexpected
Lee's parents forced them to get a job at the local pizza place owned by their family. Lee's manager makes every employee wear a clown suit to work. Lee just found out that they are going to be fired.		

Results

Of the 122 participants described previously, four indicated that they were fluent in another language other than English but failed to specify which language despite explicit instructions to do so. It was determined that these failures to respond were likely due to participants not paying close enough attention to the questions being presented to them; therefore, their data was excluded from further analysis. Of the remaining 118 participants, 11 were removed from further data analysis: three for reporting a native language other than English, four for responding incorrectly to one or more of our four catchtrials, three for not finishing the study, and one for attempting to complete the study a second time. Thus, the data for 111 participants was used in the following analyses.

Ratings We first needed to determine whether participants were sensitive to the ways in which we manipulated the three variables across the different story types; therefore, we conducted a one-way by items ANOVA for each factor. Table 2 shows that, on average, stories were rated in accordance with our manipulations.

In order to explore the roles that outcome valence and scenario expectedness might play in decisions of figure-control, we then conducted a repeated measures ANOVA on control ratings using figure-control, outcome valence, and scenario expectedness as within-subjects variables and version as a between-subjects variable. Version did have a significant effect overall, $F(7, 103) = 4.75$, $p = .004$, $\eta p^2 = .180$, suggesting that participants' control ratings differed depending on the sets of stories they received. Moreover,

every time version participated in an interaction, the interaction was statistically significant. Even though these complex interactions were not analyzed further, this pattern suggests that the following pattern of effects might be driven by only a subset of the stories presented to participants.

Table 2: Mean ratings (and standard deviations) across factor levels for figure-control, outcome valence, and scenario expectedness.

	Factor Levels		*p*-value
Figure-Control	Low	High	
	2.59(1.38)	3.53(1.45)	< .001
Outcome Valence	Negative	Positive	
	1.65(0.83)	4.18(1.06)	< .001
Scenario Expectedness	Unexpected	Expected	
	2.70(1.40)	3.26(1.26)	< .001

Of the three within-subjects variables, two had significant effects on participants' ratings of control: figure-control and valence. The significant effect of valence was such that participants' ratings of control were higher in response to high figure-control stories (M = 3.53, SD = 1.45) as compared to low figure-control stories (M = 2.59, SD = 1.38), $F(1, 103) = 143.42$, $p < .001$, $\eta p^2 = 0.533$. Such an effect is not surprising. What is more interesting is that ratings of control were also influenced by valence, $F(1, 103) = 87.17$, $p < .001$, $\eta p^2 = .458$. More specifically, ratings of control were higher in response to positive valence stories (M = 3.39, SD = 1.44) as compared to negative valence stories (M = 2.72, SD = 1.47). Unlike valence, expectedness did not have a significant impact on participants' control ratings: Control ratings made in response to stories with expected outcomes (M = 3.06, SD = 1.48) were not significantly different from stories with unexpected outcomes (M = 3.05, SD = 1.50).

Interestingly, there were two significant interactions that did not involve the between-subjects variable of version. One was an interaction of figure-control and outcome valence, $F(1, 103) = 41.02$, $p < .001$, $\eta p^2 = .285$ (see Figure 1). This interaction was such that stories with positive outcomes received higher control ratings when they described high control situations (M = 4.10, SD = 1.16) as compared to low control situations (M = 2.69, SD = 1.34), $F(1, 103) = 172.85$, $p < .001$, $\eta p^2 = 0.627$; however, these differences in control ratings were observed to a lesser degree when stories with negative outcomes described high control situations (M = 2.96, SD = 1.49) as compared to low control situations (M = 2.49, SD =1.41), $F(1, 103) = 15.85$, $p < .001$, $\eta p^2 = .133$.

The other interaction of interest involved expectedness, which alone did not have a significant impact on control ratings. The interaction of expectedness and valence, $F(1, 103) = 46.17$, $p < .001$, $\eta p^2 = .310$, was such that participants rated the figures of stories with positive outcomes as having more control when the scenario was expected than when it was unexpected, $F(1, 103) = 23.01$, $p < .001$, $\eta p^2 = .183$; however, the opposite pattern was observed for stories with negative outcomes: Participants rated figures as having less control when the scenario was expected than when it was unexpected, $F(1, 103) = 18.31$, $p = .001$, $\eta p^2 = .151$ (see Figure 2).

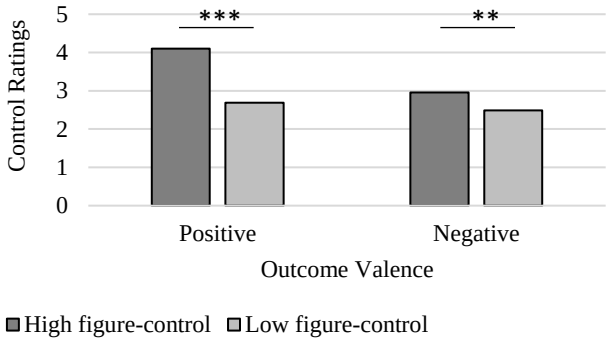

Figure 1: Mean control ratings across levels of figure-control and valence.

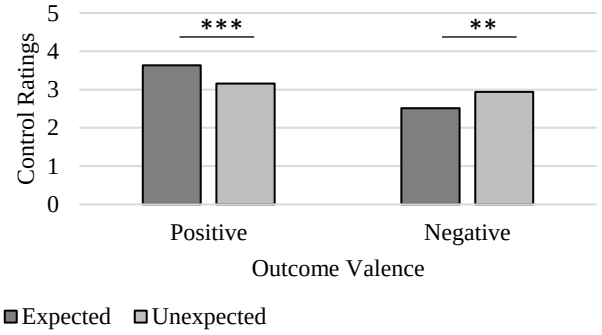

Figure 2: Mean control ratings across levels of expectedness and valence.

In addition to the pervasive influence of version, another concern arose during data analysis. Due to experimenter error 34% of the stories presented to participants actually contained the lexical items *in* and *on*; therefore, it is possible that ratings of control might have had more to do with lexical priming than the factors of interest. This lexical items confound was distributed across versions such that of the eight stories read by each participant at least one but no more than three contained a lexical item confound.

To analyze the impact that this lexical items confound may have had, we coded stories containing the word *in* as one and stories containing the word *on* as three. All "neutral" stories were coded as two, which included all stories that did not contain the lexical items *in* and *on* as well as two stories that contained both *in* an *on*. These codes were constructed such that high scores on the lexical items confound would be associated with high figure-control. The concern, then, was that high lexical confound ratings might predict high figure-control ratings; however, the results of a linear regression

actually showed the opposite to be significant: Low lexical confound ratings were associated with higher figure-control ratings, $F(1, 886) = 4.74$, $p = .030$, with an R^2 of .01. Participants' predicted control ratings decreased -.19 points for each increase in lexical confound, suggesting that seeing the lexical item *on* (as opposed to *in*) caused participants to produce lower ratings of control. This is a surprising finding that cannot be readily explained on the basis of lexical priming and does not align with the findings of Jamrozik and Gentner (2015).

Production We hypothesized that the factors of figure-control, outcome valence, and scenario expectedness would have an influence on production. In particular, we were interested in the likelihood that participants would choose either *in* or *on* to complete a novel phrase about the figure described in the story. A mixed effect logistic regression analysis looking at the choice between *in* and *on* as a function of all three within-subjects factors, the between-subjects factor of version, and all of their possible interactions revealed only significant effects involving figure-control, $F(1, 103) = 4.69$, $p = .033$, and outcome valence, $F(1, 103) = 24.13$, $p < .001$ (see Table 3). The figure-control effect was such that *on* was more preferred when figure-control was high (43%) and less preferred when figure-control was low (35%). The outcome valence effect was such that *on* was more preferred when the outcome was positive (47%) and less preferred when the outcome was negative (32%). Despite the pervasive influence of version in the ratings data, version did not play a significant role in production.

Table 3: Percentage of on responses and number of biased version across the eight story types.

Figure-Control	Outcome Valence	Scenario Expectedness	% *on* Responses	*on* vs. *in* Biased Versions
High	Positive	Expected	57	1 vs. 1
High	Positive	Unexpected	49	2 vs. 1
High	Negative	Expected	30	1 vs. 1
High	Negative	Unexpected	34	2 vs. 1
Low	Positive	Expected	41	1 vs. 2
Low	Positive	Unexpected	40	0 vs. 2
Low	Negative	Expected	31	2 vs. 2
Low	Negative	Unexpected	32	2 vs. 2

Discussion

The severe limitations related to this experiment do not allow us to make any strong claims regarding the observed findings; however, we think that a discussion of these findings is useful for generating hypotheses that can be addressed in future research. The most severe limitations of Experiment 2 involve the unaccounted for variation across the story sets that resulted in significant effects tied to version and the lexical confounds present in particular stories. Another significant limitation of Experiment 2 is a lack of counterbalancing due to the fact that participants were always presented with the same ordering of ratings: control, expectedness, valence, and production.

Very generally, the results of this experiment suggest that the relationships between control, valence, and expectedness may be more complex than we originally anticipated. For example, when stories had positive outcomes, participants' ratings of control may have been influenced more by figure-control than when stories had negative outcomes. It is possible that when situations have a negative outcome, we would prefer to think that the person did not have as much control over the events. Another potential example of these complex relationships is the significant interaction of expectedness and valence. What this interaction may suggest is that when ordinary events are involved, positive outcomes are associated with more figure control; however, when strange occurrences result in positive outcomes, people may be more likely to think that the person has less control over the situation. Interestingly, the pattern seems to switch when going from positive outcomes to negative outcomes. When something bad happens and it is an ordinary event, people may tend to sympathize and not attribute control to the person involved. When things go awry, the abnormality of a situation may cause us to think that the person had more control over the events that took place.

As for the production of *in* and *on*, our results were consistent with Jamrozik and Gentner's (2015) findings: *On* was more preferred when the person was described as having more control and less preferred when the person was described as having less control. We also found evidence to suggest that *on* may be more preferred when outcomes are positive and less preferred when outcomes are negative.

Conclusion

In the domain of spatial semantics the success of multi-componential approaches is clear. Our data is consistent with the hypothesis that non-spatial uses of prepositions have a multi-componential structure like their spatial counterparts. As a case in point, consider the title of this paper. Despite the connections *in* has with negative valence, being in shape is not perceived as significantly worse ($M = 4.57$) than being on top of it ($M = 4.63$). Even though multiple factors of meaning will likely be needed to account for the types of complex patterns we observed in our data, what is less clear is the origin of these factors and the relative impact each of them might have during either comprehension or production. It may be that the spatial and abstract meanings of spatial prepositions share features due to happenstance; however, many cognitive linguists propose that the abstract meanings associated with indirect metaphors are derived via metaphorical connections from their spatially-based meanings (e.g., Brugman & Lakoff, 1988/2006; Tyler & Evans, 2001, 2003). We argue that future research should focus on exploring the implications this type of research has for theories of indirect metaphors, specifically, and lexical semantics, more generally.

Acknowledgments

We are extremely grateful to Michele I. Feist for sharing her insights and recommendations with us during the early stages of this project. We would also like to extend our thanks to members of the Cognition and Psycholinguistics (CaP) Research Lab for their continued support. A special thanks goes out to Mateja Pavlic for her role in helping develop the stories used in Experiment 2. Finally, we would like to thank the reviewers of our original submission. Your feedback was instrumental in shaping this final product.

Children's exploration as a window into their causal learning

Abstract

How do children's beliefs about a causal system influence their exploration of that system? Children watched an experimenter try to make a machine play music by placing blocks on top; one block always activated the machine and the other block never did (Deterministic condition), or one block activated the machine a higher proportion of times than the other (Probabilistic condition). Subsequently, we measured children's exploratory behaviors without feedback (the machine never activated). We predicted that children in the two conditions would differ in their beliefs about how the system should work, leading to different hypotheses about why the machine was no longer working, and to differential exploration. Compared to the Probabilistic condition, children in the Deterministic condition intervened more often with the previously more effective block, experimented more with how to activate the machine, and explored for less time. Children's exploration provides a rich, nuanced view of their causal reasoning.

Keywords: cognitive development; causal learning; causal uncertainty; statistical learning; exploration

Introduction

Children continually learn about the causal relationships in their environment: Switches turn on lights; germs make people sick; unkind words make people sad. Learning such relationships is not trivial because causal links are not directly observable but rather inferred from statistical contingencies between events. Furthermore, causal relationships are graded in strength – you not only need to learn that a relationship exists but also the probability of the cause generating the effect, which in turn can lead to more or less certainty about the underlying causal structure (Griffiths & Tenenbaum, 2005).

From as young as 24 months, children can infer both the existence of causal links and the relative strength of different causes from deterministic and probabilistic data (Waismeyer, Meltzoff, & Gopnik, 2015; for older children see, Gopnik et al., 2004; Kushnir & Gopnik, 2007; Sobel, Tenenbaum, & Gopnik, 2004). Further, children are more likely to trust testimony that conflicts with probabilistic data (e.g., a block only sometimes makes a machine play music) than testimony conflicting with deterministic data (e.g., a block always makes a machine play music), suggesting sensitivity to the relative strength implied by these different patterns of evidence (Bridgers, Buchsbaum, Seiver, Griffiths, & Gopnik, 2016).

The majority of prior research on children's causal reasoning, however, has examined children's judgments of causal structure. That is, children are prompted to identify which objects are causes and which are not or to produce a single intervention on the system to bring about an effect (e.g., Bridgers et al., 2016; Buchanan & Sobel, 2011; Gopnik et al., 2004; Kushnir & Gopnik, 2005; Kushnir, Wellman, & Gelman, 2008; Sobel et al., 2004). These forced-choice dependent measures provide insight into children's inferences about what is and what is not a cause, but more graded measures could provide additional insight into children's sensitivity to causal strength, especially since causal strength itself is inherently graded. Such measures could also reveal children's certainty or confidence in their inferences. Here, we look to children's exploratory behavior as a window into their causal learning in the hope of gaining a more nuanced view.

Children are sophisticated active learners and acquire knowledge from their own direct exploration of the world (Schulz, 2012; Xu & Kushnir, 2013). Children's exploratory play is not just driven by their enjoyment but also by their inductive inferences and expectations about how the world works. For instance, if children learn that members of a category have an unobservable property, they expect other category members to also have that property and attempt to elicit the property from them (Baldwin, Markman, & Melartin, 1993; Butler & Markman, 2012). The stronger the cues provided to category membership are (e.g., the objects are similar vs. different in appearance; have the same vs. different labels), the longer children persist in their attempts to elicit the property, revealing sensitivity to gradations in the inductive strength of these cues (Baldwin et al., 1993; Schulz, Standing, & Bonawitz, 2008). Children also explore more when evidence is ambiguous or an event challenges their prior beliefs. They opt to play with causally confounded or belief-violating toys over novel toys (Schulz & Bonawitz, 2007; Stahl & Feigenson, 2015). In this play, they even spontaneously design novel interventions or experiments to test their beliefs, and generate sufficient evidence to disambiguate the causal system (E. B. Bonawitz, van Schijndel, Friel, & Schulz, 2012; Gweon & Schulz, 2008; Legare, 2011; Schulz & Bonawitz, 2007). Taken together, childrens certainty and surprise appear to influence how much and how long they explore, making exploration a good dependent measure of their underlying beliefs and confidence in those beliefs.

Here, we take up the hypothesis that children's free exploration of a causal system is supported by some of the same rational principles of inductive inference that inform their explicit causal judgments (e.g., Schulz, Standing, & Bonawitz, 2008). We examine children's exploration in the context of causal uncertainty, and in particular investigate how their exploration might differ after observing the deterministic vs. probabilistic patterns of evidence often used in classic ex-

periments on causal judgments. We predicted that children would be sensitive to differences in causal strength implied by deterministic vs. probabilistic data, and that this would be reflected in their free play with a causal system. Using exploration as a dependent measure has the additional benefit that it is non-verbal and so could be particularly useful in measuring young children's certainty in their inferences; explicit meta-cognition is still developing in early childhood, making it difficult to elicit explicit certainty judgments from young children (Ghetti, Hembacher, & Coughlin, 2013; Hembacher & Ghetti, 2014).

A feature common to experiments using exploration as a dependent measure is that children are presented with objects that lack the previously observed property. This design decision prevents children from eliciting confirmatory evidence and eliminates the distraction of the interesting causal property, to more easily isolate how children's expectations affect their play (see Baldwin et al., 1993; Schulz, Standing, & Bonawitz, 2008). However, it also raises the question of what conclusions children are drawing about their failed attempts to elicit the property. This failure could be due to the causal system (i.e., it does not work as expected or has stopped working) or due to one's own actions (i.e., I am doing something wrong) (Karmiloff-Smith & Inhelder, 1974), a distinction to which even 16-month-old infants are sensitive when responding to their own failed actions (Gweon & Schulz, 2011). Thus, children's exploration may not only reflect uncertainty in their prior inferences about the causal system but also uncertainty about why the system is no longer working, making it a useful measure of both their initial inductive predictions and how such predictions inform later inferences about unexpected outcomes. Next, we present our specific experimental hypotheses about how children's sensitivity to these sources of uncertainty might manifest in their exploration of an inert causal system.

Overview

In the current experiment, four- and five-year-olds were introduced to a machine that could be activated by placing blocks on top. Children observed either deterministic or probabilistic evidence that one of two blocks was better than the other at making the machine go. Children were then given the opportunity to explore the blocks and the machine on their own, but during this time, the machine never activated no matter what interventions children performed.

We predicted that children's exploration would reflect both their initial inferences from the demonstrated data about how the system works and their subsequent inferences about why it was no longer working (Legare, 2011; Schulz, Hooppell, & Jenkins, 2008). In both conditions, we predicted children would first attempt to activate the machine with the block that was demonstrated to be more causally efficacious. However, when faced with evidence that this block was no longer working, children would explore differently across conditions.

Children in the Deterministic condition will likely develop a strong expectation that the previously more effective block should work (it always did before) and that the the previously less effective block should not (it never did before), while children in the Probabilistic condition should have less certainty about the causal strength of each block (both blocks previously succeeded and failed in activating the machine). We thus predicted that children in the Deterministic condition would persist in trying to activate the machine with the previously better block more than children in the Probabilistic condition, who would be more likely to explore the previously worse block.

The stronger belief in the previously better block's efficacy might also lead children in the Deterministic condition to infer that the block is no longer working because they are doing something wrong. If that is the case, children might not only persist in trying this block but also be more likely to experiment with different ways of activating the machine (e.g., placing the block in different locations on the machine) to try and find the right way to use the block (Legare, 2011). However, this stronger initial belief in the better block's causal strength might also lead children to give up more quickly, because of a belief that they are still doing something wrong (e.g., not placing the block in the right location) or that the system has somehow changed (e.g., it is out of batteries). In contrast, children in the Probabilistic condition might explore longer overall, but produce less variable interventions. Since the system is stochastic, if it is not activating it is not necessarily because the system has stopped working or that they are doing something wrong, so it is worth continuing to test out the blocks.

Prior work has actually suggested that children engage in more variable exploration when presented with ambiguous or probabilistic evidence (see E. Bonawitz et al., 2011; Schulz, Hooppell, & Jenkins, 2008). Here, we predict that the probabilistic evidence will result in more even exploration of both blocks and longer exploration overall. In contrast to previous work, we anticipate that the deterministic evidence will render the inert system more surprising and so will lead to more novel interventions to try to figure out why this is the case.

Given these predictions, we not only look at children's overall persistence and exploration time, but also at which blocks children place on the machine and what else they try with the blocks and the machine to see if these behaviors also reflect different causal inferences and sources of uncertainty.

Methods

Participants

Seventy-seven children (41 4-year-olds and 36 5-year-olds; 38 females) were recruited from local museums in Toronto, Ontario. An additional 10 children were tested but excluded from analysis due to experimenter error ($n = 5$), missing date of birth ($n = 2$), or ending the experiment early ($n = 3$). Children were randomly assigned to the Deterministic condition ($n = 39$, $M(SD) = 59.43(6.30)$ months, 19 females) or the Probabilistic condition ($n = 38$, $M(SD) = 58.96(7.56)$ months, 19 females). The diversity of the sample was repre-

sentative of the diversity of the local population.

Materials

The causal system was presented to children as a machine that could play music when blocks were placed on top. The "machine" was a decorated cardboard box as shown in Figure 2A. There were four wooden blocks, differing in shape and color, but similar in size: the red oval, yellow square, blue triangle, and purple star blocks. The machine appeared to play music when blocks were placed on top, but in reality, it contained a wireless door bell that could be activated surreptitiously by the experimenter via a hidden remote control. For some children, a bell they could ring to indicate that they were done exploring ($n = 36$) or a distractor toy ($n = 2$) were also placed on the table.[1]

Procedure

Participants were tested individually in a quiet off-exhibit location at the museum. Children's behavior was video recorded and coded offline by the second author.

Demonstration Phase The experimenter first introduced the child to the novel machine, explained that you could make the machine play music by putting blocks on top and that some blocks made it play music while others did not. The experimenter then brought out a pair of blocks, either the yellow square and red oval blocks, or the blue triangle and purple star blocks (counterbalanced across participants) and told children that she had never played with these blocks before.

Next, the experimenter demonstrated each block on the machine. In the Deterministic condition, each block was placed on the machine six times; one block deterministically activated the machine on all six trials (*better* block), while the other block failed to activate the machine on all six trials (*worse* block). In the Probabilistic condition, one block was placed on the machine three times and activated the machine twice, always on the first and third trial (*better* block); the other block was placed on the machine six times and also activated it two times, on the second and fifth trial (*worse* block). As in previous work, this pattern of data controls for the frequency with which each block activates the toy, providing stronger evidence that children are reasoning about the probability of each cause generating the effect and not just the number of times the effect was associated with the cause (Bridgers et al., 2016; Kushnir & Gopnik, 2007). We counterbalanced which block was the better block and whether the better block was demonstrated first.

The experimenter then asked the child which block was better at making the machine play music. If the child did not answer or chose both blocks, the experimenter asked them to select one. The block children pointed to, touched, or named was coded as their answer. If children answered incorrectly, the experimenter corrected them (e.g., "Oh remember, the red oval block was better at making the machine play music.")

Exploration Phase The experimenter then informed the child that she had to leave for a bit, and that the child could play freely with the blocks and the machine while she was gone. The experimenter left the table and pretended to be busy in another part of the room. During this time, the child could explore the blocks and machine but did not receive any feedback, i.e., neither block activated the machine. If the child asked the experimenter questions, she explained that she was still working but the child could keep playing with the blocks and machine, and let the experimenter know when they were done. The experimenter returned when the child indicated they were done or after two minutes.[2] Lastly, the child was given an opportunity to activate the machine with a new pair of blocks to ensure they left in good spirits.

Exploration Phase Coding There were three main variables of interest. First, we measured the proportion of interventions children performed with the better block, out of the total interventions they made with just a single block (*single trials*). A single trial was when children placed a block that was off of the machine onto the machine, or lifted and then put back down part or all of a block that was already on the machine. Each single trial was coded according to whether the *better* or *worse* block was used. Only children who placed a block on the machine were included in this analysis (Deterministic condition: $n = 33$; Probabilistic condition: $n = 35$). A small number of trials (3.4%) in which children placed both blocks on the machine simultaneously were not included, but were considered a strategy as described below.

Second, we measured the total time in seconds children spent exploring the blocks and machine. Exploration began when children first touched a block or the machine and ended when they met any of the following criteria: They (1) explored for two minutes; (2) indicated that they were done; (3) did not interact with the blocks or machine for 15 seconds (end time was coded as the last second they touched the block and/or the machine); (4) only played with the blocks off of the machine for 15 seconds (end time was coded as the last second when they removed the block(s) from the machine). Children who never put the blocks on the machine and only played with the blocks off of the machine, were coded as having an exploration time of one second. Children who did not interact with the blocks or machine at all even after additional

[1] We initially experimented with how children could indicate that they were done. Children were either instructed to verbally alert the experimenter ($n = 39$), given a fun distractor toy they could switch to ($n = 2$), or told that the experimenter would bring out new blocks when she returned and given a bell to ring when they were done exploring ($n = 36$; we kept this latter version for our preregistered replication of this pilot experiment). These approaches were evenly distributed across conditions.

[2] We were initially concerned children might feel they had to explore until the experimenter returned and so would continue due to normative pressures rather than interest. Thus, for a subset of children (n = 23), evenly distributed across conditions, the experimenter checked-in prior to 2 minutes if they stopped exploring for 5-10 seconds, i.e., before their exploration had otherwise ended. Most children, however, did stop exploring before 2 minutes had passed, so we decided to remove these check-ins for the remaining children in this experiment and the children in our preregistered replication.

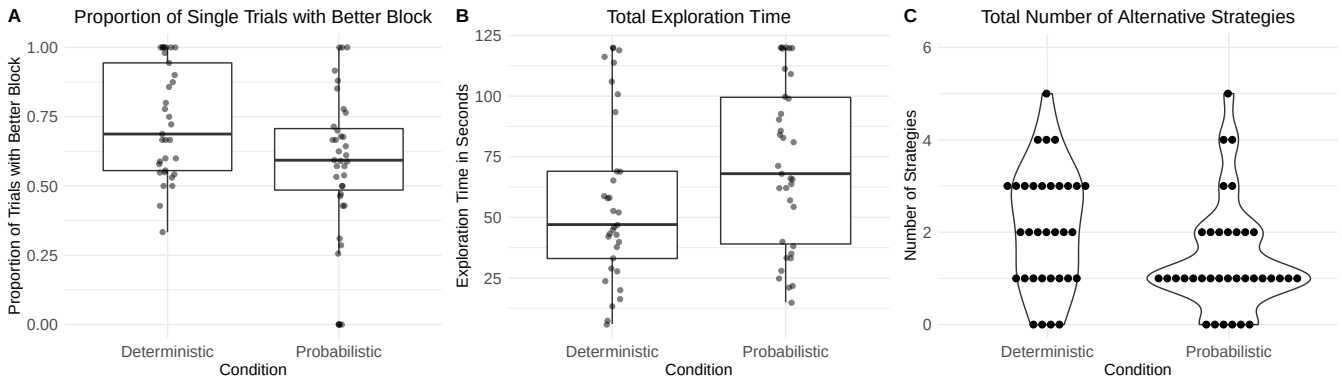

Figure 1: (A) Proportion of single trials children performed with the better block across conditions. (B) The amount of time children explored the blocks and/or the machine across conditions. Median and 1st and 3rd quartiles are displayed. (C) The total number of alternative strategies children performed across conditions. For all plots, dots are individual children.

encouragement from the experimenter were recorded as having an exploration time of zero seconds. These children did not indicate that they wanted to end the experiment; the experimenter also made clear through prompting that they could place blocks on the machine, so we were confident they understood the instructions and interpreted their lack of exploration as a choice not to explore, rather than confusion about the task. Nine children did not place a block on the machine, and this tendency did not differ by condition (Deterministic: $n = 6$; Probabilistic: $n = 3$; two-tailed Fisher's Exact test, $p = 0.481$). The end of exploration was determined offline according to the above criteria.

Third, we noticed that during children's exploration, they indeed performed alternative actions that were not demonstrated by the experimenter. We considered these different actions experimentation or alternative strategies children were employing to try to activate the machine. We identified seven different types of strategies: (1) exploring the machine alone (e.g. knocking on or poking it; flipping it over), (2) exploring the blocks alone (e.g., tapping the blocks together off of the machine or on the table), (3) flipping a block over to try a different side, (4) placing the block in a different location on the machine, (5) placing both blocks on the machine, (6) dropping the blocks onto the machine from above, and (7) applying force when placing the blocks on the machine (See Figure 2A). Children received a score of 1 for each strategy type they produced and a 0 otherwise (i.e., children could be coded as exhibiting 0 to 7 different strategies). Note that this is not a measure of how many times children produced a strategy but rather a count of how many different kinds of strategies children exhibited. Only children who interacted with the machine at some point were additionally coded for strategies (Deterministic condition: $n = 33$; Probabilistic condition: $n = 35$; same children as those included in analysis of the proportion of single trials with the better block).

Results

Consistent with previous work, in response to the explicit question about which block was better at activating the machine, the majority of children correctly selected the *better* block (two-tailed Binomial test, $p < 0.001$; Deterministic: $37/39$; Probabilistic: $33/38$; two-tailed Fisher's Exact test comparing across conditions: $p = 0.263$). This was also true when looking only at children who later placed a block on the machine during exploration (two-tailed Binomial test, $p < 0.001$; Deterministic: $31/33$; Probabilistic: $32/35$; two-tailed Fisher's Exact test across conditions: $p = 1$). These children were similarly more likely to first intervene with the better block, rather than the worse block (two-tailed Binomial test, $p < 0.001$; Deterministic: $22/33$; Probabilistic: $24/35$; two-tailed Fisher's exact test across conditions: $p = 1$). Intriguingly, these children were more likely to identify the better block as the better cause ($63/68$) than to select it first to place on the machine ($46/68$; two-tailed Fisher's Exact test, $p < 0.001$), suggesting they may have had motivations other than maximizing the probability of activating the machine when they first intervened.

To compare the proportion of single trials on which children used the better block, the total time children explored, and the total number of strategies children exhibited across conditions, we conducted three one-way ANCOVAs with condition as a factor and age in months as a covariate.

Children in the Deterministic condition intervened with the better block on a higher proportion of single trials than children in the Probabilistic condition ($M \pm$SE = 0.73 ± 0.035 v. 0.59 ± 0.041, respectively; $F(1,65) = 6.17$, $p = .016$), and this tendency to intervene with the better block did not differ by age ($F(1,65) = 0.23$, $p = .635$). Children in the Deterministic condition, however, explored for a shorter amount of time than children in the Probabilistic condition ($M \pm$SE = 48.60 ± 6.14 seconds v. 66.40 ± 6.14 seconds, respectively). This difference was significant ($F(1,74) = 4.37, p = .040$), and the length of time children explored did not differ by age ($F(1,74) = 1.26, p = .264$). If we only consider the children who placed a block on the machine, the difference in exploration time is trending (Deterministic: $M \pm$SE = 57.33 ± 6.12 seconds; Probabilistic: 71.89 ± 5.76 seconds; $F(1,65) = 3.07$, $p = .084$). (See Figure 1A-B.)

Most children employed at least one alternative strategy in their attempts to make the machine play music (Determin-

istic: 29/33; Probabilistic: 29/35), and this tendency did not differ across conditions (two-tailed Fisher's exact test, $p = .735$). However, children in the Deterministic condition employed more strategies overall than children in the Probabilistic condition ($M \pm$SE = 2.09 ± 0.23 v. 1.43 ± 0.20, respectively; $F(1,65) = 4.74, p = .033$); children's overall tendency to perform these alternative actions did not differ by age ($F(1,65) = 0.18, p = .670$). (See Figure 1C.)

Looking at the different strategies separately reveals that the modal strategy in the Deterministic condition was flipping the blocks over and in the Probabilistic condition, placing the blocks in different locations on the machine. Roughly the same number of children in both conditions changed the location of blocks (16 in Deterministic and 15 in Probabilistic) but about twice as many children flipped blocks over in the Deterministic than in the Probabilistic condition (21 v. 10 respectively), and this difference was significant (two-tailed Fisher's Exact test, $p = .007$). We are cautious to draw conclusions about the less common strategies since so few children exhibited them overall, but they do provide additional suggestive evidence that the conditions not only differed in the total number of strategies children exhibited but also in which strategies children employed. (See Figure 2B.)

Discussion

We provide evidence that children's exploratory behaviors can serve as a graded and detailed window into their causal reasoning. We find that presenting children with covariation information that deterministically or probabilistically supports a particular causal system leads them to explore this system differently, reflecting different inferences about causal strength and the uncertainty inherent in these inferences.

Children in both conditions drew rational inferences from the evidence they observed about the relative causal strength of the more effective (better) block compared to the less effective (worse) block. Children who previously observed deterministic evidence for the blocks' effectiveness attempted to activate the machine with the better block, rather than the worse block, more often than children who observed probabilistic evidence, suggesting a stronger inference that this block should work. Children's differential exploration across conditions suggests they did not simply draw a binary inference about which cause was better but rather were sensitive to the relative magnitude of causal strength.

Children's exploration also provided a richer picture of their causal inferences in this task than their causal judgments prior to the exploration phase. The causal judgments revealed that children had correctly inferred which block was more effective. If we had only considered this measure, however, we would not have seen that children were differentiating between the evidence presented in each condition and correctly retaining more uncertainty in the more ambiguous, probabilistic case. Similarly, if we had only looked at children's first intervention on the machine, we would have lacked the sensitivity to pick up on differences across conditions.

Interestingly, only about two-thirds (68%) of children across conditions first intervened with the better block, though over 90% explicitly identified this block as more effective. This is particularly surprising in the Deterministic condition; in prior work using similar or even weaker patterns of deterministic evidence, when explicitly asked to select a block to make the machine go, children overwhelmingly tended to intervene with the more effective block (e.g., Sobel et al., 2004; Sobel, Sommerville, Travers, Blumenthal, & Stoddard, 2009). Children's first intervention in our task suggests they were not simply motivated to generate the effect but rather to explore from the get go (e.g., perhaps some children wanted to understand why the worse block did not work or see if they could make it work). Direct questions likely place pressure on children to respond correctly, while self-directed exploratory play is more open-ended, removing such pressures and potentially revealing different behavior.

Prior work shows that children explore more when presented with events that violate their expectations. In many of these studies, including the present, children are not just faced with evidence that the causal system works differently than how they predicted but that it does not work at all. What inferences do children draw about the source of their own failed actions and how might their exploration reflect these inferences? Children in the Deterministic condition may have thought the problem lay with them since the evidence demonstrated by the experimenter strongly suggested that one block made the machine go and the other did not. These children tended to exhibit a wider variety of alternative actions, suggesting they may indeed have interpreted their failures to elicit music from the machine as the fault of their own actions rather than the causal system. Children in the Probabilistic condition, however, could explain away the lack of activation due to the system's stochasticity. Many did try at least one alternative strategy but overall did not experiment as much as children in the Deterministic condition, suggesting they did not necessarily think the problem lay with them but rather with the system itself. Indeed the one alternative strategy more children in the Probabilistic condition produced was exploring the machine on its own.

Though children in the Deterministic condition tried more strategies, they actually appeared to give up more quickly, exploring for a shorter amount of time overall than children in the Probabilistic condition. One possible explanation for this difference, consistent with why children in the Deterministic condition may have experimented more, is that the lack of machine activation led them to conclude more quickly that they were incapable of activating the machine either because they just could not figure out how or because it had stopped working. In contrast, children in the Probabilistic condition may have explored longer because they continued believing the machine might activate.

Taken together, these different aspects of children's exploration – their tendency to explore the better block, to experiment with different ways of activating the machine, and total

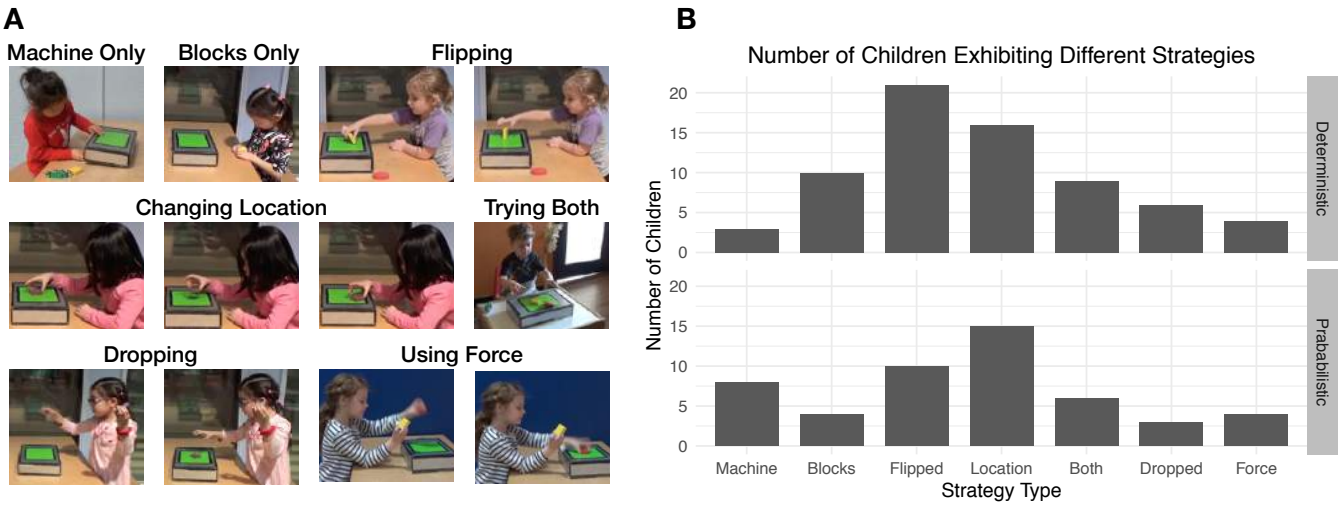

Figure 2: (A) Examples of alternative actions or strategies children performed to try to activate the machine. (B) The total number of children exhibiting each of the different strategies across conditions.

length of exploration – are suggestive of children integrating different sources of uncertainty. This includes uncertainty about the causal system itself (which block is better, and how much better) and uncertainty about the source of failure ("Is it me or the world?"; Gweon & Schulz, 2011).

In the deterministic case, children appear to persist in believing that the better block should work, so something must be wrong either with their own actions or with the blocks and the machine (e.g. it ran out of batteries). This behavior suggests continued certainty about how the causal system should work (even after receiving negative evidence about the previously better block, they still do not think it is likely that the previously worse block will work) but higher uncertainty about what has gone wrong (resulting in them trying more strategies to see if they can fix it).

In the probabilistic case, children appear less certain about the causal relationships. The better block continuing to not work is less surprising, because the system is stochastic. Children therefore demonstrate high uncertainty about the strength of the blocks and probability of activation (as evidenced by trying both blocks more evenly, rather than favoring the previously better one) but lower uncertainty about the source of failure (as evidenced by fewer strategies and overall more persistence).

Decades ago, Karmiloff-Smith and Inhelder (1974) argued that children's exploration is not just driven by their prior implicit theories but also by the evidence they generate as they explore, and that their failures to bring about an expected outcome would be interpreted as either relevant to their theory or to their action. Moving forward, looking at the time course of exploration (e.g., how early exploration differs from later exploration) could provide more compelling evidence for how children's inferences evolve as they accumulate evidence of the system's failure. For example, do the type of strategies children employ change over time? Prior work indicates children this age can design informative interventions to disambiguate causal evidence (Cook, Goodman, & Schulz, 2011). Are children's alternative strategies indeed targeting different hypotheses across conditions about why the machine is not working? In the present study, there are too few children who perform any particular strategy to probe these questions in more detail, but we are currently running a larger scale replication with over 100 children to address these questions (see `osf.io/sc54w` for preregistration).

Children's experimentation also raises interesting questions about conditions that lead to innovation. Along certain dimensions, and consistent with prior work (e.g., E. Bonawitz et al., 2011; Schulz, Hooppell, & Jenkins, 2008), deterministic evidence seemed to constrain children's exploration: they were less likely to explore the block another person had demonstrated to be less effective and explored for a shorter total amount of time than children in the Probabilistic condition. Along other dimensions however, they appeared to be more exploratory and innovative. They were more likely to experiment with how they placed blocks onto the machine. Children's ability to generate alternative means for achieving a goal and flexible problem solving in the face of failed actions is an interesting avenue for future work.

Exploration is a powerful, ecologically valid dependent measure that is more sensitive than binary questions and does not rely on children's language skills or explicit introspection. It does come with limitations; it is indirect and influenced by other factors besides children's beliefs. The use of open-ended, dynamic measures such as exploration, however, in conjunction with direct questions will allows us to paint a richer, more graded picture of children's inferences, as well as offer the potential of investigating how these inferences might change across time and affect behavior. Just as children harness the power of their exploratory play to learn about the world, we, as scientists, can harness this same play to learn more about what and how children learn.

Abstract

Quantity can be expressed in a variety of ways and at different levels of precision. One factor that influences numerical description of elements in a visual scene is how long the scene is observed. We extend a previous incremental model of numerical perception to model quantified description under time constraints. Our extended model predicts that as presentation duration decreases and as the quantity of items to be enumerated increases, the frequency of inexact quantifiers will increase. We conducted two human subject elicitation studies to test these predictions. Our findings were consistent with our model's predictions. Additionally, we demonstrate that our novel model of incremental numerical perception and quantified description closely predicts the precise proportion of exact numerical responses generated by in these experiments.

Keywords: numerical language; numerical perception; quantifiers; subitizing; counting; estimation; computational model

Introduction

Quantity can be expressed in a variety of ways and at different levels of precision. Speakers can use exact numbers to describe quantities (e.g., "there are *twenty-two* guests at the party") or they can use more vague language (e.g., "there are *many* guests at the party"). Many factors influence the form and degree of precision of quantified language a speaker uses, including pragmatic considerations (Cummins, 2015). For example, speakers can express quantities in strategically vague ways for the purpose of influencing behavior (Hesse & Benz, 2018).

In the context of visual scene description, another factor influences quantified language: how long the scene is observed. Research in numerical perception suggests that mental representation of visual quantity is incrementally acquired through temporally extended and attentionally-dependent perceptual processes (Trick & Pylyshyn, 1994; Railo, Koivisto, Revonsuo, & Hannula, 2008). Glancing at a scene allows one to form a less precise representation of quantity, while taking the time to count each relevant item gives one a precise numerical representation of quantity. Using exact numbers when insufficient time has been devoted to complete enumeration often results in incorrect numerical guesses, and psychologists studying numerical perception often rely on analysis of error patterns during exact number elicitation tasks to make inferences about underlying processes and representations (e.g., Mandler & Shebo, 1982).

However, outside psychophysics experiments, people are rarely forced to express themselves using only exact numerical expressions. Some recent work has begun to examine patterns of quantified language usage in more unconstrained situations. In particular, Barr, Deemter, and Fernández (2013) found that when individuals produce quantified reference expressions (QREs), the form of the QRE was dependent on the numerosity of the sets under consideration. When the quantities in each set were large, people tended to produce relational expressions (e.g., "my set is the largest one"). However, when the target set of objects consisted of a small quantity, people tended to produce QREs with exact numerical descriptors despite inexact QREs being sufficient to disambiguate the expression. This result suggests that people balance pragmatic concerns of informativity with minimization of perceptual effort or cost.

The contribution of this paper is two-fold. First, we extend a previous incremental model of numerical perception to model quantified description under time constraints. This provides an explicit model of perceptual cost that was lacking in prior literature. The second contribution of this paper is two novel human subject elicitation studies designed to test the predictions generated by this model. Our extended model predicts that as presentation duration decreases and as the quantity of items to be enumerated increases, the frequency of inexact quantifiers will increase. The findings from the experiments were consistent with our model's predictions. Additionally, we demonstrate that our novel model of incremental numerical perception and quantified description closely predicts the precise proportion of exact numerical responses generated by in these experiments.

Computational Models of Numerical Perception

The perception of numerosity consists of multiple processes, each occurring at different rates and resulting in mental representations of varying precision. Explicit counting provides a slow, but precise, determination of number (Gelman & Gallistel, 1986) rooted in linguistic representation in a phonological buffer (Whalen, Gallistel, & Gelman, 1999). Estimation provides a rapid but less precise judgment of the quantity of a group of objects (Barth, Kanwisher, & Spelke, 2003) rooted in what has become known as the approximate number system (ANS) (Dehaene, 2011). Between these two procedures, a third process, called subitizing, provides both rapid and pre-

cise judgments of numerosity, but only for small quantities, from one to typically around four objects (Kaufman, Lord, Reese, & Volkmann, 1949). Consequently, the range of numerosities between one and four has become known as the subitizing range. While debate still continues about the representations and processes underlying subitizing, there are converging lines of evidence that suggest that the object-tracking system (OTS) plays a central role (Feigenson, Dehaene, & Spelke, 2004).

Recently, there has been renewed interest in developing neural models of numerical perception. These models typically focus on accounting for only a single process and form of representation, such as estimation and the ANS (Chen, Zhou, Fang, & McClelland, 2018) or counting and exact number (Fang, Zhou, Chen, & McClelland, 2018). Some researchers have begun to examine the generation of quantified descriptions of visual scenes with varying levels of precision (Pezzelle, Marelli, & Bernardi, 2017). However, these models also generally do not attempt to model the time course of enumeration. The psychophysical literature on numerical perception has shown that within the subitizing range, each additional object requires only 40–100 ms to accurately enumerate, while outside the subitizing range, each additional object requires 250–350 ms to enumerate (Trick & Pylyshyn, 1994). Most existing computational models of numerical perception do not attempt to capture this aspect of enumeration, nor do they provide accounts for how estimates can be refined with additional time.

An Incremental Model

In contrast with these previous models, Briggs, Bridewell, and Bello (2017) developed a computational model, implemented in the ARCADIA cognitive system (Bridewell & Bello, 2016), that models temporally extended numerical perception and integrates various forms of numerical representation. The model contains components that implement three distinct numerical representation systems: the ANS, the OTS, and the phonological buffer. We will denote this model as `INP-Guess` (incremental numerical perception and guessing).

`INP-Guess` operates by first ascertaining an approximate, noisy estimate of quantity by deploying visual attention toward the entire group of items to be enumerated.[1] Subsequently, serial attention is deployed to each individual item in the group. This process of serial attention first fills up the visual short-term memory (vSTM) slots in ARCADIA's object-tracking system. If there are no more items to be enumerated or no more available slots in vSTM, then a lexical representation of the quantity of relevant items in vSTM is subvocalized within the system's phonological buffer. After this point, subsequent serial focus to new items is accompanied by subvocalization of the next count word in the counting sequence.

[1] We refer the reader to the original model paper for details about how visual attention is realized in the ARCADIA system.

Numerical Guessing. If the visual scene ends, or enumeration otherwise ends, the model merges both the results from the ANS and the lexicalized count into a single numerosity judgment. If time allows for an explicit count to be fully generated (i.e., all items had received individual attentional focus), the explicit count is recorded. Otherwise, an educated guess is made:

$$Guess(n_c, n_e, w) = n_c + sample(\mathcal{N}(n_e - n_c, \sqrt{w \cdot (n_e - n_c)}))$$

where w denotes the Weber fraction of the ANS, n_e denotes the number of items that collectively received attentional focus during estimation, and n_c denotes the number of items that received individual focus during subitizing and counting.

As more items are individually attended to, an exact representation of a lower bound on the number of visual items in the scene increases. The equation above reflects the variance of the noisy numerosity representation upon which linguistic description is based decreasing as this lower bound increases. Note, we are not proposing that serial deployment of attention directly affects the variance of the representation produced by the ANS. Rather, what we are proposing is that the partial exact, lexical representation of number and the noisy ANS representation are merged (Briggs, Bridewell, & Bello, 2017), such that the resulting merged representation of numerosity will have lower variance when more items have received serial focus of attention. If there is enough time to devote attention to each item individually, then $n_c = n_e$ and guess is equal to the lexicalized count n_c.

While the precise time T_{attend} it takes to fully attend to n items individually within the `INP-Guess` model depends on multiple task-related factors, we can formulate a mathematical approximation of the time required in a simple case (i.e., a single-task involving enumeration of all items in a visual scene):

$$T_{attend}(n) \approx T_f \cdot min(r_s, n) + \prod_{max(r_s,n) \leq i \leq n} T_{subvocal}(i) + T_f$$

where T_f denotes the time necessary to attend to encode a single item into vSTM, r_s denotes the subitizing limit, and $T_{subvocal}(i)$ denotes the time necessary to subvocalize the i-th count word. Based on the original parameter values used by Briggs and colleagues (2017), we set the following values: $T_f = 50$ms, $r_s = 4$. Subvocalization time $T_{subvocal}(i)$, varies by number and is based on the formula from Huss and Byrne (2003).

Therefore, the number of items n_c that can be individually attended to in `INP-Guess` within a time window of T can be approximated as:

$$n_c(T) \approx \underset{i \geq 0}{\text{argmax}} \{i | T_{attend}(i) \leq T - T_{estimate}\}$$

where $T_{estimate}$ denotes the time necessary for the initial estimation of quantity within the visual scene.

Briggs and colleagues (2017) demonstrated that the `INP-Guess` model could account for the bilinear reaction time

curve in enumeration (Trick & Pylyshyn, 1994). Additionally, the INP-Guess model could account for the pattern of error in studies of subitizing during conditions of divided attention (Railo et al., 2008).

However, while being able to capture the pattern of error in numerical guessing during tasks with time and attentional constraints is desirable in a model of numerical perception, it is an incomplete account of quantified language use. When speaking with one another, people are faced with a variety of communicative norms. Communicating exact numbers in cases of noisy numerical representations would likely violate these norms, including prohibitions against communicating without adequate evidence (Grice's Maxim of Quality) and failure to be informative about one's own certainty (Grice's Maxim of Quantity) (Grice, 1975). The use of inexact quantified description (e.g., "there are between 4 to 7 items", "there are about 6 items", etc.) is one way to satisfy these communicate norms. While the wide range of quantified language provides ample opportunity for investigation by researchers in semantics and pragmatics (Cummins, 2015), an even more basic question arises: how can we model when people decide to use inexact quantified description?

Extension to Inexact Language

To model when people use inexact quantified descriptions, we propose a simple extension to the INP-Guess model, which we will denote as INP-Hedge. Instead of sampling a single guess value, INP-Hedge obtains ν distinct guesses, which we will denote as the multiset $G = \{g_1, ..., g_\nu\}$. This corresponds to a collection of values an individual may find plausible. If all the guesses in G are the same ($g_1 = g_2 = ... = g_\nu$), then we would predict an exact numerical description is generated equivalent to the value of these guesses. Otherwise, we would predict an inexact numerical description is generated, which can be derived from the set of guesses. For instance, consider a set of guesses $G = \{6, 8, 8\}$. Potential ways to linguistically describe this set are "about eight" or "six to eight."

How particular forms of inexact quantified description are generated is a question beyond the scope of this paper. Here, we do not attempt to model the distribution of specific forms of inexact description. In the INP-Hedge model we currently generate two forms of inexact expression: hedged numbers (e.g., "about eight") and intervals (e.g., "six to eight"). If the majority of the sampled guesses are equal to a value X, then INP-Hedge produces a hedged number expression anchored in this majority guess (i.e., "about X"). Otherwise, the model produces an interval response ("between X and Y"), where X corresponds to the minimum guess and Y corresponds to the maximum guess.

This quantified description mechanism is still preliminary, and we will discuss how the INP-Hedge model can direct future work on inexact quantifier realization in the general discussion below. Overall, INP-Hedge assumes that speakers would detect the uncertainty of their mental representation of quantity by considering multiple plausible exact number responses, and then elect to hedge their quantified descriptions. Thus, the INP-Hedge model predicts that the limits of human perceptual performance would influence language usage, because there may be insufficient time to completely eliminate uncertainty about quantity through serial attention. Specifically, the INP-Hedge model predicts that enumeration duration and numerosity have the following effects on quantified language:

(P1) In the subitizing range (quantity 1-4), participants will predominately use exact quantifiers.

(P2) For indefinitely long presentation durations, participants will use exact quantifiers.

(P3) As presentation duration decreases, the frequency of inexact quantifiers will increase.

If people elect to use inexact quantified language to avoid being incorrect, as we hypothesized above, we can propose one additional prediction:

(P4) In difficult duration/quantity pairings, participants that responded by describing quantity using inexact quantifiers will indicate higher confidence in the correctness of their response vs. participants that responded in the same duration/quantity condition with exact numbers.

Experiment 1

To test our model's predictions, we conducted an online numerical perception and quantified language elicitation experiment. Participants viewed videos in which varying quantities of black dots were presented for varying durations.

Method

Participants. Thirty-nine participants (mean age = 36.3; 19 females, 19 males, and 1 other) volunteered through the Amazon Mechanical Turk online platform (Paolacci, Chandler, & Ipeirotis, 2010). All but one participant reported being native English speakers.

Design, procedure, and materials. We manipulated the duration of stimulus presentation of dot clusters and the quantity of elements (dots) presented. Three possible presentation durations were used: 200 ms, 1000 ms, and an indefinite amount of time (dots remained on the screen while participants responded). Three possible quantity ranges were used: $[1-4]$, $[5-8]$, and $[9-12]$. The dot clusters in each video were randomly arranged, and four videos were produced for each specific numerosity, yielding 16 unique videos for each stimulus duration and numerosity condition (4 videos per number with 4 possible numbers per quantity range). Participants were presented with one video from each of these duration/quantity conditions in a random order, viewing nine videos in total. Videos were 512x512 pixels in dimension with a light grey

Num. Range	Stimulus Duration		
	0.2s	1.0s	∞ s
$[1-4]$	94.9%	97.4%	100.%
$[5-8]$	61.5%	87.2%	100.%
$[9-12]$	46.2%	53.8%	100.%

Table 1: Percentage of responses categorized as EXACT-NUM by stimulus duration and numerosity range conditions in Experiment 1.

background. A dark grey fixation cross appeared for one second before the cluster of dots. A masker grid was displayed following the stimulus interval (except in the indefinite enumeration time condition). After a video had concluded, participants were asked to complete the following sentence, being as accurate and precise as possible:

"In the above video, there are _____ black dot(s)."

Additionally, participants were asked to report their confidence in their completed description (1 = very unsure to 5 = very confident). Because we were primarily interested in investigating the precision of quantified description of a visual scene, we used a free-response, sentence-completion task instead of a completely free-response task. This was done to encourage quantified description and avoid descriptions of dot clusters based on other attributes, such as spatial arrangement (e.g., "I see a group of dots shaped like a constellation of stars").

Results

Analysis. The expressions used to complete the description were categorized into five types: (1) exact numbers, which we will denote as EXACT-NUM (e.g., "In the video above, there are *four* black dot(s)"); (2) hedged numbers, denoted as HEDGED-NUM (e.g., "In the video above, there are *about ten* black dot(s)"); (3) intervals, denoted as INTERVAL (e.g., "In the video above, there are *five to seven* black dot(s)"); (4) vague quantifiers, denoted as VAGUE-Q (e.g., "In the video above, there are *several* black dots(s)"); and (5) other miscellaneous expression, denoted as OTHER (e.g., "In the video above, there are *groups of* black dot(s)"). Two annotators classified each response. High inter-annotator agreement was found (Cohen's κ = .945). The proportions of exact numerical responses (EXACT-NUM) for each duration and numerosity condition are reported in Table 1. All four predictions were supported by the data.

Consistent with P1, 114 of 117 (97.4%) of responses in conditions within the subitizing range were EXACT-NUM responses. Additionally, consistent with P2, only exact descriptions were used when participants had an unlimited amount of time to enumerate. Consistent with P3, the number of exact responses decreased from 117 out of 117 in the indefinite duration condition to 93 out of 117 with one second of duration, yielding a significant difference (Fischer exact test, $p < .001$). The number of exact responses further decreased from 93 out of 117 to 79 out of 117 in the 200ms duration condition, though this difference was only marginally significant (Fischer exact test, $p = .054$).

Finally, Wilcoxon-signed rank tests indicated confidence ratings were significantly lower for exact responses than inexact responses for quantity ranges $[5-8]$ ($p = .039$) and $[9-12]$ ($p < .001$) at 200 ms presentation time and quantity range $[9-12]$ ($p = .007$) at 1000 ms presentation time, supporting our final prediction (P4).

Intriguingly, only 23 out of the 39 participants (59%) used inexact quantifiers. The other 16 out of 39 (41%) only used exact number responses, guessing in cases of uncertainty. As previously discussed, we would expect a participant who uses inexact quantified descriptions to generate these inexact descriptions to express uncertainty and avoid incorrectness when exact enumeration is difficult. Therefore, we would predict the EXACT-NUM responses from participants who used only EXACT-NUM responses to be less accurate than those generated by participants who switch between exact and inexact expressions. The data supported this prediction. The accuracy of EXACT-NUM responses from participants who used only exact expressions (69.4%) was found to be lower than those from participants who sometimes used inexact expressions (91.8%), yielding a significant difference (Mann-Whitney U test, $p < .001$).

Model Fit

While our four main predictions were supported by the data, we also sought to test how well the INP-Hedge model predicts the precise frequency of EXACT-NUM responses in each stimulus duration and numerosity condition. We ran the INP-Hedge model[2] ten times on each video from Experiment 1. The proportion of exact quantifier responses produced by INP-Hedge, compared with the human data from Experiment 1, is found in Figure 1. The results of the human data were highly correlated with the proportion of exact/inexact quantifiers selected by the INP-Hedge model (Spearman's ρ = 0.938). Though the correlational fit is high, we can see that INP-Hedge underestimates the amount of EXACT-NUM responses in the hardest duration and numerosity conditions. Specifically, INP-Hedge underestimates exact responses in numerosity ranges $[5-8]$ and $[9-12]$ by 43% and 28%, respectively. Exact responses during medium durations (1000 ms) for larger numerosities ($[9-12]$) are also underestimated by 33%.

What could explain this underestimation? Recall that a sizable portion (41%) of participants only gave EXACT-NUM descriptions. That is to say, about 4 out of every 10 participants guessed an exact number response when they were uncertain about the quantity of dots. To account for this, we revisited the Experiment 1 videos, running the INP-Guess model four times on each video and the INP-Hedge model six times (replicating the mixed set of strategies found in human participants). Not only was the correlational fit of this

[2]Setting $\nu = 3$.

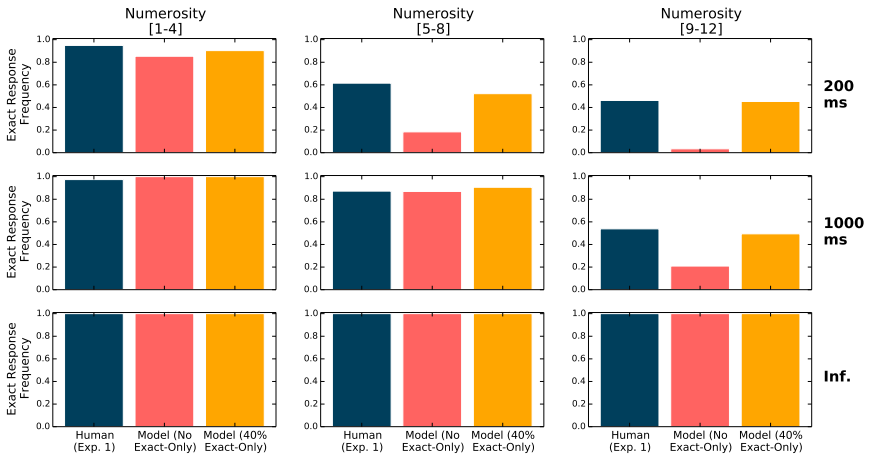

Figure 1: Predicted proportions of EXACT-NUM responses based on our model (pink) and our model adjusted for the number of participants that give only exact-number responses (yellow), compared with proportion of EXACT-NUM responses from human data in Experiment 1 (blue).

mixed-model improved (Spearman's ρ=.956), but the precise predictions about exact response frequency are much closer to the observed frequencies from the human data. Proportion differences are reduced during short stimulus durations (200ms) to 9% and 1%, for numerosity ranges $[5-8]$ and $[9-12]$, respectively. Finally, the difference in exact response proportion is reduced to approximately 4% for larger quantities ($[9-12]$) during medium durations (1000ms).

Experiment 2

Roughly 40% of participants in Experiment 1 only gave exact numerical responses. This is in line with other studies, where a subset of participants use only exact numerical expressions for all items. For instance, in a QRE elicitation task, about 20% of participants used only exact numerical expressions (Barr, Deemter, & Fernández, 2013). However, unlike in Barr and colleagues (2013), participants in Experiment 1 did not have unlimited amounts of time to view stimuli. Therefore, it seems likely that participants are limiting their set of potential quantified response forms *a priori*. One possible explanation is that because each trial in Experiment 1 involved a question asking the participant to rate the confidence of their numerical expression, participants may have felt less pressure to hedge uncertainty about the observed quantity in the language of the numerical expression itself. Rather, participants may have been more inclined to guess an exact number, then hedge their uncertainty in the confidence question. In Experiment 2, we sought to eliminate this possibility.

Method

Participants. Forty participants (mean age = 35.4; 19 females and 21 males) volunteered through the Amazon Mechanical Turk online platform. All participants reported being native English speakers.

Design, procedure, and materials. The experimental design, procedures, and materials were identical to Experiment 1, except in two respects. First, the confidence question was eliminated. Second, the number of trials each participant completed was increased to 18 (two trials per numerosity range and stimulus duration condition). Videos were randomly sampled from each stimulus duration and numerosity category without replacement.

Results

As with Experiment 1, two annotators used the same labels to categorize all the expressions participants produced. Inter-annotator agreement was again high (Cohen's $\kappa = .938$). Table 2 lists not only the proportion of exact quantified descriptions, but the precise counts of each type of expression found. We found that 14 out of 40 participants (35%) in Experiment 2 used only EXACT-NUM expressions, compared with the 16 out of 39 (41%) in Experiment 1. While the proportion of participants using only exact expressions slightly decreased in Experiment 2, this difference is not statistically significant (Fischer's exact test, $p = .647$) given the number of participants in each study. Consistent with Experiment 1, we also found that EXACT-NUM responses from participants who used only exact descriptions were less accurate (61.9%) than those from participants who sometimes used inexact expressions (88.9%), yielding a significant difference (Mann-Whitney U test, $p < .001$).

Predictions. Aside from P4, which could not be tested as there was no confidence data in this experiment, the main predictions were also still supported. Consistent with P1, 233 out of 240 (97.1%) responses in the subitizing range were exact. Also, 235 out of 240 (97.9%) responses in the

Response Type	$[1-4]$			$[5-8]$			$[9-12]$		
	0.2s	1.0s	∞	0.2s	1.0s	∞	0.2s	1.0s	∞
EXACT-NUM	75	79	79	45	67	80	35	36	76
HEDGED-NUM	2	0	0	16	8	0	13	15	1
INTERVAL	1	0	0	9	4	0	14	13	0
VAGUE-Q	2	1	1	10	0	0	17	14	3
OTHER	0	0	0	0	1	0	1	2	0
Exp. 2: Exact %	93.8	98.8	98.8	56.3	83.8	100.	43.8	45.0	95.0
Model (INP-Hedge): Exact %	85.3	100.	100.	18.4	86.9	100.	3.4	20.9	100.
Model (40% INP-Guess): Exact %	90.3	100.	100.	52.2	90.6	100.	45.3	49.4	100.

Table 2: Counts of response types by stimulus duration and numerosity conditions for Experiment 2.

indefinite duration condition were exact, consistent with P2. Consistent with P3, the number of exact responses decreased from 235 out of 240 in the indefinite duration condition to 182 out of 240 with one second of duration, yielding a significant difference (Fischer exact test, $p < .001$). The number of exact responses further decreased from 182 out of 240 to 155 out of 240 in the 200ms duration condition, yielding a significant difference (Fischer exact test, $p = .009$).

Model Fit. The pattern of exact/inexact response was similar to Experiment 1. Correlation of the proportion of exact is high (Spearman's ρ = 0.926). Underestimation of usage of exact numerical expressions remains in the post-subitizing range for short stimulus durations (200ms) and larger numerosity ranges. Specifically, INP-Hedge underestimates exact responses in numerosity ranges $[5-8]$ and $[9-12]$ by 38% and 40%, respectively. Exact responses during medium durations (1000 ms) for larger numerosities ($[9-12]$) are also underestimated by 24%. Our mixed model, (40% INP-Guess, 60% INP-Hedge) increases model correlation (Spearman's ρ = 0.944), while reducing this observed underestimation. Proportion differences are reduced during short stimulus durations (200ms) to 4% and 3%, for numerosity ranges $[5-8]$ and $[9-12]$, respectively. Finally, the difference in exact response proportion is reduced to approximately 4% for larger quantities ($[9-12]$) during medium durations (1000ms).

General Discussion

The results of our two quantified language elicitation experiments demonstrate that the use of precise quantified language to describe visual scenes decreases with decreased viewing time or increased stimulus quantity. Future computational models of quantified description of visual scenes, regardless of how they are implemented, need to account for this phenomenon to fully capture human quantified language use. We contend that to make sense of these results, one must view numerical perception as a temporally extended process in which uncertainty is reduced by additional perception of the visual scene. Both computational models we presented above, INP-Guess and INP-Hedge, account for this reduction of uncertainty by a proposed model of serial deployment of attention to individual items in the visual scene.

While we have demonstrated that a combination of these psychologically grounded and attention-driven models of numerical perception and quantifier use is able to closely fit human patterns of quantified language use under time constraints, many open questions still remain. One question raised by our quantifier elicitation experiments (and results from Barr and colleagues, 2013) is how do people decide to constrain the set of quantifiers they elect to even consider generating? Because our elicitation experiment contained relatively small quantities of visual items (1-12), participants may have felt that the degree of potential error in exact number guessing to be acceptable. With this explanation, increasing the number of potential visual items (e.g., 50-120) may reduce the proportion of participants giving only exact responses. Likewise, task motivation and context would potentially affect quantifier use. Situations were precision is critical and error may lead to highly negative consequences are likely to elicit more exact quantified language.

This work raises another series of questions regarding the realization of inexact quantified language. If people do consider multiple forms of inexact quantified language, how do people choose the precise language to use in a particular context? The mechanism for selecting different forms of quantified description in our proposed model is still rudimentary. However, it does begin to make some predictions. For instance, the current model would predict that the bounds of interval expressions would increase proportionally with reduced enumeration time or increased numerosity. In future work, we hope to address a variety of these open questions and hypotheses.

Abstract

Modern society frequently requires that we express our subjective senses in objective, shared formal systems; this entails mapping multiple internal variables onto a common scale. Here we ask whether we accomplish this feat in the case of estimating number by learning a single mapping between explicit numbers and one integrated subjective estimate of numerosity, or if we separately map different perceptual features onto numbers. We present people with arrays of dots and ask them to report how many dots there are; we rely on the systematic under/overestimation of number at higher quantities to estimate error in the mapping function. By comparing how this error changes over time, as the mapping fluctuates for different visual cues to numerosity, we can evaluate whether these cues share a single mapping, or are mapped onto number individually. We find that area, size, and density all share a common mapping, indicating that people obtain a unified subjective estimate of numerosity before mapping it onto the formal number line.

Keywords: numerosity; number; estimation

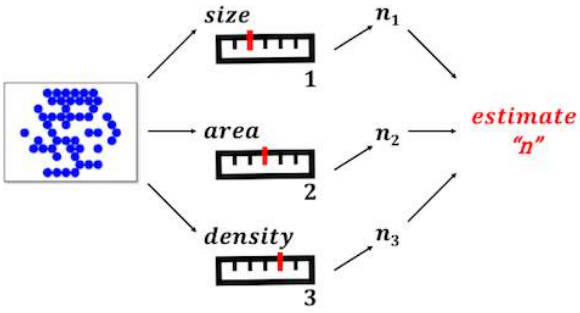
Introduction

Human reasoning and planning frequently involves mapping internal estimates onto formal systems: we can compare the weights of two rocks using our subjective sense of weight, but to provide an estimate of one rock's weight in kilograms requires mapping that subjective sense of weight onto a formal metric system. This task of expressing our internal subjective senses in objective, standard systems is commonplace, from making time estimates to evaluating prices. To accomplish this we somehow learn to map from perceptual and internal states onto formal systems like weight in kilograms. The task is often complicated by the fact that we might have many subjective variables that must map on to the same formal system: weight might be estimated by the pressure a rock exerts on our hand, or by its inertia as we try to move it. How do we deal with multiple subjective cues: do we map each one individually onto the formal system, or do we combine them to come up with a single subjective estimate, and then map that estimate onto the formal system? In this paper, we approach this question for people's ability to estimate numerosity.

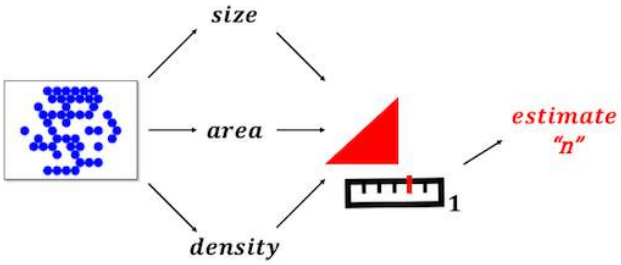
Based on a quick glance at a display of many objects, people can estimate the number of objects present in the display. Even if there is insufficient time to explicitly count the objects, there are enough visual features that correlate with number, that a number estimate may be obtained just based on these internal, analog signals which together give us a sense of "Approximate Magnitude". Imagine for example stepping into a room full of people: as you look around, you can get a rough sense of how many are present just based on the density of the crowd and the size of the room faster than you would be able to count each person individually. In general, displays with higher numerosity tend to have objects distributed over a larger portion of the visual field (area) and the number of objects in a constant area tends to be higher, either because the objects themselves tend to be smaller (size), or because the inter-object distances are smaller (spacing/density). These separate cues to numerosity may be treated in different ways by the visual system. They may be combined into one internal representation of numerosity which forms the basis of estimation. Or, because visual cues to numerosity all tend to correlate together in the real world, it may not be necessary to undertake the extra calculation of integrating them to form an internal sense of number. Instead, these features may be mapped onto numbers directly. Both explanations posit internal representations which must be mapped onto formal numbers when making estimates, but differ as to how this mapping occurs.

A large body of research has examined the representations that support our internal sense of number but comparatively little work examines how we might map from that internal sense to number estimates. The degree to which we directly perceive and represent number is an area of active debate (for a recent review see Leibovich, Katzin, Harel, and Henik (2017)). Researchers have proposed that an internal sense of number, the "Approximate Number System" or ANS, exists in many animals and is developed by infants at a young age (Feigenson, Dehaene, & Spelke, 2004). However, competing accounts emphasize that perceptual features of a quantity such as size, area, and density are highly correlated with number: this has led some to argue that our ability to estimate numerical quantities can be served directly by these continuous magnitudes without any internal number sense (Gebuis & Reynvoet, 2012) or that insofar as we have an internal representation of number, it is assembled directly from our sense of continuous magnitudes (Leibovich et al., 2017).

The present experiment is agnostic about the precise mechanisms for visual processing and internal representation of numerosity. We are interested in understanding how people map from various internal representations to the formal number line during numerical estimation. One hypothesis is that



(a) A relationship between visual properties and number estimates that relies on multiple independent mappings (numbered 1, 2, and 3) from distinct visual features to an estimate "n"



(b) A relationship between visual properties and number that specifies a *single mapping* (numbered 1) between some internal quantity representation (the red incline) and an estimate "n"

Figure 1: Two different ways of thinking about how visual cues to magnitude map onto numbers

people have multiple mappings which take as their inputs features associated with numerosity such as size, density, and area. Another hypothesis is that people instead have a single mapping from some internal representation—whether a number sense or a broader integrated magnitude—to an estimated quantity. Both mapping hypotheses are plausible a priori and might inform the broader debate about how people perceive or represent number. In what follows, we discuss in greater detail the research on number representation, which supports the availability of various possible *inputs* to this mapping function.

ANS and Continuous Magnitudes

The predominant theory in number processing holds that people have an internal approximate number system which they map onto the formal number system for purposes of estimation and other related tasks (Izard & Dehaene, 2008). Work in this space has sought to model the characteristics of this number system, including how it is represented internally (Izard & Dehaene, 2008) and how it develops in infants and young children (Carey, 2009). Research on development of the approximate number system has found that ability to distinguish between distinct numbers—the *acuity* of the approximate number system—develops independently of ability to discriminate area, density, length, and time (Odic, 2018) and that acuity of number sense in children is correlated with mathematical ability later in life (Halberda, Mazzocco, & Feigenson, 2008). In line with the idea that numerosity is a core part of how we represent the world around us, some have argued that numerosity is even available as a primary feature of perception and not reducible to related properties like texture density (Burr & Ross, 2008). In support of this, it has been shown that numerosity estimates are subject to visual adaptation effects, much like other visual properties such as color and motion (Burr & Ross, 2008).

In contrast to proposals that humans have an internal approximate number system, some have argued that number estimation is inferred directly from visual properties that correlate with number (Dakin, Tibber, Greenwood, & Morgan, 2011). Evidence that people's ability to estimate quantities stems directly from their processing of visual cues comes primarily from work showing that people struggle to infer numerosity independently of the information they receive from visual cues (Leibovich et al., 2017). For example, Gebuis and Reynvoet (2012) presented participants with a series of dot arrays which manipulated the convex hull, aggregate surface, and density of the dots such that none of these visual properties correlated with true quantity across all the trials. They found that participants' estimates of the number of dots in the arrays were largely explained by each of these features even though these features provided no information about the true number of dots. They argue that people are therefore unable to estimate numerosity independently of the visual cues which tend to provide certain signals about numerosity. More recent work has argued that the basis for our sense of number is our ability to process *continuous magnitudes* (density, area, size, etc.): Leibovich et al. (2017) challenge the degree to which research on the approximate number system is able to isolate numerosity from visual cues and argue for a more general magnitude system from which number is inferred.

Regardless of whether people have an internal sense devoted specifically to numerosity or assemble their sense of quantity from continuous magnitudes that correlate with number, it's clear from the existing research that a.) numerosity and visual features such as area, size, and density are closely tied and b.) that a mapping from internal quantity estimates onto the formal number system could plausibly take as its inputs any combination of visual features and numerical representation. In light of this, we propose two hypotheses about how such a mapping might work. One holds that we have multiple mappings from size, area, and density features to number estimates. These mappings could independently serve our estimation needs. The other holds that we have a single mapping from some internal quantity representation onto the number line. This internal representation could be our approximate number sense or a quantity estimate assembled by combining information from size, area, and density. In what follows, we summarize research which has examined people's performance on number estimation tasks and describe a novel method of investigating mappings from internal number to formal number.

Individual differences and drift in mental number-line calibration

Work investigating the approximate number system has sought to understand how we map from our internal sense of number to the verbal number system. Several key findings have informed this line of inquiry. First, people's mapping from internal quantity representations to formal numbers is often miscalibrated (Izard & Dehaene, 2008). Specifically, individuals asked to estimate quantities outside the *subitizing* range tend to systematically over- or underestimate those quantities. This relationship follows a power law: the higher the true quantity, the more people reliably over- or underestimate (Izard & Dehaene, 2008). Second, the amount that people are miscalibrated in their estimations varies considerably across individuals (Vul, Barner, & Sullivan, 2013). Some people reliably overestimate while others reliably underestimate, suggesting that whatever mapping we use onto formal number varies from person to person. Finally, the amount that people are miscalibrated in their estimations varies *within* individuals. In other words, the degree to which people over- or underestimate has been shown to *drift* over many successive estimations (Vul et al., 2013).

In this study, we use the slow drift of individuals' number estimates to investigate the mapping between internal number and quantity estimates across various visual conditions. If people rely on multiple mappings from independent visual features to numerosity estimates, then we would expect these mappings to drift independently over many estimates based on different visual features. However, if people utilize a singular mapping function from some internal quantity estimate onto number, then we would expect the drift in their estimates to be invariant to changes in the visual cues used to form each estimate. This difference is illustrated in Figure 1.

Experiment

We tested the degree to which the numerosity of a display is estimated through independent mappings from correlated visual features (e.g., size, area, and density) to number, or if these features map onto a single internal numerosity estimate, which is then mapped onto a symbolic number. We presented participants with an estimation task in which the stimuli varied along one dimension (size, area, or density) as magnitude changed, while holding the other two dimensions constant. We compared the drift in participants' magnitude estimations across the three conditions to assess whether number estimates may be independently obtained from size, area, and density cues.

Participants

Participants were 57 undergraduates at the University of California, San Diego who received course credit for their participation.

Methods

Participants were shown a series of dot arrays on a white background like those in Figure 2. The dots appeared on the screen for 500ms and then disappeared. Participants were then prompted to guess the number of dots on the screen. We did not use a mask between trials, as any aid that participants received in estimating due to an after image would have been consistent across all trials. For the first 25 trials, participants were given feedback after each round about the true number of dots they had just seen. Participants were awarded points after each round on a logarithmic scale based on the difference between their guess and the true number of dots. Participants performed 1,000 estimation trials or 50 minutes on the task, whichever came first.

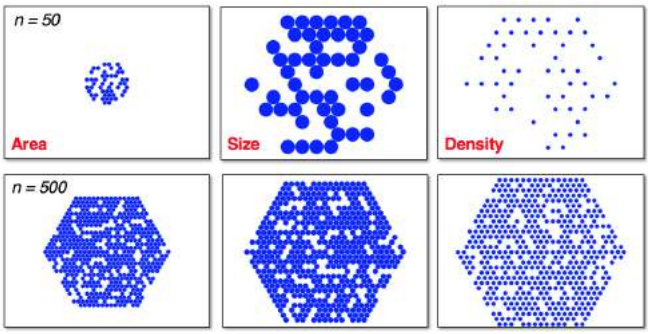


Figure 2: Sample stimuli for n = 50 and n = 500 across *area*, *size*, and *density* conditions.

Stimuli

The number of dots on each trial was selected by sampling a number between 10 and 750 from an exponential distribution with a mean of 100. Each trial of the experiment was randomly selected to vary one of the *area*, *density*, or *size* of the dots while keeping the other two constant.

Trials that varied the *area* of the dots used a predetermined constant for spacing between dots and dot size so that the number of dots on the screen was indicated by how much area the dots occupied. For trials that varied the *density* of dots, dots were populated in a constant area on the screen with a constant size: when there were more dots, the spacing between them was lower and when there were fewer dots, there was greater spacing between them. Finally, trials that varied the *size* of the dots used a consistent area of the screen and a consistent spacing between dots, generating larger dots when there were fewer in a given trial and smaller dots when the magnitude was greater. See Figure 2 for examples of dot arrays that varied each visual feature. In each trial, a random selection determined whether the dot display would vary size, area, or density so that over the course of the experiment, all three features would present cues to numerosity but on any given trial, only one would be informative.

Results

To understand how well participants estimate visual quantities based on size, area, and density inputs, we can compare their estimates for trials in which each of these features were informative to the actual numbers presented. For

perfect estimators, each estimate plotted this way would lie along the identity line. Estimates show a high degreee of variance across individuals: Figure 3 shows data from three sample participants which illustrate this. Combining this data across all participants, Figure 4 shows participants' accuracy by plotting their estimates alongside the true number presented for trials varying size, area, and density. Consistent with earlier findings, people are accurate up to numerosities of about 20-30, but they reliably underestimate larger numbers on average (even setting aside the individual variance: see Vul et al., 2013). The underestimation pattern in a given set of trials can be described as a bilinear function which follows the identity line up to a threshold, and deviates from the identity line with some slope thereafter. This slope amounts to the "calibration" of the mental number line (Izard & Dehaene, 2008), and was precisely shown to (a) vary across subjects, and (b) within subjects, slowly drift over the course of an experiment (Vul et al., 2013). Figure 4 shows that the calibration of the mapping to the formal number line is similar regardless of whether area, size, or density is the numerosity-informative variable.

Previous research has shown that perception of structure and groupings can lead to systematic underestimation. For example, objects connected by lines are underestimated relative to disconnected objects (Franconeri, Bemis, & Alvarez, 2009). When dot arrays are seen as grouped, the degree to which they're clustered increases underestimation (Im, Zhong, & Halberda, 2016). Even sub-conscious processes like statistical learning of co-occurrence in colored dot arrays can lead to underestimation (Zhao & Yu, 2016). In the stimuli presented here, it is possible that perception of grouping among dots on various trials led to underestimation. However, given the similarity in patterns of underestimation in Figure 4 across modalities, it's unlikely that underestimation due to perceptual grouping affected the size, area, or density informative trials more than any other.

Consistent individual differences across modalities

Dividing each participant's estimates into blocks of size 50 (after the initial 25 "calibration" trials), we can evaluate the best fitting slope estimates for each block in each condition. For example, block 11 for each participant will contain trials 476–525. Of these, some number will be area trials, some will be size trials, and some will be density trials. We can extract the trials belonging to each estimate condition (size, area, density) for a given block of trials for a given participant, and compute a best fitting slope for that subset of number estimates for that participant. This gives us a slope for each estimate condition, for each participant, in each block of 50 trials over the course of the experiment.

To the degree that processes of estimating quantity based on changes in size, area, and density are independently calibrated to the data participants have seen, individual differences in slopes should not be consistent across these different modalities. However, if different variables are mapped onto a subjective quantity estimate, and the uncertain, idiosyncratic mapping lies between approximate number and reported number, then an individual's slope for area-determined numerosity will be consistent with their density- and size-determined numerosity as well.

Figure 5 shows each of the possible correlations between best fitting slopes for size, area, and density estimates across participants in each block: size-area slope correlations, size-density slope correlations, and density-area slope correlations. Block zero (trials 1-25) includes the trials in which participants received feedback after each guess. In these tri-

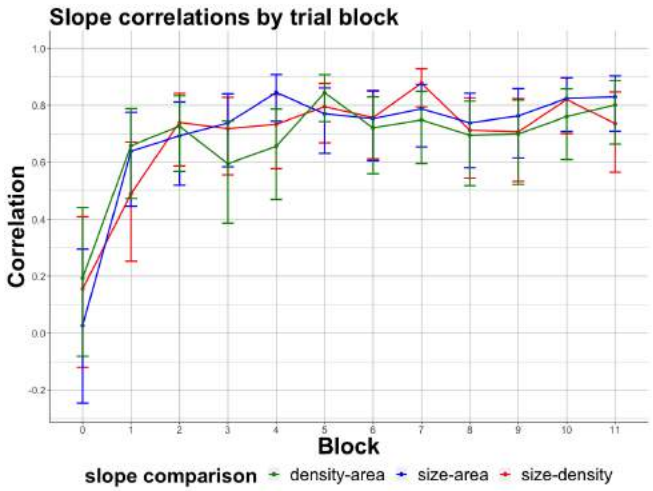

Figure 5: Slope correlations of size-area, size-density, and density-area for the first 11 blocks of the experiment. Participants received feedback in block 0. After that, correlations across estimate conditions are relatively high and are tightly coupled in remaining blocks (error bars indicate 95% confidence intervals on the correlation coefficient).

als, participants were fairly accurate in their estimates. Correlation between slope estimates in block zero is therefore low due to low variance in slope estimates across all conditions as a result of the feedback. However, from block one onwards, correlation of slope estimates between size and density trials, size and area trials, and density and area trials increases to 0.6–0.8. Critically, each of these three slope estimate correlations (size-area, size-density, and density-area) remain high and tightly in tandem from block one onwards. Such closely aligned correlations would be unusual if variations in stimulus size, density, and area across trials each directly and independently enabled an estimate of quantity.

Consistent within-individual drift across modalities

The correlation between different slope estimates for each block, described above, indicates how similar size, area, and density estimates were to each other across participants in each set of 50 trials throughout the experiment. In other words, this shows whether individual differences in numerosity estimations are consistent across modalities. Another feature of numerosity estimates is their drift in calibration over time *within individuals*. Here, we examine the data from estimation across modalities in light of this pattern: if size, area, and density each independently map to a formal number estimate, the drift in calibration for each of these modalities should be independent. However, if each modality maps to an internal estimate and the drift reflects changes in the mapping of internal estimates to formal number, then we will not detect any difference in drift across modalities. Figure 6 shows the correlation between slopes in blocks 1 – 11 for each possible comparison of estimate conditions: autocorrelation of e.g. density slopes across blocks and correlations across modalities of e.g. size to area slopes between each block. The overall pattern of correlations across blocks looks very similar for each of these comparisons, further reinforcing the idea that these features do not map separately onto number estimates. Individual drift in over- and underestimations can be seen in the lower correlation between blocks that are farther apart: this pattern is also similar across comparisons.

To better compare the slope correlations within and across modalities, we group pairs of blocks based on their temporal separation: their *trial distance*. For example, the correlation between blocks 1 and 4, and 2 and 5, and 3 and 6, all have a trial distance of 3 blocks (150 trials). The decline in correlations over longer trial distances indicates the drift of mapping over time. We can thus compare these cross-correlation functions for different modality-modality comparisons. Comparing slope estimates for each block of a given condition to those that are all an equal distance away in the same or alternate estimate conditions gives us a correlation between trials across a range of trial distances. Figure 7 shows these correlations by distance for the same combinations of estimate conditions shown in Figure 6. Across all comparisons, the correlations decrease as distance between trials increases. This drift in estimate slopes—the slopes of trial blocks farther from each other are less similar to the slopes of closer blocks—reflects the drift in calibration of the mapping function onto precise quantity over time (Vul et al., 2013).

To ensure that the "drift" shown in Figure 7 is not attributable to differential distributions of each trial type across blocks of increasing distances, we shuffled trial order for each participant and re-calculated the correlation of slopes by trial distance. For the shuffled data, the correlations within and between modalities were very stable across *all* trial distances: in other words, there was no sign of systematic drift. We fit linear models to the mean correlations at each trial distance for each modality comparison to ensure that indeed there was no drift in the shuffled data: for the six comparisons shown in Figure 7 (with shuffled trial order), none had a slope significantly different from 0[1].

Figure 7 illustrates that the drift in calibration occurs not only within each estimate condition but also across them: size-density, size-area, and density-area slope comparisons show similar decreasing correlations at greater trial distances. Most importantly, these correlations over trial distances are indistinguishable whether we consider within-modality correlations (e.g., area-area) or across-modality correlations (e.g., area-size). The correlation of slopes over varying trial distances is indistinguishable within and across modalities. If visual cues to density, size, and area each map to a subjective numerosity which *then* maps to precise quantity estimates, the similarity of slope correlations within and across esti-

[1] Shuffled trial order correlation slopes (per block): size-size 95% CI = [-0.013, 0.001] p = 0.07, density-density 95% CI = [-0.010, 0.002] p = 0.16, area-area 95% CI = [-0.001, 0.015] p = 0.08, size-density 95% CI = [-0.019, 0.003] p = 0.12, size-area 95% CI = [-0.014, 0.003] p = 0.19, density-area 95% CI = [-0.006, 0.013] p = 0.39

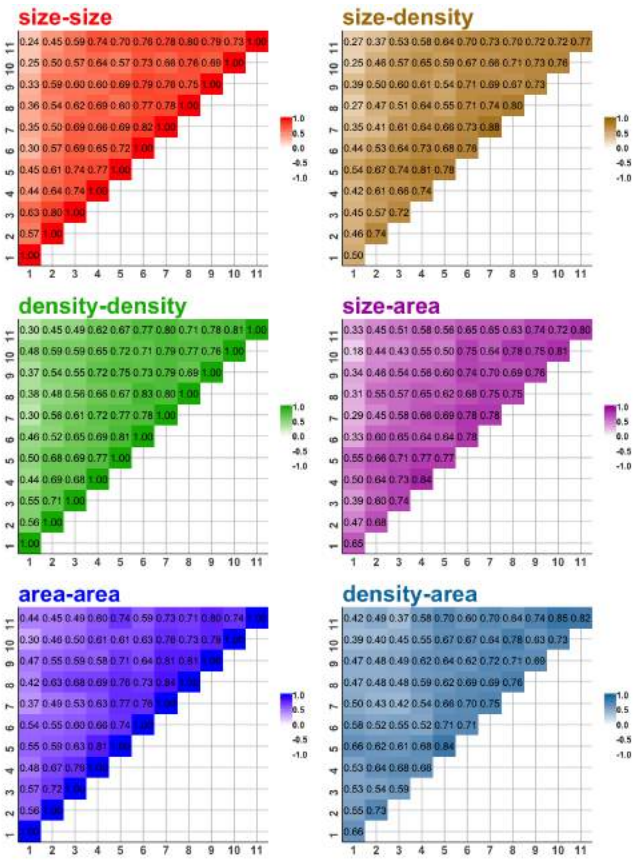

Figure 6: Slope comparisons between each block across all estimate conditions. The correlation pattern is similar across all these comparisons, a pattern seen when plotting correlation by trial distance as well.

mate conditions could be accounted for by separate mapping functions from visual properties to approximate number being similarly calibrated. The drift would then be attributed to the mapping from this internal numerosity to the number reported. If the estimation of reported quantities was accomplished by separate mapping functions from each of the visual modalities, it would be improbable for these mapping functions to change in lock-step, thus rendering the within- and across-modality correlations identical.

Conclusion

We asked how people map their analog, perceptual features onto explicit numbers. Specifically, we investigated whether (a) people have one mapping from a cohesive, internal estimate of numerosity/magnitude onto the number line, or if (b) people have multiple mappings onto number from different visual features that tend to correlate with number. In this experiment, we asked participants to estimate the number of dots present in a display, while we varied which visual feature varied with number. The numerosity of the dot arrays in a given trial could only ever be inferred from a single perceptual modality (one of size, area, or density) of the dots.

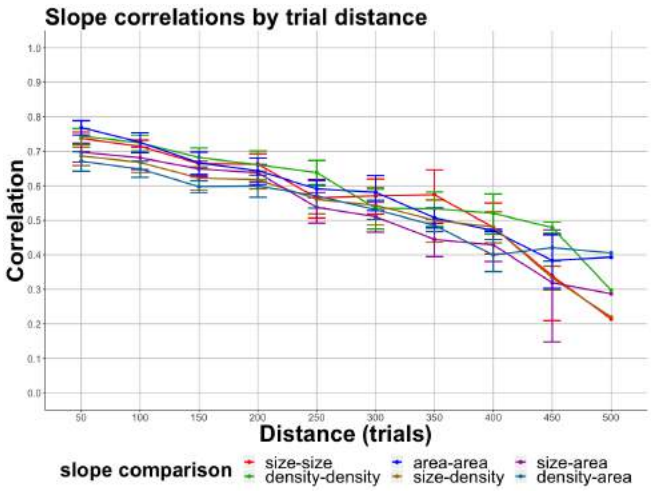

Figure 7: Slope comparisons *within* and *across* estimate conditions by trial distance. The correlation of slopes over varying trial distances is indistinguishable within and across estimate conditions (error bars represent standard error across measurements of each distance).

Using results from prior research indicating that people drift in their mapping of numerosity to number over the course of many trials (Vul et al., 2013), we analyzed whether such drift occurs independently across estimates based on size, density, and area. We find that the (mis)calibration of numerosity onto number is indistinguishable between size, area, and density trials. Moreover, as this mapping drifts over the course of many trials, it changes in lock-step for all the modalities, indicating that there is only one mapping function that drifts, which is shared across all modalities. From this we conclude that size, area, and density all share a common mapping onto formal number. In other words, perceptual features that are cues to numerosity must be combined into an internal representation of numerosity which is then mapped onto the formal number line when reporting an exact number.

It would be rash to generalize these results to all cases in which we might map subjective senses onto objective, external standards (e.g, estimating weight in kilograms, or our willingness-to-pay in dollars). It seems likely that some formal systems do not have a corresponding unified internal representation, and instead have an assortment of independent mapping functions which may be inconsistent and incommensurate. However, these results are encouraging that for at least some formal systems, we have unified, coherent internal representations that serve as their substrate. We postulate that the methods we develop here—of relying on fluctuations in the mapping of subjective states onto formal, objective systems—might be used to identify whether notions like "subjective value" are indeed unified monolithic entities, or if they are an ensemble of related, but independent, internal senses.

Acknowledgments

We thank our reviewers for their thoughtful suggestions.

Abstract

Accounts of human physical reasoning based on simulation from a noisy physics engine have enjoyed considerable success in recent years. However, simulating complex physical dynamics can be a computationally expensive process, and it is possible that people use faster, cheaper shortcuts to make predictions and inferences in complicated physical scenarios. Here we asked people to predict the eventual destination of a ball on a 2D bumper table (in the style of Smith, de Peres, Vul, and Tenenbaum (2017)). We designed scenarios that we expected would modulate the use of heuristics and simulation: the bumper table provided varying degrees of containment to constrain future outcomes and to make a containment heuristic more useful, and could have more or less internal structure to vary the reliability of noisy simulation. As the containment heuristic becomes more useful, and as simulation becomes more expensive, we expected that people would switch from using simulation to rely more on rapid heuristic-based predictions and therefore respond faster. Instead, we found that even when containment was very predictive, people were progressively slower and less accurate as simulation complexity increased, indicating that they persisted in using simulation rather than containment heuristics.

Keywords: simulation; heuristics; physics

Introduction

In everyday life we are constantly tasked with making predictions about how physical objects will behave and interact, whether changing lanes in traffic or stacking dishes in the sink. Such inferences are so commonplace that we rarely think twice about them. However, the mechanisms by which we are able to make these inferences are far from obvious: at a minimum, they require a rich understanding of how things in the world tend to move and the ability to make rapid predictions based on this knowledge, both non-trivial achievements from a computational perspective.

Prior research has shown that a range of human physical inferences can be captured by *Intuitive Physics Engine* models that rely on simulations of physical outcomes performed with a probabilistic physics engine similar to those used in computer games (Battaglia, Hamrick, & Tenenbaum, 2013). By sampling from these simulations, probabilistic models can generate a reasonable representation of the physical world and make predictions accordingly (Ullman, Spelke, Battaglia, & Tenenbaum, 2017). Such models have been successful in reproducing human judgments across a range of tasks and domains, from predictions about object balance (Battaglia et al., 2013), mass (Hamrick, Battaglia, Griffiths, & Tenenbaum, 2016), and velocity (Smith & Vul, 2013) to liquid dynamics (Bates, Yildirim, Tenenbaum, & Battaglia, 2018) and causal attribution (Gerstenberg, Peterson, Goodman, Lagnado, & Tenenbaum, 2017).

While simulation allows us to reproduce many features of human physical reasoning, there are also situations where people's behavior is inconsistent with the use of an intuitive physics engine (Smith, Battaglia, & Vul, 2018). Empirically, human behavior sometimes differs significantly from predictions made by simulation-based models, suggesting that we have sophisticated strategies for avoiding simulations when other forms of inference will suffice (Smith, Dechter, Tenenbaum, & Vul, 2013). In particular, research on errors in physical judgment have shown that people often hold a number of systematic biases which are inconsistent with even basic physical simulations (see Davis & Marcus, 2015 for an overview of some of these). Underlying this difference is a criticism of simulation as a computational account of all human physical reasoning: simulation of almost any sort, but particularly of complex physical phenomena, may require considering the interactions between a large number of objects over time. Because interactions between objects add uncertainty to predictions (Smith et al., 2013), in complex scenarios these simulations might therefore require keeping a large number of objects in mind and yet still produce very uncertain predictions. These sorts of considerations have led some to argue for a limited role of simulation in human physical reasoning (Davis & Marcus, 2016).

In light of the challenges posed to a simulation-based account of human physical reasoning, what alternatives can account for people's ability to make diverse predictions about physical interactions in the world around them? A large body of research supports the idea that humans are adept in their use of heuristics and other simplified qualitative prediction strategies, including in the domain of physical predictions (Gigerenzer & Todd, 1999). Prior work has shown that people can represent certain topological relationships like containment using only first-order logic (Davis, Marcus, & Frazier-Logue, 2017). Given the large number of strategies available to reasoners and the flexibility with which we navigate the physical world, it has been proposed that humans selectively utilize a toolbox of prediction techniques, including simulation, qualitative reasoning, and logical inference, as well as analogical and rule-based strategies (Davis & Marcus, 2015).

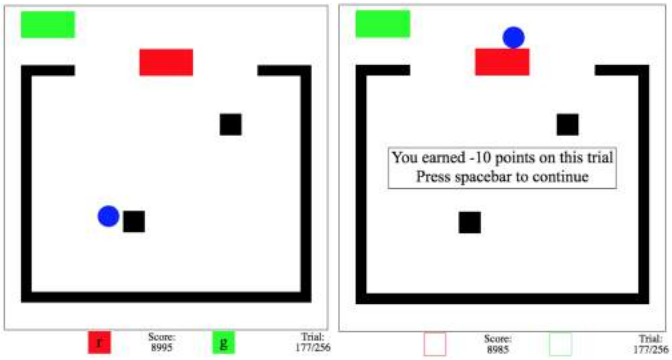

Figure 1: A simple trial with partial containment and two obstacles. At left is what participants see when prompted to guess a target after 2.5s of animated ball movement. At right is feedback after guessing "green" and seeing the ball animated on the remainder of its path.

The idea that humans are able to balance simulation-based prediction with alternative prediction strategies is intuitively appealing because it offers a way to unify simulation-based accounts with complementary accounts of physical inference based on e.g. topological and visual features. However, it raises a number of additional questions. If humans are able to flexibly recruit different strategies for making physical predictions, what determines the choice of one strategy over the other? How and when do we switch between fine-grained simulation methods and more coarse qualitative analyses? The exact mechanisms for such decisions remain poorly understood. For example, when novel but reliable and visually salient heuristics are available, people often fail to use them unless the existence of such heuristics are made explicit (Callaway, Hamrick, & Griffiths, 2017). A simple hypothesis is that compared to simulations, topological predictions are faster, lower fidelity, and less generally applicable; consequently, topology ought to be used when the scenario makes topological cues particularly useful, and renders simulations particularly imprecise and costly by complex scenarios. In other words, if computationally expensive simulations are unlikely or unable to produce a confident prediction, while topology can, a rational agent should make a guess based on simpler heuristics or visual features rather than waste resources on repeated simulations.

In the present study, we tested the hypothesis that people balance the precision and cost of simulation against the applicability of topological analysis when making physical predictions. Our experiment builds on prior research in several important ways. First, we examine people's reasoning about containment scenarios because prior research has shown that containment relationships can be expressed propositionally and that intuitive inferences about containment can be made with such knowledge-based reasoning even with very little information (Davis et al., 2017). As such, it is an ideal simplified model for physical inference. Second, containment relationships can in some cases be visually processed rapidly and automatically (Strickland & Scholl, 2015). Finally, prior research has used a similar paradigm to explore the degree to which people simulate or use topological inference when making physical predictions in scenarios involving containment relationships. Smith et al. (2013) modeled inference on a prediction task using noisy simulation but found that people's predictions were more rapid than the model predicted in scenarios involving containment. Building on these results, Smith et al. (2017) presented participants with similar tasks in which a containment heuristic was available but found evidence for simulation across all the tasks. However, in the tasks presented to participants, the simulation required was fairly straightforward and temporally limited. Therefore, insofar as simulation and topological processing happened in parallel or participants reasoned that simulation was a consistently viable strategy, they may have failed to leverage a more coarse containment-based judgment out of habit or convenience (Smith et al., 2017). We hypothesize that when topological predictions are available *and* simulation proves intractable or uncertain, participants will be more likely to make their predictions based on topology. In line with this hypothesis, Davis & Marcus (2015) argue that simulation is most effective on relatively short time scales and small spatial scales such that simulation is straightforward and reliable. Here we violate this condition by including trials in which the number of obstacles (complexity level) makes simulation both more uncertain and potentially longer. We expect that participants, faced with predictions involving unreliable simulations, will pursue alternative strategies for prediction: an agent that rationally trades off the advantages of simulated inference with the computational costs should select more favorable knowledge-based inference strategies when conditions support them.

Experiment

In the present study, we tested the hypothesis that people would switch from using slower simulation to faster heuristics when simulation becomes less efficient. Specifically, we presented participants with a task which required them to make predictions about the path of a ball in a series of two-dimensional environments. We manipulated (a) how much the topography of the environment allowed a simple topological "containment" heuristic to identify the answer (degree of containment), (b) the complexity and uncertainty of simulations in the environment (degree of complexity). The core prediction is that participants would favor using simulation to obtain an answer when simulations were easy and topology was uninformative, but would switch to relying on containment, or other coarse topological cues when they were particularly effective, and simulation was particularly ineffective. Specifically, we rely on the assumption that using a fast containment heuristic would be more efficient than simulation, thus we predict that for high-containment scenarios, increasing complexity would decrease response times.

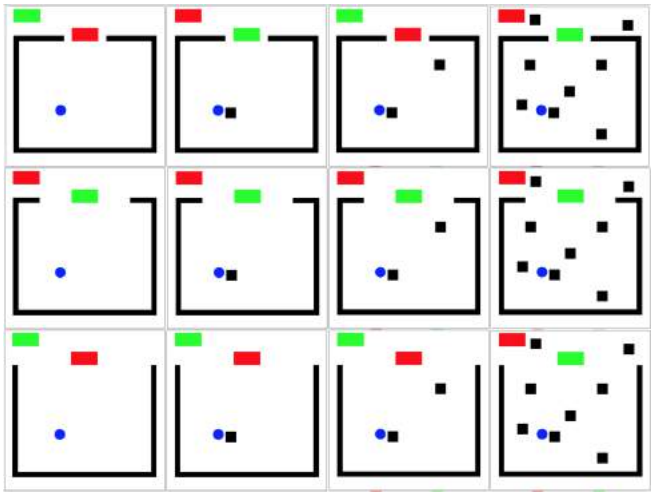

Figure 2: Twelve trials for Scenario 1, increasing in *simulation complexity* in the horizontal direction and *containment* in the vertical direction (highest containment at top). The high containment, high complexity trials offer a simple topological prediction without needing to simulate the ball's interaction with the walls and obstacles.

Participants

Participants were 81 undergraduates from the University of California, San Diego who received course credit for participation. The experiment lasted approximately 25 minutes.

Methods

We used a task that is very similar to Smith et al. (2017). During the experiment, participants were shown a series of trials depicting a blue ball on a flat surface (600 pixels by 600 pixels). The ball was surrounded by walls and square obstacles that the ball could bounce off. Each trial contained a red and a green target and the goal of the task was to determine whether the ball would hit the red target or the green target first (see Figure 1). Before making a guess, participants were shown 2.5s of the ball's movement, after which the ball paused in its trajectory and participants pressed either the "R" or "G" key to indicate their guess for the *red* or *green* target. After participants made their guess (or 10s elapsed), the ball would resume its movement until it hit one of the targets. At the end of each trial, participants received points based on their accuracy and their response time: -10 for an incorrect guess, 0 for no guess, variable points for a correct guess based on time to respond (see Figure 1). The points for a correct guess were allotted based on an exponential decay function of response time so participants were rewarded for guessing quickly if they could generate an accurate guess rapidly, but the penalty for longer response times quickly diminished. To illustrate, participants received 100 points for responses at 250ms, 71 points at 1000ms, and 45 points at 2000ms.

Participants read a brief set of instructions and completed three practice trials before doing the experimental trials. Each participant completed all trials in the experiment: 48 trials representing each complexity and containment level across four scenarios, with 64 "distractor" trials (discussed below) for a total of 256 trials. The order of the trials was randomized for each participant, as was the selection of the red and green target for reach trial.

Stimuli

The trials were grouped into four qualitative scenarios, and within each scenario they were parametrically manipulated along two dimensions that modified the uncertainty of simulations and the availability of topological predictions.

Scenario: Each trial belonged to one of four possible scenarios corresponding to the containment structure that the targets were placed in. For example, one scenario placed the ball inside variants of a box where one of the targets was placed in the opening, while another had the ball traveling down a right-angled tunnel with a target at one end. (see Figure 5).

Containment: Each scenario had three distinct *containment* levels that varied how much the ball and one of the targets were contained by the set of walls in the scenario. In the high containment trials for each scenario, the ball was virtually guaranteed to hit one of the targets because the ball and that particular target were almost entirely contained by the walls. In the low containment trials, the walls provided only minimal containment for the ball and one of the targets, rendering topology and containment fairly uninformative.

Simulation Complexity: For each scenario and containment level, there were four *complexity* levels which varied the degree of uncertainty involved in simulating the ball's path. This was accomplished by placing an increasing number of square obstacles throughout the scene: simulation therefore required accommodating the growing possibility of the ball bouncing off one or more obstacles before hitting one of the targets, making simulation results less certain. The lowest complexity levels for each scenario and containment level had no such obstacles, while the highest complexity levels had eight obstacles spread throughout the scene (see Figure 2).

Each unique scenario, containment, complexity combination was rotated 90, 180, and 270 degrees to allow for more trials and to prevent the scenarios from being too predictable. In addition, there were 64 *distractor* trials that were identical to the high containment trials in each scenario, except that both targets were placed inside or outside the containing structure. These were added to prevent participants from adopting a strategy of assuming that every trial would have a containment structure or other topological best guess once they had seen a number of trials in which that was the case.

For each trial, we captured participants' accuracy (correct or incorrect) and response time. Previous results using the same target task have provided evidence that participants are likely to make simulated inferences for this task across a range of scenarios and further that response time is correlated with time required to simulate the outcome (Hamrick, Smith, Griffiths, & Vul, 2015; Smith et al., 2017). We ex-

pected response time to be a reasonable measure of participants' reliance on simulation for the inference in the task: as the complexity of the simulation required to make a prediction increased, so too should the response time. In contrast, predictions made via topological inference should show little change in response time as complexity of the scene increased. When one of the targets was clearly contained in the same space as the ball, the uncertainty or duration of the ball's simulated path should not have had any bearing on judging which target the ball would hit first if participants were taking advantage of this containment information. Therefore, we expected to see a relationship between simulation complexity and response time which held for trials in which participants made a prediction by simulation but failed to hold for trials where participants were instead using visual cues which facilitated more coarse topological predictions.

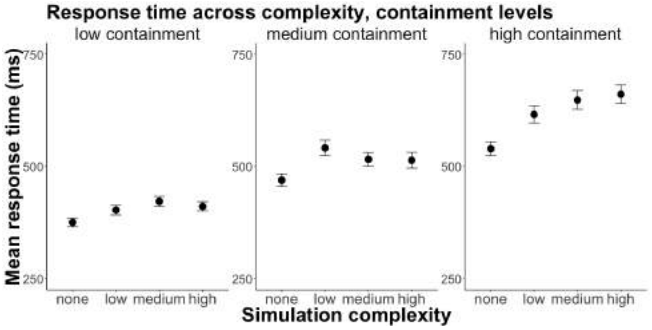
Results

Two of the 81 participants were excluded from analysis due to technical difficulties logging their data. For each participant, we excluded data from the 64 distractor trials. These were included in the experiment to prevent the inference that all trials would have a more and a less contained target. However, the data from these trials is not relevant to the present analyses. All subsequent analyses were therefore conducted with data from 79 participants over 192 trials (twelve trials for each of the four scenarios, rotated each of 0, 90, 180, and 270 degrees). For all analyses, response times were log-transformed to account for their skewed distribution (Whelan, 2008) but transformed back for reporting and display.

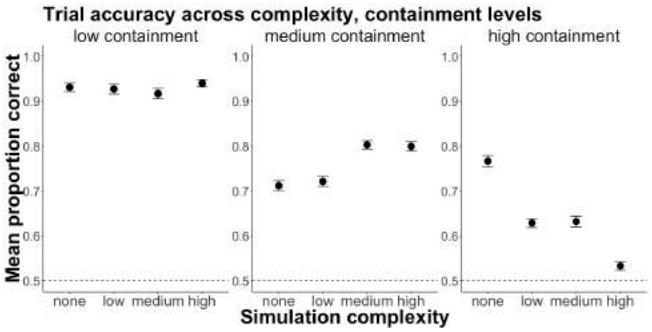
Response times

To assess whether participants were avoiding costly simulations when simulations were particularly uncertain and topological conditions supported more efficient predictions, we examined average response times across each level of complexity and containment. The results are illustrated in Figure 3a. We were interested in comparing response times in low-containment trials to high-containment trials, where an efficient topological prediction about which target the ball would hit was available. Rather than a stabilization or even a decrease in response time as complexity increased in high containment trials (signaling a switch to topological prediction), Figure 3a shows that response times increased progressively as containment increased from low to high and within each containment level as complexity increased from none to high. Moreover, the high-containment trials were slower, and less accurate (Figure 3b), than low-containment trials.

In a repeated measures ANOVA, response times vary with containment and complexity, ($F(2, 156) = 55.63$, $p < 0.001$ and $F(3, 234) = 8.87$, $p < 0.001$, respectively). However, consistent with the fact that participants are not treating complexity differently in high containment trials, there is no containment-complexity interaction ($F(6, 468) = 0.487$). Participants relying on topological information to infer which target the ball would hit in high containment trials would have been able to do so quickly. As complexity increased, so too would the time required to simulate the ball's possible outcomes. Therefore, predictions made via topological analysis in high containment, high complexity trials could potentially be done in less time than required for prediction by simulation in trials with the same degree of complexity but lower containment. Even with complexity levels which make simulation difficult and topological information which makes prediction simple, participants showed no sign of using a containment heuristic.



(a) Response times across conditions



(b) Accuracy across conditions

Figure 3: (a) Mean response time across containment and complexity levels. Despite the availability of simple topological predictions in the high containment, high complexity trials, response time is highest. (b) Mean accuracy across containment and complexity levels. Accuracy steadily decreases at higher containment levels, even though more contained trials would seem to make prediction more certain.

Accuracy

In light of our findings that response times both increased as complexity increased within each containment level and also increased across containment levels, one interpretation is that this pattern was a result of a speed-accuracy tradeoff. Insofar as additional complexity in a given scenario made simulation more difficult and uncertain, participants may have spent more time confirming their predictions without any other change in their simulations or prediction strategies. To test this, we looked at each participant's accuracy in a given containment and complexity level (there are 16 trials in a given containment and complexity level for each participant). The

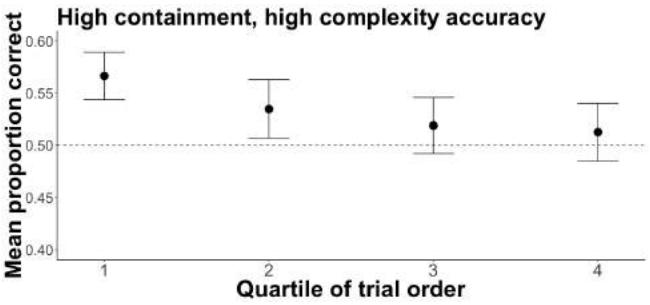


Figure 4: Performance of participants in *high containment, high complexity trials only* by trial order quartile. Accuracy remains close to chance and does not improve over the course of the experiment, suggesting that participants likely did not switch at any point to topological inference cues or other strategies that would have improved their accuracy.

mean accuracy proportions across all participants for each complexity and containment level are shown in Figure 3b.

In contrast to what would be predicted by a speed-accuracy tradeoff in which the containment and complexity levels that participants spent the most time on also have the highest accuracy, mean accuracy steadily decreases from low to high containment scenarios. In low containment trials, mean accuracy was above 90% across all complexity levels, while in high containment and high complexity trials, where participant response times were the largest, accuracy was only nominally above chance (95% CI 51.3% - 55.4%). In a repeated measures ANOVA, both containment and complexity accounted for a significant portion of the variance in accuracy ($F(2, 156) = 829.5$, $p < 0.001$ and $F(3, 234) = 15.7$, $p < 0.001$, respectively), as well as the interaction between them ($F(6, 468) = 61.79$, $p < 0.001$). As the containment and complexity of trials increased, participants spent more time making judgments and their accuracy decreased: these data are inconsistent with an account of prediction in which people process topological features to make the judgment as efficiently as possible. One alternative is that people persist in simulating outcomes in such trials even when alternatives are readily available. Under this account, participants would be expected to simulate more as complexity increased in order to overcome the uncertainty imposed by increases in complexity. They might do this even when increasing levels of containment made topological predictions simple.

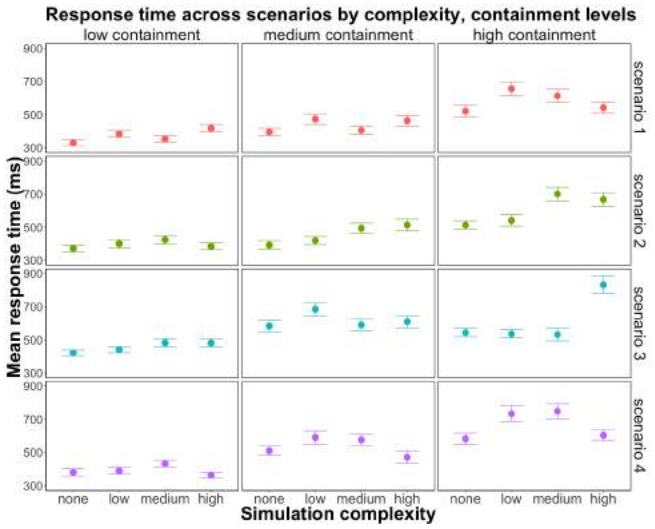
Strategy changes

Another interpretation of the current results is that people may have *eventually* switched to heuristic-based strategies in the more complex trials, but not right away. We predicted that the difficulty of simulation on high complexity trials would encourage participants to employ alternative inference strategies where available. But it may be that the complexity of a trial in and of itself is insufficient to induce strategy change. For example, participants might need to see several complex trials and infer that high complexity trials are likely to recur and are not "one offs". Or, participants might overestimate the accuracy of simulation-based inferences: only after getting wrong answers on complex trials would they pursue alternative inference strategies.

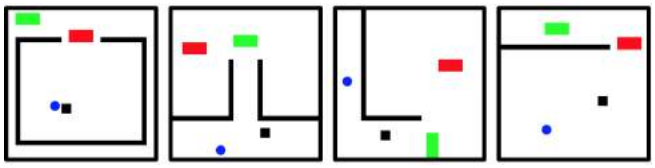
If participants were switching to heuristic-based strategies as a result of familiarity with the task or low accuracy on complex trials, we might expect a difference between high complexity, high containment trials encountered *earlier* versus *later* in the experiment. This difference would be revealed in changes in accuracy over the course of the experiment: if participants eventually ended up using a topological inference strategy for these high containment, high complexity trials, we would expect near perfect accuracy for any such trials. Figure 4 shows accuracy on *high containment, high complexity trials only*, arranged by the trial order quartile in which participants saw them. Participants performed relatively poorly on the high containment, high complexity trials at the outset. Critically, there is no sign of improvement over the course of the experiment: in an ANOVA with participants' mean accuracy by quartile, accuracy did not vary significantly across quartiles ($F(1, 78) = 2.359$, $p = 0.129$). If participants had switched to a topologically based inference strategy, we would expect an increase in accuracy since high complexity, high containment trials enable a very confident containment-based solution. Figure 4 suggests that directionally, participants appeared to get worse on the high accuracy, high containment trials and remain fairly inaccurate throughout the experiment.

Scenario and rotation differences

A third account for the higher response times and lower accuracy as containment and complexity increased is that this overall pattern reflects a great deal of variance across scenarios. In a repeated measures ANOVA of response time that adds scenario on top of containment and complexity, there are significant main effects of containment and complexity (as described before) as well as scenario ($F(3, 234) = 64.89$, $p < 0.001$), reflecting the fact that participants' response times seemed to vary across scenarios. In Figure 5, we show mean response times across containment and complexity levels but further broken down by scenario. The pattern of response times is fairly consistent for low containment trials but the directionality of response times as complexity increases in high containment trials varies across scenarios. In scenarios 1, 2, and 4, response times in high containment trials stabilize or diminish at higher complexity levels, which is qualitatively consistent with our hypothesis that participants would make faster predictions when topological conditions supported a coarse analysis and made simulation highly uncertain. Indeed, the effects of containment and complexity are not homogeneous across scenarios, revealed by significant interactions between scenario and containment ($F(6, 468) = 6.935$, $p < 0.001$), and scenario and complexity ($F(9, 702) = 4.662$, $p < 0.001$). The three-way interaction between scenario, containment, and complexity is weaker, but also significant ($F(18, 1404) = 1.626$, $p = 0.047$), indicating that the



(a) Response time broken down by scenario



(b) High containment example of each scenario (1–4)

Figure 5: (a) Response times are consistent across scenarios in lower containment and complexity levels but diverge considerably at higher containment and complexity levels. (b) A high containment (low complexity) trial for each scenario. Complexity was increased by adding more square obstacles.

pattern in scenario 3 is quite unusual. However, we cannot confidently conclude that any of the scenarios would reliably produce the sort of two-way interaction between containment and complexity that our hypothesis predicts.

Finally, it is worth noting that even though rotated versions of the trials were identical in configuration and ball movements, simply turned 90, 180, or 270 degrees, participants may have treated rotated versions of the trials differently. A repeated measures ANOVA of response time as a function of scenario and rotation found that rotation accounted for a significant amount of the variance ($F(3, 234) = 6.995$, $p < 0.001$), scenario was significant (as outlined above) and that there was a significant interaction between scenario and rotation ($F(9, 702) = 2.939$, $p = 0.002$). Whether this reflects some sort of bias towards e.g. the targets being at the top of the screen is unclear.

Conclusion

In this study we presented participants with physical prediction tasks that simultaneously varied the degree to which a simple containment heuristic could be used to make effective predictions and the complexity required to simulate outcomes instead. Our hypothesis was that as increasing complexity made simulations more and more uncertain and effortful, participants would pursue less costly topological prediction strategies. When conditions permitted such knowledge-based predictions, response times would reflect the rapid and efficient use of containment heuristics. We found no evidence of participants flexibly using heuristics when simulation was complex. In fact, participants spent the longest on trials that had the highest degree of containment; meanwhile, their accuracy was lowest on these same trials.

Why might participants have spent more time and been less accurate on trials where a simple containment-based prediction was available? First, it's possible that the structure of the task at the outset biased participants towards a simulation-based strategy in a way that might have been difficult to overcome, even when complexity of trials made simulation difficult. Earlier work that used static control stimuli in a similar task found evidence that people used simulation even with static stimuli (Smith et al., 2017). Therefore, it's possible that participants had a high "fixedness" when confronted with complex trials. Additionally, it has been shown that when explicitly instructed to apply distinct simulation strategies, participants show notable performance differences on mental rotation tasks (Flusberg & Boroditsky, 2011). In the present study, participants were not instructed to simulate or make a containment-based inference and were solving the problems as they naturally would, but future work might look at how instructions play a role in guiding more efficient strategies.

Alternatively, Smith et al. (2017) suggest that if simulation and alternative prediction strategies are running in parallel, detecting scenarios in which participants switch from a default simulation-based prediction to a more qualitative one that is quicker but more coarse might require enough time for simulation to *run out*. In the present study, average response times in the slowest high containment, high complexity trials were still less than one second on average (see Figure 3a). Perhaps participants, upon finding that they were not able to make an accurate simulation-based prediction on these trials, still did not spend long enough attempting an accurate answer to detect the containment relationship or make a prediction based on such a holistic topological feature. Insofar as the higher containment and complexity trials simply required longer to visually process the full scene, participants may have resorted to an even quicker and more general heuristic in order to respond quickly, such as the target that was the shortest Euclidean distance or seemed most directly along the ball's initial path irrespective of obstacles. Alternatively, participants may have simply persisted in slower and less efficient simulations on high containment, high complexity trials rather than pursue alternate strategies (Hamrick et al., 2015). Future research will need to carefully design stimuli in order to control for the many ways participants might make predictions and consider other hypotheses that allow for manipulation of the uncertainty of simulations during prediction.

Abstract

Children and adults prefer simpler to more complex explanations, a penchant they share with scientists and philosophers. While the preference has been widely remarked, its mechanisms and justification remain contested (Kitcher1987, Lombrozo 2007, Lombrozo2015). Explanations for the simplicity preference have included over-hypotheses, resource rationality, pragmatic justifications, and quirks of the hypothesis generation process. We present a model of key results from Pacer and Lombrozo (Pacer2017) and show that one form of the simplicity bias can be explained on probabilistic grounds alone. This modeling work provides an explanation for one manifestation of the simplicity bias, and allows us to formalize questions within the 'Explanation for Best Inference' Framework (Lombrozo2015), asking explicitly what makes the best explanation 'best.'

Memory maintenance of gradient speech representations is mediated by their expected utility

Wednesday Bushong (wbushong@ur.rochester.edu) and T. Florian Jaeger (fjaeger@ur.rochester.edu)
Department of Brain and Cognitive Sciences, University of Rochester

Abstract

Language understanding requires listeners to quickly compress large amounts of perceptual information into abstract linguistic categories. Critical cues to those categories are distributed across the speech signal, with some cues appearing substantially later. Speech perception would thus be facilitated if *gradient sub-categorical* representations of the input are maintained in memory, allowing optimal cue integration. However, indiscriminate maintenance of the high-dimensional signal would tax memory systems. We hypothesize that speech perception balances these pressures by maintaining gradient representations that are expected to facilitate category recognition. Two perception experiments test this hypothesis. Between participants, an initial exposure phase manipulated the utility of information maintenance: in the *High-Informativity* group, following context always was informative; in the *Low-Informativity group*, following context always was uninformative. A subsequent test phase measured the extent to which participants maintained gradient representations. The Low-Informativity group showed less maintenance, compared to the High-Informativity group (Experiment 1). We then increased the task demands and made the targets of the manipulation less obvious to participants (Experiment 2). We found a qualitatively similar pattern. Together, these results suggest that listeners are capable of allocating memory to gradient representations of the speech input based on the expected utility of those representations.

Keywords: speech perception; cue integration; memory; expected utility

Introduction

Spoken (and signed) language is a temporally unfolding signal. In order to comprehend language, humans must quickly compress kilobits of information per second into abstract linguistic representations and meanings that contain more manageable amounts of information. At the same time, cues to linguistic categories often do not temporallly co-occur in neatly delimited segments of the speech signal, but rather are distributed across the signal. For example, one of the primary cues to stop voicing in English is the duration of the *preceding* vowel (Klatt, 1976). To make optimal categorization judgments, listeners must retain some sub-categorical information about the preceding vowel in memory in order to integrate it with later-arriving information (i.e., the stop itself). This kind of information distribution is typical across languages and can occur at several timescales: cues to sound categories can come not only from proximate acoustic properties, but also from, e.g., later lexical and semantic context that can occur anywhere. But maintaining rich representations of all incoming input would seemingly overload working memory. Thus, many theories of language processing claim that listeners simply do not maintain gradient representations of the input on any significant timescale, but instead immediately compress input into abstract representations (Just & Carpenter, 1980; Christiansen & Chater, 2016). According to these accounts, listeners throw away rich representations of the input as soon as a categorical perceptual judgment has been made.

However, a growing body of literature has suggested that listeners can and do maintain sub-categorical representations of prior input (McMurray, Tanenhaus, & Aslin, 2009), even at quite long perceptual timescales (Connine, Blasko, & Hall, 1991; Brown-Schmidt & Toscano, 2017; Gwilliams, Linzen, Poeppel, & Marantz, 2018). For example, Connine et al. (1991) exposed participants to sentences like "When the ?ent in the [fender/campground]...", where the ?-segment ranged between /d/ and /t/ (by manipulating one of the primary cues to voicing perception, the voice-onset time or VOT). The context following the ?-segment contained additional semantic context toward the identity of the original word. Participants had to categorize whether they had heard the word "tent" or "dent" in the sentence. Connine and colleagues found that participants' categorizations were influenced *both* by the VOT of the sound *and* by subsequent context, suggesting that listeners maintained a gradient representation of the initial sound for later use in cue integration and categorization. Subsequent studies have confirmed that listeners can maintain sub-categorical representations well beyond word boundaries (Szostak & Pitt, 2013; Bushong & Jaeger, 2017; Bicknell, Bushong, Tanenhaus, & Jaeger, under review).

How is this possible when language contains too much information to be held in memory indefinitely? We hypothesize that listeners use a memory strategy based on *expected utility*: the more important a piece of input is deemed to be, the more likely a detailed gradient representation should be maintained in memory; the less important the input, the more likely a categorical, less detailed representation will be maintained. In the case of the VOT and subsequent context example above, we can operationalize utility as the likelihood that *subsequent* context will be informative for categorization of the current input—if there is likely to be later information relevant to categorization, listeners should maintain a gradient representation of the speech input in order to be able to use it during cue integration (when the relevant subsequent context arrives).

In order to test this proposal, we conduct two experiments where we manipulate the probability that subsequent content in the sentence is relevant to the target word that participants have to categorize. Participants listen to sentences where a critical target word is acoustically manipulated to range between *tent* and *dent*. Like in the experiments by Connine and colleagues, these words are embedded in sentences. Unlike in earlier work, one group of participants hears sentences

that always contain subsequent contextual information that is *informative* for categorization, whereas another group of participants hears sentences with *uninformative* subsequent context. Following exposure, we then test how much participants in the two groups maintain sub-categorical representations about the target word. Here, we operationalize whether participants are maintaining sub-categorical representations of the initial target as the extent to which each group integrates *both* acoustics of the target word *and* subsequent context into their categorization responses.

General Methods

Participants

We recruited 128 native English-speaking participants each for Experiments 1 and 2. Participants were recruited from Amazon Mechanical Turk and rewarded $3.00 for their participation. Participants could only participate in in either Experiment 1 or Experiment 2. The average age of our participants was comparable across experiments suggesting they had similar amounts of language experience (Experiment 1: 37.55 ± 12.04; Experiment 2: 34.14 ± 8.11).

Materials

We take the paradigm from Bushong and Jaeger (2017) as a starting point for our experiments. We constructed 12 sentence triplets like the following:

(1) After the ?ent Sue had found in the campgrounds collapsed, we went to a hotel. **(*tent*-biasing context)**

(2) After the ?ent Sue had found in the teapot was noticed, we threw it away. **(*dent*-biasing context)**

(3) After the ?ent was noticed, we continued on our way. **(neutral context)**

We manipulated two aspects of the sentence stimuli. First, we acoustically manipulated the "?" to range between /d/ and /t/ by changing the value of its voice-onset time (VOT), the primary cue distinguishing voiced from voiceless syllable-initial stop consonants in English. Based on norming and previous experiments, we chose to test VOT values of 10, 40, 50, 60, 70, and 85ms to cover a perceptual range from /d/ to /t/ with ambiguous points in between. Each VOT step occurred equally often. Second, we manipulated whether later context biased toward a /t/-interpretation (1) , /d/-interpretation (2), or neither (3). Informative words in the subsequent context—if present—occurred between 6-9 syllables after the target word, as in (1) and (2) above.

Procedure

Both experiments consisted of two phases (participants were unaware of this implicit structure): Exposure (72 trials) and Test (48 trials). Participants were randomly assigned to one of two groups: Low-Informativity exposure and High-Informativity exposure. During exposure, the Low-Informativity exposure group only heard sentences with neutral subsequent context (e.g., sentence (3) above), such that the only relevant information to sound categorization was VOT. The High-Informativity exposure group, by contrast, always heard sentences that contained informative later context (split evenly between /t/-biasing and /d/-biasing contexts), as in previous studies. In the test phase, both groups heard sentences that contained informative later context (split evenly between /t/-biasing and /d/-biasing contexts). This allowed us to assess context effects during the test phase, following Connine et al. (1991). Figure 1 illustrates the design of both experiments.

Both during exposure and test, participants' task was simply to categorize whether they heard one of two alternative words after they heard the full sentence. In Experiment 1, participants always made judgments about our critical target words of interest—i.e., they were asked whether they heard "tent" or "dent" on every trial. In Experiment 2, on half of all trials, participants instead had to categorize another word in the sentence (e.g., for sentence (3) above they were asked whether they heard "way" or "day"). We motivate this difference in design after presenting Experiment 1.

Predictions

We analyze responses from the test phase. Specifically, we analyze the influence of VOT and subsequent context on categorization responses to assess whether listeners maintained gradient representations of VOT. If participants maintain sub-categorical information about the /t/ and /d/ in the target word *?ent* until the end of the sentence, we should see effects of both VOT and context. Critically, if listeners can monitor the utility of subsequent context for the target word, and if expectations about this utility affect the degree to which listeners maintain sub-categorical representations, we should see that the main effect of context is smaller in the Low-Informativity exposure group, compared to the High-Informativity exposure group. Note that observing a continuous effect of VOT is not sufficient to establish that listeners maintain gradient representations of VOT since this could still reflect initial deterministic categorizations; it is the ability for listeners to integrate continuous VOT information with later-arriving context that is critical (for more discussion of this point, see Bicknell et al., under review).

Experiment 1

The goal of Experiment 1 was to test the simplest version of our proposal, whether listeners can adapt their expectations about the utility of subsequent context and use them to guide whether to maintain gradient representations of initial acoustic input.

Analysis

Following previous work (Bicknell et al., under review; Bushong & Jaeger, 2017), we excluded participants whose

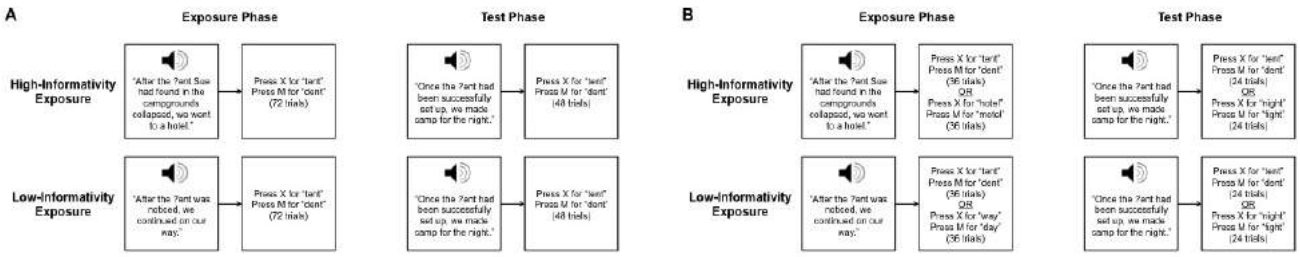

Figure 1: Design of the two experiments. **A**: Experiment 1. **B**: Experiment 2.

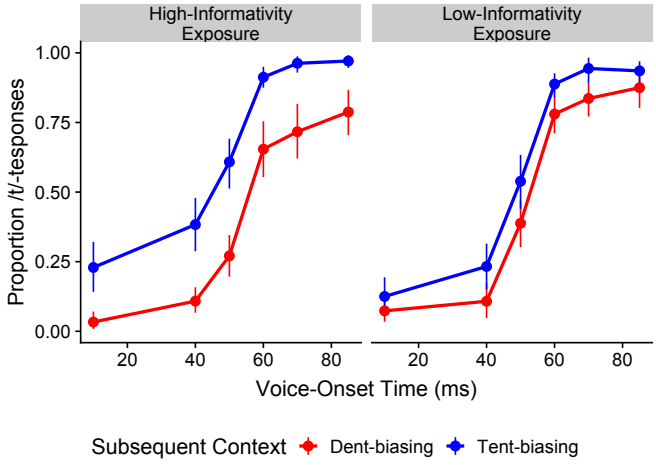

Figure 2: Experiment 1 test phase categorization results by VOT, subsequent context, and exposure group. Error bars are bootstrapped 95% confidence intervals over subject means.

categorization responses were not modulated by VOT, suggesting that they did not understand the task. This resulted in the exclusion of 11 participants for Experiment 1 (8.6%).

We fit mixed-effects logistic regression (Jaeger, 2008) predicting the proportion of /t/ responses in the test phase from VOT (z-scored to help with model convergence), squared VOT (z-scored), subsequent context (sum-coded: 1 = *tent*-biasing vs. -1 = *dent*-biasing), group (sum-coded: 1 = High-Informativity vs. -1 = Low-Informativity exposure), the two-way interaction of group with subsequent context, and the two-way interaction of subsequent context and squared VOT.[1] We included the interaction between squared VOT and context to test whether listeners' behavior was ideal observer-like (for a longer discussion on why this is important, see Bicknell et al., under review). The analysis also contained the full random effects structure that allowed model convergence. Analyses were conducted in the `lme4` package in `R` (Bates, Maechler, Bolker, Walker, et al., 2014).

Results

Figure 2 shows /t/-responses by group, VOT, and subsequent context over the test phase.

We found main effects of VOT ($\hat{\beta} = 2.87, p < 0.001$), squared VOT ($\hat{\beta} = 1.15, p = 0.01$) and subsequent context ($\hat{\beta} = 0.88, p < 0.001$) such that participants were more likely to respond /t/ when VOT increased and when subsequent context was /t/-biasing. The interaction between squared VOT and context was not significant ($\hat{\beta} = 0.06, p = 0.47$), replicating previous findings that suggest rational information integration.

There was no main effect of group on /t/-responses ($\hat{\beta} = 0.01, p = 0.89$). Crucially, there was a significant interaction between group and context ($\hat{\beta} = 0.41, p = 0.001$) such that the High-Informativity group showed a larger context effect than the Low-Informativity group. A simple effects analysis[2] revealed that both groups showed a significant context effect in the same direction (High-Informativity group: $\hat{\beta} = 1.25, p < 0.001$; Low-Informativity group: $\hat{\beta} = 0.47, p = 0.007$).

Discussion

We found that both exposure groups showed effects of VOT and subsequent context on their categorization responses, suggesting that they maintained gradient representations of speech input (VOT) in memory. As predicted, however, the effect of context was much smaller for the Low-Informativity group as compared to the High-Informativity group. These results suggest that the average informativity of later context influences whether listeners maintain gradient information about VOT in memory.

Experiment 1 shares with most previous work on the maintenance of sub-categorical representations that our paradigm involved a large degree of repetition (see Connine et al., 1991; Szostak & Pitt, 2013; Bicknell et al., under review; Bushong & Jaeger, 2017). This raises questions about the extent to which the results of Experiment 1 generalize to scenarios that more closely resemble the task demands of everyday language processing. In particular, participants in Experiment 1 were asked to make categorization judgments about the same critical target words of interest (*tent* and *dent*) throughout the entire experiment. This target word always occurred in

[1] Fixed effects R formula: `/t/-response ~ VOT + VOT^2 Context + Group + Group:Context + VOT^2:Context`.

[2] R formula: `/t/-response ~ VOT + Group / Context` plus the same random effects as the main analysis.

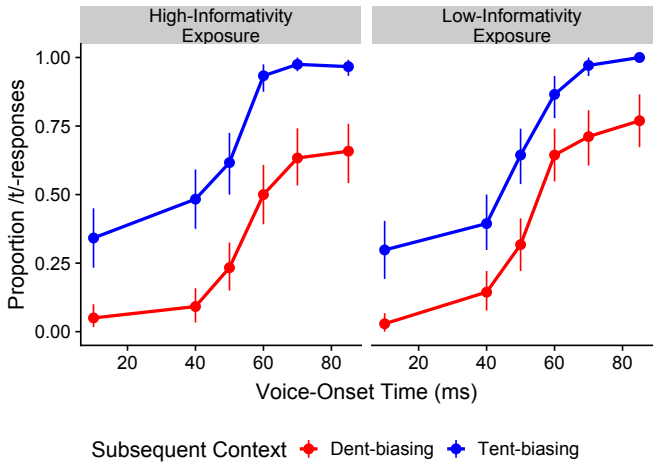

Figure 3: Experiment 2 Test Phase categorization results by VOT, subsequent context, and group. Error bars are bootstrapped 95% confidence intervals over subject means.

the same position within the 12 different sentence contexts. Additionally, subsequent information context (in the High-Informativity exposure group) always occurred about 6-9 syllables after the target. All of these factors likely directed participants' attention towards the target words.

One possibility is thus that the large context effects in the High-Informativity group is due to participants limiting their attention solely on the target word and the informative context. Similarly, the small context effect in the Low-Informativity group might be due to participants recognizing that they can do the task just as well while tuning out after hearing the target word, as they always get asked about the same target word. Experiment 2 presents a first step towards addressing this question.

Experiment 2

Experiment 2 is identical to Experiment 1, except that participants in both exposure groups of Experiment 2 only made judgments about the target words of interest (*tent* and *dent*) on half of the trials. On the other half of trials, participants were instead asked to categorize another word in the sentence; these alternate target words were never the informative subsequent context words for our critical words of interest—i.e., participants were never asked about the word "campgrounds" in sentence (1) above. This change from Experiment 1 had two purposes: (i) it directed participants' attention away from the target words, thus allowing us to test how participants behave when targets are not perfectly predictable, as in natural speech; and (ii) made it more likely that participants in both exposure groups remained attentive throughout the entire sentence. One of our concerns about Experiment 1 is that participants in the low-informativity group may have just 'tuned out' the rest of the sentence, and thus subsequent biasing context in the test phase, after hearing the target word. We reasoned that asking participants about words near the end of the sentence would generally increase attention toward those areas of the sentence, thus making it more likely that they heard and processed the later context. Participants were not told before the experiment what types of words they would be making judgments about or how often, so it is unlikely that they had a priori expectations about the distribution of target words (beyond general expectations about what kinds of words are usually tested in experiments, e.g. content words).

Analysis

Analyses were identical to Experiment 1. Our exclusion criteria resulted in the removal of 16 participants (12.5%) from analysis.

Results

Figure 3 shows /t/-responses by group, VOT, and subsequent context over the test phase.

We found main effects of VOT ($\hat{\beta} = 0.71, p = 0.01$), squared VOT ($\hat{\beta} = 1.68, p < 0.001$) and subsequent context ($\hat{\beta} = 1.26, p < 0.001$) such that participants were more likely to respond /t/ when VOT increased and when subsequent context was /t/-biasing. The interaction between squared VOT and context was significant ($\hat{\beta} = 0.22, p = 0.01$), in contrast to Experiment 1. In Experiment 2, we did not find an interaction between group and context ($\hat{\beta} = 0.18, p = 0.14$), although the numerical difference was in the same direction. The simple effects analysis revealed that both groups showed a significant context effect in the same direction (High-Informativity group: $\hat{\beta} = 1.39, p < 0.001$; Low-Informativity group: $\hat{\beta} = 1.01, p < 0.001$).

Discussion

The results of Experiment 2 are qualitatively similar to Experiment 1: participants overall showed evidence of integration of VOT and context into their responses, but the effect of context was numerically smaller in the Low-Informativity group than in the High-Informativity group. In contrast to Experiment 1, this difference between groups was not significant. This may suggest that shifting participants' attention away from our main manipulation made it harder to track how informative subsequent context was for our target words. However, it is hard to draw firm conclusions from a null result. To investigate whether the context effect difference is different between the two experiments, we directly compare them.

Interestingly, we also found a significant interaction between squared VOT and context, suggesting that participants' integration of VOT and context was non-optimal—unintuitively, participants seemed to use context more for *unambiguous* stimuli. This seems to contradict previous proposals that context is either integrated as a constant regardless of ambiguity (optimal integration, Bicknell et al., under review), or is used more for ambiguous than unambiguous stimuli (Connine et al., 1991). Since this aspect was not the focus of this experiment we will not discuss it further here, but further work should investigate why we observe suboptimal integration behavior in this more naturalistic setting

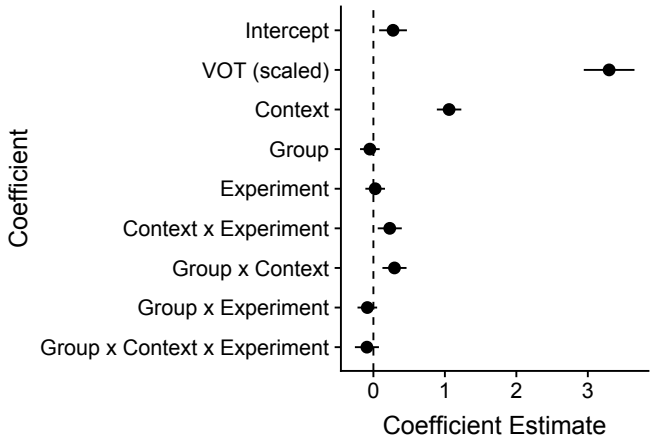

Figure 4: Model coefficients from combined analysis of Experiments 1 and 2. Error bars are 95% confidence intervals.

(for a first step in modeling sub-optimal integration strategies in this paradigm, see Bushong & Jaeger, 2019).

Comparison of Experiment 1 & 2

Since we observed a different pattern of results in Experiments 1 and 2, we conducted a post-hoc combined analysis in an attempt to assess overall evidence for the group by context interaction across experiments. In order to test the relationship between the group and context interaction and experiment, we fit a combined regression model to both of the datasets, allowing experiment (sum coded such that Experiment 1 = -1, Experiment 2 = 1) to interact with context and group. The other fixed effects remained the same as the above analyses for both experiments.

Results

Figure 4 shows the results of the combined analysis of Experiments 1 and 2.

In the combined analysis, we found main effects of VOT ($\hat{\beta} = 3.3, p < 0.001$) and subsequent context ($\hat{\beta} = 1.06, p < 0.001$). There was also a significant interaction between group and context ($\hat{\beta} = 0.29, p < 0.001$) such that the context effect was larger for the High-Informativity group than the Low-Informativity group. Critically, there was no three-way interaction between experiment, group, and context ($\hat{\beta} = -0.09, p = 0.29$), suggesting that the two-way interaction between group and context did *not* differ significantly across experiments.

We also found an unexpected two-way interaction between experiment and context ($\hat{\beta} = 0.23, p = 0.008$), such that the context effect was larger in Experiment 2 than Experiment 1. We return to this difference below. None of the other effects reached significance ($p > .2$).

General Discussion

When comprehending language, listeners must process thousands of bits of incoming information per second, compressing it into more manageable abstract representations. However, sub-categorical information about input can be useful to maintain in memory for later integration with relevant cues. Previous work has shown that listeners seem to be able to maintain such gradient representations in memory for up to several seconds. Here, we asked how this is possible when maintaining gradient representations of all incoming input would presumably overload short-term memory. We proposed that these effects may be driven by the *expected utility* of maintaining such information. In the case of these experiments, we tested this by manipulating the informativity of subsequent context: we reasoned that if subsequent context is likely to be informative for phonemic categorization, then the utility of maintaining gradient representations of VOT is higher, since it will be available for cue integration.

In Experiment 1, we found that both experimental groups maintained gradient representations of VOT over the timescale tested in this experiment (6-9 syllables). In line with our predictions, this effect was significantly smaller in the Low-Informativity group compared to the High-Informativity group. This provides support for our hypothesis that expected utility mediates maintenance of gradient representations of speech input in memory.

In order to make our experiments more naturalistic, we added an additional manipulation in Experiment 2. Participants were not always making judgments about our critical target words of interest. Instead, on half of all trials (during exposure and test), they made categorization judgments about non-critical words in the sentence. This change in the design takes a (small) step towards the task demands of natural language use: listeners don't necessarily *a priori* know which parts of the speech input they will need to comprehend and respond to. When we made this change, we observed the same numerical trend toward a smaller context effect in the Low-Informativity group, but this difference was not significant ($p = 0.14$). It is possible our manipulation in Experiment 2 successfully directed participants' attention away from the *tent*- and *dent*-biasing context, so that participants had a harder time estimating the informativity of subsequent context.[3] A follow-up combined analysis found no evidence that there was a difference in the interaction between the two experiments, though such an interaction might have been difficult to detect. We tentatively conclude that both experiments support the hypothesis that listeners maintain gradient representations according to their expected utility, but further experimentation with similar design is needed.

Of note, our follow-up analysis also found that participants in Experiment 2 exhibited an even *larger* context effect as compared to participants in Experiment 1. This might be seen as surprising: if anything Experiment 2 directed atten-

[3] As suggested by Figures 2 and 3, the difference in the context effects between experiments was driven by the Low-Informativity group: post-hoc analyses revealed that the context effect was larger in the Low-Informativity group in Experiment 2 compared to Experiment 1, but there were no differences in the High-Informativity group.

tion *away* from the critical word, compared to Experiment 1. In Experiment 2, participants had to make categorization judgments about words that occurred in different parts of the sentence rather than only the *tent* and *dent*. Critically, participants were never asked to make judgments about the *tent*- and *dent*-biasing context. The large context effect in Experiment 2 would thus seem to suggest that maintenance of gradient representations in memory is the default during speech perception, rather than the exception. While this interpretation stands in stark contrast with received wisdom (Just & Carpenter, 1980; Christiansen & Chater, 2016), it is line with a number of other recent findings that have found maintenance, for example, on the first trial of experiments (Bushong & Jaeger, 2017) or for lexically heterogeneous stimuli in naturalistic task-based language use (Burchill, Liu, & Jaeger, 2018; Brown-Schmidt & Toscano, 2017). Thus the present results may suggest that 'turning off' maintenance, rather than continued maintenance of gradient representations, requires sustained attention to specific, known targets.

Why would listeners show such a robust maintenance effect? One possible explanation consistent with our expected utility proposal is that natural language is *typically* informative: not only are low-level features like acoustic cues highly correlated even at long distances (providing helpful redundancy in light of perceptual inferences over noisy input, Hermansky, 2018), speakers talk about coherent topics that naturally provide semantic context that adds categorization-relevant information about the speech signal. Given these long-distance informational dependencies, maintaining gradient representations will typically be beneficial since it allows for optimal integration of these cues (Bicknell et al., under review). This would explain why we observe robust maintenance effects in paradigms that test sentences which follow these general natural constraints.

The present paradigm shares some caveats with previous work (Bicknell et al., under review; Connine et al., 1991; Szostak & Pitt, 2013): Experiments 1 and 2 involve a high degree of repetition; very much unlike in everyday language use, participants had to categorize the same word dozens of times. While the results of Experiment 2 show that listeners *do* maintain gradient representations about the speech input even when the target word is not *perfectly* predictable, Experiment 2 still allowed listeners to limit their attention—and maintenance of gradient representations: the critical target words (*tent* and *dent*) were the target of categorization on half of all trials. It is thus an open question whether equally strong maintenance of gradient representations is observed when it is less clear which aspects of the speech signal will turn out to be particularly relevant later (for preliminary evidence, see Burchill et al., 2018; Brown-Schmidt & Toscano, 2017).

Executive Functions in Aging: An Experimental and Computational Study of the Wisconsin Card Sorting Task

Andrea Caso

Richard Cooper
Birkbeck, University of London, London, United Kingdom

Abstract

In this paper we explore the effect of normal aging on executive function and present a computational account of the effect of aging in a standard executive task. We tested 25 younger adults and 25 older adults (both with no known neurological condition) on the Wisconsin Card Sorting Task (WCST), a classic test of executive function. The test produces multiple measures related to the types of error made by participants, the rate of learning, and so on. As hypothesised, results show no difference between the groups in the number of perseverative errors (i.e., in continuing with a previously successful rule in the presence of negative feedback), but a significantly increased tendency for older adults relative to younger adults to commit set loss errors (i.e., to switch away from a rule despite positive feedback). We fit an existing neurocomputational model of the task to the experimental data by searching through the models parameter space in order to find the best set of parameter values for the two different age groups. This leads to a proposition regarding the effect of aging on the value of the epsilon_ctx parameter, which we argue elsewhere reflects cortical dopamine concentration. We further reanalyse the data by clustering participants by performance (rather than by age) and show that there are multiple points in parameter space that fit each cluster of participants. We argue on the basis of this and the behavioural data, that different parameter values reflect different solutions to optimizing task performance, and that older participants may compensate for changes in epsilon_ctx (reflecting dopamine concentration) by effortful changes in other parameters (specifically, by increasing attentional focus).

Abstract

We propose a neural network model that accounts for the emergence of the taxonomic constraint and for the whole object constraint in early word learning. Our proposal is based on Mayor and Plunkett (2010)'s neurocomputational model of the taxonomic constraint and extends it in two directions. Firstly, we deal with realistic visual and acoustic stimuli. Secondly, we model the well-known whole object constraint in the visual component. We show that, despite the augmented input complexity, the proposed model compares favorably with respect to previous systems.

Keywords: Neural Networks; Children; Language acquisition.

Introduction

How do infants learn the referent of words? As Quine (1960) famously pointed out, for every word heard in a given circumstance, there are several possible referents: in order to infer the appropriate one, infants have to rule out several possible alternatives. But how? Markman (1989) proposed that infants rule out inappropriate referents by means of three constraints. By the *taxonomic constraint* children extend words to taxonomically-related objects: when a child hears the word "dog" pronounced by a caregiver while pointing at a specific dog, she generalizes the referent of "dog" to all dogs, not just to the one in front of her. By the *whole object constraint* children assume that novel words refer to objects as a whole, rather than to their parts, substance, color, or the visual context in which it appears. Lastly, by the *mutual exclusivity constraint* children assume that two labels usually do not refer to the same object.

This paper concerns the first two constraints, namely the taxonomic and the whole object constraint.

Our starting point is Mayor and Plunkett (2010)'s neurocomputational model of the taxonomic constraint. Their model provides an account of how the taxonomic constraint may emerge from infant experience, as the result of the interplay between (i) taxonomic organization of visual inputs in visual areas, (ii) phonetic organization of the acoustic inputs in acoustic areas, (iii) Hebbian learning developing connections between the two organizing areas. The model uses self-organizing maps (Kohonen, 2001) and Hebbian learning (Hebb, 1949), which are considered cognitively plausible mechanisms, describing at an abstract level realistic forms of information organization in the brain (Hebb, 1949; Miikkulainen, Bednar, Choe, & Sirosh, 2005). The powerful interplay between these structures allows word-object associations to taxonomically generalize after a single (*one-shot*) joint word object presentation[1].

Here we extend Mayor and Plunkett (2010)'s seminal model in two directions:

1. We intend to investigate whether the taxonomic constraint can emerge from experience if we consider *realistic visual and acoustic* stimuli (photographic images with different size, color, location in the picture, point of view, etc. and audio excerpts embodying spoken words synthesized via software) instead of the very simple, artificially built stimuli examined in the original model. A first effort in this direction was undertaken by (Fenoglio, Esposito, & Gliozzi, 2017), in which, however, only realistic visual stimuli were considered. Here we enrich that proposal by considering visual *and acoustic* realistic stimuli (as well as the whole object constraint, see below). To this purpose, we insert in the model two deep architectures, one convolutional to process visual stimuli and the other recurrent to process realistic acoustic stimuli.

2. We insert the *whole object constraint* in the model. Whether early learned or innate, the capacity of picking up the objects in a scene is present in early infancy (see e.g. Spelke, 1990). However, this primacy of the object concept

[1] For a critical discussion of the breadth of one shot learning and fast mapping see for instance (Yurovsky, Fricker, Yu, & Smith, 2014) or (McMurray, Horst, & Samuelson, 2012).

in visual scene analysis is not present in most recent convolutional neural network (CNN) models, that are the state of the art in vision tasks. In fact, these models usually process visual images as a whole (object and background context together), see e.g., (Zhu, Xie, & Yuille, 2017). Here we overcome this limitation of CNNs by inserting a segmentation module that extracts the object from the visual scene before feeding it to the CNN for feature extraction. In the experimental section we show that the whole object constraint improves the performance of the model.

Remarkably, our model replicates Mayor and Plunkett (2010)'s performance with realistic visual and acoustic stimuli, albeit requiring *very-few* joint presentations of image and spoken word pairs.

It is worth mentioning here that we do not try to maintain that CNNs or LSTMs are cognitively plausible models of how realistic stimuli are processed in biological brains – more details about this point in the "New Model" Section. We are just validating the hypothesis that the (Mayor & Plunkett, 2010) model could generalize to more complex stimuli and that the whole-object constraint can be helpful in this model.

Mayor and Plunkett (2010)'s model

Mayor and Plunkett (2010) neurocomputational model of taxonomic constraint (Figure 1) is based on (i) a visual self-organizing map (SOM) that processes visual inputs, (ii) an acoustic SOM that processes acoustic inputs, (iii) Hebbian connections between the two maps. Both self-organizing maps and Hebbian learning are considered cognitively plausible mechanisms (Hebb, 1949; Miikkulainen et al., 2005)

Firstly, the two maps are independently trained (using the standard learning algorithm for self-organizing maps, see Kohonen, 2001) to categorize the visual and the acoustic stimuli. This first learning phase is preliminary to word learning, and unsupervised, proper word learning starting to occur once infants have already started to learn to organize visual and acoustic information in isolation.

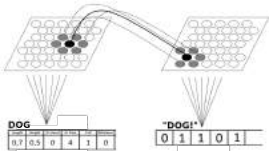

Figure 1: Mayor and Plunkett (2010)'s model

In this way, the two maps learn to represent the stimuli of their training set in a topologically significant way: close units respond (activate) similarly to similar stimuli. The *neural activation* a_j of a neuron j in response to a stimulus x is defined as: $a_j = e^{-\frac{q_j}{\tau}}$, where q_j is the *quantization error* (i.e., the distance between the input vector x and j's weight vector: $q_j = \|\mathbf{x} - \mathbf{w}_j\|$)), and τ is a parameter that modulates the neural activation. The neuron having the strongest activation is the stimulus' Best Matching Unit (BMU).

Once this first phase of learning is complete, the actual word learning can start. This is the Hebbian Learning phase, in which visual and acoustic stimulus are presented to their respective maps and the synapses between the two maps are strengthened. In particular, for each neuron v on the visual map and neuron p on the acoustic map, the Hebbian connection $u_{v,p}$ is strengthened proportionally to the resulting neural activations a_v and a_p, as follows:

$$u'_{v,p} = u_{v,p} + 1 - e^{-\lambda a_v a_p}$$

where λ is the Hebbian training learning rate, and $u'_{v,p}$ is the Hebbian connection after the update.

A single Hebbian learning event, combined with the previously acquired categorization capabilities of the visual and acoustic SOMs, allows the model to generalize the association to other stimuli belonging to the same category.

Comprehension is assessed by considering what visual category is retrieved when a word is presented to the auditory map and its activation is propagated via Hebbian connections. *Production* is assessed by considering what word is produced by the auditory map when a visual stimulus is presented to the visual map and the resulting activation is propagated through Hebbian connections.

The ability of the model to extend the learned word-object associations to other words and objects belonging to the same category is measured by the *Taxonomic Factor*, which is the percentage of correct word-object associations generated by the model (i.e., the average of the Production and Comprehension statistics). Results show that when the SOMs are adequately trained the Taxonomic Factor reaches 80% after a single joint word-object presentation.

New Model

We have enriched the original Mayor & Plunkett model (2010) (and Fenoglio et al. (2017)) so that (i) it can deal with realistic visual *and acoustic stimuli*, and (ii) it captures *the whole object constraint*. A graphical representation of the overall model is contained in Figure 2. For the visual and the acoustic stimuli we propose to use Deep Neural Networks to act as powerful feature extractors: we use two deep convolutional neural networks (Mask R-CNN and Inception V3) to process visual information and a deep recurrent neural network (Deep Speech) to process acoustic information. These models have been widely adopted for this purpose by the Machine Learning community, as they are able to output highly discriminative features (Razavian, Azizpour, Sullivan, & Carlsson, 2014; Graves, Mohamed, & Hinton, 2013; Hannun et al., 2014). Even if it is not the main focus of this paper, it is worth mentioning that these models have also been proposed as realistic models of visual and acoustic processing. Several studies establish a parallel between the representations of the visual input created by the different levels of CNNs and the way in which visual stimuli are processed by the visual cortex (Serre, 2016; Kriegeskorte, 2015; Khaligh-Razavi & Kriegeskorte, 2014). Furthermore, comparisons have been drawn between Recurrent Networks units (specifically the LSTM cell (Hochreiter & Schmidhuber, 1997)) and biologically plausible models of working memory such as the

PBWM model (prefrontal cortex and basal ganglia) (O'Reilly & Frank, 2006).

Visual Component

The visual stimuli that we consider are images taken from the Common Objects in COntext (COCO) dataset (Lin et al., 2014). In this dataset images are labelled pixel-wise, meaning that it is possible to extract the foreground objects from the background scene (i.e. performing image *segmentation*). As a first component of the visual module, we included a Mask R-CNN segmentation model (He, Gkioxari, Dollár, & Girshick, 2017), which separates foreground objects from the background content. Then the foreground object is cut from the background, the background erased and the new image so obtained is fed into an InceptionV3 Deep Convolutional Network (Szegedy, Vanhoucke, Ioffe, Shlens, & Wojna, 2016), an architecture which displays human-like performance on Object Recognition tasks. The deep network processes the object and builds a representation for it. We extract the representations (i.e. the neural activations) that are found in the deepest layer before the fully connected neural classifier (as they contain the most abstract features which have the best chance to depict the abstract concept the object instance refers to), and feed these representations to the visual self-organizing map.

To summarise, we employ a stack of two Deep Neural Networks in our visual module: the first one segmenting the object from the context; the second one analysing that output by means of a standard convolutional deep network. This architecture allows the model to overcome one limitation of standard deep convolutional models that, differently from humans (Spelke, 1990), do not use the notion of object when processing an image, and, on the contrary, rely very much on background information in object recognition tasks (Zhu et al., 2017).

Acoustic Component

We process spoken words using a Deep Speech Recurrent Network (Hannun et al., 2014) which is close to the state of the art in the Speech Recognition (i.e. parsing speech into text) task. This network is able to extract highly discriminative representations from our input stimuli, which have been generated using a realistic voice synthesizer that can be set up to use both male and female voices as well as different regional English accents. In our experiments, we had the generator pronounce labels from the COCO dataset. Similarly to the visual module, we extract features by concatenating the hidden state of the recurrent units after each time step. The resulting vector representations are then truncated to the same length and reduced in dimensionality by means of principal component analysis.

Overall Model

The upper component of the model, comprising the visual and acoustic self-organizing maps and their Hebbian connections, is trained as in the original (Mayor & Plunkett, 2010) model:

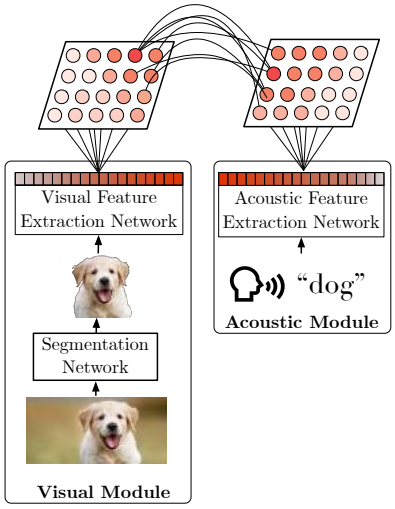

Figure 2: Our model

at first the visual and acoustic self-organizing maps are separately trained to organize their stimuli, then Hebbian learning starts.

Similarly to the original model, in order to assess the quality of the word/object association (the Comprehension and Production ability), we proceed as follows. For Production, we present to the visual map a visual stimulus, individuate a BMU, propagate its activity through Hebbian connections, and then evaluate the induced activation on the acoustic map with a cascading mechanism where neurons are interrogated in order of activation intensity. The first neuron corresponding to a single spoken word (i.e. a neuron that is the BMU for a single acoustic stimulus category) indicates which word is produced. We say that a Production task is successful if the category of the word matches the category of the visual stimulus. We proceed in a similar way for Comprehension.

Experiments

In our experimental phase, we set out to answer the following two questions:

1. Does our extension to the original word learning model by (Mayor & Plunkett, 2010) still account for the taxonomic constraint? In other words, is it possible to use realistic auditory and visual stimuli and achieve good word learning performance?

2. Is the whole object constraint beneficial to the word learning process?

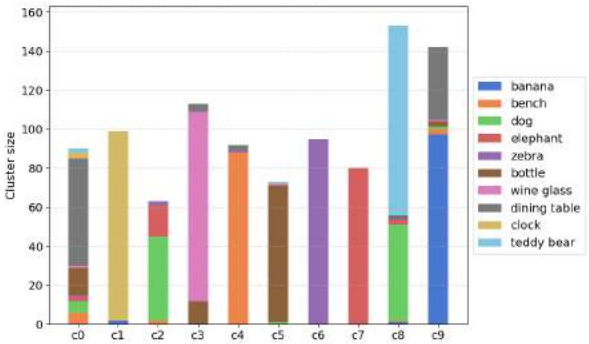
In order to extract whole object and non whole object representations (the inputs of the visual SOM), we trained two separate InceptionV3 networks for the same amount of time (i.e. epochs, full passes of the COCO dataset). However, one network was trained on images where the main object was cut out using the Mask R-CNN model, while the other one em-

ployed images that include a portion of the full visual scene[2]. We refer to these models respectively as the "whole object" and "non whole object" networks. Therefore, we explored the impact of using one network or the other in our visual module as a way to quantify the impact of including the whole object constraint in the overall model. An early evidence of the importance of the whole object constraint is provided by the performances (in terms of Object Recognition accuracy) of the two networks: the whole object network reaches a higher accuracy (93%) than the non-whole object network (77%) after the same amount of training time and similar learning rate schedules[3]. For the experiments that follow, however, we decided to only use as visual stimuli those images that have been correctly classified by both networks; thus, both convolutional models have perfect accuracy on the final visual dataset and can be compared on a fair ground. As far as the acoustic stimuli are concerned, we used a voice synthesizer to generate realistic voice recordings of both male and female voices pronouncing the object categories which appear in the visual dataset. To augment the size of the auditory dataset, we also varied the synthesizer's pronunciation speed. The representations were then extracted using a pre-trained Deep Speech network[4]. We truncated the representations to a length of 25 and kept the 20 most informative factors of variation using PCA. In the following sections, we report representation quality, SOM quality and taxonomic factor measurements for a dataset composed by 1000 visual stimuli and 390 acoustic stimuli belonging to 10 different word-object categories.

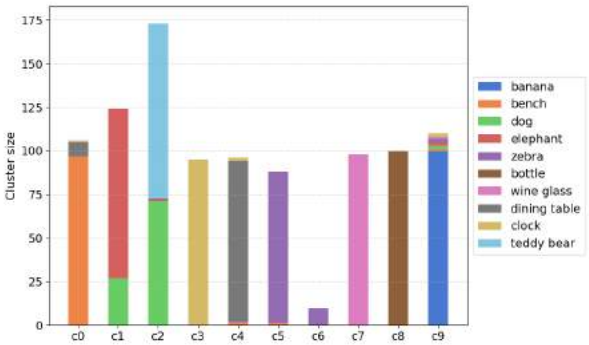
Representation Quality

First off, we set out to understand whether the representations extracted from the realistic stimuli are well-behaved. To this end, we performed an experiment in which the representations are used as input for the k-Means clustering algorithm with k, the number of clusters, set to 10. After fitting the clustering model, we visualize the resulting clusters (see Figure 3) using a histogram plot.

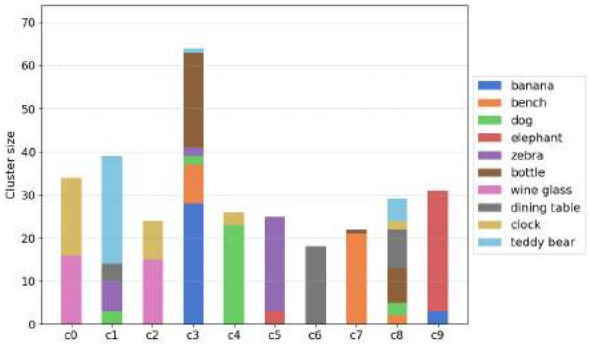
We also assess the trained SOMs' topological organization by visualizing them. In Figure 4, we see that representations belonging to the same category are mapped on neurons that are topologically close. Moreover, we evaluate the organization quality by using the *class compactness* measure; this is computed by averaging the Euclidean distances between neurons that are BMUs for stimuli belonging to the same class and dividing by the average distance between BMUs for any stimulus. Lower values indicate better topological structure.



(a) Non whole object representations.



(b) Whole object representations.



(c) Audio representations.

Figure 3: K-means clusters. Colors show how representations of each category contribute to the clusters.

[2]More specifically, we used the bounding box information for each object in COCO and expanded it by 40% so to preserve a significant amount of visual context.

[3]We trained the whole object network for 60 epochs. We used a learning rate of 10^{-3}, decreasing it to 10^{-4} after 40 epochs. This schedule, however, appeared to be very sub-optimal when training the non whole learning network, as the object recognition accuracy progressed very slowly. Therefore, the second network was trained with a learning rate of 10^{-2} and decreased it to 10^{-3} after 40 epochs.

[4]https://github.com/mozilla/DeepSpeech/

Averaging this formula over the categories in the dataset results in the overall *SOM compactness* value. We report (Table 1) lower compactness values for the SOM we trained on the whole object representations, and robust compactness for the non whole object and acoustic SOMs.

Word Learning

As an experimental evaluation of the overall model, we compare the word learning capabilities of our model with and without the whole object constraint. After training with a number of joint word-object presentations, the model has to be able to produce an appropriate acoustic stimulus when presented with an image (*understanding*) and viceversa (*comprehension*). The algorithm used to obtain the final word-object association is described in the "New Model" Section.

In Figure 5 we report the understanding and comprehension performances alongside the Taxonomic Factor (their average). A set of stimuli (20% of all the visual and acoustic representations) was reserved for testing and was excluded from the training sets.

Discussion

Coming back to the questions we set out to answer at the start of the section, Figure 5 makes apparent that our model manages to perform word learning with appropriate performance (set at a Taxonomic Factor of over 80% in (Mayor & Plunkett, 2010)) after very few word-object presentations. The performance is also in line with previous work on this model (Fenoglio et al., 2017), in which, however, very simplified acoustic stimuli were considered. Therefore, this computational model can still account for the taxonomic constraint even in the face of realistic visual and acoustic stimuli. As for the contribution of the whole object constraint to the model, we first observe that the comparison of the clusters is favorable to the whole object model (Figure 3); furthermore, the self-organizing maps that were trained using the aforementioned representations display good topological organization (Figure 4) and solid compactness values. In addition, as implied by Table 1, the SOM trained with the whole object representations displays stronger topological organization. As for the word learning performance, we obtain a significantly higher Taxonomic Factor when using the whole object representations and conclude that including the whole object constraint in this model is highly beneficial.

Related Work

Our model bears some family resemblance to recent models of image-speech association learning (Synnaeve, Versteegh, & Dupoux, 2014; Harwath & Glass, 2015; Harwath, Torralba, & Glass, 2016; Chrupala, Gelderloos, & Alishahi, 2017), which, at least in part, have been proposed as cognitive models of spoken words referent acquisition. Similarly to Synnaeve et al. (2014), here we consider associations between images and single spoken words, whereas Harwath and Glass (2015); Harwath et al. (2016); Chrupala et al. (2017) consider associations between images and

more complex acoustic stimuli, as whole spoken sentences (Harwath & Glass, 2015; Harwath et al., 2016; Chrupala et al., 2017). With respect to all these models, the specificity of our model is that it learns to generalize image-speech associations to whole visual categories and all phonetic variants of a corresponding word, out of few *positive* joint image-speech presentations, without any need of explicit counterexamples. This parallels the training schedule by which humans usually learn to associate words (or sentences) to visual stimuli.

Vinyals, Blundell, Lillicrap, Kavukcuoglu, and Wierstra (2016) address the problem of *One Shot Learning*: how to build models that reproduce the crucial ability of humans, infants and adults, of learning out of *few examples*, as opposed to the massive training currently used for many neural network models? The proposed model is trained to integrate in one-shot new observations into pre-existent knowledge, represented by a support set. Similarly to our work, representations extracted from pre-trained neural networks are also employed. The authors test their model on classification tasks in which the training dataset is composed by 1 or 5 examples for each category; while a direct comparison would not be proper, as the experimental setups and datasets are fundamentally different, it is worth mentioning that word learning in the present approach does not rely on the supervised, gradient-based optimization of a training objective (i.e. a loss function). On the contrary, in our model word learning emerges after the unsupervised training of the SOMs and a few joint, positive presentations of word-object pairs.

Conclusions

In this paper we expand on the the model originally introduced by (Mayor & Plunkett, 2010) and extended by (Fenoglio et al., 2017). Our work focused on two objectives: allowing the model to process realistic acoustic stimuli, and injecting the whole object constraint into it. We also introduce experiments allowing one to assess the effects of these two changes to the model.

In summary, the empirical evidence shows that the realistic stimuli are not hindering the ability of the model to learn the association between objects and word. In fact, even though the greater complexity of the stimuli representation makes the task harder, the system only requires a few joint presentations to reach the 80% taxonomic accuracy performance shown in the original work by Mayor and Plunkett (2010).

For what concerns the whole object constraint, the evidence demonstrates the remarkable impact of this constraint on the performances of the system. In practice the whole object constraint allows for better performances with respect to the model by Fenoglio et al. (2017) even considering that the latter is dealing with simpler acoustic stimuli. It is worth debating whether the whole-object representations extracted by the visual module contain all the parts of the original objects. Indeed, given the discriminative nature of the CNN training process, the representations may only contain few, very specialized features which suffice for the classification task. As a future work, one may investigate this problem by designing experiments in which one studies whether the activation of the visual SOM, elicited by an acoustic stimulus (a word), allows one to reconstruct a prototypical version of the object referenced by the word. Furthermore, we intend to investigate how to cope with the uttering of whole sentences instead of single words.

Abstract

Children learning language in multilingual settings have to learn that objects take different labels within each different language to which they are exposed. Previous research has shown that adults can learn one-to-one and two-to-one word-object mappings via cross-situational statistical learning (CSSL), and that socio-pragmatic cues may differentially influence monolingual and bilingual adults' learning of such mappings. However, the extent to which monolingual and bilingual learners can keep track of multiple labels from multiple speakers has not yet been investigated. We manipulated the number of speakers in a CSSL task that involved learning both mapping types. We successfully replicated previous studies that found that both monolinguals and bilinguals could learn both types of mappings via CSSL. In addition, we found that bilinguals showed a steeper learning rate for two-to-one mappings than monolinguals, and bilinguals were more likely to accept two words for the same object than monolinguals. These results show that the effect of speaker identity on tracking word-object mappings varies according to language experience.

Keywords: statistical learning; bilingualism; mutual exclusivity; cross-situational learning; word learning

The learning of the mapping between a word and its referent is difficult, as there are infinitely many potential referents for a word. This uncertainty is referred to as the "Gavagai" problem (Quine, 1960). The uncertainty is increased still further when children grow up in multilingual environments, as this means there are multiple words for a particular referent. The present study aims to investigate how speaker identity, as a socio-pragmatic cue, impacts on language learning under such conditions of referential and reference uncertainty.

A prominent suggestion as to how language learners overcome the "Gavagai" problem has been that language learners make use of constraints on which mappings can be formed. For instance, the ME constraint suggests that language learners tend to assign only one word to a referent (Markman & Wachtel, 1988). When language learners hear a novel word and see a familiar object, of which they already know the name, and an unfamiliar object, they would, based on ME, pair the novel word with the unfamiliar object. Other constraints include the whole-object assumption and the taxonomic assumption (Markman, 1991; Markman & Hutchinson, 1984; Markman & Wachtel, 1988). Another account of word learning is the socio-pragmatic account, which suggests that language learners' word learning rely on their socio-cognitive skills and the social cues available in communicative contexts (Tomasello, 2000). This account explains word learning in terms of language learners' ability to actively monitor others' attention (Akhtar & Tomasello, 1996) and intention (Tomasello & Barton, 1994) to discover intended referents of novel words. In general, both of these accounts posit that language learners make use of certain strategies to limit the number of potential referents for a word to help solve the "Gavagai" problem. Yet, constraining the problem space is not the only way to solve the word-learning problem.

Recently, cross-situational statistical learning (CSSL) ability has been proposed as a valuable contributor to word learning. Though the referent of a novel word might be ambiguous within the context of a single learning instance, across multiple learning instances, learners would be able to track the co-occurrences of the novel word and its referent, with which it reliably appears. This statistical information can then help learners to disambiguate which words refer to which referents. Yu and Smith (2007) presented adults with a series of trials containing two to four unfamiliar objects and novel words. Within each trial, the word-object pairings were ambiguous (i.e., novel words were presented in a random order in all trials and there was no correspondence between the order of words and the location of objects on the computer screen), but across trials, with the presentation of different combinations of novel words and their referring objects, the word-object pairings could become apparent. Yu and Smith found that adults could learn the meanings of words via CSSL. This finding has been replicated in various similar studies (e.g., Fitneva & Christiansen, 2011; Hamrick & Rebuschat, 2012; Monaghan & Mattock, 2012; Vouloumanos, 2008).

In these studies, only one-to-one word-object pairs were used. Yet, although learners favour ME (i.e., one-to-one word-referent mappings) when learning the meaning of words, overcoming ME is important for learning categories, homonyms, and synonyms (e.g., Markman & Wachtel, 1988). It is also particularly important for bilinguals as they have to learn translation equivalents (forming many-to-one word-referent mappings; e.g., both "apple" and "manzana" refer to a particular fruit) and interlingual homographs (forming one-to-many word-referent mappings; e.g., "tuna" refers to a kind of fish in English but prickly pear in Spanish).

Ichinco, Frank and Saxe (2009) familiarised and then tested adults on a set of one-to-one word-object pairs. Then, the participants were familiarised to a second set of one-to-one word-object pairs. Some of the pairs in the second set required the remapping of objects or words. Thus, although each set consisted of one-to-one word-object pairs, across the two sets, there was a combination of one-to-one, two-to-one, and one-to-two word-object pairs. The two-to-one and one-to-two word-object pairs were critical for testing whether adults could relax ME during a CSSL task. It was found that the participants were successful in learning the one-to-one word-object pairs and the first mapping of the two-to-one and one-to-two word-object pairs. By contrast, they failed to learn the second mapping of the two-to-one and one-to-two word-object pairs. Ichinco et al. took the results of their study as evidence against a simple associative learning account of word learning.

Yet, Kachergis, Yu and Shiffrin (2009) argued that the results of Ichinco et al.'s (2009) study could be due to a blocking effect, giving rise to the participants favouring the first mapping learnt. Using a similar paradigm to that in Ichinco et al.'s study, Kachergis et al. manipulated the number of occurrences of the second mapping of the word-object pairs. It was found that the extent to which the participants relaxed ME – successful at learning the second mapping of the word-object pairs – was associated with the number of times they had been exposed to the pairs, such that the participants were more likely to relax ME when there was more evidence (i.e., exposure) in the input for the second mapping.

These CSSL studies examined CSSL in a monolingual population. Only a few studies have looked at CSSL in a bilingual population. A study similar to that of Yu and Smith's (2007) by Escudero, Mulak, Fu and Singh (2016) showed that bilingual adults could learn one-to-one word-object pairs via CSSL, outperforming their monolingual counterparts. Another study by Poepsel and Weiss (2016) investigated whether bilingual adults would learn one-to-two word-object pairs better than monolingual adults do, owing to them encountering more instances where they have to relax ME in order to learn new words. They tested the participants' learning of the first and second word-object mappings of the one-to-two word-object pairs in separate testing blocks after the first and second block of learning trials respectively, and tested all word-object mappings in the final testing block after the third learning block. Consistent with Poepsel and Weiss' prediction, it was found that the bilingual adults were quicker than the monolingual adults at learning and showed higher proficiency in learning the one-to-two word-object pairs.

Further, Benitez, Yurovsky and Smith (2016) familiarised monolingual and bilingual adults with a set of one-to-one and two-to-one word-object pairs and tested their learning of the word-object mappings. They found that the monolingual and bilingual adults performed similarly on the task. Both groups showed learning of both the one-to-one and two-to-one word-object pairs, but both groups were better at learning the one-to-one pairs. This is surprising, but not unreasonable, as monolinguals, who have to learn synonyms, are also experienced in learning two-to-one word-object mappings. An interesting finding of their study was that when a phonological cue distinguished sets of labels, the bilingual adults were more likely to learn both words of the two-to-one pairs. This suggests that bilingual adults are more sensitive to the linguistic cues that hint at different languages present in the linguistic input. Taken together, there is evidence that bilingual adults are better than their monolingual counterparts when it comes to learning word-object pairs that violate ME via CSSL.

Other studies have investigated whether socio-pragmatic cues in the linguistic input would affect learners' cross-situational word learning (e.g., Metzing & Brennan, 2003; Trude & Brown-Schmidt, 2012). Poepsel and Weiss (2014) manipulated the socio-pragmatic information available to participants. In one condition, the participants were told that there were two languages involved in the task. In the other two conditions, the participants were not told anything explicitly, but in one of these conditions, the participants were provided with information on speaker identity – they heard a male and a female voice. In the two-voice condition, the two speakers used the same word to refer to a different object, which could be seen as an implicit cue that there could be two different linguistic structures involved in the task. It was found that the manipulation of socio-pragmatic information did not affect the monolingual adults' performance on learning one-to-two word-object pairs. Yet, in multilingual environments it is more usual for one object to be labelled differently by distinct speakers. Whether varying speaker identity would affect bilingual adults' cross-situational word learning, and whether speaker identity can influence learning of two-to-one mappings is as yet unknown.

The aim of the present study was to examine whether speaker identity would differentially affect monolingual and bilingual adults' performance on a CSSL task that involved the learning of one-to-one and two-to-one word-object pairs. We included two conditions – one where there was a single speaker labelling objects in two ways, and one where different speakers labeleld objects in two ways. The present study employed a CSSL paradigm similar to that in Monaghan and Mattock's (2012) study, which is slightly different from many of the CSSL paradigms used in other studies. The crucial difference was that the CSSL paradigm used in the present study did not distinguish between familiarisation and test trials – participants were required to make a forced choice response, without feedback, between two objects in all trials. This allowed an online measure of how quickly and reliably participants form one-to-one and two-to-one word-object mappings across trials.

Another unique feature of the present study was that an additional ME block was administered at the end of the CSSL paradigm to determine whether successful learning of two-to-one word-object pairs was due to successful tracking of two structures in the linguistic input or a general tendency to relax ME.

It was predicted that bilingual adults would be quicker and more accurate at learning two-to-one word-object pairs than monolingual adults. Also, it was predicted that the presence of speaker identity would further benefit bilingual adults' learning of two-to-one word-object pairs due to them being more experienced than monolingual adults in using socio-pragmatic information to track multiple structures in their linguistic input.

Method

Participants

Forty monolingual (M_{age} = 22.80, SD = 4.56, 4 male) and forty bilingual (M_{age} = 23.58, SD = 3.71, 10 male) participants were recruited through SONA (the departmental online recruitment system) and advertisements on social networking websites. Half of the participants in each language group were randomly assigned to the one-speaker condition, and the other half the two-speaker condition. Nine additional participants were tested but excluded due to technical difficulties (n = 8) and experimenter error (n = 1).

Participants rated their language proficiency on a 10-point Likert scale from 1 (limited knowledge) to 10 (highly proficient). Monolinguals rated their English proficiency at an average of 9.95 (SD = 0.22). Ten monolingual participants indicated exposure to additional languages, but were considered functionally monolingual, as all such proficiency ratings were below 4 (M = 2.23, SD = 0.93), a similar cut-off to that used in Poepsel and Weiss (2016). The bilingual group rated the proficiency of their first language at an average of 9.85 (SD = 0.43) and that of their additional languages at an average of 7.36 (SD = 2.01).

Materials and apparatus

Fourteen images of unfamiliar objects and 20 novel words were selected from the Novel Object and Unusual Name (NOUN) Database (Horst & Hout, 2016). Sound files of the novel words were generated using the system voices Kate (female voice) and Daniel (male voice) on Macintosh computers. Pictures were randomly paired with the novel words for each participant, such that there were eight one-to-one word-object pairs and six two-to-one word-object pairs. In the one-speaker condition, all words were uttered by the same speaker. The gender of the speaker was counterbalanced across participants assigned to the one-speaker condition. In the two-speaker condition, half of the words were uttered by a male, and the other half a female. For words in the two-to-one word-object pairs, the two words referring to the same object were uttered by voices of different gender. The gender of speaker of each word was counterbalanced across participants assigned to the two-speaker condition. In addition, eight images of familiar objects were selected from the TarrLab Object Databank (1996) for use in the familiarisation trials. Sound files of the familiar words were generated using the system voice Allison (female voice) on Macintosh computers. Note that this was a different voice from those used in the test trials, so that the participants did not have any reliable information on what language(s) the speakers in the test trials spoke. The pictures and audio files of words were presented on a Macintosh computer using PsychoPy (Peirce, 2009).

Procedure

The experiment took place in a quiet room. Participants were tested in groups of less than five people. After receiving an information sheet and signing informed consent, each participant was asked to complete the experiment on a Macintosh computer. Participants were asked to put on headphones for the experiment.

For each trial, the participants saw two pictures presented on the screen. After 500 ms, they heard a word. The target and foil were randomised for screen position (left vs. right) across trials. The participants were instructed to press the right arrow key if they thought the word presented refers to the object on the right and press the left arrow key if they thought the word presented refers to the object on the left. The participants were also instructed to make a guess if they did not know the answer to any of the test trials.

The participants first took part in a familiarisation block, in which they were presented with four trials containing known words and objects. This was to familiarise the participants with the experimental procedure. For the main experiment, the participants first took part in eight CSSL blocks of 40 test trials each. Within each of the CSSL blocks, each object occurred four times as the target and four times as the foil. The screen position of the target and foil were pseudo-randomised, such that the target appeared an equal number of times as the left and as the right object. Words in the one-to-one word-object pairs occurred four times within a block, whereas those in the two-to-one word-object pairs occurred only two times within a block. The order of trials within each block was pseudo-randomised, such that none of the objects appeared in two consecutive trials. An important point to note is that the participants were not provided with any information on the number of languages involved in the main experiment – the only socio-pragmatic cue available to them was the number of speakers in the task. The participants were allowed to take a short break after every two blocks. After all eight blocks, the participants were exposed to each one-to-one word-object pair 32 times and each two-to-one word-object pairs 16 times.

Immediately after the eighth CSSL block, the participants took part in an ME block containing eight test trials. Each trial featured one of the objects from the one-to-one pairs from the CSSL blocks and a new unfamiliar object. Each object occurred one time as the target and one time as the foil. As in the CSSL blocks, the screen positions of the target and foil were pseudo-randomised. For each of the first four trials, the participants heard a word that they had just had the opportunity to learn during the CSSL blocks. These four trials served the purpose of familiarising the participants with the new unfamiliar objects and to control for a possible novelty bias during later trials, where the new unfamiliar objects were the target. For each of the final four trials, the participants

heard a new novel word, which was spoken by the speaker who spoke the word for the foil in the same trial. These final trials were critical for determining the extent to which the participants relied on ME when learning new words. If a participant was relying on ME, they would be more likely to choose the familiar object in the first four trials and the less familiar objects in the last four trials. However, if a participant was relaxing ME, their performance would be at chance level – choosing either object as the answer in any given trial.

Upon completing the ME block, all participants were given a full debrief and received £3.50 for taking part in the experiment. Each testing session lasted less than 30 minutes.

Results

Learning over the training blocks

Data from six participants, one from the monolingual group and five from the bilingual group were excluded from analysis, due to them not demonstrating learning across testing blocks (i.e., average proportion correct across first two blocks > average proportion correct across final two blocks).

To compare whether number of speakers had influenced the monolingual and bilingual adults' learning of the two types of mappings, generalised linear mixed-effects (GLM) modelling was used to predict the adults' response accuracy. The data for GLM modelling consisted of the response accuracy from each participant on each trial, giving a total of 23680 observations.

A series of GLM models were fitted using the glmer function (family = binomial) in the lme 4 package in R. A backwards elimination approach was used, entering as fixed factors: language group, speaker number, block, mapping type of the target (whether it had one or two labels), and mapping type of the foil. Extraneous variables, including participant gender and speaker gender, did not influence the participants' performance. For training accuracy, the best model (*AIC* = 19977.7, *BIC* = 20131.1, *logLik* = -9969.9, deviance = 19939.7) given the data is the model with the following fixed effects: the three-way interaction, all two-way interactions, and main effects of block, language group, and target mapping and the main effect of foil mapping; the following random intercepts: subject, word, target, and foil; and the following random slopes: block on subject and language group on word and target.

As expected, there was a significant effect of block (β = 0.26655, 95% CI [0.2204, 0.3127]), suggesting that, in general, performance improved across testing blocks. The main effect of target mapping was also significant (β = 0.74309, 95% CI [0.5191, 0.9670]). To our surprise, and contrary to Benitez et al. (2016), the participants were *better* at learning the two-to-one than one-to-one mappings. There was also a significant main effect of foil mapping (β = 0.26248, 95% CI [0.1826, 0.3424]), suggesting that performance was better if the foil in a given trial was a two-to-one mapping. In addition, the interaction between block and target mapping was also significant (β = 0.06914, 95% CI [0.0194, 0.1189]), showing a convergence of the participants' performance in learning the two mapping types across blocks, such that although their learning of the two-to-one mappings was better than that of the one-to-one mappings across blocks, their learning rate for the one-to-one mappings was steeper.

Though there was no significant main effect of language group, the interaction between language group and target mapping was significant (β = -0.49190, 95% CI [-0.8068, -0.1770]), indicating that although both language groups were better at learning the two-to-one mappings, the monolingual group's performance difference between the two mapping types was greater than that of the bilingual group.

Finally, there was a significant three-way interaction between block, language group, and target mapping (β = 0.08267, 95% CI [0.0103, 0.1551]; see Figure 1). The three-way interaction suggests that, for the monolingual group, the learning rate of the two-to-one mappings was more gradual than that of the one-to-one mappings, whereas for the bilingual group, there was faster learning of the two-to-one mappings over the blocks.

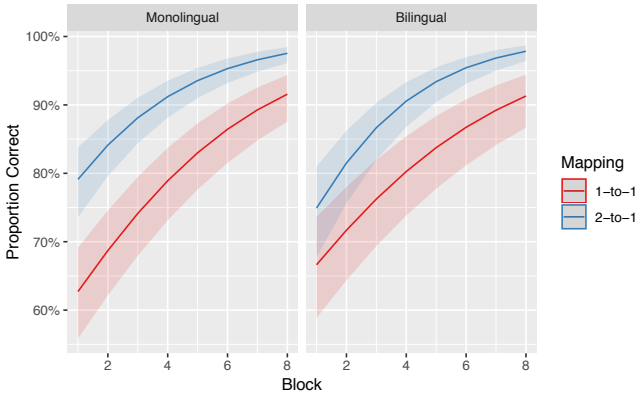

Figure 1: Three-way interaction of block, language group and target mapping.

Performance on the ME task

Though there were no significant main effect or interactions with number of speakers in the task, it was possible that monolingual and bilingual speakers relied on different strategies – either relaxing ME or successfully tracking two labels in the linguistic input would produce a similar pattern of results. In order to determine whether the two language groups relied on similar strategies, their performance in the ME block was analysed. In any given trial, if a participant picked the object that was in line with the application of ME, they scored 1, otherwise they scored 0. Similar to the treatment of the data from the CSSL blocks, GLM models were fitted to participants' scores on each trial (592 observations). Predictor variables of the GLM models were language group, speaker number, and word type (familiar vs. new), and a backwards elimination approach was used.

Extraneous variables, including participant gender and speaker gender, did not influence the participants'

performance. The best model (*AIC* = 180.6, *BIC* = 202.6, *logLik* = -85.3, deviance = 170.6) given the data is the model with the following fixed effects: the two-way interaction and the main effects of language group and speaker number; and the random intercept of subject.

Of particular note, the significant interaction between language group and speaker number (β = 3.3748, 95% CI [0.0054, 6.7442]; see Figure 2) suggests that although both language groups were able to systematically apply ME, there was a tendency for the bilingual group to relax ME when there was only one speaker in the task.

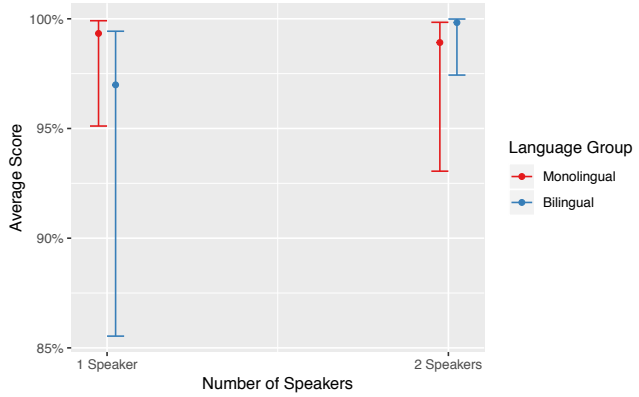

Figure 2: Interaction between speaker number and language group.

Discussion

Using a CSSL paradigm, the influence of speaker identity on monolingual and bilingual adults' learning of one-to-one and two-to-one word-object pairs was examined. In line with previous research (e.g., Benitez et al., 2016), our results showed that both monolingual and bilingual adults are capable of learning one-to-one and two-to-one word-object mappings through CSSL. Yet, inconsistent with Benitez et al.'s main finding, both groups of participants in the present study were better at learning the two-to-one than one-to-one word-object mappings. This could be due to the imbalanced number of objects for each type of mapping – there were six objects that mapped onto two words, whereas only four objects mapped onto one word. As the majority of the objects had two names, it was possible that the participants had formed an expectation that each object could take on two names and used this as a learning strategy for the task.

This explanation is given further weight by the finding that the participants were more likely to accurately map a label to the target object if the foil object was a referent of a two-to-one mapping. The indication here is that, in any given trial, if a participant had already learnt two labels for the foil, they would map the different word presented to the target, due to the foil already taking on the expected maximum number of words. Yet, in order to detect that some objects were named with one, and others with two, labels, participants had to gain this knowledge from tracking implicitly the association between particular words and objects over multiple scenes. That participants were adept at acquiring both one and two labels for objects so early in training demonstrates the power of this learning mechanism. Yet, it should also be noted in Benitez et al.'s study, there were instances where two-to-one mappings were better learnt than one-to-one mappings in that the presence of a second label seemed to have improved learning of the first label. Our task could be showing a similar advantage.

However, there were subtle differences in the learning trajectory of the monolingual and bilingual speakers in our study. The significant three-way interaction between block, language group, and target mapping shows that the learning of the two-to-one mappings was different for the two language groups. The performance of the monolingual group showed less improvement in learning of the two-to-one mappings, whereas the bilingual group had a steeper learning rate for the two-to-one compared to one-to-one mappings. This steeper learning rate could be due to their experience with language. In bilingual adults' linguistic environment, two-to-one word-object mappings would be more dominant than one-to-one word-object mappings. This experience could have benefited them in learning the two-to-one mappings in the task, which is in line with the finding of Kalashnikova, Mattock and Monaghan's (2015) study that bilingual experience would lead to more flexible use of ME, exhibited by higher tendency to accept lexical overlap.

Alternatively, the observed difference between the two language groups could be due to the monolingual adults displaying an early advantage in learning the two-to-one mappings from the first testing block, whereas the bilingual adults' learning of the two mapping types did not differ until the third testing block. A possible explanation to this initial difference of the learning of the two-to-one mappings could, again, relate to the imbalanced number of objects pertaining to each type of mapping. The imbalanced number may have served as a cue for the monolingual adults to more readily learn two words for one object, which could have been salient because this was inconsistent with their usual experience (i.e., one-to-one word-object mappings being the norm). For the bilingual adults, as they frequently confront two-to-one word-object mappings, the imbalance may be less salient and thus a less effective cue to influence their cross-situational learning early on in the experiment. These significant interactions suggest that language experience plays a role in the application of different word-learning strategies.

However, our results for the bilingual participants do not tally with those of Benitez et al.'s (2016) finding, which showed that bilingual adults' learning of two-to-one word-object mappings in a CSSL task was worse than their learning of one-to-one mappings. In Benitez et al.'s study, participants were presented with four objects and four words at a time during training, whereas the participants in the present study were only presented with two objects and one word at a time. The complexity of Benitez et al.'s task could have favoured the learning of one-to-one mappings. In their study, although the number of co-occurrences of each corresponding word-object pair was the same for both mapping types, the spurious

co-occurrences of unpaired word-object mappings was higher for the two-to-one mappings, making the learning of the two-to-one mappings more difficult than that of the one-to-one mappings. In the present study, although the participants were presented with fewer tokens of the two-to-one mappings, the reduced number of objects and words in a given trial were likely to have more closely mimicked actual word-learning experiences than Benitez et al.'s task, making the learning of both types of mapping relatively easy to the participants in the present study.

In addition, the design of the present study required participants to make a decision about a pairing on every trial, unlike in previous studies where participants went through a familiarization phase and then a test phase. This could have made the participants' learning of the word-object mappings more explicit and highlighted to the participants that the majority of the mappings were two-to-one, giving rise to the observed better learning of the two-to-one mappings. Determining the extent of referential ambiguity and the relative occurrence of two-to-one versus one-to-one mappings in the language learner's experience will enable us to determine more closely which experimental task better resembles natural language learning.

In contrast to our prediction, manipulating speaker identity did not influence CSSL of either language group. It was perhaps less surprising for the monolingual group, as Poepsel and Weiss (2014) found that manipulating speaker identity did not affect monolingual adults' learning of word-object mappings that violate ME. Taking into account Benitez et al.'s (2016) finding that linguistic cue could affect bilingual adults' learning of two-to-one word-object mappings and the non-significant effect of speaker identity in the present study, it is likely that information about the languages involved in the linguistic input per se is more important than speaker identity as a cue in influencing bilingual adults' word learning. In reality, information about languages in the input is a more reliable cue than speaker identity, as one speaker could speak multiple languages and different speakers could speak the same language.

Nevertheless, speaker identity did seem to have an effect on the strategy used by the two language groups. In the ME block, both language groups demonstrated majority use of ME. Yet, when there was only one speaker involved in naming objects, the bilingual group showed a greater tendency to relax ME (Kalashnikova et al., 2015). This suggests that although speaker identity did not have an effect on the observed responses of the participants in the CSSL task, it may have altered the strategies that they use. The bilingual speakers were more likely than the monolingual speakers to relax ME when more than one language structure was used by the same speaker. This may have been due to greater familiarity by bilingual speakers that individuals may speak more than one language.

In a broader sense, the results of the present study have demonstrated that language learners can flexibly use multiple word-learning strategies to learn different language structures in solving the "Gavagai" problem. In an environment with multiple language structures, learners have to quickly discriminate the different structures (Gebhart, Aslin & Newport, 2009). Previous studies (e.g., Qian, Jaeger & Aslin, 2012) have shown that socio-pragmatic cues, such as a voice change, can help learners focus on the syntactic structures available in the input. The lack of overall influence of speaker identity on the CSSL task in the present study should, therefore, not be taken as evidence that socio-pragmatic cues do not contribute to word learning, as it could instead be that word learning across multiple situations does not rely so heavily on this particular socio-pragmatic cue. Other socio-pragmatic cues, for example information on the languages that the speakers in the CSSL task speak or more information on the speakers' linguistic identities, might be more effective in influencing learners' reliance of word-learning strategies. Nevertheless, the results of the present study, in terms of trajectory of learning on the CSSL task and performance in the ME task, suggest that the extent to which a word learning strategy is relied upon depends in part on an individual learner's previous experience with languages and the learning context. These results also begin to give us some insights into how language experience, contextual cues and task design contribute to shaping learners' use of different word-learning strategies.

In summary, we replicated previous studies that found that language learners are adept at accepting multiple labels for the same object. Curiously, when only one word is heard, and two possible objects viewed, both monolingual and bilingual speakers were better at learning two labels for an object than one label for an object. The effects of participants' linguistic background exerted subtle effects on this ability, with a steeper learning rate of two-to-one mappings for bilinguals compared to monolinguals, and a greater ability for bilinguals to be flexible in the application of the ME constraint. These results show that the parameters determining how word-object mappings are acquired and the role of language experience in driving this learning are complex and varied.

Abstract

We explore a nonparametric approach to cognitive modeling. Traditionally, models in cognitive science have been parametric. As such, the model relies on the assumption that the data distribution can be defined by a finite set of parameters. However, there is no guarantee that such an assumption will hold, and it may introduce undesirable biases. For these reasons, a nonparametric approach to model building is appealing. We propose a novel framework that combines Gaussian Processes with active learning (GPAL), and evaluate it in the context of delay discounting (DD), a well-studied task in decision making. We evaluate GPAL in a simulation and a behavioral experiment, and compare it against a traditional parametric model. The results show that GPAL is a suitable modeling framework that is robust, reliable, and efficient, exhibiting high sensitivity to individual differences.

Keywords: Gaussian processes; optimal experimental design; delay discounting; nonparametric modeling; Bayesian inference

Introduction

Models of human cognition are built by designing an explanatory or descriptive model that fits data generated in a behavioral experiment. Although a model's parameterization is motivated by assumptions about the cognitive process under study, the empirical data strongly influence model design. Because of this, the design of the behavioral experiment from which the data were generated (e.g., which stimuli were presented to participants) can introduce bias into the model. This can occur, for example, by not sampling the stimulus space adequately, which can then lead to an incomplete or imprecise model. Two ways to reduce such bias are to not commit in advance to which stimuli should be sampled and to make as few assumptions about the cognitive model as possible, such as parameterization and functional form. In other words, make model-building and data collection as data-driven as possible, at least in the initial stage of model development. Gaussian processes (GP) provide a means of achieving these two goals, functioning as a nonparametric framework for experimentation. We evaluated the viability of a GP-based approach for cognitive modeling in humans.

Researchers in psychology have explored the use of GP to model human behavior (e.g., Cox, Kachergis, & Shiffrin, 2012; Griffiths, Lucas, Williams, & Kalish, 2009; Schulz, Speekenbrink, & Krause, 2018; Song, Sukesan, & Barbour, 2018) but it has yet to be a wide-spread approach. Here, we propose a flexible framework for cognitive modeling by combining GP with active learning (GPAL). GPAL extends traditional GP regression by including appealing features for cognitive science tasks. GPAL is capable of simultaneously modeling the data with minimal assumptions and optimizing the experimental design to find the underlying function efficiently. By virtue of being nonparametric, GPAL shows high sensitivity to individual differences and is able to capture a wider array of patterns compared to parametric approaches. This sensitivity should provide high-fidelity models. Optimization is desirable to minimize the length of a testing session, such as when experimentation is expensive (neuroimaging research) or time-constrained (clinical or special populations). While models produced by the nonparametric framework may not provide interpretable parameters, inferences about cognitive functioning can still be made by examining mathematical properties of the function, such as gradient, curvature or area under the curve.

In our study here, we examined the efficiency, reliability, robustness, and sensitivity of GPAL in the context of modeling delay discounting (DD). Data were collected from 30 participants in a delayed discounting task (e.g., "Do you prefer $10 today or $40 dollars in two weeks?"), which measures an individual's ability to delay gratification. This is a common task in decision-making research, and performance shows a strong correlation with other psychological phenomena, including impulsivity and addiction (Green & Myerson, 2004). The one-parameter hyperbolic model is a popular model that assumes future rewards decline in value hyperbolically with the length of the delay. Recent work from Cavagnaro, Aranovich, McClure, Pitt, and Myung (2016) used adaptive design optimization (ADO) to estimate the parameters of the function in an active learning fashion. One of the conclusions from that study is that none of the six models tested were able to capture the full range of behavioral patterns participants displayed in the task. Thus, DD provides a good test-bed in which to evaluate GPAL. The present investigation represents the first step toward validating GPAL as a premier modeling tool for cognitive science research.

Gaussian Process with Active Learning (GPAL)

This section provides background on each component of the proposed GPAL framework. Figure 1 shows a schematic representation of it.

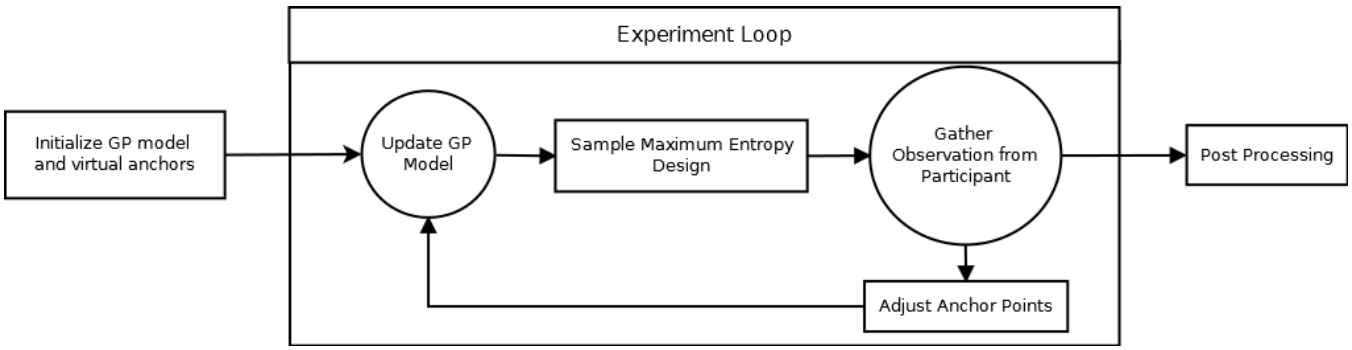

Figure 1: Schematic representation of the GPAL framework. The task is formulated as an active learning based classification task. Virtual anchors are used to restrict the sampling of the design space. On each trial in the experiment loop, an optimal design is picked from the restricted design space according to the maximum entropy criterion, an observation is made, and the GP model and virtual anchors are updated. After the looping, a post processing step may be used to refine the final GP model.

Gaussian Processes

Gaussian processes (GP) are tools for nonparametric Bayesian modeling that establish priors over functions and are a popular approach in machine learning for regression and classification tasks (Rasmussen & Williams, 2006). Formally, GP is a stochastic (random) process where any subset of random variables forms a Gaussian distribution. For a set of observed value pairs (X, f) and a set of unobserved pairs $(\widetilde{X}, \widetilde{f})$, the joint posterior distribution under GP is given by

$$\begin{bmatrix} f \\ \widetilde{f} \end{bmatrix} \sim \mathcal{N}\left(\begin{bmatrix} \mu \\ \widetilde{\mu} \end{bmatrix}, \begin{bmatrix} K_{f,f} & K_{f,\widetilde{f}} \\ K_{\widetilde{f},f} & K_{\widetilde{f},\widetilde{f}} \end{bmatrix} \right) \tag{1}$$

where K is a kernel function that defines the covariance between two function values. The kernel function used in this study is the squared exponential kernel which is defined by a length scale parameter l that controls the smoothness and the variance parameter σ^2, which is a measure of the average distance to the mean. This kernel function is a popular choice that has several desirable properties and is known to work well with very smooth functions. The posterior in Eq. 1 can then be used to model $\widetilde{F}$ using the conditional of the multivariate normal distribution.

Many tasks in cognitive science such as DD are not able to observe f directly due to the nature of human experiments. Instead, it is common to give participant choices resulting in multinomial observations. In the case of DD, participants are given two choices on each trial, thus resulting in binomial observations which can then be modeled as a GP binary classification task. This is commonly done by applying a sigmoid transformation function (e.g., probit in our case) to restrict the predicted values to a unit interval. As a consequence of this transformation, the likelihood is no longer Gaussian and requires the use of approximate methods to be estimated, such as expectation propagation as done here. We direct the readers to Rasmussen and Williams (2006), and Vanhatalo et al. (2012) for a comprehensive tutorial on GP and related techniques.

Active Learning

Behavioral experiments can be expensive in terms of both money and time, and the more time an experiment takes, the greater the chance that data quality will suffer due to fatigue or boredom. Systems that incorporate active learning are appealing because they mitigate these problems by optimizing efficiency through identifying highly informative design points based on previous observations (e.g., Cohn, Ghahramani, & Jordan, 1996). It is possible to incorporate active learning in GP based system by deriving a measure of information from the GP and then finding the design point that maximizes this objective function. For our experiment, we used entropy as an information theoretic objective function. We use the derivation of entropy in Houlsby, Huszr, Ghahramani, and Lengyel (2011) which approximates the entropy for GP classification.

Like many tasks in cognitive science, design points in DD are sampled from a discrete space. This space needs to be sparse enough to allow human subjects to make meaningful and differentiable choices. Thus, the search space for optimizing experiments is significantly smaller than in other areas that would use this kind of approach, thereby making grid search a better choice to maximize the entropy function than the proposed method in Houlsby et al. (2011).

Constrained Gaussian Process

Models of natural phenomena are often constrained by prior knowledge or experimental design. For example, when studying natural organisms, the range of the model can be constrained by the physical limitations of such organism. Similarly, a model can be constrained by the experimental design. For example, researchers often design experiments such that some of the outcomes are trivial and well-anticipated. Traditionally, these factors are incorporated in the model design and the range of the parameters and design space. This is a bit more difficult to do in GPAL since it is built to be a fully general modeling tool. It is, however, possible to impose some "reasonable" constraints on the bounds, derivatives, and convexity of a GP. For a more detailed explanation of these

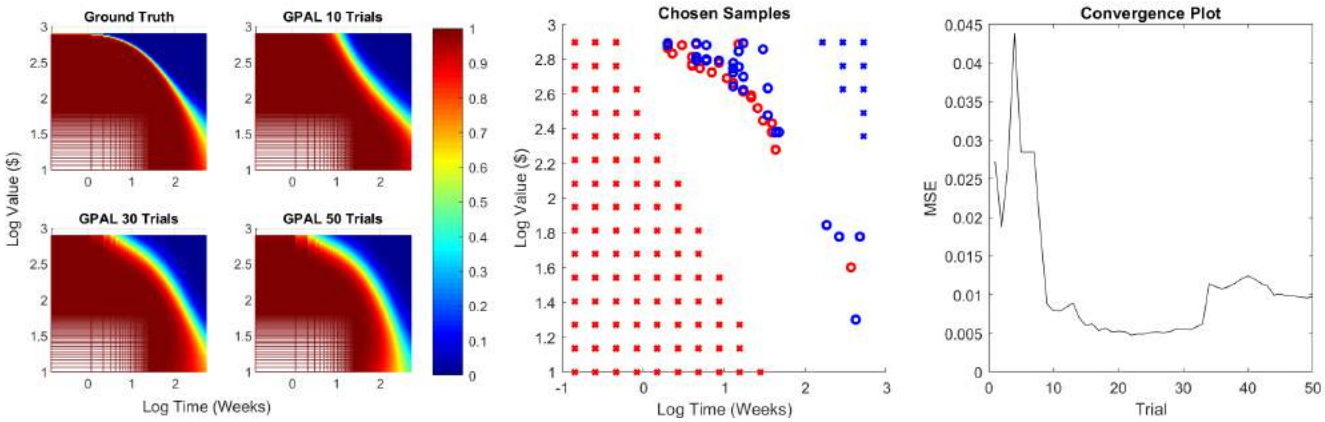

Figure 2: Example of a GPAL simulation using a hyperbolic model as the ground truth. The left panel show GPAL estimated models at four different trials in a top-down view where the z-axis represents the probability of choosing the delayed reward as a function of the two-dimensional, logarithmically scaled design space of (t_{LL}, A_{SS}). The x-shaped and circle-shaped samples in the middle panel represent virtual anchor points and design points selected by GPAL, respectively. The blue and red circles represent choosing the immediate and delayed reward, respectively. The convergence plot in the right panel represents the mean squared error (MSE) between the model at each trial and the ground truth.

methods, see Da Veiga and Marrel (2012). For our delay discounting experiment, we focus on two properties that are often desired in psychological tasks: (a) monotonicity; and (b) local constraints.

Tasks based on subjective preference such as DD often assume that humans follow the axioms of rationality. This leads to researchers building monotonic models that predict a preference for a choice with a higher reward value (or a shorter delay) over another choice with a lower reward value (or a longer delay), if all other things are equal. One way to force monotonicity in GP models is by systematically adding virtual observations in areas where the constraint is violated (Riihimki & Vehtari, 2010). Specifically, this is done by building a joint model of the GP and its derivative. The derivative domain is then used to inject virtual observations into the model when the derivative of the GP violates the monotonicity constraint.

Regarding local constraints, experiments are often designed in a way such that the outcomes are trivial for some design points. For instance, the probability of preferring a choice of $790 now to another choice of $800 in 10 years should be virtually equally to 1. Ideally, we would like GPAL to avoid sampling such trivial design points. Again, inspired by Riihimki and Vehtari (2010), GPAL implements local constraints as follows: We can extend their idea of virtual noiseless observations to local constraints by placing them in trivial regions. We refer to these virtual observations as "virtual anchors". Virtual anchors act as a prior to the function being estimated by reducing its variance so as to avoid sampling in this region. They also have the benefit of removing the need for initial random sampling to start the active learning process. Further expanding on this idea, we can cover large areas of the design space with virtual anchors and systematically remove them using a moving margin that recedes when a design point is sampled nearby. In our simulations and experiment with human participants described below, we used a linear receding margin, though other schemes could also be used, depending upon the problem at hand. We would like to note that these are preliminary results and future work will focus on increasing the robustness of the model.

Models of Delay Discounting

Delay discounting (DD) is a preferential choice task that is often employed to measure impulsivity by quantifying the preference of an sooner-smaller reward (*SS*) against a later-larger reward (*LL*). This measure of impulsivity has been linked to various mental illnesses such as addiction, gambling, and ADHD (Koffarnus, Jarmolowicz, Mueller, & Bickel, 2013; Sharp et al., 2012; Reynolds, 2007). Models of DD typically start by defining the relation between the value of a reward A at time t as:

$$V = AD_t \tag{2}$$

where V represents the discounted value of A, and D_t the discounting factor. Under this framework, DD behavior is modeled by fitting choice data to a discounting curve that models D_t as a function of t. A popular model of choices is the 1-parameter hyperbolic model (Mazur [1987]):

$$D_t = \frac{1}{1+kt} \tag{3}$$

where $k(>0)$ is the parameter related to impulsivity in that high values of k are associated with high levels of impulsivity. Participant choices are fitted to this model by defining a sigmoid choice function for the probability of choosing the LL option over the SS option:

$$P(LL|k,\varepsilon) = \frac{1}{1+e^{\varepsilon(V_{SS}-V_{LL})}} \tag{4}$$

where V_{SS} and V_{LL} are the discounted values of the SS and LL choice options, respectively, and ε (>0) is a free parameter

reflecting consistency of choice behavior. To aid participants in making more meaningful choices and ease visualization, we fix A_{LL} to \$800 and t_{SS} to 0 weeks (i.e., an immediate reward). Thus, the design space becomes a two-dimensional space of (t_{LL}, A_{SS}).

Cavagnaro et al. (2016) extended the hyperbolic model to include active learning by using an adaptive design optimization (ADO) framework. ADO is a parametric framework for Bayesian optimal adaptive experimentation that can be used to select the most informative design for parameter estimation as well as model discrimination (Cavagnaro, Myung, Pitt, & Kujala, 2010; Myung, Cavagnaro, & Pitt, 2013). For our experiments, we use ADO as baseline to compare the performance of GPAL against a parametric model.

Simulations of GPAL

We first tested the feasibility of GPAL in a simulation study in which GPAL was to recover a hyperbolic function used in Cavagnaro et al. (2010) with 10% noise in the observations. Virtual anchor points were incorporated by adding noiseless design points with a value of one or zero at the extreme values of the design space. Figure 2 (left panel) shows an example of the performance with a top-down view of the GPAL estimated DD models at four different trials. Each plot in the left panel represents the probability of choosing the delayed reward as a function of the "later-larger" time t_{LL} and the "sooner-smaller" value A_{SS}. Both dimensions are plotted in the log domain to highlight the difference between functions in our experiments. The decision boundary refers to the regions of interest where the probabilities are closer to 0.5.

The results suggest that GPAL can achieve reasonable convergence within the first 20 trials. Afterwards, as shown in the right panel, we see a decrease in performance (rise in MSE), likely due to Gaussian noise. The design points (red and blue circles) sampled by GPAL at the end of 50 trials, as shown in the middle panel of Figure 2, are reasonable choices that lie close to the decision boundary. The virtual anchors (red and blue x-shaped symbols) provide a reasonable starting point and leave enough distance in case the decision boundary needs to be pushed in one direction or the other. That is, the example shown on the left panel shows that by trial 10 the curvature hasn't been captured yet and the model is still heavily influenced by the anchors. By trial 30, we see a generally close match in shape, with a slight difference in very steep regions as expected due to Gaussian noise.

Modeling Delay Discounting Using GPAL

Experiment

We recruited 30 participants from a pool of undergraduate students at Ohio State University. Participants were asked to perform a DD task over two sessions, ADO and GPAL. The ADO session used ADO to fit the participant choices to the hyperbolic model. The GPAL session fit the data using the GPAL framework with virtual anchors. Both sessions were further divided into two identical and independent sub-sessions to test for reliability.

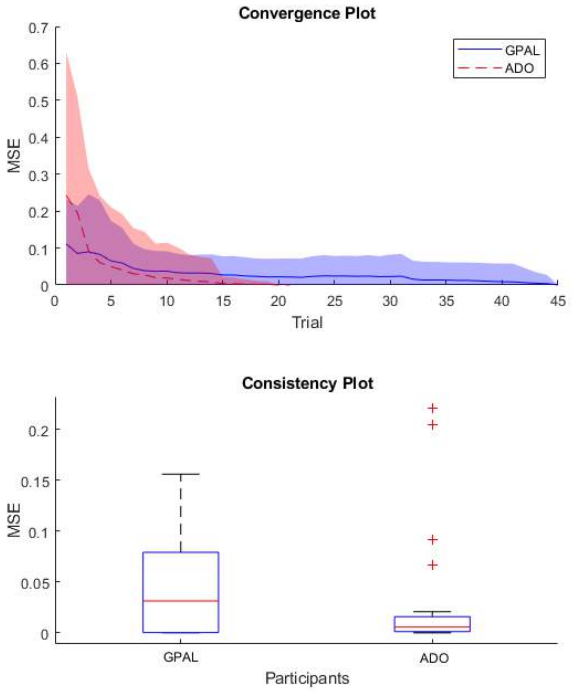

Figure 3: Aggregated results from the experiment. The top panel shows the MSE between the model at each trial and the last. The bottom panel shows the MSE between the first and second session for both experimental conditions.

The sessions were presented in random order and participants were unaware of the identity of the session they were in. Each trial consists of a preference choice presented in the format "\$$X$ now or \$800 in Y time in the future". The value of X (i.e., A_{SS}) ranged from \$10 to \$790 in multiples of 10 whereas the value of Y (i.e., t_{LL}) took on 48 values ranging from 1 day to 10 years spaced on a logarithmic scale. Each session started with 5 practice trials to familiarize participants with the task. This was followed by 20 trials for ADO and 50 trials for each of the two GPAL sub-sessions, for a total of 120 experimental trials. The two GPAL sessions were presented as a single testing block with no break between them. The number of trials was chosen based on previous ADO experiments and GPAL simulations. All the GPAL software was developed and implemented in MATLAB with the aid of *GPStuff* library for Gaussian processes (Vanhatalo et al., 2012).

Results and Analysis

We tested GPAL on its efficiency, reliability, robustness and sensitivity. Efficiency was assessed by comparing the convergence speed between the two frameworks, ADO and GPAL. We expect efficient models to converge quickly to a final solution. We measured this by the speed at which they approach their final solution. Figure 3 (top panel) shows the MSE at

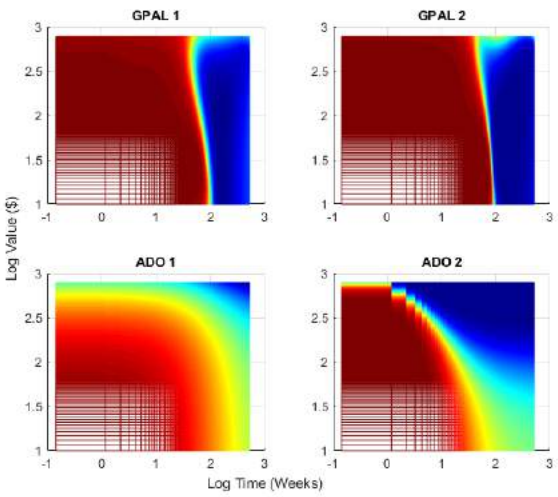

Figure 4: An example participant with consistent results between sessions in the GPAL condition but with inconsistent results in the ADO condition.

each trial between the current estimated model and the last model of the experiment. Both models achieve reasonable convergence quickly with ADO flattening out at around 20 trials and GPAL at 30. GPAL starts with the advantage of having access to the virtual anchors, which act as priors. This means that the initial estimate is much closer to the its final solution compared to ADO which is reflected in the initial values of the results. However, ADO shows faster convergence, which can be seen in the rate and consistency at which the MSE decreases. This is an expected result since ADO assumes a hyperbolic model which allows it to make stronger inferences. We also expect efficient models to pick design points that lie close to the decision boundary of each participant, as these represent the most informative points.

One way to assess reliability is by comparing the GPAL function across the two testing sessions. GPAL, if reliable, should produce consistent results across the sessions, and this is what we find. Figure 3 (bottom panel) shows the MSE between sessions for all 30 participants in both conditions. Overall GPAL performance was good, with an average difference of 0.047, which is deemed quite small. For comparison the average MSE between ADO sessions was 0.026. Again, this is expected due to the added flexibility of GPAL.

As seen in Figure 3, the ADO condition had several outliers that were very inconsistent across sessions. Interestingly, these participants were much more consistent in the GPAL condition. Figure 4 shows an example in which the results for the GPAL condition are significantly more consistent than their ADO counterpart. This was the case for all the outliers in the ADO condition. We find that this phenomena tends to happen when GPAL predicts a function shape that is hard for the hyperbolic model to fit in ADO.

Further inspecting the GPAL results, we find that inconsistent samples are largely produced by a shift in the decision

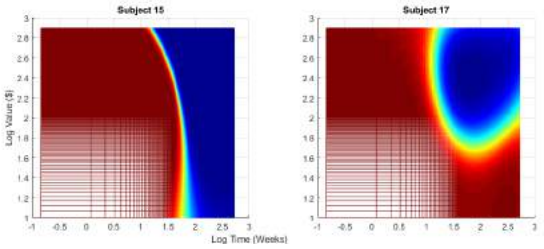

Figure 5: Two selected examples of non-monotonic patterns that consistently emerged during our experiments. The left panel is an example of a non-monotonic pattern with respect to the monetary reward dimension (i.e., y-axis). The right is an example of a non-monotonic pattern with respect to both dimensions.

boundary in the extremes of the design space. Points in this region are also more influential for GPAL because they determine the concavity of the function whereas for ADO, this is determined by the form of the hyperbolic function. These results also suggest that participants tend to be less consistent for designs in this region. Methods to address this problem will be discussed in the next section.

Regarding robustness, we assessed this property by examining a model's ability to predict unseen data. Operationally, robustness was measured by turning an estimated model, whether ADO or GPAL, into a classifier by setting a decision threshold for the predicted probability to generate predicted outcomes. We then tested classification performance by performing cross validation between the observations of each session. In other words, the GPAL-estimated model was used to predict the designs picked by ADO and the ADO-estimated model was used to predict the designs picked by GPAL. Note that both datasets are comprised of data points that are considered to be hard by their respective framework, making them significantly harder to predict than a random sample. We found that ADO performed literally at the chance level of 49.99% accuracy whereas GPAL achieved a 56.53% accuracy. While this result is not particularly impressive, we take this result as evidence that GPAL is able to produce a better classifier or learn better from noisier data than ADO. This result can also be taken as evidence of higher sensitivity to individual differences, since we expect a sensitive model to produce a better and more robust classifier.

Discussion and Conclusion

How does one build a model of human cognition? We introduced GPAL as a data-driven (bottom-up), nonparametric approach with the aim of overcoming biases in parametric modeling approaches for model development and inference. The diversity of data patterns in our experiments illustrates these features of GPAL. GPAL can uncover concave, convex and approximately linear shapes, and do so quickly, providing the modeler with a higher fidelity description of performance. We envision researchers using this information in one of two ways. The straightforward way is to use GPAL as an exploratory tool for providing an unbiased picture of the raw

data to aid the formulation of a parametric model. This gives traditional models a stronger justification in which to ground their assumptions. A second way to utilize GPAL is to replace parametric models altogether. While this second approach requires a paradigm shift in the way models are interpreted, it comes with the potential benefit of providing more accurate measurements. Below we illustrate these ideas by discussing the benefits of GPAL in the context of DD.

Previous models of DD have assumed a monotonic function in both dimensions of money and time. This is a reasonable assumption to make since participants are expected to prefer larger sums of money and shorter time spans. However, Figure 5 shows a few instances that violate this "rationality" assumption. It might be enticing to think that non-monotonic functions in GPAL are a product of noise or model biases. If this is the case, GPAL can be adapted to produce monotonic function using the approach in Riihimki and Vehtari (2010). However, we believe that these non-monotonic patterns are not caused by artifacts. To show this, we focus on the two patterns exemplified in Figure 5. These patterns can be seen across several different participants which we do not show in the interest of space. Since these patterns are repeatable and present across several participants, we find it is unlikely that they are a product of random noise. To support this hypothesis, participants that showed non-monotonic behavior were given five additional trials in which GPAL picked designs using gradient information to identify key regions of non-monotonocity. This process gave a chance for participants to correct their choices to reflect a more conventional function. However, only about a fourth of the participants corrected themselves with the rest confirming their previous behavior. We hypothesize that this non-monotonic, irrational behavior is caused by the interaction between non-linearities in the perceived value of money and delay time. Using the two non-monotonic patterns shown in Figure 5, we provide two possible explanations that would produce this outcome. The first pattern on the left could be caused by a "soft" threshold at which the value of money rapidly decreases, making the time component less relevant. Similarly, the pattern on the right could be caused by a threshold in time at which the delayed reward becomes significantly less appealing. In short, we think that being able to observe these kinds of patterns using GPAL can be a powerful tool to justify choices in parametric models.

A more radical idea is to use GPAL as the primary modeling tool. One of the main benefits of a parametric approach is the ability to formulate theories based on a small set of parameter values. In the case of DD, the k parameter of the hyperbolic model is of particular interest because it is thought to be related to an individual's impulsivity. An analysis such as this is not possible when using a nonparametric model like GPAL since the number of parameters is not constant. However, one could still extract meaningfully information from a GPAL-estimated model. One approach that has been explored in the literature is to interpret the hyperparameters of the kernel function (e.g. Wu, Schulz, Speekenbrink, Nelson, & Meder, 2018). In our case however, the hyperparameters of the square exponential kernel do not relate well to the k parameter. A different alternative could be to use the (parameter-free) estimate of the area under the curve (AUC) of the GPAL function across the input space as an alternative to the k parameter. When this was done for the data from our experiment, the AUC shows a positive correlation to the k parameter. This suggest that the AUC could be used as a measure of impulsivity in a fully nonparametric model but more work needs to be done in this regard. More generally, it is possible to attribute meaning to mathematical properties of GPAL models, which would allow GPAL to function as a primary modeling tool. One benefit of this approach is that the increased sensitivity of the framework might produce more accurate measurements compared to their more constrained counterpart. Additionally, these measurements come from mathematical properties which can be applied to other types of models allowing for easier comparison between models.

Future work will also focus on evaluating the performance of GPAL in a wider array of behavioral tasks. This will allow us to show additional techniques that were not applicable to the DD task. We must also address issues that come from combining GP with active learning. We found that GPAL can be overly sensitive when observations were sparse. While our data suggest that the model is likely to converge within 30 trials, we need to develop the means of ensuring model fidelity while not sacrificing efficiency. The source of this problem is likely due to the greedy nature of active learning. One way to address this problem is to extend active learning to include a bias towards region that are hard for human subjects.

In conclusion, the work in this paper represents a first step towards the development of a novel modeling framework in cognitive science. We propose the use of a nonparametric, model-free approach for cognitive modeling based on GP. This framework serves as a middle ground between raw-data, which are hard to visualize, and parametric models, which rely on strong assumptions. The experiments in the DD task showed that GPAL is a practical framework that yields consistent results efficiently. GPAL showed a high degree of sensitivity to individual differences that were able to uncover non-trivial patterns. This is exemplified by the presence of non-monotonic discounting functions that are present in several participants. These characteristics make GPAL a promising tool for constructing unbiased and sensitive models of cognition.

Abstract

There has been much discussion around the Linguistic-Savings Hypothesis (LSH), which postulates that language can affect intertemporal choices of its speakers; the validity of this claim has remained controversial. To test the LSH independent from the possible influencing factors, such as cultural differences, we focused on the Japanese language, which features asymmetric tense marking, in that past tense is grammatically marked but future tense is not. Adopting a within-participant design, we compared the discounting behavior between past and future gains in native Japanese participants. Our results revealed that Japanese speakers tended to discount the values placed on rewards in an asymmetry way: to discount the value of past gains more heavily than that of future gains. We believed our results corroborated the LSH and linguistic relativity.

Keywords: Intertemporal discounting; Intertemporal choice; Linguistic-Savings Hypothesis; Tense; Linguistic relativity

Introduction

Intertemporal choices, regarding trade-offs between time and benefits, are very common in everyday life, such as the decision on whether to spend the salary on a trip to Kyoto immediately after receiving it, or whether to save up for years to buy an apartment in Tokyo. Economical behaviors such as investment and insurance purchasing, as well as health issues such as nicotine addiction and drug abuse, are also manifestations of intertemporal decisions (see Thaler, 1981; Frederick, Loewenstein & O'Donoghue, 2002 for reviews). On a macro level, it may even play a part in very important economic issues such as national saving rates (Springstead & Wilson, 2000). Because of this ubiquity and significance, intertemporal choices remain a topic of lasting research interest.

Numerous studies dealing with intertemporal preference and temporal discounting behavior have shown that people psychologically discount future gain or loss, and tend to discount more for longer temporal distance (Thaler, 1981; Kirby& Marakovic, 1996).

Previous studies have also found that intertemporal discounting behaviors vary individually and culturally (Gell, 1992; Hofstede, 1997). One of the most intriguing hypotheses holds that people's native language may exert an influence on their intertemporal choices (Chen, 2013).

Does language matter in intertemporal discounting?

Whether the language people speak will influence their intertemporal choices has recently been under hot debate. Linguistic-Savings Hypothesis (LSH), proposed by Chen (2013), has been one of the most intriguing hypotheses on this topic. According to Chen (2013), speakers of languages which grammatically distinguish between present and future, such as English, and speakers of languages with no such distinction, such as Mandarin, tend to have different feelings about temporal information, leading to different discounting behaviors. Specifically, for futureless language speakers, the distinction between present and future is vaguely construed, while speakers of languages with separate tense marking for present and future tend to perceive the distinction more clearly. As a result, speakers of a futured language tend to discount future rewards more heavily than those of a futureless language. Chen (2013) substantiated the hypothesis by results from analysis of massive databases of savings rates, health behaviors and retirement assets across many countries. This simple yet intriguing hypothesis has attracted major attention (e.g., by 2018, over 1,790 thousand views on TED talk, 2012).

Meanwhile, the hypothesis has been also criticized and challenged from multiple perspectives. First of all, it has been pointed out that the analysis of massive database is basically indirect (i.e., focusing on correlational relationships). Thus, the validity of causal inferences may be doubtful (Roberts &Winters, 2013). Secondly, it may be difficult to eliminate the influence of cultural differences. Previous cross-cultural analyses of temporal discounting behavior have generated contradictory results (Thoma & Tytus, 2018), thus rendering the results indefensible when taking cultural differences into account. Lastly, empirical evidence on the hypothesis is

mixed. While there is evidence from behavioral experiments in support of the LSH (e.g., Lergetporer et al., 2014), opposite results have also been obtained (e.g., Thoma & Tytus, 2018).

Against this background, our research started with the same point of view with the LSH, but tried to eliminate the influence of alternative explanations, such as the influence of cultural differences, by conducting the experiment using within-participant design.

Asymmetric tense marking in Japanese

In the present study, we examined how Japanese people discounted the value of past and that of future.

Even though the measurement of the intertemporal discount in past is not as familiar as that of future in the field of economics and psychology, it is widely applied in the field of health behavior. The discounting rate of past can be a valid indicator of patience as well as an effective predictor of cigarette and drug abuse.

Previous research found native speakers of English in the U.S. tend to discount the value of future and past gains in a symmetrical way, with no significant difference between the discounting rate for past and future gains (Bickel et al., 2008; Yi et al., 2006). This finding can be explained by the LSH, which predicts that the tense encoding in a language can influence its speakers' time perception and intertemporal discounting behavior. Therefore, native speakers of English are predicted to discount the future and past values in the same way since both past tense and future tense exist in the English language. This symmetric tense marking in English can lead to the symmetric discounting behavior towards past and future gains.

However, not all languages encode tense in the same way. Japanese, for example, has asymmetric encoding in marking only the past tense. The grammaticalization of tense in English, Japanese, and Mandarin is summarized in Table 1.

The LSH can be tested in the Japanese language which features asymmetric tense marking. According to the LSH, the grammaticalization of tense in a language will influence its speakers' discounting behavior towards past and future gains. Therefore, Japanese speakers are predicted to showcase discounting behaviors also in an asymmetric way. To be specific, since there is past tense and no future tense in Japanese, speakers may feel the distinction between past and present more clearly (i.e., larger) than that between present and future, leading to higher discounting rate for past gains than that for future gains.

In the current research, we recruited native speakers of Japanese as participants, and compared the discounting rate of past gains with that of future gains of each participant. Since only Japanese speakers were targeted, the effect of culture was controlled for. Furthermore, the within-participant design also excluded the influence of other potent factors such as individual characteristics, educational level, and economic status between different groups.

To our knowledge, this is the first study to examine LSH directly by comparing discounting rates of past and future gains while excluding the influence of cultural differences as well as other factors.

Table 1: Tense marking in English, Japanese, and Mandarin.

	Past Tense	Future Tense
English	+	+
Japanese	+	-
Mandarin	-	-

Statistical analyses

Indicators and models of temporal discounting

A brief account of the analytical procedure is given in this sub-section. The first step is to estimate the indifference point between two intertemporal choices (e.g., Kirby & Marakovic, 1996; Toubia et al, 2013). An indifference point is reached where the amount available now (following Yi et al., (2006), we regarded 'one hour ago' and 'in one hour' as 'now') is equivalent to the delayed amount in the future. For instance, if a participant preferred to 'receive ¥80,000 (¥10,000 is approximately $100) in one hour' rather than 'receive ¥100,000 in seven days,' but meanwhile chose to 'receive ¥100,000 in seven days' rather than 'receive ¥70,000 in one hour,' we thus assume that the indifference point between now and a delay of seven days lies between ¥70,000 and ¥80,000 and we determined the indifference point at a delay of seven days of ¥100,000 to be the average of two amounts (in the above example, ¥75,000 in one hour). Likewise, the indifference points can be located for the past scenarios. For example, if a participant preferred to 'receive ¥60,000 one hour ago' rather than 'receive ¥100,000 seven days ago,' but at the same time chose to 'receive ¥100,000 seven days ago' rather than 'receive ¥50,000 one hour ago,' we assumed ¥55,000 as the indifference point.

Based on the estimated indifference points, we conducted both statistical and model-based analyses. For statistical analysis, we compared discounting rate and the Area Under the Curve (AUC) between values in the past versus future scenarios. Analysis was based on four models: linear model, exponential model, hyperbolic model, and q-exponential model, among which the fitted models serves as a basis for discussion on participants discounting behavior.

In the following section, we shall explain these methods in detail.

Discounting rate

Discounting rate of specific temporal distance (r_d) can be calculated with the following equation:

$$r_d = \frac{V_0 - \mathrm{V}'}{V_0}$$

where V_0 is the original value and V' the discounted value.

This equation estimates the discounting rate for each specific temporal distance. To reveal the general tendency in

individual participant's discounting behavior, we also adopted AUC and model-based approaches.

AUC

AUC is a very common model-free approach to estimate the discounting behavior (Myerson et al., 2001). To calculate AUC, each indifferent value point should be plotted in the same figure and then lined up to form a curve. The area under the curve is then calculated to be AUC. In general, as a participant discounts the value more heavily, the AUC value become lower.

In the current study, we used the standardized AUC (i.e., ranging from 0 to 1) as an indicator of a general tendency of discounting.

Model-based analyses

In the following explanation of the four models, V', V_0, and d denote discounted value, original value, and the temporal distance, respectively. k and q are discounting and adjusting parameter, respectively.

Linear Model

Linear model is the simplest model to predict how value is discounted with the span of time.

$$V' = V_0 - \mathrm{kd}$$

Exponential Model

Exponential model is the standard model adopted in related empirical works, with an advantage in explaining drastic discounting behaviors.

$$V' = V_0 \cdot e^{-\mathrm{kd}}$$

Hyperbolic Model

Overall, the hyperbolic model (Mazur, 1987) shows a better fit than the exponential model for its strength in predicting a more decelerated rate of value depreciation over time, which resembles discounting behavior.

$$V' = \frac{V_0}{1 + kd}$$

Q-exponential Model

Apart from the most popular models (i.e., the exponential model and the hyperbolic model) in intertemporal behavior study, recent research suggests that q-exponential model could be a better fit since it can be seen as the generalized style of the above models (Cajueiro, 2006; Takahashi et al., 2014).

$$V' = \frac{V_0}{(1 + k(1-q)d)^{\frac{1}{1-q}}}$$

In this model, q is the adjusting parameter and determines the form of fitting model. When q reaches 1, the model equals the exponential model. In contrast, when q reaches 0, the model equals the hyperbolic model.

Behavioral experiment

Participants Five hundred and five Japanese people (M_{age} = 45.08, SD_{age} = 14.55) participated in this experiment, with balanced age groups, i.e., 98, 102, 102, 102, 101 participants respectively in their 20s, 30s, 40s, 50s and over 50s. There were 255 males and 250 females. They were recruited online and enrolled the study via the Qualtrics system (https://www.qualtrics.com). As a reward, each participant received a coupon which could be redeemed for online shopping in Japan.

Tasks Participants were instructed to perform altogether the following three tasks.

Task 1: Binary choice task Participants were instructed to make a series of binary choices in two hypothetical scenarios, i.e., past (Figure 1) and future (Figure 2).

In both scenarios, instructions were given (i.e., 'Which option would you prefer?') and participants were required to make binary choices between an ¥100,000 reward with temporal distance, and an immediate reward with 10 monetary amounts evenly divided between ¥100,000 and ¥10,000 (i.e. ¥10,000, ¥20,000, ¥30,000, …¥100,000). In the example, the temporal distance is 30 days and the choices are presented in a descending order (from ¥100,000 to ¥10,000). Six temporal distances (i.e., 1, 7, 30, 90, 180, and 365 days) were involved and the amounts were presented in two possible orders (ascending or descending).

Altogether, each participant was required to make 120 binary choices (two tense scenarios × 10 monetary amounts × six temporal distances) in this task. Presentation was counterbalanced for tense scenario (past or future) and order of amount (ascending or descending) and randomized for temporal distances.

Task 2: Impulsiveness measurement Participants were then asked to answer the questionnaire of Barratt Impulsiveness Scale 11 (BIS11), a widely-used measure of individual impulsivity (Patton et al., 1995) containing 30 questions. The Japanese version of the scale was used in the present study (Someya et al., 2001).

Task 3: Demographic information collection Participants were requested to report age, sex, nationality and language skills. The language skills reported included four languages, i.e., Japanese, English, Mandarin and French, and participants' self-evaluation was anchored on a scale of 101 points, from 0 (Unable to Understand), 40 (Conversational Level), 70 (Business Level) to 100 (Native Speaker Level).

Procedure All the participants were presented with the same questions, and with the order of task 1, task 2 and task 3. The questions in the task 2 and task 3 were presented in the same order for all participants and the questions in task 1 were kept counting balanced (as described above). All the questions were presented in Japanese.

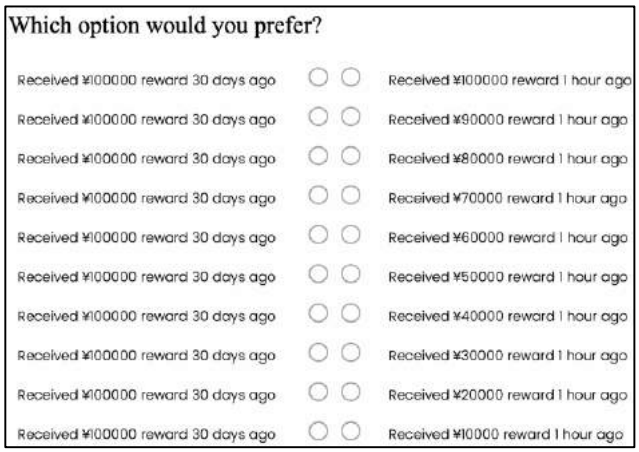

Figure 1: Binary choice task: past scenario

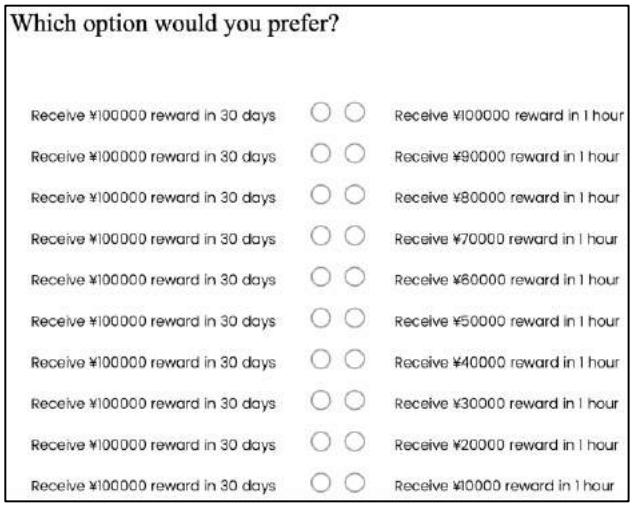

Figure 2: Binary choice task: future scenario

Results

General tendency

Based on participants' answers in the discounting task, we identified the points where the immediate reward of ¥100,000 was equivalent to the amount at temporal distances of 1, 7, 30, 90, 180, 365 days in the past as well as in the future scenario for each participant.

Then, we calculated the indifference points by averaging the equivalent amounts for each temporal distance and plotted them. We fitted the four models to data and chose the best one based on Akaike information criterion (AIC). AIC for each model is summarized in Table 2. It was found that q-exponential was the best model for both past and future discounting. Thus, we analyzed the data based on the q-exponential model.

Figure 3 showed the indifference points plot and q-exponential model for past and future discounting. Overall, as predicted, Japanese speakers discounted past gains ($k_{past}=0.480$) more heavily than future gains ($k_{future}=0.229$). We also used the indicator of (Area Under the Curve) to evaluate the temporal discount. We standardize the area to restrict the value from 0 to 1. The average AUC of past gains ($M_{AUCpast}=0.547$) is significantly smaller than that of future gains ($M_{AUCfuture}=0.624$, $t(504) = 6.843$, $p < .001$, $d = 0.305$), suggesting that the value of past is more sensitive to time transition.

Figure 4 shows the discounting rates for each temporal distance (1, 7, 30, 90, 180, and 365 days) in past and future scenarios, with significant differences between the two scenarios for all temporal distances: 1d ($t(504) = 4.770$, $p < .001$, $d = 0.212$), 7d ($t(504)= 3.980$, $p < .001$, $d = 0.177$), 30d ($t(504) = 5.602$, $p < .001$, $d = 0.249$), 90d ($t(504) = 4.780$, $p < .001$, $d = 0.213$), 180d ($t(504) = 5.503$, $p < .001$, $d = 0.245$) and 365d ($t(504) = 5.710$, $p < .001$, $d = 0.254$).

In line with our prediction, results suggest that Japanese speakers tended to discount past gains more drastically than future gains, as indicated by data of discounting rate, AUC and q-exponential model. This finding also supported the LSH.

Table 2: AIC for the models.

	Past	Future
Linear	15.092	13.789
Exponential	28.231	25.576
Hyperbolic	26.249	23.906
Q-exponential	9.472	8.031

Individual differences and personal characteristics

To further assess individual differences and the effect of demographic factors, we fitted individual participants' data with each of the four models to decide on the best-fitting model for individuals (evaluated by AIC), as summarized in Table 3. Although the q-exponential model was found to be the best-fitting for the overall data, the linear model explained the individual data the best. However, other models were also selected with non-negligible proportions, making it difficult to directly compare individual behaviors. Therefore, we used AUC to evaluate the discounting behavior at the individual level.

To identify the tendency of individuals, we first executed k-means clustering to categorize the AUC values obtained in past and future scenarios.

The first step is to determine the optimal number of clusters. We applied 30 indices in the R package 'NbClust' (Charrad et al.,2014) and experimented with the optimal cluster number from two to ten. Among the 30 indices, 27 returned valid results. Although two clusters were suggested by the largest number of indices (*8/27*), it gave much less information than three clusters, suggested by the second largest number of indices (*6/27*). Balance between parsimony and informativeness, we decided on three as the optimal number of clusters as shown in Figure 5. Each dot displays data for one individual, and the triangles represent the center of each cluster.

Figure 5 showcases the plausible clustering of participants' discounting behavior into three groups, i.e. high discounting group (green dots, n=136), middle discounting group (blue dots, n=183) and low discounting group (red dots, n=186). The diagonal line represents identical discounting rate of past and future gains. The dots above the line are individuals who discounted the value of future gains more, while those below the line denote individuals who discounted the value of past gains more.

As the figure illustrates, individuals of the three clusters show very different tendencies. On average, the discounting rate for past and future gains is very close in both high ($M_{AUCpast}$=*0.205*, $M_{AUCfuture}$=*0.200*) and low ($M_{AUCpast}$=*0.905*, $M_{AUCfuture}$=*0.883*) discounting group. However, it is obvious that participants in the middle discounting group discount the value of past gains much more heavily than that of future gains ($M_{AUCpast}$=*0.436*, $M_{AUCfuture}$=*0.676*). Thus, although the LSH well predicted the general tendency of the participants' discounting behaviors, it failed to capture the specificity at the individual level as it was found to have explained individuals with middle level discounting behaviors better than on average.

We then conducted multiple regression analysis to identify individual characteristics that have influenced discounting behavior. To reveal a full picture, we included age, impulsiveness (measured by BIS-11 questionnaire), language ability (in English, Mandarin and French) as numerical independent variables, and sex (male = 1, female = 0) and tense (past = 1, future = 0) as dummy independent variables, to predict AUC. Since we have confirmed that all participants reported that Japanese is their native language, we excluded the variable of Japanese skill. We also confirmed that correlations between every two variables were low (*cor*<.2).

As multiple regression results (Table 4) show, among all variables, tense (past or future) and impulsiveness had

significant influences on discounting behaviors ($p < .01$). The significant effect of tense is consistent with our major finding that people have the tendency to discount the value of past gains more strongly than that of future gains. With regard to impulsiveness, participants who scored high in the BIS-11 questionnaire tended to have stronger discounting behaviors than those with lower scores in the measurement. This result is consistent with that in the previous study, suggesting that in general impulsive individuals tend to showcase more drastic discounting behaviors (Bickel et al., 2008). No significant influence was found for the other variables. These results indicated that the difference of discounting behavior was explained more in terms of impulsiveness than other demographic factors such as age and sex. Besides, we tried to include the interaction factor of tense and impulsiveness in the model and found there was no significant interaction between tense and impulsiveness ($p > .1$). The result implied that impulsiveness and tense functions on temporal discounting separately.

Table 3: Individual best model percentage.

	Past	Future
Linear	264 (52.3%)	286 (56.6%)
Exponential	90 (17.8%)	78 (15.5%)
Hyperbolic	80 (15.8%)	59 (11.7%)
Q-exponential	71 (14.1%)	82 (16.2%)

Table 4: Multiple regression results for AUC values.

	Est.	SE	p
Tense	**-0.077**	**0.020**	***p<.001***
Age	0.000	0.001	*p=.966*
Sex	0.008	0.020	*p=.683*

Discussion

The present study examined the LSH by comparing past and future discounting behaviors of individual Japanese speakers to eliminate the influence of potent factors such as culture. We found that Japanese speakers discounted the value of past gains more than that of future gains. This pattern was consistent with the prediction based on the asymmetric grammatical marking of tense in Japanese as there is grammatically marked past tense but no future tense. Thus, our results supported the LSH.

Moreover, detailed analysis of individual characteristics revealed that although the theory could explain the general tendency of discounting behavior, remarkable individual differences remained unexplained. Furthermore, our results suggested that the difference in discounting behavior was explained more in terms of impulsiveness than in terms of demographic characteristics.

Finally, we need to acknowledge that our study focused only on Japanese speakers. Even though there were several previous studies on native English speakers in the U.S. and found they discounted the value of future and past gains in a symmetrical way, we haven't replicated this result and executed the direct comparative analysis by far. This may cause some doubt and alternative explanations here. Our next step is to collect data from native speakers of English and Mandarin for comparative studies to strengthen and broaden our conclusion.

The Goal-Dependent Nature of Automatic Semantic Priming

Lin Khern A. Chia (lachia2@illinois.edu)

Department of Psychology, University of Illinois at Urbana-Champaign, IL 61820 USA

Abstract

Despite the fact that priming is one of the most studied phenomena in cognitive psychology, many questions remain about exactly when, why and under what task conditions we ought to observe priming in the lab, and what types of relationships between words or concepts reliably lead to priming. This project contrasted two priming experiments where the primary manipulation was the decision the subjects were making about words (as well as manipulating other factors, like relatedness proportion, known to affect priming). We found evidence that: 1) automatic priming for semantically related words does happen under some conditions, but 2) semantic priming, and whether it happens independent of association, is dependent on the task in which participants are engaged. These results provide evidence for the context sensitive nature of the activation of semantic memory.

Keywords: Semantic memory**;** Semantic Priming; Associative Priming; Goals; Explicit Awareness

Introduction

Priming, or the improvement in performance in a perceptual or cognitive task relative to some baseline, is one of the most studied effects in cognition (McNamara, 2005). Much of this interest is because of priming's potential for giving us a window into our representations and how we access them. For example, if the word or concept *dog* is responded to more quickly when it is preceded by the word or concept *cat* then when it is preceded by *shoe*, it suggests that our representation of *dog* and *cat* share some relation, association, or overlap that *dog* and *shoe* do not (Collins & Loftus, 1975).

By discovering systematicities about what kinds of words or concepts prime each other, cognitive scientists hope to unravel the nature and structure of how knowledge is represented. For example, McRae, de Sa, & Seidenberg (1997) found different patterns of priming for human-made artifact and natural kind words, leading to claims about differences in the nature of the representations of those words' meanings. Statistically significant priming was only found between natural kind words if those words had high correlated feature overlap. In other words, priming was observed between words like *canary* and *robin*, which share a set of intercorrelated features that co-occur across a broad range of words, like "*has wings*", "*has feathers*", and "*can fly*". But no priming was observed between words like *raspberry* and *ruby*, despite the fact that they superficially share many features in common (like "*is red*", "*is small*" and "*is round*"). Unlike "*has wings*", "*has feathers*", and "*can fly*", these features are not correlated across a broad set of items. McRae et al found that, in contrast to natural kind words, priming occurred for human-made artifact words that had high feature overlap, regardless of whether those features were correlated or uncorrelated. Based on these results, McRae et al. argued that correlated features are in some way important to the representational structure of natural kind concepts but not artifact concepts.

Decades of research has investigated a wide range of relationships between words, and whether those relationships lead to priming, including: normative association strength, co-occurrence in language, synonymy, antonymy, perceptual similarity, feature overlap, shared category membership, shared script/schema membership, functional relations, and others (for review, see Hutchison, 2003; & McNamara, 2005). However, conclusions about what types of relations systematically lead to priming are made difficult by the fact that many factors unrelated to the target-prime relationship also influence the extent to which semantic priming occurs. One such factor found by Moss et al. (1995) is that words belonging to the same category prime when presented auditorily, but not as text.

A second moderating factor is the type of task subjects are asked to perform during presentation of a target, can influence priming results. Examples of tasks are naming the target word aloud, or deciding whether the target is a legal string in the English language. The latter is called a lexical decision task, which we will abbreviate LDT.

A third moderating factor is the time duration between the prime and target (the stimulus onset asynchrony, or SOA). Hutchison (2003) reviewed 36 experiments (shown in Figure 1 below) examining priming for words belonging to the same category (and which were not normatively associated). He found that in experiments where the task was lexical decision, priming almost always occurred regardless of SOA, whereas in naming studies, priming effects were much less consistent.

A final moderating factor is the relatedness proportion (RP) of words in the study. In a typical study this can range from as high as 50% of the items being related, to sometimes being as low as 5% (Hutchison, 2003). Like SOA, RP effects can dramatically alter whether words of certain types prime each other. RP and SOA are often seen as working in a similar mechanistic fashion, by altering the extent to which the subject is explicitly aware of the potential for a relationship between the prime and target.

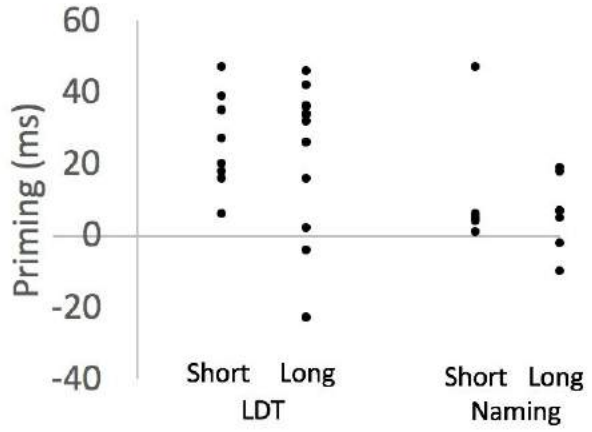

Figure 1. Priming effect sizes for same category words (in ms) in 36 experiments, as a function of task (lexical decision vs. naming) and short (<300 ms) or long (>300 ms) SOA. Data taken from Hutchison (2003) Table 4.

When subjects have a long time to process the prime, and a high proportion of items are related, there is a high chance they are making active, explicit, or strategic predictions about the items (Neely, 1991). In contrast, when the speed is very quick, or a small proportion of items are related, the chance of this is much reduced, and priming effects are often attributed to unconscious or automatic effects like spreading activation (Collins & Loftus, 1975).

With so many factors moderating or eliminating priming effects, we do not yet understand priming well enough to use it as a tool for probing which words' or concepts' representations are related. In this paper, we hope to bring some clarity to these issues. We do so by controlling and contrasting task, SOA, and RP within the same experiment and using the same items. This will allow us to see if semantic priming can be consistently obtained and the factors that affect these priming effects. In doing so, we hope to answer three primary questions.

First, can we reliably obtain priming for items that are semantically related (in terms of being from the same category), in the absence of other types of relations? For example, one other factor moderating the studies shown in Figure 1 was the extent to which the words were normatively associated (e.g. the prime reliably elicited the target in a free association task). Of the studies shown that failed to find semantic priming, the overwhelming majority used same category words that were not normatively associated, whereas the studies that did find priming used words that were both associated and from the same category. This had led some to argue that most priming is "associative" priming, and that purely semantic (e.g. category or feature-based) priming are rare, weak, or nonexistent. This explanation is somewhat dissatisfying, however, because the fact that two words are associated in a normative task does not tell us much about the nature or cause of that association.

One possible explanation for the lack of priming without association deals with the strength of the similarity of the items. In some of the studies testing same-category priming for unassociated words, the category-based relationship was rather weak. For example, Shelton & Martin (1992)'s experiments 2 and 3 found priming times of 2 ms and -23 ms (in a long SOA LDT task), but many of their "related" items were of questionable relatedness, including *dirt* and *cement*, *soup* and *juice*, *barn* and *home*, and *duck* and *cow*. Thus, in this experiment the lack of associativity was confounded with the lack of strong semantic similarity (in terms of feature overlap or any other definition). Other studies, such as McRae and Boisvert (1998) that used more strongly related words, found evidence for semantic priming in the absence of association. In order to address the question of whether semantic priming exists independent of association, in our experiments we choose items that are from the same set of eight categories (mammals, birds, fruits, vegetables, vehicles, clothing, weapons, and tools), and were as highly similar as possible, but varied the degree of association so that its effect could be investigated statistically as a covariate in our analyses.

Second, is semantic category-based priming consistent across different relatedness proportions and stimulus onset asynchronies? As noted, there has been inconsistency in whether semantic priming is found with short SOAs or low RPs, leading some to suggest that semantic priming (as opposed to associative priming) is only an explicit or strategic phenomenon that occurs when subjects might be aware of the fact that words in the study are related, and that therefore automatic unconscious semantic priming does not occur. But again, many of these studies have problems, ranging from small sample sizes to relatively dissimilar "semantically related" words, to not fully crossing RP and SOA. In the experiments described below we ran different sets of subjects in a 2x2x2 design crossing extremely short SOAs (50ms) and moderately short SOAs (250ms), two RP conditions (0.25 and 0.50 related), in addition to whether the words' meanings are related or unrelated (priming would or would not be expected).

A **third** question being tested in this paper is whether automatic priming is dependent on the task-related goals of the subject. Contrary to the depiction of semantic priming as a static phenomenon by a large majority of the literature, Willits et al. (2015) found that what types of

verb-instrument relations led to priming could be manipulated by changing the task. In tasks that had a linguistic bias (such as naming words aloud), priming was observed for words that that have strong linguistic co-occurrence relationships, but not for words that were semantically related that do not co-occur frequently. In contrast, in tasks that were heavily semantic (such as making a category decision about the target word), priming occurred for those words that shared a semantic relationship, regardless of their linguistic co-occurrence probability. Across the current two experiments, we manipulated the task in a similar fashion, observing whether semantic priming is independent of the tasks-specific goals. In Experiment 1, subjects' task was to decide whether the target was a concrete (vs. abstract) entity. Unlike other tasks often used in semantic priming (like naming and lexical decision), this task is one that involves activation of semantic information, and thus may make semantic priming more likely. In Experiment 2, the subjects performed a semantic categorization decision, deciding if words belonged to a particular category (selected from the same eight categories from which the stimulus words were drawn). Critically, sometimes the related pairs were aligned with the category decision being made (e.g. *eagle-hawk* for "is the second word a bird" vs. "is the second word a vehicle). Thus, the contrast between Experiments 1 and 2 allows us to investigate the extent to which semantic priming is consistent across tasks, and whether or not it matters that the kind of semantic relationship being primed is consistent with the subject's current goal.

Experiment 1: Priming in a Concrete/Abstract Decision Task

In Experiment 1, subjects saw a sequence of 128 prime-target pairs. They were asked to judge whether the target was a concrete real object (like a *rock*, *bird*, or *cloud*) or an abstract concept (like *truth*, *beauty*, or *honesty*). Half the items were concrete, and half the items were abstract. Among the concrete items, either 50% or 25% of the items were semantically related. Subjects were randomly assigned to each RP condition, and to either a 50 ms or 250 ms SOA condition. This resulted in a 2x2x2 mixed design, with RP and SOA as between-subject factors, and prime-target relatedness as a within-subject factor.

Method

Subjects. There were 339 undergraduate students who participated in the experiment for course credit. All subjects were fluent speakers of English.

Procedure. Subjects were seated in front of a computer screen. Each of 128 trials consisted of the presentation of the following sequence of events. First, a fixation cross for 50 ms. Second, the prime word (for either 25 ms or 225 ms, depending on SOA condition). Third, a pattern mask ("&&&&&&") for 25 ms (with the duration of the prime word plus the pattern mask constituting the SOA). Fourth, the target word, which stayed on the screen until a response. The inter trial interval was one second. Subjects were required to answer yes or no as to whether the target word was a concrete real object. The trials were randomly divided into eight blocks of 16 words, allowing the subjects a brief resting period between each block.

Materials. Each subject saw 128 noun-noun trials which consisted of 64 concrete-abstract pairs and 64 concrete-concrete pairs. The specific 64 concrete-concrete trials varied across subjects depending on their RP condition. The 128 words making up the 64 concrete-concrete pairs were chosen according the following parameters. First, 16 words from eight semantic categories (mammals, birds, fruits, vegetables, vehicles, clothing, weapons, and tools) were chosen resulting in 64 pairs that were from the same category, maximized semantic similarity, while varying normative association strength.

The experiment's 64 related pairs were then arranged into counterbalanced lists that re-paired 50% or 75% of the targets with unrelated primes (depending on the RP condition). These lists also ensured that each prime and target occurred only once in each list, and that each word occurred as a related prime and target, and as an unrelated prime and target across different lists. For example, the RP=.50 condition had four lists, so that *dog* could occur as a related prime and target (*dog-cat*, and *cat-dog*) and an unrelated prime and target (*dog-shoe* and *shoe-dog*) across the four lists. Each subject saw only one list.

The 128 words making up the concrete-abstract trials were chosen by selecting 64 abstract words and then pairing each one with an unrelated concrete prime word (chosen equally distributed from the same eight categories). These same 64 concrete-abstract pairs were added to each of the lists described above. Note that this means that the RP conditions could be considered .25 and .125 rather than .5 and .25, depending on whether you are considering the relatedness of all trials, or of just the concrete-concrete *yes* trials which constituted our analyses.

Results and Discussion

As per standard convention in priming experiments, we first inspected accuracy scores to check to make sure there were no speed accuracy tradeoffs. Then we analysed the reaction times in the *yes* trials, after removing outlier trials that were shorter than 400 ms or greater than three standard deviations of the mean leaving 20,560 trials (out of 21,234 total *yes* trials) left for analyses. The resulting mean reaction times for related and unrelated trials in our four RP-by-SOA conditions are shown in Figure 2.

Next, we used relatedness, SOA, and RP as fixed factors predicting RT in a mixed-effects regression model, with subject and target word as random factors (Bates, Maechler, Bolker & Walker, 2015). The results of this model are shown in Table 1. We found significant main

effects of relatedness which did not interact with either SOA or RP. Thus we found evidence for a priming effect independent of SOA or RP, and no evidence that our subjects were generating strategic expectations about prime-target relationships, even in SOA/RP conditions that encouraged such expectations.

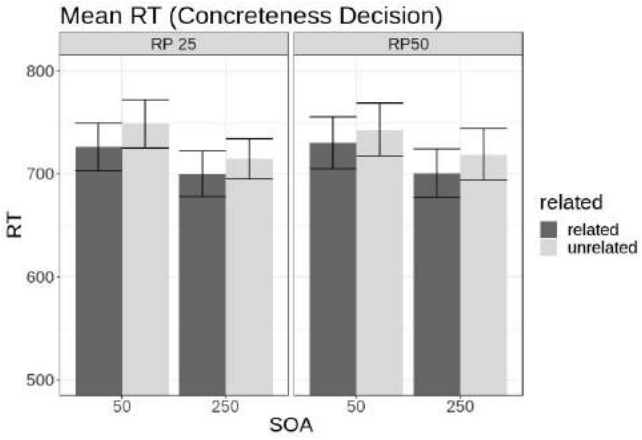

Figure 2. Mean reaction times (and standard deviations computed across subjects) in an abstract/concrete judgement task for related and unrelated trials as a function of relatedness proportion and stimulus onset asynchrony.

Table 1. Fixed effects of mixed effect model analyzing reaction time on *yes* trials in Experiment 1. As per convention, t scores of greater than 2 are typically considered statistically "significant" (Baayen, 2008).

Fixed Effect	b	t
Relatedness	-15.6	-5.39*
SOA	-26.7	-2.34*
RP	-1.20	-0.10
Relatedness x SOA	-2.92	-0.51
Relatedness x RP	5.74	0.99
SOA x RP	7.58	0.33
Relatedness x SOA x RP	-21.6	-1.87

Table 2. Fixed effects predicting residual variance in RT after removing variance in RT predictable by normative association strength in Experiment 1.

Fixed Effect	b	t
Relatedness	-8.22	-1.48
SOA	-21.9	-1.73
RP	-2.76	-0.22
Relatedness x SOA	3.97	0.36
Relatedness x RP	12.4	1.11
SOA x RP	-1.06	-0.04
Relatedness x SOA x RP	-38.0	-1.71

We also fit a second model to the RT data after removing the variance in RT that could be predicted by association strength. This removal of variance was done by excluding the 15,175 trials that: 1) involved normatively associated prime-target pairs, and 2) included targets shared by the normatively associated prime-target pairs so as to ensure equal treatment, leaving 5385 trials for analysis. The effect of relatedness disappeared after removing variance in RT predictable by normative association strength. Thus, in an abstractness judgement task, although we found evidence for an RP and SOA-independent priming effect, we did not find evidence for priming due to "semantic" relatedness (i.e. high similarity items belonging to the same category), when the effect of normative association was removed. This is true even though our items were picked to maximize strength of the relationship between the related prime and target items.

Experiment 2: Priming in a Category Decision Task

Experiment 2 was designed to investigate the extent to which the priming results found in Experiment 1 were dependent on the task in which the subject was engaged. In Experiment 2, subjects' performed a category decision task, deciding if the target word belonged to a specific category (one of the same eight from which the stimuli were drawn).

Method

Subjects. There were 253 undergraduate students who participated in the experiment for course credit. All subjects were fluent speakers of English.

Materials. Items here were identical to those of experiment 1 but for one difference: the *no* trials were, like the *yes* trials, concrete-concrete pairs drawn from the same eight categories. These *no* trials were chosen such that their relatedness proportion matched that of the subject's condition (either 0.25 or 0.50). Thus, each block consisted of related pairs that aligned with the category decision relevant for that block, unrelated pairs with either prime or targets (but not both) aligned with the category, as well as related trials that were misaligned with the category. As an example, consider Table 3, with a sample showing two counterbalanced lists of eight items.

Table 3. Sample items demonstrating related and unrelated pairings in Experiment 2 when task was to decide "Is the second word a mammal?" and RP=0.50. For this sample of words, other counterbalancing lists would have been created allowing all words to serve as both primes and targets in both related and unrelated trials, across different subjects.

Prime	Target	Condition	Correct Response
dog	cat	Related	Yes
rat	mouse	Related	Yes
eagle	deer	Unrelated	Yes
hammer	cow	Unrelated	Yes
sword	knife	Related	No
subway	train	Related	No
moose	shirt	Unrelated	No
zebra	blueberry	Unrelated	No

Procedure. The procedure in Experiment 2 was identical to that of Experiment 1 except for the nature of the yes-no decision, now a category decision. The 128 trials were divided into eight blocks, such that the specific category about which the subject was evaluating the word changed every 16 trials. These eight categories were the same from which the items were drawn. The order of the eight blocks was randomized across subjects.

Results and Discussion

Data in Experiment 2 were analyzed the same way as we analyzed the data in Experiment 1. 14,977 trials (out of 17,092 total *yes* trials) were left after our trimming process. The mean reaction times in each condition are shown in Figure 3.

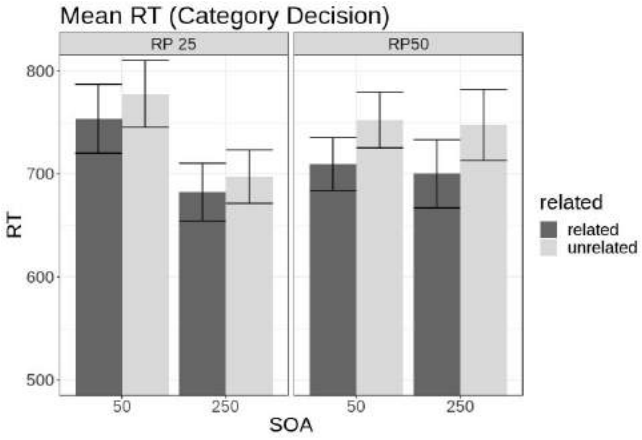

Figure 3. Mean reaction times (and standard deviations computed across subjects) in a category judgement task.

Again, we used relatedness, SOA, and RP as fixed factors predicting RT in a mixed-effects regression model, with subject and target word as random factors. The results of this model are shown in Table 3. We found a significant main effect of relatedness, and also a significant interaction of relatedness with RP (but not SOA).

Table 4. Fixed effects of mixed effect model analyzing reaction time on *yes* trials in Experiment 2.

Fixed Effect	b	t
Relatedness	-22.1	-4.95
SOA	-42.6	-2.95
RP	-3.15	-0.22
Relatedness x SOA	4.76	0.69
Relatedness x RP	-19.3	-2.77
SOA x RP	67.8	2.35
Relatedness x SOA x RP	-4.35	-0.31

As per Experiment 1, we also fit a second model to the RT data after removing the variance in RT that could be predicted by association strength. This removal of variance was done by excluding the 10,563 trials that 1) involved normatively associated prime-target pairs, and 2) included targets shared by the normatively associated prime-target pairs so as to ensure equal treatment, leaving 4414 trials for analysis.

The results of Experiment 2 turned out interestingly different than those of Experiment 1. Here, the main effect

Table 5. Fixed effects predicting residual variance in RT after removing variance in RT predictable by normative association strength in Experiment 2.

Fixed Effect	b	t
Relatedness	-33.4	-3.05
SOA	-40.2	-2.40
RP	9.36	0.56
Relatedness x SOA	-2.23	-0.17
Relatedness x RP	-2.10	-0.16
SOA x RP	80.8	2.41
Relatedness x SOA x RP	0.63	0.02

of relatedness survived the removal of normatively associated word pairs. Thus, the priming observed in Experiment 2 was at least partly due to semantic relatedness, independent of association. This stands in sharp contrast to the way that the priming observed in Experiment 1 can be attributable to effects of normative association.

Why the difference between Experiments 1 and 2? In comparison to an abstract/concrete judgement decision, semantic information (in particular, semantic similarity, overlapping semantic features, or the category to which a word belongs) is clearly more relevant when the task in which the subject is engaged is a category judgment decision. The results of Experiment 2, and their contrast with Experiment 1, strongly suggested that the manifestation of semantic priming depends on the goals or task in which a person is engaged. If their goals beg heavy use of knowledge about semantic features, empirical phenomena of cognitive access like priming should be organized semantically.

There was a significant Relatedness x RP interaction found in the model that included normatively associated pairs. However, this interaction disappeared in the model that excluded normatively associated pairs. This is a curious finding. Alone, these results might suggest that RP effects are selective and only relevant to associative priming. Unfortunately, this conclusion is untenable. Experiment 1, where priming was associative in nature, showed no RP effect at all. We are still left with some uncertainty about the exact role that RP plays in priming.

General Discussion

"Priming is an improvement in performance in a perceptual or cognitive task, relative to an appropriate baseline, produced by context or prior experience." (McNamara, 2005). Priming is typically called semantic when the improvement in performance is brought about by prior experience with semantically related concepts. Due to the fleeting nature of semantic priming, some have expressed doubts that it reflects the true organization of

concepts in our mind. If semantic priming only manifested itself in conditions that encouraged strategic processing, no researcher would be able to use it as evidence that semantic memory is organized semantically. Given further evidence that semantic priming is predictable by word association norms, it might even be reasonable to say that semantic memory is instead organized associatively. However, this is not the conclusion warranted by our data. In Experiment 2, we found evidence for automatic priming (i.e. priming even with very short SOAs and low RPs) for words with no associative relationship.

Despite these findings, it should be stressed that automatic semantic priming is nonetheless a fleeting phenomenon. Consistent with other work about the task and/or goal dependent nature of semantic activation (Willits et al., 2015), we found that priming does not occur independent of task, or with words of low relatedness (Shelton & Martin, 1992). Our results indicate that semantic priming should only manifest reliably when subjects' goals involve heavy usage of semantic information. Subjects' task in Experiment 2 was heavily reliant on semantic information, where they were required to make decisions about the words' membership to categories that were directly aligned to the related vs. unrelated contrasts in stimuli. Experiment 1 on the other hand, required a lighter use of semantic information where nuanced distinctions between and matches of sets of features were not needed. Instead, all that was needed was whether or not the word referred to something that is tangible.

Given the ubiquity of SOA effects in the priming literature, it might be remarkable that our experiments showed no effects of SOA on priming at all. It is worth noting, though, that one of our limitations lie in our SOA manipulations: they were relatively small (50 ms vs. 250 ms) compared to some previous work (which has investigated SOAs as long as 1000 ms). While many have argued that 250 ms is where strategic effects begin to appear, it lies too close to the borderline for us to be certain of any conclusions drawn about pure-SOA effects. Future work could extend these studies to using much longer SOAs, resolving this uncertainty about strategic effects.

Other future directions include investigating the true nature of associative priming, a phenomenon that, because it is defined by a word norm task, is unsatisfying as a mechanistic explanation for priming. An alternative would be to ground associative priming in something more tangible as a mechanistic explanation. Willits et al. (2015), for example, used language co-occurrence statistics to fruitfully predict priming results. Corpora analyses therefore offers a step away from defining the phenomenon by a word norm task. Finally, given our promising results of the existence of semantic priming under at least some circumstances, it is natural that another next steps would be a computational model that is able to predict priming at the level of individual words and/or subjects. Such a model would be a major step towards a truly mechanistic and unambiguous account of the source of lexical priming effects.

The Explanatory Value of Mathematical Information in Everyday Explanations

Abstract

With two experiments, we begin an inquiry into the perceived explanatory value of mathematical entities in everyday explanations. This work is motivated by a philosophical debate about the role mathematical entities play in explanation. Simply put, are the mathematical entities themselves explanatory, or is mathematical talk elliptical or shorthand for talk about the physical entities we are concerned with? Across the two experiments, we found clear evidence that situational factors affected how the mathematical entities were considered. However, when those situational factors are accounted for, participants tended to see more explanatory value for mathematical entities that point to other objects involved in the explanation as opposed to mathematical entities that assume the explanatory role themselves.

Keywords: explanation; mathematical explanation; indispensability argument; nominalism; platonism

As scientists, we often appeal to mathematical entities within the explanatory frameworks we adopt. These entities can take a variety of forms, from simple numerals (e.g., '7' and 'thirty') and functions (e.g., '*f(x)*') to complex computational models. Most cognitive scientists, but by no means all, recognize the usefulness of this mathematical information, and there has been extensive commentary on its role and how it should be interpreted. In recent years, philosophers have taken up this question with an increased focus on historical and contemporary case studies in the natural sciences (e.g. Lange, 2016; Pincock, 2011). However, outside of these formal, scientific frameworks, there is arguably a less well developed sense of what role mathematical entities play in explanations.

In this paper, we consider how a live philosophical debate about the explanatory role of mathematical entities relates to everyday explanations. Do mathematical entities contribute to the explanatory work themselves or are they "merely" drawing out the structure necessary for the explanation, identifying the relevant conceptual entities that are actually doing the explanatory work?

Within philosophy of mathematics, platonists affirm the existence of mind-independent and abstract mathematical objects, while nominalists deny that there are any such entities (see Cowling, 2017, for a general discussion of the platonist-nominalist debate). An influential line of argument in defense of platonism is the "Indispensability Argument", which posits that an ontological commitment to mathematical entities of the sort held by platonists is warranted because mathematical entities like numbers and functions play an indispensable explanatory role (Colyvan, 1998). Put differently, platonists make a claim about what exists—namely, that along with concrete entities like electrons and tables, there are also imperceptible, non-spatiotemporal mathematical entities. In contrast, nominalists deny that mathematical entities exist while acknowledging that we must nevertheless explain their usefulness in explanations. We examine whether this distinction that has motivated philosophical debate plays a role in everyday explanation.

In most scientific frameworks, mathematical entities are used to provide formal descriptions of processes and components theorized within conceptual frameworks. For instance, in the categorization literature numerous mathematical models have been proposed to account for how individuals organize items into coherent classes. These models vary from rather simple computations of feature overlap among the items to complex systems of probabilistic computation. They employ mathematical entities in a variety of ways, but there is no assumption that the explanatory value of the models rests on a commitment to the existence of those mathematical entities. Instead, the mathematical entities reference the things, e.g. the features, that are doing the explanatory work. We describe this approach as a *nominalist friendly* (NF) position. On nominalism and the various accounts that have been developed to account for mathematical explanation, see Burgess and Rosen (1997).

One can also accept an ontological commitment to the mathematical entities and allow them to assume explanatory relevance. In this case, the mathematical entities themselves ground the explanation as opposed to simply representing the physical-causal entities and their relations. For instance, consider the explanation for why certain species of cicadas emerge from their nymph state in either 13 or 17 year cycles. The explanation for these life cycles can be understood in terms of avoiding predation

(the cicadas would evolve to have a life cycle that minimizes overlap with the life cycle of predators), but that explanation ultimately rests on the fact that 13 and 17 are prime numbers. The mathematical reality of prime numbers is that they cannot be factored. The explanation for the life cycle of these species of cicada thus relies on a commitment to the mathematical entities as having particular qualities and would therefore be no less real or existent than familiar objects like chairs and racecars (Baker, 2005). We describe this stance as a *platonist friendly* (PF) position.

We use this philosophical debate to background an initial inquiry into how lay people use and evaluate mathematical entities in everyday explanations. We want to be clear that we do not think that people ponder the ontological commitments they are making as they produce or evaluate these kinds of explanations. However, there may be an effect tied to whether the explanations induce genuine ontological commitments to mathematical entities. Indeed, platonists who endorse the indispensability argument standardly assert that, without PF-friendly claims, certain proposed explanations will seem non-explanatory and that, generally, PF explanations are superior to NF explanations (Colyvan, 2018). As we consider below, whether the mathematical entities are represented with regard to their number theoretic value or are merely non-referring placeholders for information about the items they reference will, according to platonists, impact explanatory processes.

Psychologists have examined why people engage in explanation, what implications explaining has for other cognitive activities, and what cognitive structures underlie explanation. There is evidence that people value explanations that are simple and provide coverage in terms of how widely the explanation can be applied (Lombrozo, 2012). There is also evidence that explanatory processes rely on structured internal representations (Chin-Parker & Bradner, 2017; Johnson, Johnston, Koven, & Keil, 2018). These two aspects of explanation suggest that the ontological commitment could indeed play a role in how people regard explanations. For instance, if an explanatory relationship is represented in terms of the number theoretical values (e.g. $5 < 6$), it might be considered simple and widely applicable. If the mathematical entities facilitate the kind of structured representations implicated in explanatory processes, there could be a preference for PF explanations.

However, insights from the psychological study of mathematical reasoning complicate this simplistic rendering of the situation. This literature is vast, so we focus here on two issues. First, there is variability in the ability of people to use and understand mathematical information (Rittle-Johnson, 2017). This variability in mathematical reasoning would likely impact whether an individual is able to easily use the mathematical information to instantiate the requisite representations that the explanatory processes operate over. Second, how the information is presented also impacts mathematical reasoning (Koedinger, Alibali, & Nathan, 2008). In a simple problem, people tend to be more successful when the relevant information is grounded, when it has a clear relationship to concrete referents. When the information is presented in a more abstract manner, e.g. algebraic notation, people are less able to solve the problem. At the same time, the more abstract mathematical entities can facilitate more complex mathematical reasoning. Given these patterns, we expect the type of explanation may interact with the content of the explanation.

We use the logical form of the sentence to determine the ontological commitment of a mathematical statement. For example, 'Thirteen is prime' is PF because it entails that there is something that is prime, which is logically equivalent to the claim that thirteen—a mathematical entity—exists. A NF stance would, consequently, be one in which mathematical terms only appear in non-subject positions—e.g., 'There are thirteen dogs'. Here, 'thirteen' merely modifies the subject, dogs, and the sentence directly entails that there are dogs, but does not, without auxiliary logical assumptions, entail that there is a number thirteen. We note, however, that this assumption is a familiar point of controversy among philosophers and linguists and it is far from clear that lay persons are sensitive to the complex relationship between syntactic position and ontological commitment even if such a view is defensible upon sustained philosophical analysis (see Hofweber, 2016, for a recent discussion). In taking on this account of ontological commitment for the present study, we are, in part, investigating whether certain factors that philosophers of mathematics to take to be of paramount importance are represented in everyday explanatory practices.

To begin our inquiry (Experiments 1a and 1b), we asked participants to generate, and subsequently evaluate, explanations for a series of scenarios. The scenarios varied in terms of their content so that we could assess the generalizability of the participants' ontological commitments across situations. By asking the participants to both generate and evaluate explanations, we were also able to assess whether those commitments vary across different explanatory processes. Thus, the first experiments allowed us to examine whether there is a consistent preference for one type of explanation over the other, or whether the explanation and, in turn, commitment to mathematical entities varies between individuals, situations, and how the information is used. Because of the exploratory nature of this inquiry, we focus on describing the patterns of participant responses relevant to these topics as opposed to testing a priori hypotheses.

Experiment 2 presents a more controlled examination of the issue. We used modified versions of the cicada life-

cycle scenario (Baker, 2005) and asked participants to rate the explanatory value and complexity of various explanations the cicada life cycle. As prior, the explanations varied in terms of whether the mathematical entities made a NF or PF commitment. Also, we varied whether the mathematical terms were developed using a more or less specific example. This manipulation was intended to affect the ease with which participants could represent the information provided in the explanation.

When the explanation was developed using a more specific example, we expected that the participants should find the explanation to be less complex and they should give higher explanatory ratings for PF explanations. This prediction rests on the idea that the grounded mathematical terms could be more easily incorporated into an internal representation and the PF explanation would provide better coverage because it reflects the existence of those entities. However, when the explanation was developed with a less specific example, we expected that the participants would rate it as more complex and they should give higher explanatory ratings for the NF explanations. If the participant has more difficulty representing the situation due to the development of the mathematical terms, an explanation that does not rely on the existence of those mathematical terms should be seen as more explanatory.

In sum, we predict a main effect of the information in the explanation (specific vs. non-specific) on the complexity ratings, and an interaction between the development and the ontological commitment (PF vs. NF) for the explanatory ratings. These predictions rest on the assumption that the explanatory value will reflect both the generalizability and simplicity of the explanation. In order to get a better understanding of the individual differences in play, we also asked participants to report their comfort with mathematics and belief about the existence of mathematical entities.

Experiments 1a and 1b

Methods

Participants Undergraduate students participated as partial fulfillment of a requirement for an introductory psychology course. Thirty participants completed Exp. 1a. Forty participants completed Exp. 1b. Two participants in Exp. 1b failed to complete the explanation generation task, but they did provide ratings of the explanations.

Materials and Procedure The two studies used the same materials, but the method of data collection differed. In Exp. 1a, participants completed the study in small groups. Materials were projected onto a screen, and participants wrote out their responses in prepared packets. In Exp. 1b, participants completed the study on-line by completing a questionnaire created using the Qualtrics platform. See the *Appendix* for the full set of materials used in Exp. 1a and Exp. 1b.

Four scenarios were developed for this experiment. Each scenario presented a set of initial conditions that included mathematical entities (e.g. "The editor of the Daily News has 127 remaining newspapers to deliver and only three paperboys to deliver them.") and then a specific why-question related to those conditions (e.g. "Why can't the editor distribute the papers equally to each of the paperboys?"). The scenarios were designed such that it was possible to answer the question by positing the existence of the mathematical entities (a PF explanation), but a suitable explanation could be made without such a commitment (a NF explanation). In Exp. 1a, the order of the scenarios was balanced, and in Exp. 1b, the order of the scenarios was randomized. In both cases, participants were presented with the scenario and why-question and asked to generate a response.

After responding to all of the scenarios, the participants were told that other students had also generated explanations and those explanations needed to be evaluated. The participants were presented with the same four scenarios – the order of the situations was again balanced (Exp. 1a) or randomized (Exp. 1b). Each scenario was accompanied by two short explanations. One of the explanations reflected PF commitment (e.g. "Because 127 is not divisible by three") and the other reflected NF commitment (e.g. "Because if he gives each paperboy 42 papers, there will be one paper remaining"). In Exp. 1a, participants were asked to select which of the two explanations they considered to be the better explanation. In Exp. 1b, the participants were asked to rate how explanatory each explanation was. Along with each explanation was a slider that could be adjusted from 0 ("not explanatory") to 10 ("ideally explanatory").

Results

Explanation Generation The explanations generated by the participants were coded as to whether they rested on a PF claim, a NF claim, or whether the claim was ambiguous. The explanations were independently coded by two of the study authors, and disagreements were resolved through discussion including the third author. The inter-rater agreement was 87% for the responses from Exp. 1a and 84% for responses from Exp. 1b. Disagreements were easily resolved.

The distribution of the explanatory claims was similar across the two studies. In Exp. 1a, 62% of the explanations were NF, 31% PF, and 8% ambiguous. In Exp. 1b, 65% were NF, 31% PF, and 4% ambiguous. The results indicated that people tend to rely more on NF claims, but that they also will invoke PF claims when deemed appropriate. None of the participants in either study

generated PF explanations for all four scenarios, 8% generated three PF explanations, 22% generated two PF explanations, 49% generated a single PF explanation, and 16% generated no PF explanations. The scenario being explained had an effect on the type of explanation generated. In the "paperboy" scenario, participants readily generated PF explanations (85% of the explanations), while in the other three scenarios, they tended to rely on NF explanations (over 75% of the explanations for each scenario).

Explanation Selection, Exp. 1a The variability between participants and among scenarios is also evident in Exp. 1a when the participants were asked to select one explanation, NF or PF, as more explanatory. No participant consistently selected the PF explanation for every scenario while only six participants consistently selected the NF.

Table 1: Explanation Selection in Exp. 1a

Scenario	PF Selection	NF Selection
Championship	13/30	17/30
Fishing	5/30	25/30
Paperboy	22/30	8/30
Wheat	9/30	21/30

In order to assess explanatory preference, the selection data for each situation were compared to an assumed equal distribution of explanation types using a one-sample binomial test. In both the "fishing" and "wheat" scenarios, the participants showed a consistent preference for the NF explanations (both $ps < .05$). In the "paperboy" scenario, the participants showed a clear preference for the PF explanation ($p < .05$). Only the "championship" scenario had a distribution that indicated that the participants had no preference for the type of explanation.

We did not find evidence that participants made a consistent ontological commitment across the generation and selection tasks. When the participant generated a PF (or NF) explanation for a particular scenario, they subsequently selected the same type of explanation for that scenario only 52% of the time.

Explanation Rating, Exp. 1b The participant ratings for the PF and NF explanations for each scenario were analyzed using a 2 (type of explanation) X 4 (scenario) repeated measures ANOVA. There was no overall effect of the type of explanation, $F(1, 37) = 0.37, p = .55, \eta_p^2 = .01$, a significant effect of the scenario, $F(3, 111) = 6.70, p < .001, \eta_p^2 = .15$, and a significant interaction between the type of explanation and the scenario, $F(3, 111) = 8.54, p < .001, \eta_p^2 = .18$. As can be seen in *Figure 1*, the explanations for the "championship" scenario were significantly lower than the ratings for the other three scenarios (all $ps < .01$).

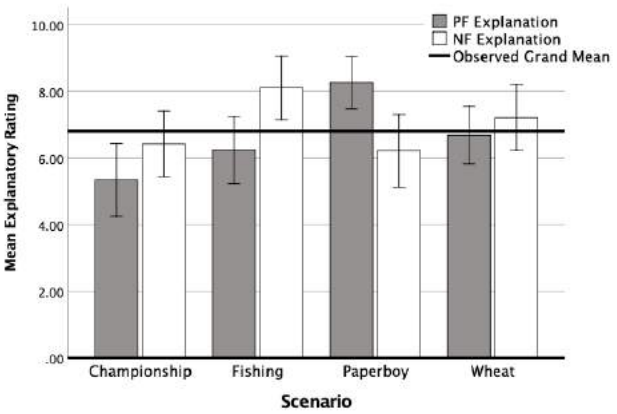

Figure 1: Mean Rating for PF and NF Explanations by Scenario from Exp. 1b

Note. Error bars represent 95% confidence intervals.

The other scenarios did not differ significantly from one another. Paired sample *t*-tests revealed that the ratings for the PF and NF explanations in the "championship" and "wheat" scenarios were not different; $t(39) = -1.25, p = .22$, and $t(39) = -0.64, p = .53$, respectively. However, the type of explanation did affect the ratings in the "paperboy" scenario, $t(39) = 3.14, p < .01$, and "fishing" scenario, $t(39) = -3.03, p < .01$, although in opposite directions.

In Exp. 1b, the participants showed a more consistent pattern of commitment to a particular type of explanation than in Exp. 1a. Overall, the participants gave a higher rating to the explanation that matched the type of explanation they had generated 66% of the time. However, this was primarily driven by participants that generated NF explanations and subsequently rated the NF explanations as better. The participants that initially generated PF explanations rated the PF explanations as better only 50% of the time.

Experiment 2

Methods

Participants Participants ($n = 173$) were obtained using the Mechanical Turk platform. They had to have above a 98% positive approval rating and successfully completed at least 100 tasks within the system. Eight participants were removed for not following directions. The questions included in this study were embedded within an unrelated memory study. Participants were paid for their participation.

Design Explanations varied in terms of commitment of the mathematical entities (either NF or PF) and how the mathematical terms were developed in the explanation (whether they contained a specific or non-specific example). Combining these factors created four conditions, and participants were randomly assigned to one condition.

Materials and Procedure Participants completed the study online using the Qualtrics platform. Each participant read a short passage about cicadas that provided some basic information about their appearance and diet. Importantly, they were informed about the cicada life-cycle being either thirteen or seventeen years. The description ended with the statement, "A question that has interested scientists is why cicadas have this particular life-cycle." Four different explanations were created to address that question.

All of the explanations consisted of six sentences, the first and last sentences were identical across all of the explanations. The second sentence reintroduced the idea that the life cycle of the cicadas was either thirteen or seventeen years. In PF explanations that point was connected to the notion that these numbers are prime:

Interestingly, 13 and 17 are prime numbers – this means that no smaller value (such as 2 or 3) can be divided into these numbers.

In the NF explanations, the number of years was connected to the notion that those numbers could not be evenly segmented:

Interestingly, cicadas' life-cycles are 13 or 17 years long – this means that these periods cannot be segmented evenly into durations of two years, durations of three years, and so on.

In all explanations, the next (third) sentence noted that the length of the life cycle minimized overlap with potential predators. In the PF explanations, this point was explicitly tied to the fact that the length of the life-cycle was a prime number. In the NF explanations, the point was tied to the length of the life-cycle generally. The fourth and fifth sentences developed the idea raised in the third sentence with either a specific or non-specific example. For instance, in the specific PF explanation, the example described how a predator with a three year life cycle would overlap with cicadas with a thirteen year life cycle only once every 39 years, but it would overlap every life cycle with a cicada that had a twelve year life cycle. In the non-specific PF explanation, the development of the explanation relied on algebraic notation:

*If a predator of the cicada had a life-cycle of x years (where x is equal to 2, 3, or 4), it would threaten cicadas with a 13 year life-cycle only once every 13*x years because that number would be the first number that can be divided by both x and 13.*

In the NF explanations, the specific and non-specific examples differed similarly except the examples referred to how the life-cycle could be segmented as opposed to the characteristics of prime numbers.

Immediately following the explanation, two rating scales were presented. The first scale asked participants, "How well does the above account explain the cicada life-cycle?". The participants could move a slider along a scale from 1 ("Not at all explanatory") to 9 ("Very explanatory"). The second scale asked, "How complex would you consider the explanation provided above?". The scale went from 1 ("Extremely simple") to 9 ("Extremely complex").

Following the critical questions, the participant was asked, "Would you consider yourself to be a scientist?" and "Are numbers real?" (Yes/No options for both measures). There was also a measure where the participant was asked to report their comfort with math from 1 ("Not comfortable") to 9 ("Very comfortable").

Results

The participants in the study predominately reported that they did not consider themselves scientists, (7.5% responded "yes" and 92.5% responded "no") and that they considered numbers to be real (95.4% responded "yes" and 4.6% responded "no"). Overall, they reported that they were "reasonably comfortable" with math (m = 5.62, s = 2.23), but there was some variability in those responses. Importantly, the reported comfort with math did not meaningfully vary by condition, $F(3, 169) = 1.71$, $p = .16$, $\eta^2 = .03$.

The explanatory ratings were analyzed using a 2 (specificity) X 2 (commitment) ANOVA (see Figure 2). There was no effect of specificity on the explanatory rating, $F(1, 169) = 0.12$, $p = .73$, $\eta_p^2 = .001$. The mean for the specific explanations ($m = 6.41$, $s = 2.03$) was similar to the mean for the non-specific explanations ($m = 6.32$, $s = 2.05$). There was a significant effect of the mathematical commitment on the ratings, $F(1, 169) = 3.85$, $p = .05$, $\eta_p^2 = .02$. The mean for the NF explanations ($m = 6.67$, $s = 1.86$) was significantly higher than the mean for the PF explanations ($m = 6.06$, $s = 2.17$). There was no interaction between the specificity and mathematical commitment of the explanations, $F(1, 169) = 1.19$, $p = .28$, $\eta_p^2 = .01$.

The complexity ratings were similarly analyzed (see Figure 3). There was no effect of specificity on the complexity rating, $F(1, 169) = 1.88$, $p = .17$, $\eta_p^2 = .01$. The

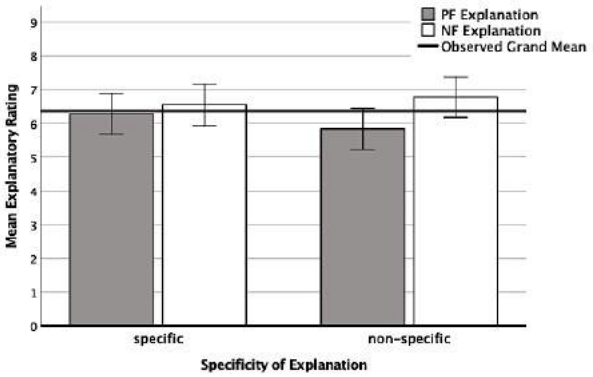

Figure 2: Mean Explanatory Ratings from Exp. 2
Note. Error bars represent 95% confidence intervals.

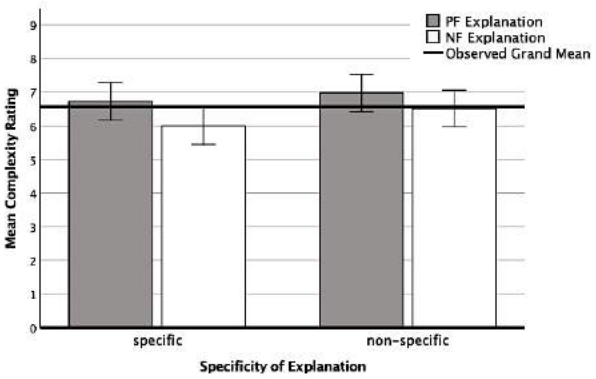

Figure 3: Mean Complexity Ratings from Exp. 2
Note. Error bars represent 95% confidence intervals.

mean for the specific explanations ($m = 6.36$, $s = 1.90$) was similar to the mean for the non-specific explanations ($m = 6.74$, $s = 1.82$). There was a significant effect of the mathematical commitment on the ratings, $F(1, 169) = 4.49$, $p = .04$, $\eta_p^2 = .03$. The mean for the NF explanations ($m = 6.26$, $s = 1.88$) was significantly lower than the mean for the PF explanations ($m = 6.85$, $s = 1.81$). There was no interaction between the specificity and the mathematical commitment, $F(1, 169) = 0.21$, $p = .65$, $\eta_p^2 = .001$.

The participant ratings of how explanatory and complex the explanations were had a weak, negative relationship, $r = -0.12$, $p = .10$. There was no relationship between the participants' reported comfort with math and their explanatory ($r = -0.02$, $p = .80$) or complexity ($r = -0.01$, $p = .88$) ratings. There were too few people that reported themselves to be scientists (or to not believe numbers to be real) to assess how those factors might have impacted their ratings of the explanations.

Discussion

Experiments 1a and 1b showed that there is variability in the mathematical commitments people are willing to make when generating or evaluating explanations for relatively simple situations. It was clear that the variability was not simply an individual difference issue – i.e. there was no evidence that some people always use and value PF entities and other people do not. This result suggests, contrary to some philosophical discourse, that there are not distinctively nominalist or platonist reasoners.

The variation in Exp. 1a and 1b appeared to be largely driven by differences among the scenarios. Across both samples and all measures, participants readily committed to PF explanations for the "paperboy" scenario. It involves the simplest mathematical relations as the explanatory value rests on a single mathematical operation. The "fishing" scenario tended to be the one where explanations ontologically committed to mathematical entities were least valued, and that scenario involves multiple operations across several potential numerical values. The other two scenarios tended to show less consistent patterns of response. This suggests to us that the complexity of the structure of putative explanations might drive much of the variation seen in the participants' preferences for the different types of mathematical explanations. Further study, and more careful control, of the various factors that differentiate these kinds of everyday explanations should provide more clarity as to why people shift in the ontological commitments.

In Experiment 2, we did not find the predicted effect of the specificity on the rated complexity of the explanations. We also did not find the predicted interaction between the specificity and the type of mathematical commitment on the explanatory value. However, among the non-specific explanations, the explanatory ratings differed between the PF and NF conditions ($p = .03$). Even though our manipulation of specificity did not have the expected effect on the complexity ratings, the participants responded to the PF and NF explanations differently when the information was non-specific.

The main results of Experiment 2 were that participants considered the PF explanations to be less explanatory and more complex than the NF explanations. It is possible that the mathematical relations underlying prime numbers are more difficult for people to grasp than we had anticipated. If that is the case, the results across the two experiments align; with more difficult mathematical relations, people perceive the explanations are being less explanatory. This assessment fits with recent work by Johnson, Johnston, Koven, and Keil (2017) and aligns with findings that there is a negative relationship between complexity and explanatoriness in non-mathematical explanations (Lombrozo, 2012). However, that relationship may not always hold (Johnson, Valenti, & Keil, 2017). Alternatively, it is possible that the participants were receptive to the more verbal depictions of the mathematical relations found in the NF explanations (see Koedinger & Nathan, 2004). This would suggest that it could relate more generally to how easily participants are able to represent the relations that underlie the explanation.

The present results suggest that lay people often find NF explanations satisfactory and, in certain instances, preferable to PF explanations. So, if platonists seek to defend the existence of mathematical entities because of their explanatory value or because of the manifest superiority of platonist over nominalist explanations, the present study provides preliminary evidence that such claims cannot be substantiated by our everyday explanatory practices, which are often quite friendly to would-be nominalists. We fully recognize we are not able to resolve the philosophical debate that backgrounds this study, but it does provide an interesting glimpse into how people use mathematical information in explanations.

Appendix: Exp. 1a and 1b Materials

Championship Scenario

Central High School hosts the league basketball championship game every three years and they host the league volleyball championship every four years. Eighteen years ago, they won both championships on their home court. Why can't they duplicate that feat this year?

(PF) Because the 18 is a multiple of three, but not four.

(NF) Because it will be another six years until they host both championship games again.

Fishing Scenario

Lana has $30 and wants to buy a fishing rod, fishing reel, and fishing line. There are two rods priced at $21 and $22. There are three reels priced at $7, $8, and $9. Fishing line is $2. Lana wants to spend exactly $30. Why should Lana buy the $21 rod?

(PF) Because the sum of 22, 7, and 2 is greater than 30.

(NF) Because any way of combining the $22 rod purchase with the purchase of a fishing reel and fishing line requires spending more than $30.

Paperboy Scenario

The editor of the Daily News has 127 remaining newspapers to deliver and only three paperboys to deliver them. Why can't the editor distribute the papers equally to each of the paperboys?

(PF) Because 127 is not divisible by three.

(NF) Because, if he gives each paperboy 42 papers, there will be one paper remaining.

Wheat Scenario

Fred needs 86 lbs of wheat for winter and he can't afford to waste any money on unused wheat. Wheat comes in bags of 8 lbs. He has 54 lbs of wheat already. Why can Fred avoid buying any unnecessary bags of wheat?

(PF) Because Fred must buy 32 lbs of wheat, and thirty-two divided by eight is four.

(NF) Because Fred must buy 32 lbs of wheat, and if Fred buys four 8 lb bags, he will have 32 lbs.

Problem Difficulty in Arithmetic Cognition: Humans and Connectionist Models

Abstract

In mathematical cognition, problem difficulty is a central variable. In the present study, problem difficulty was operationalized through five arithmetic operators — addition, subtraction, multiplication, division, and modulo — and through the number of carries required to correctly solve a problem. The present study collected data from human participants solving arithmetic problems, and from multilayer perceptrons (MLPs) that learn arithmetic problems. Binary numeral problems were chosen in order to minimize other criteria that may affect problem difficulty, such as problem familiarity and the problem size effect. In both humans and MLPs, problem difficulty was highest for multiplication, followed by modulo and then subtraction. The human study found that problem difficulty was monotonically increasing with respect to the number of carries, across all five operators. Furthermore, a strict increase was also observed for addition in the MLP study.

Keywords: problem difficulty; arithmetic cognition; binary numeral system; connectionist model; multilayer perceptron

Introduction

Mathematical cognition is the field of research concerned with the cognitive processes that underlie mathematical abilities (Campbell, 2005). Mathematical cognition involves complex mental activities, such as identification of relevant quantities, encoding those quantities into an internal representation, mental comparisons, and cognitive arithmetic. Most notably, cognitive arithmetic is concerned with the mental representation of numbers and arithmetic, and the processes that access and use this knowledge (Ashcraft, 1992).

In cognitive arithmetic, problem difficulty is a central variable (Ashcraft, 1992, 1995). There are at least three criteria for operationalizing problem difficulty: (a) operand magnitude (e.g., 1 + 1 vs. 8 + 8); (b) number of digits in the operands (e.g., 3 + 7 vs. 34 + 78); and (c) the presence or absence of carry[1] operations (e.g., 15 + 31 vs. 19 + 37). In particular, criterion (c) has been further investigated with regard to the number of carries required to correctly solve a problem (Fürst & Hitch, 2000; Imbo, Vandierendonck, & Vergauwe, 2007). In the present study, we investigated how the number of carries affected problem difficulty. *Response time* (RT) from the time a participant sees a problem to the time the participant answers the problem was used in the present study to measure problem difficulty.

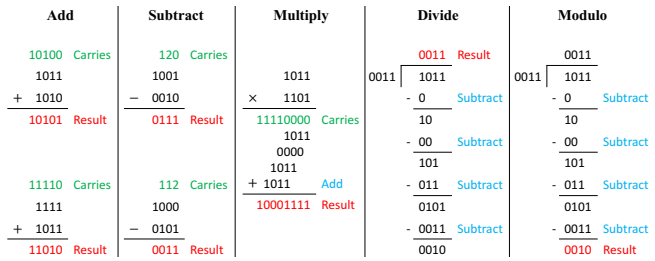

Figure 1: Guiding examples of the five operators with carries.

Previous studies that examine the ways humans process numbers are mostly based on the highly familiar decimal numeral system. Instead, the present study used the binary numeral system, which may offer a novel way to mitigate against the effect of previous experience with conventional mathematical operations. Moreover, since the binary system uses only 0 or 1 digits, it may reduce the *problem size effect*; criterion (a): problems with smaller operands (e.g., $5+2$, $4-1$) are solved more quickly and accurately than problems with larger operands (e.g., $7+6$, $9-6$) (Campbell, 1994; LeFevre et al., 1996; Miller, Perlmutter, & Keating, 1984). Therefore, to observe the effect of carries on problem difficulty, the present study employed the binary system to control for familiarity with the decimal system and criterion (a).

Extending the connectionist approach (Rumelhart & Mcclelland, 1986) to address problems of mathematical cognition may help us understand in detail why mathematics is hard (McClelland, Mickey, Hansen, Yuan, & Lu, 2016). This approach is effective because connectionist models are able to learn many aspects of mathematical cognition. Also, these models offer the possibility to provide concrete instantiations of the mechanisms that grasp the nature of human knowledge and learning within the domain of mathematics.

Previous research has demonstrated how the connectionist model can simulate arithmetic operations. For instance, McCloskey and Lindemann (1992) simulated associative-memory neural networks that learn single-digit multiplication operations. However, these networks were unable to learn all the given arithmetic operations. Utilizing recent advances in

[1] A *carry* in binary addition is the leading digit 1 shifted from one column to a more significant column when the sum of the less significant column exceeds a single digit. A *borrow* in binary subtraction is the digit $10_{(2)} = 2$ shifted to a less significant column in order to obtain a positive difference in that column. This paper refers to borrows as carries.

deep learning, Kaiser and Sutskever (2016) implemented a recurrent network capable of learning either addition or multiplication of two long binary numbers. This model achieved 100% test accuracy. Franco and Cannas (1998) designed multilayer perceptrons (MLPs) that computed either the addition or multiplication of two binary numbers. The MLPs were constructed with at least one hidden layer and binary step functions as activations. Instead of being learned from data, the weights of the MLPs above were analytically designed. Hoshen and Peleg (2016) made MLPs that learned arithmetic addition, subtraction and multiplication from images of two 7-digit decimal integers through a numerical method.

The MLP was chosen as the connectionist model for the present study due to its strong learning ability, owing to the universal approximation theorem. According to the theorem, an MLP can learn any function if its hidden layers are large enough and its activation functions are squashing functions like sigmoid (Hornik, Stinchcombe, & White, 1989). This implies that MLPs should be capable of learning arithmetic/modulo operations including addition, subtraction, multiplication, division, and modulo[2]. Also, MLPs are a general type of neural networks capable of learning through backpropagation (Rumelhart, Hinton, & Williams, 1986). Based on these properties, we applied the MLP model to help better understand problem difficulty in arithmetic/modulo operations. In order to measure MLP's problem difficulty, we used *conquest epoch*, which is the number of epochs taken by a model to correctly learn a given problem set. We propose this empirical measure since complex nonlinear mappings from harder problems to their correct answers tend to require more epochs than easier problems. In this regard, the conquest epoch can be used to measure the difficulty of learning and solving a particular problem set by MLPs.

Previous studies used one or two arithmetic operators to study problem difficulty. In contrast, the present study investigated problem difficulty across five arithmetic operators[3] — addition, subtraction, multiplication, division, and modulo. The present study also examined problem difficulty across the number of carries for each operator. This provides a more complete view of the impact of both arithmetic operators and carries on problem difficulty. Furthermore, as far as we know, the present study is the first to investigate the impact of operators and carries on problem difficulty in the context of both humans and connectionist models.

Datasets

Operation Datasets For each operator, we constructed an *operation dataset*, containing all possible operations between two 4-digit binary nonnegative integers (ranging $[0, 2^4 - 1]$) that generate nonnegative results. The dataset consists of $(\mathbf{x}, \mathbf{y})$ where $\mathbf{x}$ is an 8-dimensional input vector that is a concatenation of the two operands, and $\mathbf{y}$ is an 8-dimensional output vector that is the result of computing the operands. In Table 1, 'Total' is the number of pairs in each operation dataset. Let us simply refer to, for example, the operation dataset of subtraction as the *subtraction dataset*, and problems from the subtraction dataset as *subtraction problems*. The subtraction dataset is nearly half the size of any other dataset because only problems satisfying $a - b \geq 0$ were included. In the case of division and modulo, the dataset size is $240 = 2^8 - 2^4$ because $a \div b$ where $b = 0$ were excluded. The entirety of these operation datasets was used to train MLPs.

Table 1: Operation and carry datasets. One operation dataset exists for each operator, and this dataset is subdivided into carry datasets.

	Operation datasets			
# Carries (n)	$+$	$-$	$\times$	$\div$, mod
0	81	81	161	214
1	54	27	11	13
2	52	19	17	9
3	42	9	20	4
4	27		29	
5			5	
6			4	
8			8	
12			1	
Total	256	136	256	240
Carry datasets	5	4	9	4

Carry Datasets Operation datasets were further subdivided into carry datasets. A *carry dataset* refers to the total set of problems requiring a specific number of carries to solve correctly, for a given operator. With n denoting the number of carries required to correctly solve a problem, multiplication has 9 possible n. Hence, multiplication has 9 carry datatsets. The number of carry datasets for the other operators are shown in Table 1. Let us simply refer to the carry dataset involving n carries as the *n-carry dataset*, and problems from the n-carry dataset as *n-carry problems*.

Experiment 1: Humans

Participants

153 undergraduate students (89 men, 64 women) from various departments completed the experiment for course credit. The average age of participants was 21.3 ($SD = 1.8$).

Materials

Problem Sets A *problem set* for a specific operator was given to participants. Problems in a problem set were evenly distributed across carry datasets so that participants answered equal numbers of questions from each carry dataset. Question distributions per problem set were as follows: addition – 50 problems across 5 carry datasets; subtraction – 40 problems across 4 carry datasets; multiplication – 45 problems across 9 carry datasets; division – 40 problems across 4 carry datasets;

[2]The present study refers to the modulo operation as modulo.

[3]Strictly speaking, modulo is not an arithmetic operator; however, for simplicity, the present study assumes there are five arithmetic operators including modulo.

modulo – 40 problems across 4 carry datasets. Arithmetic problems were randomly sampled from each carry dataset without replacement; let us refer to a set of problems sampled from an n-carry dataset as an *n-carry problem set*. Sampling without replacement prevented participants from answering previously seen problems. However, in rare cases where the number of problems in a specific carry problem set were insufficient[4], participants were presented with the same problem multiple times. Each participant was given a unique randomly sampled problem set. In a given problem, two operands were given in a fixed 4-digit format (Figure 2). This was done in order to control for the extraneous influence of the number of operand digits on problem difficulty, as outlined by criterion (b) in the introduction.

Calculation Guidelines Calculation guidelines were prepared for participants because of their unfamiliarity with the binary system. The guidelines first explained the concept of binary numbers, followed by guiding examples with detailed step-by-step calculations, based on the right-to-left standard algorithm (Wu, 2011). Guiding examples (Figure 1) for each operator were organized as follows: addition – 2 addition problems; subtraction – 2 subtraction problems; multiplication – 1 multiplication problem with 2 addition problems; division – 1 division problems with 2 subtraction problems; modulo – 1 modulo problem with 2 subtraction problems. More than one carry was involved in all guiding examples so that participants grasped the mechanism of carry operations.

Procedure

Participants were randomly assigned to a subset of problems pertaining to one of the five operators; 30 students were assigned to addition, 30 to subtraction, 33 to multiplication, 30 to division, and 30 to modulo. Participants studied detailed calculation guidelines containing one or two guiding examples (Figure 1) for a given operator until they fully understood the given operator. Participants then began the experiment, solving problems through the command line interface (Figure 2). The use of pen and paper was permitted to assist in problem solving. After solving each problem, the true answer was displayed (Figure 2) in order to help participants understand their mistakes and perform more accurately for subsequent problems.

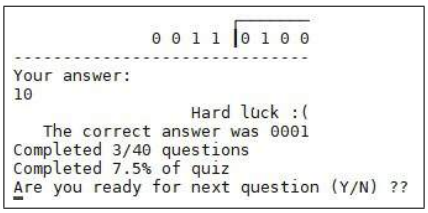

Figure 2: Sample program output.

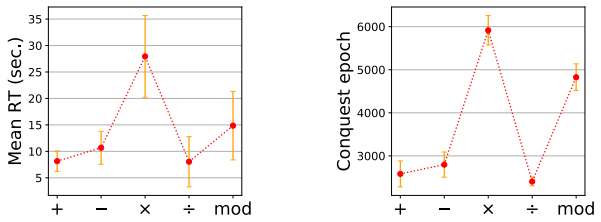
[4]This was the case for the multiplication 6-carry and 12-carry problem sets, the subtraction 3-carry problem set, and the division/modulo 2-carry and 3-carry problem sets.

Results

If a participant provided a correct answer for a problem, it is reasonable to assume that this participant performed the correct number of carries to arrive at that answer. As such, only RTs for correct answers were used in Experiment 1. Data and detailed analytical results are available in the footnoted repository[5].

Response Time by Operator Each participant's mean RTs across all five operators were analyzed. Let us denote the mean RT for a problem set of operator $*$ as RT^*. Analysis of Variance (ANOVA) was used to investigate differences in RT^* across the five operators $* \in \{+, -, \times, \div, mod\}$. ANOVA showed significant differences between all RT^* [$F(4,148) = 78.65$, $p < .001$, $\eta^2 = .68$]. Further, a post hoc analysis was performed to analyze comparisons between all RT^*. The results of the Games-Howell post hoc test can be denoted by using the following notation[6]: $RT^\times > RT^+$, $RT^\times > RT^-$, $RT^\times > RT^\div$, $RT^\times > RT^{mod}$, $RT^{mod} > RT^+$, $RT^{mod} > RT^\div$ [$p < .001$], $RT^{mod} > RT^-$ [$p < .05$], $RT^+ < RT^-$ [$p < .01$], but $RT^+ \approx RT^\div$, $RT^- \approx RT^\div$ [$p > .05$]. These results can be summarized as: $RT^+ \lessapprox RT^\div \lessapprox RT^- < RT^{mod} < RT^\times$ (Figure 3a).



(a) Humans: Mean RT. (b) MLPs: Conquest epoch.

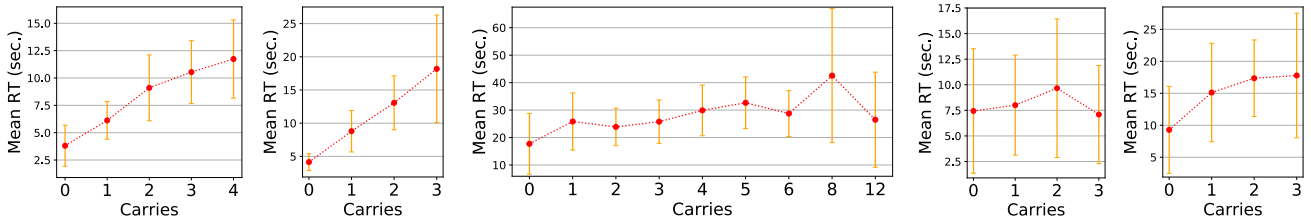
Figure 3: Problem difficulty by operator. The error bars are $\pm 1SD$.

Response Time by Carries Each participant's mean RTs across carry problem sets were analyzed. Let us denote the mean RT for an n-carry problem set of operator $*$ as RT^*_n.

Addition had 5 types of n-carry problems, $n \in \{0,1,2,3,4\}$. ANOVA showed significant differences between all RT^+_n [$F(4,145) = 43.45$, $p < .001$, $\eta^2 = .55$]. The Games-Howell post hoc test revealed that $RT^+_0 < RT^+_1 < RT^+_2$, $RT^+_0 < RT^+_3$, $RT^+_0 < RT^+_4$, $RT^+_1 < RT^+_3$, $RT^+_1 < RT^+_4$ [$p < .001$], $RT^+_2 < RT^+_4$ [$p < .05$], but $RT^+_2 \approx RT^+_3$, $RT^+_3 \approx RT^+_4$ [$p > .05$]. These results can be summarized as: $RT^+_0 < RT^+_1 < RT^+_2 \lessapprox RT^+_3 \lessapprox RT^+_4$ (Figure 4a). As such, for

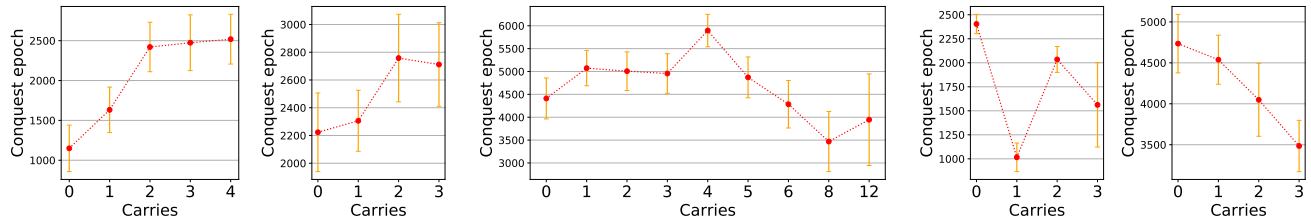
[5]https://github.com/sungjae-cho/cogsci2019-appendix/tree/master/human

[6]$A \approx B$ denotes $E[A]$ and $E[B]$ are not significantly different [$p > .05$]. $A < B$ and $B > A$ denote A and B are significantly different [$p < .05$] and their expectations hold $E[A] < E[B]$. $A \lessapprox B \lessapprox C \lessapprox D$ represents $A \approx B$ but A is less than any other right-hand operand (C, D); namely, $A < C$ and $A < D$. Likewise, concerning D, it indicates $C \approx D$, $A < D$ and $B < D$.



(a) Addition. (b) Subtraction. (c) Multiplication. (d) Division. (e) Modulo.

Figure 4: Humans: Mean RT by carries. The error bars are $\pm 1SD$.



(a) Addition. (b) Subtraction. (c) Multiplication. (d) Division. (e) Modulo.

Figure 5: MLPs: Conquest epoch by carries. The error bars are $\pm 1SD$.

$n \in [0,2]$, RT_n^+ was strictly increasing[7], but for all n, RT_n^+ was monotonically increasing[8].

Subtraction had 4 types of n-carry problems, $n \in \{0,1,2,3\}$. ANOVA showed significant differences between all RT_n^- [$F(3,116) = 46.07$, $p < .001$, $\eta^2 = .54$]. The Games-Howell post hoc test revealed all pairs of RT_n^- had significant differences. More specifically, $RT_0^- < RT_1^- < RT_2^-$, $RT_0^- < RT_1^- < RT_3^-$ [$p < .001$], $RT_2^- < RT_3^-$ [$p < .05$]. The results can be summarized as follows: $RT_0^- < RT_1^- < RT_2^- < RT_3^-$ (Figure 4b). Therefore, RT_n^- was strictly increasing with respect to the number of carries n.

Multiplication had 9 types of n-carry problems, $n \in \{0,1,2,3,4,5,6,8,12\}$. ANOVA showed significant differences between all $RT_n^\times$ [$F(8,284) = 9.24$, $p < .001$, $\eta^2 = .21$]. The results of the Games-Howell post hoc test can be summarized as follows: $RT_0^\times < RT_3^\times$ [$p < .05$], $RT_0^\times < RT_6^\times$ [$p < .01$], $RT_0^\times < RT_4^\times$, $RT_0^\times < RT_5^\times$, $RT_0^\times < RT_8^\times$ [$p < .001$], $RT_1^\times < RT_8^\times$ [$p < .05$], $RT_2^\times < RT_5^\times$, $RT_2^\times < RT_8^\times$ [$p < .01$], $RT_3^\times < RT_8^\times$ [$p < .05$]; there were no significant difference between the remaining pairs $RT_n^\times$, and only $RT_{12}^\times$ was not significantly different from any other $RT_n^\times$. These results can be summarized as: for $n \in [0,8]$, $RT_n^\times$ was monotonically increasing (Figure 4c).

Division had 4 types of n-carry problems, $n \in \{0,1,2,3\}$. ANOVA showed no significant differences between all $RT_n^\div$ [$F(3,116) = 1.20$, $p > .05$, $\eta^2 = .03$]. These results can be summarized as: $RT_0^\div \approx RT_1^\div \approx RT_2^\div \approx RT_3^\div$. Despite no significant difference between any $RT_n^\div$, a weak monotonically increasing trend in mean RT was observable (Figure 4d).

Modulo had 4 types of n-carry problems, $n \in \{0,1,2,3\}$. ANOVA showed significant differences between all RT_n^{mod} [$F(3,116) = 7.78$, $p < .001$, $\eta^2 = .17$]. The Tukey HSD post hoc test revealed that only RT_0^{mod} had significant differences from any other RT_n^{mod}. Specifically, $RT_0^{mod} < RT_1^{mod}$ [$p < .05$], $RT_0^{mod} < RT_2^{mod}$, $RT_0^{mod} < RT_3^{mod}$ [$p < .001$]. These results can be summarized as: $RT_0^{mod} < RT_1^{mod} \approx RT_2^{mod} \approx RT_3^{mod}$ (Figure 4e). RT_n^{mod} was monotonically increasing.

Experiment 2: Connectionist Models

Model

3000 MLPs (Figure 6) were trained for each operator. An 8-dimensional input vector comprised of two concatenated 4-digit operands was fed to the MLP. The MLPs had only one 2^6-unit hidden layer with sigmoid. An 8-dimensional output

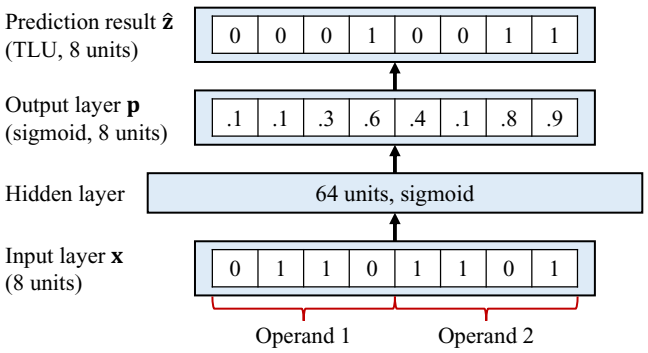


Figure 6: The structure of the multilayer perceptron. The model above predicts that $110 + 1101$ is equal to 10011.

[7]For every x and x' such that $x < x'$, if $f(x) < f(x')$, then we say f is *strictly increasing*.

[8]For every x and x' such that $x < x'$, if $f(x) \leq f(x')$, then we say f is *monotonically increasing*.

vector with sigmoid was used in order to match the maximum digit output of the arithmetic results. The predicted result is acquired by processing the output layer through the threshold logic unit (TLU), which transforms output numbers to 1 if they are greater than 0.5, and to 0 otherwise.

Training Settings

MLPs learned arithmetic operations by using backpropagation (Rumelhart et al., 1986) and a stochastic gradient method (Bottou, 1998) called Adam optimization (Kingma & Ba, 2015) with settings: $\alpha = .001$, $\beta_1 = .9$, $\beta_2 = .999$, $\varepsilon = 10^{-8}$. An entire operation dataset was utilized as a training set to train an MLP. For each epoch, a 32-sized mini-batch was randomly sampled without replacement (Shamir, 2016) from the training set. The weight matrix $W^{[l]}$ in layer l was initialized to samples from the truncated normal distribution ranging $[-1/\sqrt{n^{[l-1]}}, 1/\sqrt{n^{[l-1]}}]$ where $n^{[l]}$ is the number of units in the l-th layer; all bias vectors $b^{[l]}$ were initialized to 0. The objective function was the sum of the cross-entropy H between the true result $\mathbf{z}(\mathbf{x})$ and output activation vector $\mathbf{p}(\mathbf{x})$ where $\mathbf{x}$ is an input vector from a mini-batch: $\sum_{\mathbf{x}} H(\mathbf{z},\mathbf{p}) = \sum_{\mathbf{x}} [-\mathbf{z}(\mathbf{x}) \cdot \log(\mathbf{p}(\mathbf{x})) - (1-\mathbf{z}(\mathbf{x})) \cdot \{1 - \log(\mathbf{p}(\mathbf{x}))\}]$.

For every epoch, accuracy was evaluated on the total operation dataset and each carry dataset (Table 1). When 100% accuracy for a carry or operation dataset was attained, the current number of epochs was recorded as the conquest epoch of the dataset. Training was stopped when 100% accuracy for the operation dataset was reached.

Results

Data and detailed analytical results are available in the footnoted repository[9].

Conquest Epoch by Operator The conquest epochs of MLPs across operation datasets were analyzed. Let us denote the conquest epoch for the operation dataset of operator $* \in \{+,-,\times,\div,mod\}$ as e^*. ANOVA showed significant differences between all e^* [$F(4,14995) = 92838.78$, $p < .001$, $\eta^2 = .96$]. The Games-Howell post hoc test revealed that the differences between all pairs of e^* were significant [$p < .001$]. More specifically, these results can be summarized as: $e^{\div} < e^{+} < e^{-} < e^{mod} < e^{\times}$ (Figure 3b). This mirrors the ordering of the three highest mean RT in humans, as seen in Experiment 1.

Conquest Epoch by Carries The conquest epochs of MLPs across carry datasets were analyzed for each operator. Let us denote the conquest epoch of the n-carry dataset for operator $*$ as e^*_n.

Addition had 5 carry datasets, $n \in \{0,1,2,3,4\}$. ANOVA showed significant differences between all e^+_n [$F(4,14995) = 11835.66$, $p < .001$, $\eta^2 = .76$]. The Games-Howell post hoc test revealed that all pairs of e^+_n were significantly different [$p < .001$]. These results can be summarized as: $e^+_0 < e^+_1 < e^+_2 < e^+_3 < e^+_4$ (Figure 5a). As such, the conquest epoch e^+_n was strictly increasing with respect to n. Again, this mirrors results of RT^+_n from Experiment 1.

Subtraction had 4 carry datasets, $n \in \{0,1,2,3\}$. ANOVA showed significant differences among all e^-_n [$F(3,11996) = 2831.77$, $p < .001$, $\eta^2 = .41$]. The Games-Howell post hoc test revealed that all pairs of e^-_n were significantly different [$p < .001$]. These results can be summarized as: $e^-_0 < e^-_1 < e^-_3 < e^-_2$ (Figure 5b). Therefore, the conquest epoch e^-_n was strictly increasing for both $n \in \{0,1,2\}$ and $n \in \{0,1,3\}$.

Multiplication had 9 carry datasets, $n \in \{0,1,2,3,4,5,6,8,12\}$. ANOVA showed significant differences between all $e^\times_n$ [$F(8,26991) = 5024.17$, $p < .001$, $\eta^2 = .60$]. The Games-Howell post hoc test revealed that differences between all pairs of $e^\times_n$ were significant [$p < .001$]. Specifically, the results can be summarized as: $e^\times_8 < e^\times_{12} < e^\times_6 < e^\times_0 < e^\times_5 < e^\times_3 < e^\times_2 < e^\times_1 < e^\times_4$ (Figure 5c).

Division had 4 carry datasets, $n \in \{0,1,2,3\}$. ANOVA showed significant differences between all $e^\div_n$ [$F(3,11996) = 17788.62$, $p < .001$, $\eta^2 = .82$]. The Games-Howell post hoc test revealed that all pairs of $e^\div_n$ had significant differences [$p < .001$]. More specifically, the results can be summarized as follows: $e^\div_1 < e^\div_3 < e^\div_2 < e^\div_0$ (Figure 5d). Thus, the conquest epoch $e^\div_n$ was not increasing with respect to n.

Modulo had 4 carry datasets, $n \in \{0,1,2,3\}$. ANOVA showed significant differences between all e^{mod}_n [$F(3,11996) = 7281.45$, $p < .001$, $\eta^2 = .65$]. The Games-Howell post hoc test revealed that all pairs of $e^\div_n$ had significant differences [$p < .001$]. The results can be summarized as follows: $e^{mod}_0 > e^{mod}_1 > e^{mod}_2 > e^{mod}_3$ (Figure 5e). Hence, the conquest epoch e^{mod}_n was strictly decreasing with respect to n.

Discussion and Conclusion

Experiment 1 Results of the present study demonstrate how problem difficulty varies depending on the five arithmetic operators and the number of carries. In Experiment 1, results showed that for the five operators, problem difficulty was monotonically increasing with respect to the number of carries (Figure 4). Notably, for subtraction, RT was strictly increasing (Figure 4b). Another notable result was that RT for multiplication was the highest among the five operators (Figure 3a). In order to successfully perform multiplication, several sub-multiplication steps must first be completed (e.g. $1011 \times 1 = 1011$, $1011 \times 0 = 0$, see Figure 1). A participant may have to complete as many as 4-operand addition steps in order to correctly solve a single multiplication problem (Figure 1). It has been shown that the number of steps (DeStefano & LeFevre, 2004) and operands (Seitz & Schumann-Hengsteler, 2000, 2002) involved in arithmetic problems increases working memory demands. As such, the additional arithmetic steps involved in multiplication problems may have led to multiplication having the highest RT among the five operators. It is worth highlighting that participants solved the same 12-carry problem five times, due to

[9] https://github.com/sungjae-cho/cogsci2019-appendix/tree/master/mlp

there being only one problem in the 12-carry dataset (Table 1). This problem repetition may be responsible for the decreased RTs seen in the 12-carry problem set, relative to the 8-carry problem set (Figure 4c). As such, it is not valid to compare RT of the 12-carry problem set to other carry problem sets. Like multiplication, modulo problems also require many sub-operations to solve correctly. This may explain why modulo had substantially higher RT than addition, subtraction, and division (Figure 3a). Within the modulo problem set, RT for the 0-carry problems was significantly less than RT for problems involving carries (Figure 4e). However, no significant difference was found in RT between any pair of problem sets involving carries. Modulo involves the use of arithmetic sub-operations in order to correctly answer problems (Figure 1). However, unlike in multiplication, the subtraction sub-operations involved in modulo problems showed consistent patterns. The second operand of the sub-operations was always equivalent to either 0 or the denominator (e.g. 11, see Figure 1). These patterns may have lowered RT for higher n-carry datasets (Figure 4e). For division, even if a given problem was an n-carry problem, it did not necessarily involve n carries, as the final subtraction sub-operation may have been unnecessary in solving the problem (Figure 1). This may have meant that the number of carries in a division problem did not always impact on RT (Figure 4d).

Experiment 2 Experiment 2 found that problem difficulty (conquest epoch) for addition, subtraction, and division was substantially less than problem difficulty for multiplication and modulo. Addition, subtraction, and division may have been easier for MLPs to learn than the other two operators, due to the repeated occurrence of digit patterns in these problems. This implies MLPs learned multiplication and modulo problems by memorizing each problem, rather than by finding digit patterns. This experiment also found that addition problem difficulty for MLPs was strictly increasing with respect to the number of carries involved in a problem (Figure 5a). However, no such increase was seen in the other operators (Figure 5b, 5c, 5d, 5e). Generally, MLPs are sensitive to statistical properties of experience, such as the frequency and typicality of patterns they meet while they learn (Rumelhart & McClelland, 1986). In this regard, MLPs appear to require more epochs to conquer datasets that contain lots of infrequent and atypical patterns. However, the frequency and typicality of patterns in our datasets does not offer a satisfactory explanation as to why an increasing relationship between problem difficulty and carries was observed in addition, but not for the other operators.

Experiments 1 & 2 Comparing Experiment 1 with Experiment 2, humans and the MLPs showed partial similarities in their solving of binary arithmetic problems. For both humans and the MLPs, problem difficulty was highest for multiplication, followed by modulo and then subtraction. (Figure 3). Addition problem difficulty for both humans and MLPs showed increasing trends as a function of the number of carries (Figure 4a, 5a). However, the trajectories of these increases followed notably different paths (Figure 4a, 5a).

Contributions The present study makes four notable contributions to the current literature on mathematical cognition and cognitive science: Firstly, the present study compares problem difficulty across the five operators. This contrasts with preceding work, which has generally dealt with three or fewer operators. Furthermore, to the best of our knowledge, the present study is the first to investigate problem difficulty with regards to the modulo operation. Secondly, the present study for humans showed that the number of carries had a discernible effect on problem difficulty across four of the five arithmetic operators: addition, subtraction, multiplication, and modulo. Thirdly, the use of the binary numeral system allowed the present study to somewhat control for other criteria that may have impacted problem difficulty. These criteria include the problem size effect and over-familiarity with the decimal numeral system. This allowed for a targeted investigation into the effect of carries on problem difficulty. Finally, the present study found that MLPs experienced problem difficulty for some operators similarly to humans: For both humans and MLPs, problem difficulty was highest for multiplication, followed by modulo and then subtraction (Figure 3a, 3b). Also, the effect of carries on problem difficulty in addition problems showed increasing trajectories for both agents (Figure 4a, 5a). This supports previous research (McClelland et al., 2016) suggesting that there may be some similar cognitive processes underlying mathematical cognition in both humans and connectionist models.

Future Study Future studies should aim to uncover what underlying mechanisms caused the MLPs to experience relative problem difficulty similarly to humans across the five operators. Also, the internal representations MLPs use to perform arithmetic operations could be investigated. However, MLPs do not have the innate ability to dynamically process information as humans do. MLPs always take a fixed number of computational steps to produce answers, while humans take a variable amount of time to produce answers. One direction for future work could introduce a new dynamic connectionist model to learn arithmetic, namely, a recurrent network such as the Elman network (Elman, 1990) or the Jordan network (Jordan, 1997). Such recurrent networks can produce answers through variable computational steps depending on the problem. These variable steps can be directly compared to humans' RT, providing a more valid comparison to human arithmetic cognition.

Observing child-led exploration improves parents' causal inferences

Abstract

Do children's flexible causal inferences promote more creative causal discovery for observing adults? Inspired by a task in which children are more likely to consider unconventional causal forms (Lucas, Bridgers, Griffiths, & Gopnik, 2014; Wente et al., 2019), we designed a new method in which child-adult pairs work together to solve a causal task and assessed the relative influence of each member of the pair on the other's causal inference. Consistent with previous research, children were better than parents at learning the unusual conjunctive relationship, suggesting that children make more flexible causal inferences than adults. Our research also revealed a surprising and new result – that observing a child explore broadly helped parents to be more flexible and open-minded in their causal learning. In contrast, a child observing an adult's exploratory interventions had no negative consequence on the child's ability to infer the correct relation. Follow-up experiments explored the degree to which this child-led bootstrapping for adults was due to the particular exploratory evidence generated by the child during play, or merely the presence of a child. Results suggest that both factors may play a role in shaping adult's causal inferences.

Keywords: causality, cognitive development, parent-child interaction

Introduction

Like scientists, children explore, discover, and learn. Those of us with the good fortune to spend ample time with these little scientists can't help but be inspired by their curiosity and reminded of our own creative and inquisitive pasts. As Gopnik (2016) has suggested, childhood may be a unique time for greater exploration, cognitive flexibility, and creativity, leading to innovation for our species driven by our youngest. Of course, much research has focused on how children learn from adults, but perhaps there are cases when adults can learn from these innovative explorers. Perhaps there are cases when the flexible minds of children lead to knowledge and learning when adults lack.

Indeed, evidence from several research studies indicated that children learn specific and abstract causal structure and sometimes do so more readily than adults (Gopnik et al., 2017; Lucas et al., 2014; Wente et al., 2019). These findings suggest that children may be more open to new possibilities and willing to consider different hypotheses than adults (Gopnik et al., 2017). Often times, children encounter and explore new information in the presence of adults who may hold contrasting ideas about the world. Here we ask, how do children and adults interact with each other to explore and come to understand the world around them? In this study, using a new method in which child-adult pairs work together to solve a causal task, we look at whether exploratory patterns differ between children and adults and the extent to which these differences have consequences for causal inference in the observers.

Young children's ability to infer abstract causal principles has been studied using the forms of overhypotheses including conjunctive and disjunctive causal relationships. An overhypothesis is a broad framework that constrains the range of hypothesis learners consider (Goodman, 1955; Griffiths & Tenenbaum, 2007). A conjunctive causal relation is a functional form in which multiple causes jointly produced an effect; a disjunctive relation is a functional form in which a single cause can bring out an outcome independently (e.g., see Cheng, 1997). These overhypotheses are not bounded to a particular context but are applicable to many other scenarios, and having these assumptions shape future learning by limiting the number of possible hypotheses that are considered.

Prior research has revealed developmental differences in inferring a certain form of overhypotheses (Lucas et al., 2014). After having the same amount of exposure to evidence that is statistically best explained by (the unconventional) conjunctive causal form, children outperformed adults by correctly generalizing the conjunctive causal relationship to new objects. While both adults and children were successful at inferring a disjunctive form, the ability to infer conjunctive forms appears to be decreased with age. When given evidence that supported a conjunctive form, adults instead maintained a disjunctive relationship (Lucas et al., 2014). The developmental differences in learning of the conjunctive (but not disjunctive) causal form suggest that young children are more flexible than adults in incorporating evidence to guide future learning (See also Gopnik et al., 2017; Wente et al., 2019; Gopnik, Griffiths, & Lucas, 2015).

In these past studies, participant's ability to infer abstract causal forms was tested by asking for judgments about the causal efficacy of each cause or to use potential causes to produce an outcome. However, in these studies, participants were not given the opportunity to explore and generate their own evidence. Thus, it remains an open question whether adult and child participants will generate different patterns of exploration when given the opportunity to test out possible causal forms.

One concern is whether children will be able to generate meaningful play at all. However, recent findings are supporting the claim that young children may be more competent and capable explorers than previously believed. For example, children shape their explorations to conduct inter-

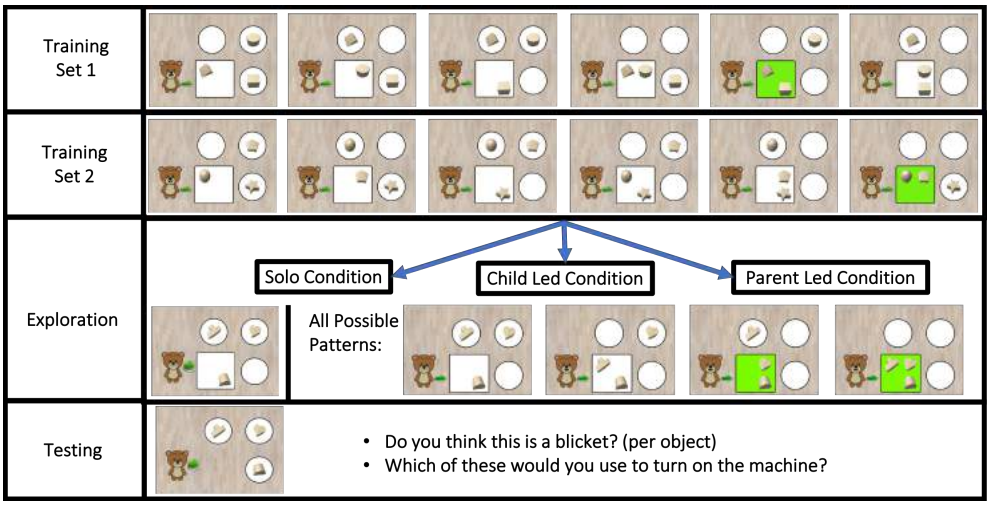

Figure 1: Stimuli and task procedure; During two sets of training, parent-child pairs watched experimenter demonstrating evidence in favor of a conjunctive causal form. Following the training, parent-child pairs were randomly assigned to solo, child-led, and parent-led conditions. In the solo condition, the parent and child each explored the set of testing objects. In the child-led group, the child explored the testing objects while parent watched. In the parent-led group, the parent explored the testing objects while the child watched. Finally, the experimenter asked the parent and child individually to judge whether each object was a blicket and to turn on the machine.

ventions to deconfound variables (Schulz & Bonawitz, 2007; Schulz, Kushnir, & Gopnik, 2007; Schulz, 2012; Schulz, Gopnik, & Glymour, 2007). Further, children plan their future exploration based on the inference about pedagogical goals of teachers based on available information (Bonawitz et al., 2011; Eaves & Shafto, 2012; Gweon, Pelton, Konopka, & Schulz, 2014). These studies provide evidence for the claim that children's exploration is guided by the evidence. However, it remains an open question whether the evidence generated during children's and adults' explorations may differently reflect beliefs going into the task.

Prior studies revealed developmental differences in the conjunctive causal inference by examining child and adult groups individually. Despite the importance of caregiver-child interaction on play and development (Weisberg, Hirsh-Pasek, & Golinkoff, 2013; Fisher, Hirsh-Pasek, Newcombe, & Golinkoff, 2013; Honomichl & Chen, 2012), little is known about the impact of observing either child's or parent's patterns of exploration on one another. Thus, we were also interested in whether observing children's broad hypothesis search would promote more creative and flexible thinking in causal learning for observing adults. Of course, observing adults' exploration may also influence children's conjunctive causal learning. For example, instructions constrain children's explorations indicating that children are sensitive to inductive biases in their explorations (Bonawitz et al., 2011). Similarly, a body of literature on guided play highlights that it is critical for adults to scaffold learning goals as well as let children direct their exploration and discovery (Weisberg et al., 2013; Fisher et al., 2013). This balance between scaffolding and letting the child take the lead could be particularly important when children and adults hold different assumptions about the world.

In the present work, we examined the extent to which exploration patterns differed between children and adults and whether observing another's exploration shaped consequent learning. In Experiment 1, we examined children and their parents' exploration and learning following the exposure to evidence consistent with a conjunctive causal relationship. Critically, we manipulated who the actor was generating the evidence including a child-led condition, parent-led condition, and solo conditions for each group as controls. Consistent with prior research, we hypothesized that children would be more likely than adults to generalize a conjunctive causal relationship. However, we also predicted differential exploratory patterns for children and adults. We looked at whether these differences have consequences for learning in the observers. Specifically, observing parent-led exploration may restrict children's causal inference, thus resulting in more adult-like responses. On the other hand, observing child-led exploration may result in flexible learning in parents.

Experiment 1

Methods

Participants Seventy-two parent-child dyads were recruited from various settings (i.e., museum, home, and community event; Children: n = 72, 53% Female, M = 5.03, SD = 0.84, Range = 4.0-6.9 years; Parents: n = 72, 56% Mothers). The dyads were randomly assigned to the Solo (n = 24), Child-Led (n = 24), and Parent-Led (n = 24) conditions.

Additional two dyads were recruited but excluded due to not finishing the study ($n = 1$) or experimental errors ($n = 1$).

Stimuli and Apparatus Our procedure involved both real objects and interactive video stimuli. The interactive video stimuli were developed using jsPsych (De Leeuw, 2015) and displayed on a touch-screen tablet computer (10.1-in. Galaxy Tab; Samsung America, San Jose, CA). The video included images of three circles, a square, a green button, and a cartoon bear (see Figure 1). Images of objects were presented on the three circles, and each object moved to the square when tapped. The button was designed to test objects once they were placed on the square. In addition, to provide a way for participants to respond without influencing the listening other, two identical yes-no response sheets were created so participants could silently point to their response behind a barrier. The sheets included two rectangles (green and red), each includes a smiley or frowny face with "yes" or "no" written at the bottom, respectively.

Procedure Participants were tested in a quite place. The yes-no response sheets were placed in front of the participants. The experimenter asked a simple question about color (i.e., Is this white?) to both the child and the parent. If participants pointed to the wrong answer or responded verbally, the experimenter asked additional questions until children successfully responded using the yes-no response sheet.

Next, a backward blocking task was conducted (e.g. see Sobel, Tenenbaum, & Gopnik, 2004). This task was designed to acclimate the participants to an ambiguous causal reasoning task as well as familiarize participants with the instructions. The participants were introduced to a machine that detects "wugness". The experimenter explicitly stated that wugs are very rare and can not be judged solely by looking, but they possess wugness inside them. First, the experimenter placed two potential causes (Objects A and B) on the machine, which produced an outcome. Then the participants observed that the outcome occurred with the presence of only one of the causes (A). After observing these two events, the participants were asked to judge whether each object (A, B) was a wug, respectively.

Upon the completion of the backward blocking task, the experimenter introduced the tablet and stated that they would now play a completely different game (see Figure 1). The experimenter also mentioned that blickets are very rare and can not be judged just by looking, but have blicketness inside them. After a brief introduction to the features of the tablet game, the experimenter introduced an object (C) and ask if the participant thought that object as a blicket without any evidence; this allowed us to test participants' priors for the probability of an object being a blicket. Then the experimenter presented the first set of three training objects (D, E, F) which activated the machine according to a conjunctive causal rule. This was followed by another set of different training objects (D', E', F') that also provided evidence for a conjunctive rule, as in Lucas et al. (2014).

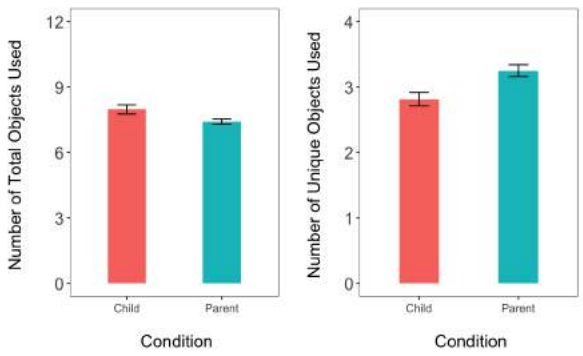

Figure 2: Differing exploratory patterns as measured by total object used (left) and unique actions (right) during the Exploration Phase. Compared to children, parents used more unique combinations of objects, but also fewer objects were tried on each trial. Error bars denote *SE*.

Following the two training trials, the experimenter introduced the new set of three testing objects (G, H, I) that the participants would have the opportunity to explore and test themselves. During this phase, one object (I) was permanently attached to the square. This was designed so that the evidence generated during the free intervention phase would maintain ambiguity. At the beginning of the exploration phase, the participants were told that the object (I) was stuck on the machine and that they can test the object (I) by itself or with the other objects. There were four exploration trials, and participants could choose one of the four possible options (I, GI, HI, GHI) in each trial. Our critical between-subjects design varied who controlled the interventions. In the solo condition, both parent and child had their own tablets, and could not see the screens or exploratory choices of the other. In the Child-Led condition, the child made all intervention choices while the parent watched. In the Parent-Led condition, the parent made all intervention choices while the child watched. Participants were given four intervention trials (a trial was counted once the participant depressed the test button); the intervention choices were recorded automatically with the tablet software. Next, the experimenter asked the parent and child to judge whether each object was a blicket. Lastly, as our critical test measure, the experimenter asked the parent and child individually to generate the effect using the objects ("Which of these objects would you use to turn on the machine?"). We coded whether two or more objects were used.

Results

We first assessed what kinds of interventions children and adults performed during the exploration phase. Results revealed that overall, children were more likely than adults to explore objects jointly, Welch $t(90.5) = 3.19$, $p = .001$ (Figure 2, left), suggesting that children may have been more amenable to the conjunctive rule as early as the exploration

phase. However, the quality of children's interventions was not strictly better than adults: parents tried more deconfounding causal explorations by testing more unique combinations of objects, $t(72.9)$= -2.36, p = .021 (Figure 2, right). Within each age group (child and adult, respectively), there was no significant difference between solo and joint groups, $p >$ .250.

Critically, we explored whether any particular group was more successful at generating the correct response in the final test phase. Overall, and replicating previous findings, children performed better on average than the adults, $\chi^2(1)$ = 20.39, $p < .001$. We conducted a logistic regression to predict the probability of selecting one or more objects to activate the machine as a function of condition. As shown in Figure 3, the parents in the Child-Led group were more likely to use multiple objects to activate the machine than those in the Parent-Led group, b = 1.44, p = .022, suggesting that observing evidence generated by children helped parents to be more flexible and exploratory in their own causal inferences. The probability of choosing multiple objects as blickets in the Parent-Solo condition did not differ from that in the Child-Led condition b = 0.84, p = .152, or the Parent-Led condition, b = 0.59, p = .353.

Consistent with previous research, children were better than parents at learning the unusual conjunctive relationship, suggesting that children make more flexible causal inferences than adults. Our research also revealed a surprising result – that merely observing a child's exploratory behavior may suffice to help parents to be more flexible and open-minded in their causal learning. Two possible explanations exist for this result. One possibility is simply that watching a child interact with the toy (regardless of the patterns of exploration) was sufficient to get adults in a childlike frame of reference, opening their mind to a broader set of hypotheses. Another possibility is that the particular evidence generated by children (which differed from adults) was critical in helping adults infer the conjunctive form. In Experiment 2, we explored these possibilities by having adults view a child actor perform interventions for all conditions. Critically we varied the particular interventions presented, yolking the evidence to the specific interventions attempted in the Child-Solo, Child-Led, and Parent-Led conditions of Experiment 1.

Experiment 2

Methods

Adults participants were recruited from Amazon Mechanical Turk. The final sample of 72 participants were randomly assigned to the Child-Solo-Exploration-Data (n = 24), Child-Led-Exploration-Data (n = 24), and Parent-Led-Exploration-Data (n = 24) conditions. An additional 10 participants were excluded from analysis because of the failure to pass an attention check question. Participants were paid $.75 for completing the 6-8 minute survey.

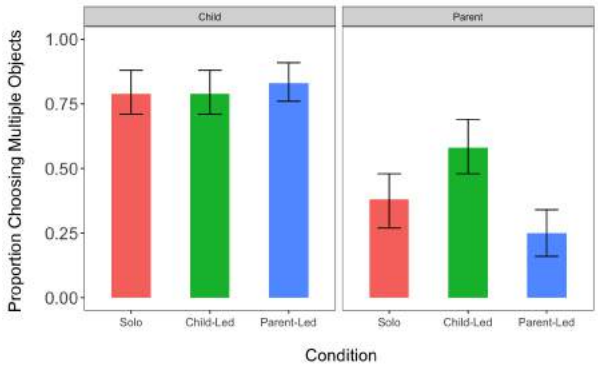

Figure 3: Proportion of participants who selected multiple objects on the final test trial by condition (Solo, Child-Led, Parent-Led). Children correctly attempted multiple objects to turn on the machine regardless of condition. However, adults were only more likely to test multiple objects in the Child-Led condition. Error bars denote *SE*.

Procedure

The stimuli and procedure was the same as that of Experiment 1 except the following differences. First, the data collection was conducted online; thus, the training phase was introduced with a series of screenshots of tablet games, and the participants were required to click a button to proceed. Second, for the exploration phase, the participants saw a video of a preschooler trying to figure out which objects are blickets using the tablet game. The same child actor generated different exploratory patterns, which was organized to match the patterns of exploration data generated from the three conditions (Child-Solo, Child-Led, Parent-Led) in Experiment 1. The preschooler was described to the participants as being a randomly selected example of a child exploring the toy.

Results

We used a logistic regression model as a function of condition (Child-Solo-Exploration-Data, Child-Led-Exploration-Data, Parent-Led-Exploration-Data) to predict the probability of using two or more objects to turn on the machine. There was a significant difference between the Child-Solo-Exploration-Data (67%) condition and the Parent-Led-Exploration-Data (38%) condition such that the group of participants who observed child-solo-exploration data showed a higher probability of using multiple objects to activate the machine compared to those who observed parent-led-exploration data, b = 1.20, p = .046. Unexpectedly, there was also a marginally significant difference between the Child-Solo-Exploration-Data (67%) and Child-Led-Exploration-Data condition (42%), b = 1.02, p = .085.

These results revealed that observing children's exploratory patterns based on broad, exploratory hypotheses supported adults' learning of an unconventional abstract causal form (at least in cases when data from the Child-Solo-Exploration-Data condition were observed). Experi-

ment 2 provides additional support for the idea that observing child-generated exploratory patterns increases the flexibility of adult's causal reasoning. It remains unclear whether the child-generated exploratory evidence alone would be sufficient to promote adults' causal reasoning, or whether it is this evidence *in conjunction* with a child-directed play that helps adults. Further, Experiment 2 was conducted via an online survey platform; thus, the findings may be limited in their generalization to adults in a live setting. To explore this further, in Experiment 3, we used an in-lab setting to conduct child-yoked interventions, but performed by adults. We focus our attention on the two critically different yolked-data conditions: Child-Led-Exploration-Data and Parent-Led-Exploration-Data.

Experiment 3

Methods

Forty-eight undergraduate students (M = 20.60, SD = 3.13, range: 18-31 years) were randomly assigned to the Child-Led-Exploration-Data (n = 24) or Parent-Led-Exploration-Data (n = 24) conditions. An additional 5 participants were excluded from analysis because of experimental errors in generating the data from the yolked trials.

Procedure

The stimuli and procedure was the same as to that of Experiment 1 except the following differences. First, the data collection was conducted in the lab. Second, each participant was paired with a confederate who secretly worked with the lab but who was introduced as another naive participant. During the exploration phase, the participant observed the confederate exploring the testing objects, as if choices were "in the moment" decisions. Instead, however, the confederate completed the four exploration trials as yolked to the data generated from the two conditions (Child-Led, Parent-Led) in Experiment 1.

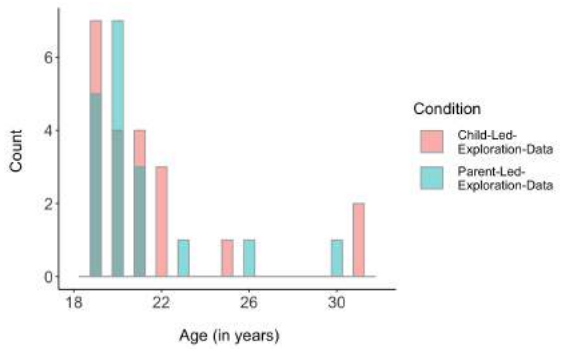

Figure 4: Histogram of age of participants for each condition (Child-Led-Exploration-Data, Parent-Led-Exploration-Data) in the sample. Age was ranged from 18 to 31 years.

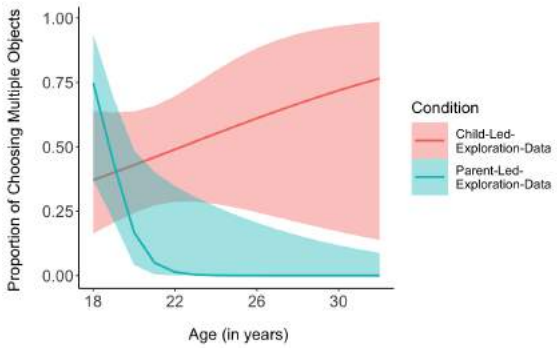

Figure 5: Proportion of participants who selected multiple objects for each condition (Child-Led-Exploration-Data, Parent-Led-Exploration-Data). Adults in the Child-Led-Exploration-Data condition were more likely to use two or more objects to turn on the machine than those in the Parent-Led-Exploration-Data condition. Shading indicates 95% confidence intervals.

Results

Comparing overall performance in terms of endorsement of two or more casual blocks between Child-Led-Exploration-Data and Parent-Led-Exploration-Data conditions revealed no overall differences, $\chi^2(1) = 0.35$, $p = .555$. This result is surprising, given the condition differences observed in Experiment 2. One possible explanation for this difference is that indeed the presence of the child generating the particular interventions was required to help adults consider the unlikely conjunctive form.

However, we also noticed that the age of the participants in our lab sample (ranging from 18-31 years; see Figure 4) significantly differed from the parents in Experiment 1 (ranging in mid-thirties to forties), and so we performed an unplanned exploratory analysis using a logistic regression model with age as a continuous variable and condition (Child-Led-Exploration-Data, Parent-Led-Exploration-Data) to predict the probability of using two or more objects to turn on the machine. In fact, there was a significant interaction between age and condition such that the group of participants who observed child-led-exploration data showed a higher probability of using multiple objects to activate the machine compared to those who observed parent-led-exploration data with increasing age, $b = 1.46$, $p = .018$ (see Figure 5). The pattern stayed the same for a narrower age range (18-24 years).

These results suggest that while child-yoked interventions may assist adults with causal form inferences, age may moderate this effect. Specifically, observing child-generated evidence was particularly helpful for the older participants of our sample.

Discussion

Consistent with previous research showing that adults are less likely to generate a conjunctive causal form than children, children were better than parents at generalizing the unusual

conjunctive form to their exploration and learning (Gopnik et al., 2017; Lucas et al., 2014; Wente et al., 2019). By examining exploration, we revealed that parents tried more deconfounding explorations than children. In contrast, children performed more interventions that involved multiple blocks, suggesting that children were engaging in hypothesis confirmation consistent with having inferred the conjunctive form from the previous training trails.

Strikingly, parents in the Child-Led group were more likely to generalize the conjunctive relationship than those in the Parent-Led group. Child-yoked interventions performed by either a child or adult similarly improved causal form inferences, suggesting that observing evidence generated by children may help adults to be more flexible in their own causal inferences.

In our study, young children generalized the unconventional conjunctive relationship to their exploration and learning regardless of whether the free play period was led by an adult or not. Of course, if children had already inferred the correct causal form from the initial training trials, than any intervention observed would continue to confirm children's overhypothesis because we designed the toy to produce outcomes consistent with the conjunctive form. In contrast, if adults had not yet inferred the correct form prior to the exploration phase, then observing their children repeatedly use multiple blocks to activate the machine may have been sufficient to raise the salience of this alternative hypothesis and facilitate learning.

The results from Experiments 2 and 3 suggest that adults' causal inferences can benefit from observing child-yoked explorations, especially when those exploratory patterns were generated by a child than an adult. However, as these two experiments were conducted in different environments (in-person vs. online), the contextual factor may have contributed to the differences. Thus, an important next step would be to test the effect of the age of the model who demonstrates child-led exploratory patterns in the same setting. Future work will examine whether watching a video of an adult demonstrator performing child-yoked interventions similarly improves adults' causal form inferences, controlling for the familiarity of the adults to the demonstrator. Further, future studies could explore the characteristics of adult observers such as age and experience working with young children.

The current findings show the importance of observing other's exploration when beliefs are in conflict with each other. Adults at least may be able to recognize the relationship between attempted interventions and considered hypotheses, raising awareness of hypotheses that were not previously considered. Such an account is consistent with the Wisdom of the Crowds (Vul & Pashler, 2008) or the adage that two heads are better than one. However, our results go one step further, suggesting that even observing the exploratory actions of another may help bootstrap inference to the best explanation.

More broadly, these findings support the importance of adult-child play, but with a surprising twist. Adults may benefit from play with children (rather than the other way around, as is often considered in the literature). Such work suggests the importance of giving children opportunities to lead their own exploration and discovery.

Parent-child joint play occurs in numerous settings involving both concrete and digital materials. In light of the pervasive interactive technology in young childrens everyday lives, it is important to understand how these tools can be used not only to transmit information but also support active exploration and discovery. This line of research can help us understand the ways in which parents and children conjunctively learn about the world.

Acknowledgments

We thank staff, parents, and children of Newark Museum for their participation and Cierra Clark, Kiabeth Guazhco, and Micah Connolly for data collection. This research has been supported by NSF-CNS-1623486 (EB), Jacobs Foundation Fellowship (EB), and NSF-SES 1627971 (EB).

Abstract

How do we seek information from our environment to find solutions to the questions facing us? We pose an open-ended visual search problem to adult participants, asking them to identify targets of questions in scenes guided by only an incomplete question prefix (e.g. Why is..., Where will...). Participants converged on visual targets and question completions given just these function words, but the preferred targets and completions for a given scene varied dramatically depending on the query. We account for this systematic query-guided behavior with a model linking conventions of linguistic reference to abstract representations of scene events. The ability to predict and find probable targets of incomplete queries may be just one example of a more general ability to pay attention to what problems require of their solutions, and to use those requirements as a helpful guide in searching for solutions.

Female advantage in visual working memory capacity for familiar shapes but not for abstract symbols

Abstract

Both behavioral studies and the neurophysiological data modelling suggested female advantage in memory for objects, however, most research pertained to long-term memory, whereas data from visual working memory (VWM) are scanty. In a large sample of 2044 people, the number of objects supposedly encoded in VWM was measured during the change detection task. The stimuli were either relatively familiar geometric shapes or less familiar Greek symbols. Controlling for the general ability level, a small but significant advantage for memorizing shapes in VWM was found in females over males, but no effect was observed for memorizing abstract symbols. The present results support neuroimaging models of human cognitive architecture, suggesting that female VWM relies on a more complex network of domain-specific brain modules, as compared to males. Consequently, formal models of VWM and related cognitive processes should account for sex and material type.

Keywords: visual working memory, sex differences, change detection task, neural architecture of memory

Introduction

Notable sex differences are observed in human memory, especially in long-term memory (LTM) and episodic memory (Halpern, 2013; Kimura, 1999). Research suggested that female brains are more effective in encoding and retrieving information pertaining to objects, episodes, faces, and verbal material, whereas males seem to better memorize spatial information (for reviews see Cahill, 2006; Herlitz & Rehnman, 2008). However, a relatively smaller number of studies were devoted to sex differences in working memory (WM), making this topic worth of closer examination.

WM is defined as a key neurocognitive mechanism responsible for active maintenance, effective updating, and controlled retrieval of task-relevant information during short periods of time (Cowan, 2001). At the same time, WM is believed to block task-irrelevant and distracting information (Kane & Engle, 2002). WM operation relies on short-term memory (STM), but most likely also involves memory processes beyond the sheer passive storage in STM. The key feature of WM is its limited capacity comprising the simultaneous representation of only several "chunks of information," being objects, their features, and their bindings. Given that WM is a key construct in psychology as well as a strong predictor of complex cognitive abilities, such as problem solving, fluid reasoning, and education (Kane, Hambrick, & Conway, 2005), vast research has been devoted to the neurocognitive underpinnings of WM. Establishing whether sex differences, commonly observed in other types of memory, do exist also in the case of WM performance, may contribute to our understanding of WM mechanisms. Moreover, if potential sex differences in WM are driven by the type of to-be-memorized content, in either a similar or a different way, in comparison to the content effects found for the other memory systems, such an observation may provide additional evidence for theoretical models that assume either close links between WM and LTM (Crowder, 1993; Nairne, 2002; Neath & Suprenant, 2003) or their relative separateness (e.g., Cowan, 2001; Kane & Engle, 2002; Vogel, Woodman, & Luck, 2001). The data can also guide design of the future studies on WM.

Sex differences in working memory

Early studies reported sex differences in WM that matched those found for LTM, with verbal tasks such as the reading span favoring females (e.g., Cochran & Davis, 1987), whereas spatial tasks such as the Corsi blocks favoring males (e.g., Grossi, Matarese, & Orsini, 1980). However, later studies reported differences that either were negligible, or highly variable from task to task (e.g., Duff & Hampson, 2001; Lejbak, Crossley, & Vrbancic, 2011; Postma, Jager, Kessels, Koppeschaar, & van Honk, 2004; Reed, Gallagher, Sullivan, Callicott, & Green, 2017; Robert & Savoie, 2006; for meta-analyses see Halpern, 2013; Voyer, Postma, Brake, & Imperato-McGinley, 2007; Voyer, Voyer, & Saint-Aubin, 2017; Wang & Carr, 2014).

Crucially, Speck et al. (2000) suggested that most of these cognitive studies were underpowered to detect robust sex differences in WM, whereas functional brain connectivity patterns differentiating females and males may be more informative than comparing WM capacity between females and males. Indeed, such patterns have been found (Filippi et al., 2013; Grabowski, Damasio, Eichhorn, & Tranel, 2003; Piefke et al., 2005). A comprehensive meta-analysis of 44

neuroimaging papers that studied males and another 15 that studies females, which used activation likelihood estimation (ALE) method, identified the brain regions most likely associated with sex differences. It showed that besides large overlapping structures in the frontal and parietal cortices, which are commonly attributed to WM, the female performance seems to depend also on additional prefrontal sites as well as hippocampus and anterior cingulate, whereas the male performance relies on additional parietal sites as well as insula (Hill, Laird, & Robinson, 2014).

However, it is still interesting to see how the observed sex differences in the brain activations might translate into behavioral differences in coping with tasks tapping WM. Only, a larger power is most likely needed to detect such behavioral consequences of neural differences. The present study aimed to investigate sex differences in visual working memory (VWM) using the varied types of to-be-memorized content. On the basis of previous research on sex differences in LTM, as well as interpreting the Hill et al.'s findings, it was assumed that the involvement of hippocampal regions in female WM may result in a better encoding of more concrete and familiar objects by females, as compared to males, because neurons in and around hippocampus are known to encode episodic information that can be linked to existing memory traces (see Eichenbaum, Yonelinas, & Ranganath, 2007; Wixted et al., 2014). The involvement in male WM of parietal and insular regions, commonly associated with awareness and attention (see Cowan et al., 2011; Eckert et al., 2009), can in turn yield the male advantage in encoding of less concrete and unfamiliar objects, which cannot be easily memorized using episodic and semantic traces, and thus require increased attentional effort. Indeed, some studies on episodic memory suggested the female advantage in recall and recognition of concrete pictures (Herlitz, Airaksinen, & Nordström, 1999) and familiar odors (Lehrner, 1993), but no advantage for more abstract images (ink blots and snow crystals; Goldstein & Chance, 1970) and unfamiliar odors (Öberg et al., 2002). Unfortunately, such a prediction has never been tested with regard to WM nor in large samples.

The present study analyzed data of 2044 people, collected over several published studies, conducted in the authors' laboratory between year 2007 and 2018. All these studies assessed VWM capacity using a simple recognition paradigm, called the change detection task, with stimuli being either geometric shapes or Greek symbols. The systematic use of the shape and the symbol variant of the change detection task gave an unique opportunity to check the sex × material interaction in a sample size never examined to date, which might allow to overpass the Speck et al. objections regarding the behavioral studies of sex differences in WM. In line with Hill et al. (2014), the female advantage in VWM capacity for more concrete, more familiar geometric figures was expected, as such figures could be encoded via episodic/semantic traces in and around hippocampus, which was a brain structure identified as a more specific to females. The male advantage in VMW capacity for more abstract, more unfamiliar Greek symbols was predicted, as such symbols could not be easily associated with episodic/semantic information, and might require increased attentional effort supported by the parietal sites and insula, found to be more active in males. Although the classification of shapes as more concrete, while Greek symbols as more abstract is not univocal (see Discussion), these two kinds of material were clearly different, and the examination of sex × material interaction was worthwhile.

The study

Participants

The total sample encompassed 1310 females (aged 17 to 46 years, M = 23.2, SD = 4.6) and 734 males (aged 18 to 46 years, M = 23.7, SD = 4.7). All participants were recruited from general population via internet adverts, in a Central-European city. The prevalence of females in the sample unfortunately resulted from the robust tendency for female enrolment in the psychological study recruitment. All participants signed a written consent to participate, were screened for normal or corrected-to-normal vision and no history of neurological problems, and were informed that they could stop the experiment and leave the lab at will. All data were anonymized. All other procedural aspects of the study conformed to the WMA's Declaration of Helsinki.

Materials

The stimuli in each trial of the symbol variant of the change-detection task were randomly drawn from the set of 16 small Greek letters (α, β, δ, θ, λ, μ, π, etc.), whereas in the shape variant they were drawn from the set of 16 simple shapes (circle, square, rhombus, etc.). Each stimulus was approximately 2×2 cm in size and was presented in black on a grey background. Each variant included either 60 or 90 trials, depending on a study (preceded by several training trials). Each trial consisted of a virtual, 4 × 4 array filled with several stimuli (see Fig. 1). From four to nine stimuli were used across studies. The array was visible between 1 s and 4 s (depending on set size), and was followed by a 1-s black square mask. On random, either the second array was identical to the first or both differed by exactly one item at one location. Either the new or random item, respectively, was highlighted by a square border. The task was to press one of two response keys (Z, M) depending on whether the highlighted item differed or not. The order of task variants was random between the studies, and they were preceded and followed by other tasks. The task score was the estimated average number of objects that were effectively maintained in VWM (k; Rouder et al., 2011), calculated as the participant' difference between the proportion of correct responses for arrays with the item change and the proportion of incorrect responses for unchanged arrays, multiplied by

the set size. For example, if in a six-object condition 80% correct was scored in the former trials, and 70% correct was scored in the latter trials, formula yielded $k = 6 \times (.80 - .30) = 3$ objects supposedly maintained in VWM. Thus, the k value is relatively insensitive to the actual set size.

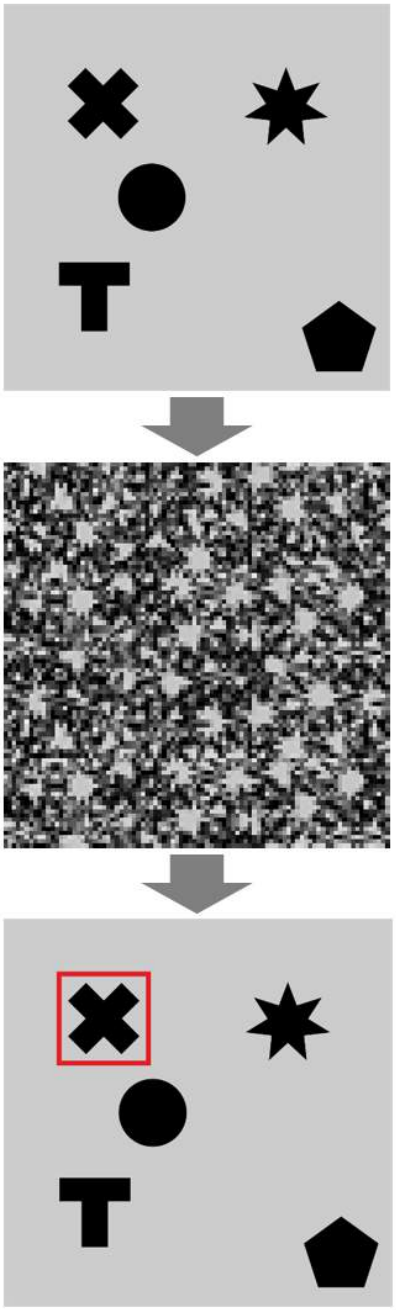

Fig. 1: Example stimuli and the sequence of events in the change detection task used in the study. The familiar shapes condition is shown; in the abstract symbols condition the task was identical except for Greek symbols were displayed. The "no-change" trial is shown; the "change trial was identical except for the shape (or symbol) surrounded by the rim in the bottom screen differed from the respective shape (or symbol) in the top screen.

As a short presentation time (2.5 s on average) and the graphical nature of stimuli practically eliminated their verbalization, it was assumed that the main difference between the tasks pertained to the concreteness and familiarity of stimuli, predicted to be larger for geometric shapes that commonly appear in the environment, whereas expected to be smaller for foreign Greek symbols that are not taught in schools and are rarely encountered in daily life and media in Poland, where the studies were held.

Additionally, general fluid intelligence (*gf*) was screened with two reasoning tests, Raven's APM (Raven et al., 1983) and (depending on a study) either Figural analogies (Chuderski & Nęcka, 2012) or Culture Fair Test Version 3 (Cattell & Cattell, 1961). The test results were converted to *Z* scores, separately for each study, and then averaged to yield the *gf* factor value. As VWM capacity strongly correlates with fluid intelligence (see Kane et al., 2005), this *gf* factor was used as a covariate in comparisons between females' and males' VWM scores, in order to make sure that any sex difference in fluid intelligence does not account for the expected sex differences in VWM.

Results

Males displayed the mean *gf* value of 0.047 ($SD = 0.960$), whereas females scored $gf = -0.019$ ($SD = 0.883$), and this difference was not statistically significant, $t(2042) = 1.59$, $p = .112$. Fig. 2 presents the female and male distribution of k values, separately for each material variant. All four distributions were normal, and yielded comparable standard deviations both for the shape variant, $SD_{female} = 1.49$, $SD_{male} = 1.52$, and the symbol variant, $SD_{female} = 1.49$, $SD_{male} = 1.52$. Visual inspection of Fig. 2 suggests that in the shape variant the female distribution was shifted right, relative to the male distribution, while in the symbol variant the distributions closely matched.

To formally test this observation, the k values were submitted to ANCOVA, with sex and material as two factors, and the *gf* factor as a covariate. Fig. 2 shows the respective means and 95% CIs. The shape variant yielded a comparable performance ($k = 3.05$) to the symbol variant ($k = 2.98$), $F(1, 4080) = 2.17$, $p = .141$, suggesting that overall both materials were equally demanding. The key analysis pertained to sex differences. There was a marginal effect of sex ($k_{female} = 3.04$, $k_{male} = 2.99$), $F(1, 4080) = 4.09$, $p = .043$, but the sex effect was qualified by its significant interaction with material, $F(1, 4080) = 8.15$, $p = .004$, $\eta^2 = .002$. In the shape variant, females performed significantly better than males ($\Delta k = 0.18$), $F(1, 4080) = 11.94$, $p = .0005$, $d = .20$, but no significant sex difference was noted for the symbol variant, ($\Delta k = -0.08$), $F(1, 4080) = 0.34$, $p = .559$. For females, the difference between variants was statistically significant in favor of the shape variant ($\Delta k = 0.20$), $F(1, 4080) = 8.15$, $p = .004$, Cohen's $d = .13$, while for males there was no significant difference between the two variants ($\Delta k = -0.06$), $F(1, 4080) = 0.75$, $p = .385$.

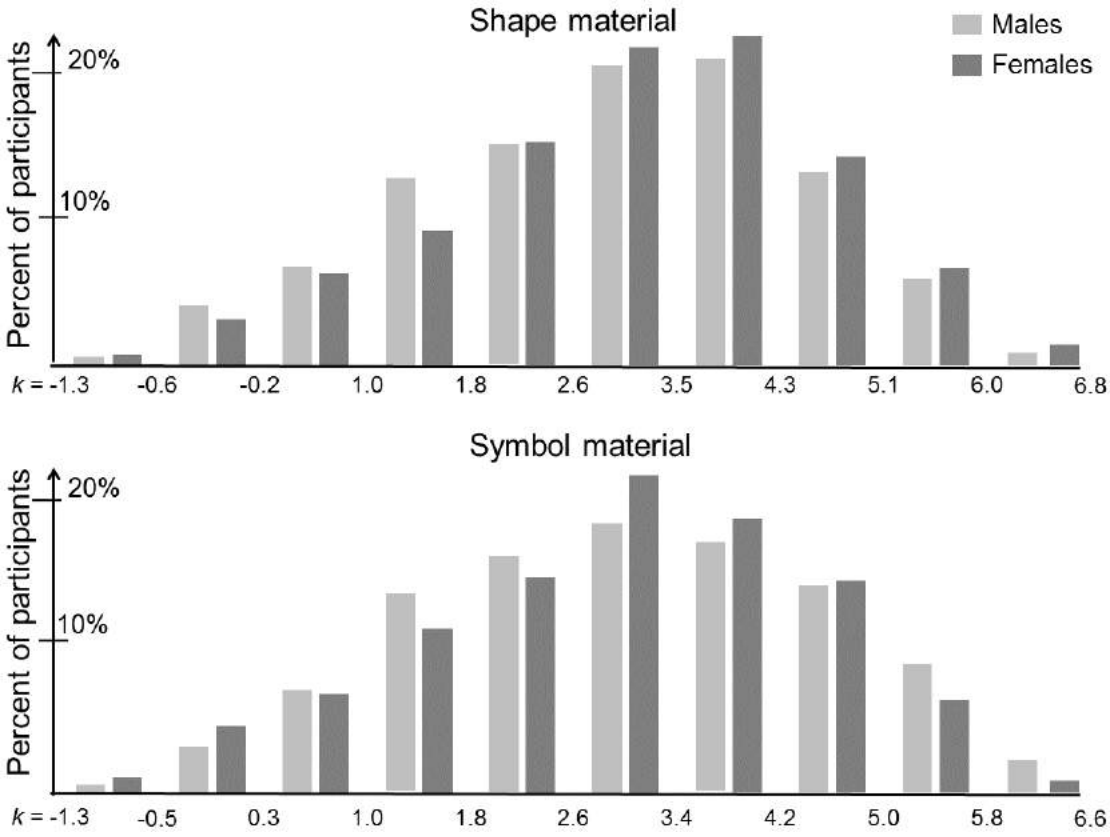

Figure 2: The distribution of *k* values for females and males.

The above analysis was also run without *gf* as a covariate, using rmANOVA with sex as a between-subjects factor and material as a within-subjects factor. The effect of sex was no longer statistically significant, $F(1, 2042) = 0.73$, $p = .392$, but the interaction of this factor with material was fully comparable with the preceding analysis, $F(1, 2042) = 15.21$, $p = .0001$, $\eta^2 = .001$. Female advantage over males for the shape material was highly significant, $F(1, 2042) = 7.03$, $p = .008$, while for the symbol material again there was no significant sex difference, $F(1, 2042) = 1.35$, $p = .246$. The shape material, as compared to symbols, yielded larger *k* values in females, $F(1, 2042) = 23.67$, $p < .0001$, but no significant difference related to material was noted for males, $F(1, 2042) = 1.51$, $p = .215$

In order to validate the null sex effect for the symbol material, ANCOVA was applied to another sample of 1486 people (aged 15 to 46, $M = 22.76$, $SD = 4.06$, $N_{female} = 938$), who performed only the symbol variant. They were also screened with two reasoning tests, which this time more visibly differentiated the two sexes, $t(1484) = 2.41$, $p = .016$ ($gf_{female} = -0.052$, $gf_{male} = 0.075$, $SD_{female} = 0.89$, $SD_{male} = 0.96$). However, also in this sample ANCOVA showed no significant difference for the symbol material between females ($k = 3.21$) and males ($k = 3.31$), $F(1, 1483) = 0.36$, $p = .546$. This difference was not significant even when the two samples were combined, $F(1, 2527) = 0.74$, $p = .389$.

Finally, no differences in correlation between the *k* and *gf* values was observed. For the shape material, the respective correlation coefficient was numerically the same both in the female and the male sub-sample, $r = 40$, $p < .0001$. It was quite comparable to the respective coefficients for the symbol material, $r_{female} = .37$, $r_{male} = .34$, ps $< .0001$.

Discussion

Neuroimaging data (Hill et al., 2014) suggested that WM tasks, besides the common prefrontal and parietal sites, activate additional prefrontal and hippocampal regions in the female brains, whereas additional parietal and insular regions in the male brains. The present analysis of the large set of scores in the change detection task tested behavioral consequences of this female/male neuronal specificity. Results indicated that one potential consequence of the sex differences in brain networks underlying WM is the female advantage in VWM capacity for more concrete, more familiar stimuli (possibly encoded by episodic/semantic traces in and around hippocampus), which is absent for more abstract, less familiar stimuli (possibly requiring more attention rooted in parietal sites and insula). As the sample size was particularly large as for the WM research, the data were *gf*-corrected, and the female advantage was specific for one type of material but not for the other, the reported effect very likely reflects factual difference between the sexes, and not just a sample-dependent variation.

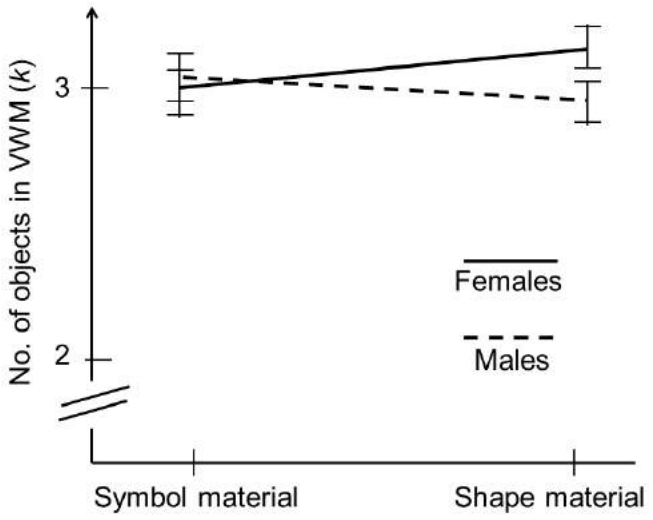

Fig. 3: Mean *k* values for females and males, depending on material type. Bars = 95% confidence intervals.

However, the female advantage for the shape material was quite small (Δk = .18). As the average VWM capacity was about three objects, females surpassed males by around 6%. This amount is in line with the Hill et al. conclusion that the lion's share of WM processing in both females and males relies on the shared prefrontal and parietal regions. However, given a strongly limited nature of WM, even such 6% can count, and females' potential reliance on specialized memory mechanisms may boost memory performance when a memorized content is compatible with those mechanisms. The present effect of stimulus familiarity was also much smaller than differences in episodic and semantic memory that were reported in the literature (see Cahill, 2006; Halpern, 2013; Herlitz & Rehnman, 2008; Kimura, 1999).

In contrast, the initially predicted male advantage for the symbol material was not observed in the data. After consideration, it seems that this prediction might be premature. Male advantage has been reported primarily for spatial material (Cahill, 2006; Grossi et al., 1980; Herlitz & Rehnman, 2008; Lewin, Wolgers, & Herlitz, 2001; Voyer et al., 2017), whereas more abstract material in fact did not differentiate the sexes (Goldstein & Chance, 1970). A more plausible interpretation of the null effect for the abstract symbols is that the additional involvement of attention might just have eliminated the female advantage rooted in more effective specialized memory processes (Herlitz & Rehnman, 2008; Voyer et al., 2007), but its contribution was too weak to yield the performance advantage of males.

One limitation of the study was the material used. Using other material than geometric shapes and Greek symbols would broaden the scope of conclusions that could be drawn from the present study. However, this study relied on the already existing data set, which included only two types of material. Moreover, the assumption that only shapes were familar to participants, and could be encoded in episodic memory, but the symbols could not, might be objected. Obviously, Greek symbols are also a kind of shapes, and at least some of them (e.g., α, β) could be verbalized, what helps in episodic encoding. So, we agree with all those objections. However, we think that the attenuated variant of this assumption, stating that shapes are *relatively* more familiar than Greek symbols (at least in the population with minimal exposure to Greek alphabet), and can be *relatively* more easily encoded in episodic memory, can be valid.

Summary

The present analysis of the existing large-size data set revealed the statistically significant difference between female and male WM performance on the relatively familiar, graphical material (but not on the more abstract material), which, on the one hand, most likely would be overlooked by a single study, whereas, on the other hand, might not be easily identifiable in meta-analyses of multiple studies applying diverse and not easily comparable methods. Overall, this kind of neuroimaging-driven psychometric analyses of sex differences in memory performance can shed light on the mechanisms underlying various memory systems as well as human cognitive architecture. The present study suggests that formal models of memory and related processes should account for sex and material type.

Abstract

In the present study, we combined tDCS and EEG to examine the electrophysiological responses to the tDCS-induced effects on the face inversion effect showed in recent studies. A double-blind procedure with a between-subjects design (n=48) was used with the subjects, recruited from the student population, being randomly assigned to either tDCS anodal or sham condition. The tDCS stimulation was delivered over the DLPFC at Fp3 site for 10 min at an intensity of 1.5mA while subjects engaged in an old/new recognition task traditionally used to obtain the inversion effect. The behavioural results generally confirmed previous findings. Critically, the results from the N170 show an effect of tDCS. Specifically, the tDCS procedure was able to modulate the N170 peak component by reducing the inversion effect on the latencies (i.e. less delay between upright and inverted faces) and by increasing the inversion effect on the amplitudes (i.e. larger N170 for inverted vs upright faces). We interpret the results based on the previous literature in regard to the inversion effect on the N170 component.

Keywords: Inversion effect; tDCS; N170, perceptual learning

Introduction

Several researchers have studied the nature of face recognition skills by investigating the causes of a robust phenomenon known as the face inversion effect. This refers to reduced performance when we try to recognize familiar faces turned upside down (Yin, 1969). When it was first discovered this phenomenon was used as a marker for "specificity" of face processing. This was because the inversion effect was found to be larger for faces than for other visual stimuli such as houses or planes (Valentine & Bruce, 1986; Yovel & Kanwisher, 2005). However, Diamond and Carey's (1986) finding of a large inversion effect for dog images when participants were dog breeders (vs that exhibited by novices), and Gauthier's work on perceptual expertise and the inversion effect for novel categories of objects named Greebles (Gauthier & Tarr, 1997) challenged the idea that faces are special and introduced "expertise" as a contributing factor to the inversion effect. Importantly, in 1997, McLaren using a set of artificial stimuli, checkerboards (so that expertise can be fully controlled), reported the first evidence of an inversion effect for novel stimuli that was predicted based on a specific model of perceptual learning, the MKM model (McLaren, Kaye & Mackintosh, 1989; McLaren & Mackintosh, 2000). Following this, Civile et al. (2014) extended McLaren's findings to the type of *old/new recognition task* originally used to investigate the face inversion effect (e.g. Yin, 1969). Taken together, Gauthier and Tarr's (1997), McLaren's (1997), and Civile et al's (2014) studies provide support for the Diamond and Carey's (1986) expertise account of face recognition; they have also served as a basis for further investigations of face and object recognition using Electroencephalogram (EEG) derived event-related potentials (ERPs).

Early studies on face recognition claimed the N170 ERP component to be the neural signature for face stimuli (Bentin et al., 1996). The N170 is a negative-polarity ERP deflection (peak) maximal at 140-200ms usually found at occipital-temporal electrodes after a face stimulus is presented (Bentin et al., 1996; George et al., 1996). The N170 has been found to be larger in amplitude and delayed in latency for inverted faces compared to upright faces. This is what has been commonly defined as the inversion effect on the N170 (Eimer, 2000). Rossion et al (2002) directly compared the N170 for faces and Greebles demonstrating how after the training phase with upright Greebles, the inversion effect (i.e. delayed and larger amplitude for inverted stimuli) was of a similar magnitude for both faces and Greebles. In a similar vein, Busey and Vanderkolk (2005) showed that

fingerprint experts exhibited an inversion effect on the N170 (similar to that for faces) in response to images of fingerprints. Furthermore, Civile et al. (2014a, Exp. 4), found an inversion effect on the N170 for checkerboards drawn from a familiar prototype-defined category (a larger and delayed N170 for inverted checkerboards compared to upright ones). The results from these studies provided motivation for a departure from the original account of the N170 component as being specific to faces, toward a position where the inversion-induced enhancement and delay of the N170 can be obtained for non-face categories of stimuli if they are made sufficiently familiar.

In recent years, Civile et al (2016) first, and then Civile, McLaren, and McLaren (2018a) (for a pilot see also Civile, Obhi & McLaren, 2018b) strengthened the analogy between the inversion effect for checkerboards (Civile et al., 2014), and that for faces, through demonstrating that they both share the same causal mechanism. Using a specific tDCS paradigm, the authors were able to modulate perceptual learning and selectively affect the robust inversion effect that otherwise would have been obtained for checkerboards and face stimuli. Anodal tDCS delivered over the DLPFC at Fp3 site (see Ambrus et al., 2011 for an example of previous studies targeting the same brain area to modulate categorization for prototype-defined stimuli) for 10 mins at an intensity of 1.5mA eliminated the inversion effect found for checkerboards by reducing performance for upright checkerboards taken from a familiar category (compared to controls) (Civile et al., 2016). Critically, the same tDCS paradigm is also able to reduce the robust face inversion effect by affecting recognition performance for upright faces (Exp.1 and the replication Exp.2 in Civile et al., 2018a). Furthermore, through an *active control* study the authors showed that applying the same tDCS anodal stimulation on a different brain area did not result in any difference between the face inversion effect compared to the sham group (Exp.3, Civile et al., 2018a). Overall the results from these studies using tDCS show how a particular tDCS procedure can modulate perceptual learning and so reduce the robust inversion effect that would otherwise be obtained with checkerboards (after participants have gained enough expertise with them) or faces.

In the present study, we extended the tDCS procedure adopted by Civile et al (2016) and Civile et al (2018a) to the face inversion effect on the N170 ERP component. To our knowledge, this is the first study that attempts to examine the behavioural tDCS-induced effects on the inversion effect to electrophysiological responses on the N170. Showing that the tDCS procedure used to affect the inversion effect for checkerboards and for faces can also modulate the N170, would strengthen the link between perceptual learning (and in general the expertise account) and face reocognition.

Method

Subjects

Overall, 48 naïve (right-handed) subjects (18 male, 30 Female; Mean age = 21.3 years, age range= 18-27, *SD*= 2.25) took part in the study. Subjects were randomly assigned to either sham or anodal tDCS groups (24 in each group). All the subjects were students from the University of Exeter and were selected according to the safety screening criteria approved by the Research Ethics Committee at the University of Exeter. The sample size was determined from earlier studies that used the same tDCS paradigm, EEG paradigm, face stimuli, and counterbalancing (Civile et al., 2018a, b, c).

Materials

The study used a set of 256 face images standardized to grayscale on a black background (Civile et al., 2018a, b, c). All stimuli images were cropped removing distracting features such as hairline, and adjusted for extreme differences in image luminance. The stimuli, whose dimensions were 5.63 cm x 7.84 cm, were presented at resolution of 1280 x 960 pixels. The experiment was run using. Examples of the stimuli used are given in Figure 1. The experiment was run using E-prime software Version 1.1 installed on a PC computer.

The Behavioural Task

The experiment consisted of a 'study phase' and an 'old/new recognition phase' (Civile et al., 2018a,b,c).

Study Phase. Once subjects gave their consent, the instructions for the Study Phase were presented on the screen. The aim of the task was for the subjects to try to memorize the faces presented on the screen. The trial started with a fixation cross (500ms) in the center of the screen, immediately followed by a blank screen (500ms), and then by a facial stimulus (3000ms). Then the fixation cross and the black screen were repeated, and another face presented, until all stimuli had been presented. Overall, 128 face stimuli were presented, 64 in their upright orientation and 64 were presented inverted. After all the 128 face stimuli had been presented, the program displayed another set of instructions, explaining the recognition task.

Recognition Task. In this task, subjects were asked to press the 'z' key if they recognized the face stimulus as having been shown in the study phase on any given trial, or press 'm' if they did not (the keys were counterbalanced). All the stimuli previously seen in the study phase were presented again, "old", intermixed with 128 "new" faces split by the two conditions (upright and inverted). All the faces were presented one at a time at random order. The trial structure was as that in the study phase however this time the stimuli were presented for a longer period (4000ms).

The tDCS Paradigm

Stimulation was delivered by a battery driven constant current stimulator (neuroConn DC-Stimulator Plus) using a pair of surface sponge electrodes (7cm x 5cm i.e.35 cm^2) soaked in saline solution and applied to the scalp at the target area of stimulation. We adopted the same tDCS montage used in Civile et al (2018a)'s study (Exp. 1 & 2). Hence, one of the electrodes (anode) was placed over the target

stimulation area (Fp3) and the other (cathode) on the forehead over the reference area (right eyebrow). The study was conducted using a double-blind procedure reliant on the neuroConn study mode in which the experimenter inputs numerical codes (provided by another experimenter otherwise unconnected with running the experiment), that switch the stimulation mode between "normal" (i.e. anodal) and "sham" stimulation. In the anodal condition, a direct current stimulation of 1.5mA was delivered for 10 mins (5 s fade-in and 5 s fade-out) starting as soon as the subjects began the behavioral task and continuing throughout the study. In the sham group, the identical stimulation mode was displayed on the stimulator and subjects experienced the same 5 s fade-in and 5 s fade-out, but with the stimulation intensity of 1.5mA delivered for just 30 s, following which a small current pulse (3 ms) was delivered every 550 ms (0.1mA over 15 ms) for the remainder of the 10 mins to check impedance levels. Subjects were randomly assigned to one of the tDCS groups (Sham or Anodal). For every subject the stimulation started at the beginning of the Study Phase and finished before the Old/New Recognition Task started.

Given the novelty inherent in combining tDCS and EEG techniques, especially with using two separate pieces of equipment, it is worth noting some of the practical challenges faced during the implementation of the study. Specifically, we realised the tDCS stimulation (both sham and anodal) induced strong artefacts on the EEG data. Thus, we made sure that the tDCS stimulation ended by the end of the study phase before we started recording the EEG for the recognition phase. Hence, our analysis of the EEG data will be entirely for the recognition phase.

EEG Recordings

The EEG was sampled at 1000 Hz, with a band-pass of 0.016-100 Hz, the reference at Cz and the ground at AFz using 32 Ag/AgCl active electrodes and BrainAmp amplifiers. The electrodes were placed on the scalp in an extended 10-20 configuration plus one on each earlobe (references during online recording). Their impedances were kept below 10 kΩ.

Data Processing and Analysis

As mentioned above in the *tDCS Paradigm* section the ERP analysis was limited to the recognition phase. Data processing was performed in BrainVision Analyzer. The data was first filtered offline using a Butterworth Zero Phase filter with a low cutoff of 0.5 Hz and a high cutoff of 30 Hz, each with a 24 dB/oct slope. Individual channels were manually inspected and removed from further analysis where physical interference from a tDCS electrode was noted during set-up, or where data otherwise showed signs of significant artefacts throughout. Electrodes retained the online reference to Cz. Peak amplitudes of the N170 were examined for differences between the experimental conditions. To improve the estimates of the amplitude and latency the N170 extraction was aided by linear decomposition of the EEG using Independent Component Analysis (ICA, Bell & Sejnowski, 1995). The ICA was run separately for each subject using all scalp channels and the entire dataset. The EEG segments were then averaged for every participant and experimental condition. For each subject, we identified ICA components that: (1) showed a deflection (peak) in the N170 time-range (at 160-220 ms following stimulus onset), and (2) had a scalp distribution containing an occipital-temporal negativity characteristic of N170 (the scalp distributions of components are the columns of the inverted unmixing matrix). This resulted in 1-4 ICA components corresponding to the N170 identified in most subjects - these were back-transformed into the EEG electrode space (by multiplying the components with the inverted unmixing matrix that had the columns corresponding to other components set to zero) and submitted to statistical analysis of N170 peak amplitude and latency. N170 latency and amplitude analyses were restricted to electrode PO8, (over the right temporal hemisphere) which often in the literature has shown bigger effects on the N170 (Civile et al., 2018c; Civile et al., 2014; Civile et al., 2012; Rossion & Jacques, 2008).

Results

Behavioral Results

Following Civile et al (2018a,b,c) the data from all the participants were used in the signal detection d' sensitivity analysis of the recognition task (seen and not seen stimuli for each stimulus type) where a *d'* = of 0.00 indicates chance-level performance (Stanislaw & Todorov, 1999). We assessed performance against chance to show that both upright and inverted face stimuli in both the tDCS sham and anodal groups across the three experiments were recognized significantly above chance (for Sham Inverted, Sham Upright and Anodal Upright we found $p < .001$ for this analysis, for Anodal Inverted we found $p = .016$). Each p-value reported for the comparisons between conditions is *two-tailed*, and we also report the F or t value along with effect size. We also analyzed the reaction times (RTs) data to check for any speed-accuracy trade-off. We do not report this analysis here because it does not add anything to the interpretation of our results. For completeness, we give mean RTs for each of the stimulus' conditions: Sham Upright = 1240 ms; Sham Inverted = 1277 ms; Anodal Upright = 1263 ms; Anodal Inverted = 1267 ms.

d-Prime Analysis

We computed a 2 x 2 mixed model design using, as a within-subjects factor, *Face Orientation* (upright or inverted), and the between-subjects factor *tDCS Stimulation* (sham or anodal). Based on previous studies (Civile et al., 2018a,b) we expected the inversion effect for the anodal group to be smaller than that in the sham group. Analysis of Variance (ANOVA) revealed that numerically this was case but this time the interaction was not statistically significant, $F(1, 46) = .947$, $p = .33$, $\eta^2_p = .02$. There was a significant main effect of *Orientation* $F(1, 46) = 43.95$, $p < .001$, $\eta^2_p = .48$, which confirmed that upright faces were better responded to than inverted ones. A main effect of *tDCS Stimulation* was found with performance in the anodal

stimulation (M=.343, SE=.06) being significantly reduced compared to that in sham group (M=.542, SE=.05), $F(1, 46) = 5.39$, $p = .025$, $\eta^2_p = .10$. Paired t test analyses were conducted to compare performance on upright and inverted face stimuli (the inversion effect) in each tDCS group (sham, anodal). Based on previous studies that used the same stimuli and tDCS paradigm (Civile et al., 2018a,b) our primary measure was the face inversion effect given by comparing performance on upright and inverted faces in each tDCS group. We also directly compared the performance for upright faces in the sham vs tDCS group. This is particularly appropriate because the same stimulus sets are rotated across participants in a counterbalanced manner; so that each upright face seen in the anodal group for a given participant will equally often serve as an upright face for the participants in the sham group. A significant inversion effect was found in the sham group (M=.495, SE=.10), $t(23) = 4.97$, $p < .001$, $\eta^2_p = .38$, and a numerically reduced inversion effect was found in the tDCS anodal group (M=.368, SE=.07), $t(23) = 4.62$, $p < .001$, $\eta^2_p = .25$ (see Figure 1). Recognition for upright face stimuli in the anodal group was lower compared to that in the sham group, $t(46) = 2.05$, $p = .051$, $\eta^2_p = .19$. We also found a trend towards performance for inverted faces being reduced in the anodal relative to the sham group, $t(46) = 1.81$, $p = .083$, $\eta^2_p = .16$.

Bayes Factor Analysis

Because we did not find a significant interaction in this experiment, as we had expected, we performed Bayesian analyses to check that our results fell within the usual parameters of our previous work. Using the procedure outlined by Dienes (2011), we first conducted a Bayes analysis on the Face Orientation by Stimulation interaction. Thus, we used the interaction effect averaged over Experiments 1 and 2 (0.30) from Civile et al. (2018a; same tDCS procedure, behavioural paradigm, stimuli, and sample size as in the study here reported)'s work as the prior (standard deviation of p). Then we used the standard error (0.03) and mean difference (0.13) for the interaction in our study, assumed a one-tailed distribution for our theory, and gave it a mean of 0. This resulted in a Bayes factor of 2162.84, which is strong evidence (greater than 10, for the conventional cut-offs see Jeffrey, 1961 and Dienes, 2011) indeed for the theory, in this case that the interaction will be positive and non-zero. Next, because in Civile et al. (2018a) both Experiments 1 & 2 had performance for the upright faces significantly better in the sham group compared to that in the anodal group, we calculated the Bayes factor for this effect in our study using as the prior the difference between sham minus anodal upright faces averaged over Civile et al. (2018a)'s Experiments 1 & 2 (0.28). We then used the standard error (0.11) and mean difference (0.26) between sham upright faces minus anodal upright faces in our study and assumed a one-tailed distribution for our theory with a mean of 0. This gave a Bayes factor of 8.10, which provides good evidence (as greater than 3) that sham performance on upright faces is higher than that under tDCS.

N170 ERP Results

In analyzing the N170 peak component we computed the same statistical analyses as for the behavioral data.

N170 Peak Latency Analysis

A 2 x 2 repeated measure ANOVA revealed a trend towards a significant interaction for peak latency, $F(1,46) = 3.26$, $p = .077$, $\eta^2_p = .06$. A significant main effect of *Orientation* was found, $F(1, 46) = 51.19$, $p < .001$, $\eta^2_p = .52$. No main effect of *tDCS Stimulation* was found, $F(1, 46) = .077$, $p = .783$, $\eta^2_p = .00$. A significant inversion effect (i.e. a delayed N170 peak for inverted vs upright faces) was found in the sham group (M=7.95ms, SE=1.28), $t(23) = 6.20$, $p < .001$, $\eta^2_p = .62$, and a numerically reduced inversion effect was found in the tDCS anodal group (M=4.70ms, SE=1.22), $t(23) = 3.86$, $p < .001$, $\eta^2_p = .39$. No difference was found between the N170 latencies for upright stimuli in the anodal vs sham group, $t(46) = .235$, $p = .815$, $\eta^2_p = .00$. No significant difference was found between inverted faces in the anodal vs sham group, $t(46) = .903$, $p = .375$, $\eta^2_p = .04$.

N170 Peak Amplitude Analysis

A 2 x 2 ANOVA revealed a significant *Orientation* by *Stimulation* interaction for peak amplitude, $F(1,46) = 4.06$, $p = .049$, $\eta^2_p = .09$, and a main effect of *Orientation*, $F(1, 46) = 45.47$, $p < .001$, $\eta^2_p = .49$. No main effect of *tDCS Stimulation* was found, $F(1, 46) = .178$, $p = .679$, $\eta^2_p = .00$. Contrarily to what we found for N170 latencies, the inversion effect (larger N170 for inverted vs upright faces) was found to be larger in amplitude in the anodal group (M=3.32μV, SE=.63) $t(23) = 5.22$, $p < .001$, $\eta^2_p = .54$, compared to that found in the sham group (M=2.41, SE=.52) $t(23) = 4.32$, $p < .001$, $\eta^2_p = .44$ (see Figure 2). No difference was found between the N170 amplitude for upright stimuli in the anodal vs sham group, $t(46) = .033$, $p = .975$, $\eta^2_p = .00$. Despite a numerically larger N170 for the inverted faces in the anodal vs sham group, no significant difference was found, $t(46) = .882$, $p = .386$, $\eta^2_p = .03$.

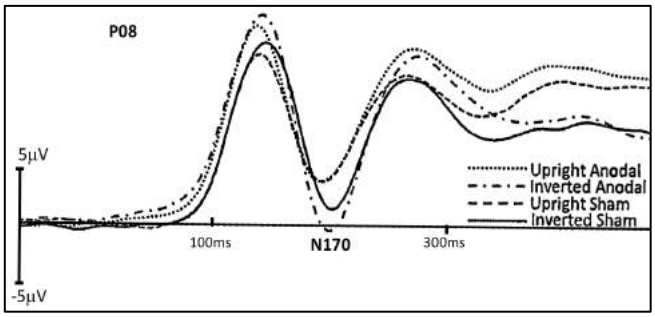

Figure 2. Waveforms at electrode P08 for the four conditions. The X axis shows the elapsed time after a stimulus was presented. The Y axis gives the amplitudes (μV) of the ERPs in the recognition phase of the experiment.

General Discussion

In the study reported here we examined the effects of tDCS on electrophysiological correlates of the face inversion effect. Specifically, we adopted the same tDCS procedure used by Civile et al (2018a,b) and Civile et al (2016) to modulate perceptual learning and affect the inversion effect for newly acquired stimuli (i.e. checkerboards) and long-term learnt stimuli i.e. faces. Our behavioral results are in line with previous work. Despite the inversion effect in the anodal group being only numerically reduced compared to sham, the additional Bayes Factor analysis gives us confidence that our effects are in line with previous work (Civile et al., 2018a). Importantly, as in previous studies, we find that anodal tDCS is particularly effective in reducing the recognition performance for upright faces, a result also supported by the Bayes Factor analysis. Our behavioral results also hint at a tendency (not significant) for anodal tDCS to reduce performance for the inverted faces. This is a new trend that previous studies (Civile et al., 2018a,b) did not show.

The most novel aspect of the present study involves the ERP results. To our knowledge, the current study provides the first evidence for tDCS being able to modulate a robust ERP component such as the N170 often associated with faces as well as sets of prototype-defined artificial stimuli that participants have become familiar with (Rossion et al., 2002; Civile et al., 2014). Intriguingly, our results suggest a dissociation of the effects that tDCS has on the N170. Specifically, in the latencies we find tDCS reduces the inversion effect compared to sham (less delay between the peaks for inverted vs upright faces). At the same time, tDCS increases the inversion effect on the N170 amplitudes compared to sham (a larger difference between the peak amplitude of the N170 for inverted vs upright faces). The effects of tDCS on the N170 latencies are more easily interpreted. Specifically, on the expertise account we can argue that a delayed N170 is recorded for a target face or familiar stimulus as a consequence of the familiarity lost when the target stimulus is turned upside down. We know from the behavioral results that anodal tDCS affects perceptual learning (by reducing expertise) for upright faces, making them more similar to stimuli drawn from an unfamiliar category, and thus this would result in a latency more similar to that for inverted faces.

Remarkably, the results from the N170 amplitude analysis provide some evidence for a dissociation from the tDCS-induced effects on the ERP latencies. Here anodal tDCS increased the inversion effect seen in the N170 amplitudes, and the inverted faces in this condition were found to elicit the largest N170 (i.e. more negative) compared to all the other stimulus conditions. But we should beware of attributing this effect to the impact of tDCS on the inverted faces, as this wasn't independently significant. All we can be sure of is that the inversion effect (difference between peak amplitudes) increased as a result of tDCS. In line with our explanation for the N170 latencies, if we assume that anodal tDCS is affecting participant's expertise for faces, then why would this have any impact on inverted faces when we have already argued that it will affect upright ones? Instead, it may be better to just focus on the significant effect (i.e. the difference between upright and inverted), and speculate that there may be some shift in baseline effects in our tDCS condition (not unlikely, we are, after all, activating a substantial region of frontal cortex using anodal stimulation) that results in the inverted face ERP apparently showing the greatest effect.

That still leaves us with the effect on peak amplitude to explain, and here it may be that we have to appeal to the difference between upright faces, for which we have expertise, and two different types of stimuli for which we do not. We assume that inverted faces do not benefit from our expertise with upright faces, whilst still acknowledging that they are readily recognized as faces. Another type of stimulus that would not benefit from expertise would be an entirely novel stimulus (a Greeble, a checkerboard). But this stimulus is not an inverted face. Now, if we postulate that tDCS makes the upright faces more like a novel stimulus, and that novel stimuli, other things being equal, do not show such a pronounced N170, then the greater difference from the inverted face N170 could be explained. Essentially, we would argue that tDCS shifts the upright face N170 towards that of a novel stimulus, which has a smaller amplitude and a greater latency, and that this is why we get our apparently "opposite" effects.

Interestingly, something like this pattern of results has previously been found in EEG studies where the level of familiarity for the stimuli presented was manipulated directly by means of training to the stimuli or by altering the typical familiar stimulus configuration (e.g. rearrange the locations of the features within a face). In Civile et al. (2014)'s study, the N170 peak amplitudes for inverted checkerboards taken from a familiar category were larger compared to the other conditions (upright checkerboards from a familiar category and upright and inverted novel checkerboards). Furthermore, Civile et al (2018c) found normal inverted faces elicited a larger N170 amplitude compared to normal upright faces and scrambled (i.e. the facial features were shuffled) upright/inverted faces (see also Civile et al., 2012 for similar results using Thatcherised faces). Finally, also Rossion et al. (2002) showed (in the pre-training phase) the N170 peak

amplitude being larger for normal inverted faces compared to normal upright faces, and upright/inverted Greebles. Civile et al (2018c) suggested that this effect is due to the fact that the normal inverted faces possess all the configural information (spatial relations) of a normal upright face, but presented in an orientation that not only makes it difficult to make use of them but imposes an additional cost. Thus the idea here would be that the differences in the N170 caused by inversion only partly index the effect of perceptual learning (in the latencies), the amplitude difference reflects something else (perceptual effort perhaps).

In conclusion, in the study reported here, we have provided some evidence in support of a tDCS procedure able to modulate the face inversion of the N170 component. Importantly, the tDCS-induced effects on the N170 seem to dissociate between latencies and amplitudes of the N170. Further studies will be needed to establish these effects.

Abstract

The phenomenon of insight (also called "Aha!" or "Eureka!" moments) is considered a core component of creative cognition. It is also a puzzle and a challenge for statistics-based approaches to behavior such as associative learning and reinforcement learning. We simulate a classic experiment on insight in pigeons using deep Reinforcement Learning. We show that prior experience may produce large and rapid performance improvements reminiscent of insights, and we suggest theoretical connections between concepts from machine learning (such as the value function or overfitting) and concepts from psychology (such as feelings-of-warmth and the einstellung effect). However, the simulated pigeons were slower than the real pigeons at solving the test problem, requiring a greater amount of trial and error: their "insightful" behavior was sudden by comparison with learning from scratch, but slow by comparison with real pigeons. This leaves open the question of whether incremental improvements to reinforcement learning algorithms will be sufficient to produce insightful behavior.

Keywords: reinforcement learning; insight; creativity

Introduction

Insight moments are one of the most spectacular manifestations of human creativity. Revolutionary insights are paradigmatic examples of creativity, whether historically suspicious (Aristotles' "Eureka!", Newton's apple), or better documented such as those described by the mathematician Poincaré (1909) or the chemist Kekulé (Rothenberg, 1995). In this article, however, we focus on the insights which occur in everyday human and animal problem-solving.

Over a century of research in psychology underlies our knowledge of insightful problem-solving. In contrast, to our knowledge there has been relatively little work considering insight from an artificial intelligence perspective, especially since the momentous advent of deep learning techniques in AI. We seek to remedy this omission. The objective is not to build a precise model of biological neural processes, but to uncover analogies between the two domains of deep Reinforcement Learning (RL) and biological insight. We do this by simulating a classic experiment on insight (Epstein, Kirshnit, Lanza, & Rubins, 1984), dealing with insight in the pigeon.

We will first discuss established results from insight research in psychology on humans and animals, and the difficulties associated with modeling insight problems from a machine learning perspective. We will then describe the original experiment and its simulation, and the results obtained using a simple deep RL approach (a deep actor-critic). Finally, we discuss the analogies between insight and various sub-disciplines within reinforcement learning, suggesting directions for future research.

Background: insight

Psychological research on insight begins with studies on chimpanzees by Köhler (1921). These studies sought to demonstrate that animals, far from being Cartesian automatas as suggested in the work of Thorndike (1898), are capable of human-like intelligence. One of Köhler's experiments involved attaching a banana to the ceiling of the chimpanzee enclosure, and placing a box within the enclosure. The chimpanzees had to carry the box underneath the banana and climb onto it in order to reach the fruit. When solving the problem, the chimpanzees displayed behavior that more closely resembled Aristotle's "Eureka!" than the trial-and-error learning of cats locked in puzzle-boxes by Thorndike (1898). In Köhler's "gestalt" perspective, it was understood that chimpanzees had to interpret the situation from scratch in order to discover the "roundabout" way of reaching for the objective.

Later work by Birch (1945) showed that chimpanzee insight was not achieved from scratch, but was instead made possible by relevant prior experiences. Epstein et al. (1984) showed that with adequate training, "even" pigeons could display the kind of insight observed in chimpanzees. Epstein's findings are robust: several variations of this experiment were performed by Epstein and colleagues, and the original was recently replicated by Cook and Fowler (2014). For Epstein, who was a student of Skinner, this made the argument that seemingly complex mental processes could be explained from behaviorist principles.

There has been continued interest in insight since the cognitive turn in psychology. This body of work has established several key behavioral, cognitive, and metacognitive characteristics of insight:

1. The insight sequence: search – (impasse) – restructuring – verification (Ohlsson, 2011; Weisberg, 2015).
2. Insights are sudden and surprising to the problem-solver, as evidenced by "feeling-of-warmth" ratings measuring subjective closeness to the solution (Metcalfe & Wiebe, 1987).
3. The "restructuring" which accompany insight involves

changes in problem representation (Knoblich, Ohlsson, & Raney, 2001), in the heuristics used (Kaplan & Simon, 1990), and in the constraints on operators (MacGregor, Ormerod, & Chronicle, 2001).

4. Insight depends on previous experience (Wiley, 1998) and is facilitated by sleep (Wagner, Gais, Haider, Verleger, & Born, 2004).

Recent research on insight has used imaging techniques such as fMRI[1]. Much of this work has focused on associative cortices (notably middle and temporal gyri) and on hemispheric differences (Kounios & Beeman, 2015); however the involvement of structures associated with executive control is a robust finding (prefrontal cortex, especially anterior cingulate cortex), and recent ultra high-field work (Tik et al., 2018) suggests the involvement of deeper brain structures during insight, including those underlying biological reinforcement learning (subcortical dopaminergic structures including the striatum, thalamus, nucleus accumbens and ventral tegmental area).

Summarizing: a rich body of research has investigated insight according to different psychological research paradigms, establishing the key characteristics of insight enumerated above. However, the precise nature of the cognitive mechanisms that enable insight remains unclear.

This is not to say that there have not been models, or theories, of the cognitive basis of insight (computational, mathematical, or otherwise); those of Hélie and Sun (2010), Friston et al. (2017), Schilling (2005), and Stephen, Boncoddo, Magnuson, and Dixon (2009) are among the most influential. A review of and comparison with these variegated models is beyond the scope of this paper, if only due to their great diversity, which ranges from bayesian inference (Friston et al., 2017) to dynamical systems (Stephen et al., 2009) and graph theory (Schilling, 2005). We note in passing that the model presented later in this article may be compatible with several of these other models: for instance phase transitions such as those described by Stephen et al. (2009) are conjectured to occur in neural networks.

None of the four models mentioned above aim to give rise to artificial agents capable of solving problems through insight[2]. In contrast, we seek to produce a model of insight problem-solving which, when implemented, not only predicts the behavior of a biological insightful problem-solver, but also solves the problem.

AI: which insight problems to model?

Most of the contemporary insight literature focuses on humans, using a wide array of experimental designs (for instance, the nine-dots problem (MacGregor et al., 2001), the mutilated checkerboard problem (Kaplan & Simon, 1990), or the Compound Remote Associates (Bowden & Jung-Beeman, 2003)). Despite their apparent variety, virtually all insight studies involving humans make use of verbal instructions which define the objective for the problem-solver in their language.

Consider the nine-dot problem: the instructions specify the number of segments, with constraints over their properties (four segments, drawn in a sequence "without lifting the pen"; every dot should end up on one of the segments). Language thus allows for a description of the desired "goal-state" which is abstract enough to specify the solution without giving it away. Simulating such a problem using AI would require either very task-specific algorithms (which seems to defeat the point of replicating human insight), or the algorithmic mastery of language as a prerequisite for understanding instructions.

A "roundabout" solution is to focus instead on insight experiments which feature animals solving problems that are not specified by instructions, but instead by some intrinsic need, typically for food, and by the situation in which the experimenter puts the animal[3]. This is the approach taken in this article.

Insightful (real) pigeons

The experiment by Epstein et al. (1984) is a reproduction of Köhler's banana-and-box experiment, adapted for pigeons. Chimpanzees would naturally want to acquire a banana; but pigeons might not be interested in that fruit. Therefore Epstein et al. first reinforced pecking a facsimile banana (hereafter just "the banana") by providing a suitable food reward upon pecks. In the "test" situation, the banana is suspended from the ceiling of the room, such that pigeons cannot reach it by stretching towards it (they do not attempt to fly towards it (Cook & Fowler, 2014)). However, a small cardboard cube ("the box") has been placed in the pigeon's Skinner box. The problem is solved when the animal pushes/pecks the box underneath the banana and, standing on the box, reaches for/pecks at the banana; see figure 1.

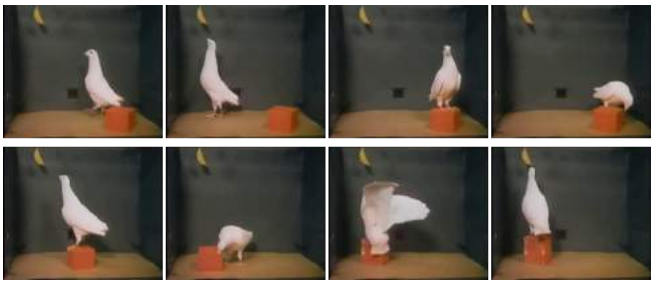

Figure 1: Left-to-right, then top-to-bottom: a pigeon solves the banana-and-box test (snapshots from https://youtu.be/mDntbGRPeEU, with permission from Dr. Epstein).

[1] See Sprugnoli et al. (2017) for a review of brain imaging studies.

[2] A notable exception is the model of MacLellan (2011), who investigates insight as a change of heuristics in a search process, and tests this on the nine-dot problem.

[3] See Shettleworth (2012) for a judicious review of insight research on animals.

Prior to this apparent display of ingenuity, the behavior of Epstein's pigeons was carefully *shaped*. Shaping is a technique used in animal training (with closely related applications in certain behavioural therapies for humans), consisting of reinforcing successive approximations of a desired behavior. Two skills ("behavioural repertoires") are taught to the pigeons by reinforcing the corresponding behaviors:

- In the absence of the banana: push a box to a green spot.
- With the box nailed underneath the banana, and in the absence of a spot: jump on the box and peck the banana.

Teaching pigeons to push a box towards an objective is considerably more difficult than getting them to hop onto the pre-placed box. To achieve this, Epstein et al. proceeded gradually, the shaping sequence including teaching the pigeons to move the box, then progressively placing the box at an increased distance from the spot. Additionally, the pigeons were sometimes put in the presence of the box and in the absence of both banana and spot, in order to extinguish aimless pushing behavior (which eventually would result, via a random walk within the Skinner box, in reaching the correct position and thereby triggering the food reward).

It is of special importance that the two behaviors are not exactly applicable to the final test: the pigeons are trained to push the box towards a green spot, but in the test situation they must spontaneously generalize this behavior to a slightly different problem: pushing towards the yellow banana. It is by combining two behaviors, and generalizing one behavior to a novel situation, that the pigeons solve the test task.

Epstein's pigeons proved remarkably adept in the test - all of them succeeding in minutes, save for one, and presenting behavior that seemed insightful: after a period of hesitation and some trial and error, the pigeons began acting in a seemingly directed, intentional manner, moving the box towards the banana and jumping on top of it. The lone laggard failed in a manner reminiscent of AI failures: during the test, a projector had been used to illuminate the (filmed) performance. When the additional lighting was turned off, the pigeon succeeded quickly.

Simulation

Admittedly, the displays of insight by Epstein's pigeons are less impressive than those of Köhler's chimpanzees: they received substantial training in the form of shaping. However, just as pigeons could not solve the test without having first acquired relevant skills, so chimpanzees were not able to solve insight problems without having first engaged in spontaneous play with the relevant objects (Birch, 1945). This suggests that similar cognitive mechanisms may be at play, and that it may be wise to begin by modeling the version of the task completed by pigeons.

In addition to requiring no instructions or verbal skill, the task used by Epstein et al. (1984) allows for a simulation which preserves much of what makes the task difficult: the pigeons had to combine pre-existing skills (pushing the box, and jumping on top of it to peck at the banana) while also generalizing to a new stimulus (pushing is shaped using a green dot, but in the test situation the pigeons must aim instead for a banana).

Thus, in simulating this task, we seek to preserve the difficulty inasmuch as it is relevant to problem solving, as opposed to the complete difficulty of the task including subjective perception and full physical coordination.

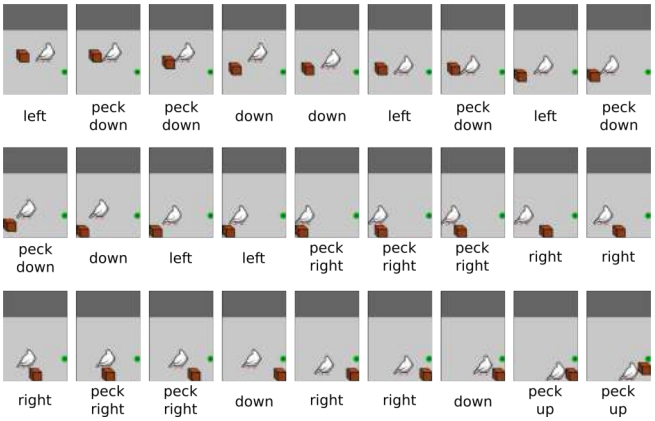

Figure 2: Successive frames of an artificial pigeon solving the "push box to spot" shaping task. The pigeon succeeded despite a sub-optimal policy (first pushing the box in the wrong direction, then pecking it out of corners). Also note the stochasticity of the "peck" actions: pecking actions have up to 4 different outcomes.

Task and shaping model

We model the task as an RGB image, such that the complete situation is perceived at each time-step. The pigeon, box, banana and spot consist of squares identifiable by size and color. For visualization, an interpretable representation is also provided (see figure 2). The dimensions of the various elements, and the dynamics of the actions are chosen to match those observed in the experiment. In particular, the size of the various elements (Skinner box, pigeon, box, banana, spot), the effects of the actions (walking, directional pecking, and jumping) and the consequences of interactions (box movement) closely match those of the initial experiment.

Specifically, the pigeon has 9 actions: walking in either cardinal direction, pecking towards either cardinal direction, and jumping on/off the box. Walking is deterministic and moves the pigeon by 1 square in the corresponding cardinal direction unless an obstacle is present. Pecking the box will result in its stochastic displacement in the general direction opposite to that from which it was pecked: assuming there are no obstacles and the box is not fixed in place, the box moves with equal probability (0.25) by 1 or 2 squares forward, or by 1 square forward and 1 in either perpendicular direction. With respect to direction, the pigeon can push the box south if the northern edge of the pigeon is at least as far north as the northern edge of the box, and if the pigeon is adjacent to the box;

likewise (mutadis mutandis) for the other directions (refer to figure 2 for some examples of stochastic box movement and pigeon positioning). The white pigeon is 3×3, the orange box 2×2, the green spot and yellow banana are 1 square each, and the background environment 10×10. Assuming squares approximately 4cm across, this roughly matches the size of the real objects (10x10cm box, 7x2cm facsimile banana, 4x4cm spot, approx. 25x8cm pigeons), Skinner box (45x45cm for the square box), and the effects of recognizable discrete actions in the original. In Skinner boxes, pigeons are rewarded by receiving food through a little window; in this simulation, a reward of 10 is provided instantaneously upon success.

The artificial pigeons undergo shaping similar to that used by Epstein et al.: artificial pigeons perform the **push-to-spot**, **jump-and-peck**, or **push-extinction** tasks. In the push-to-spot task, the box is initially placed immediately next to the spot. The distance between the box and the spot is sampled uniformly between 0 and X, where X increases progressively as the artificial pigeons become more adept at solving the task: pigeons "graduate" to the next distance once they achieve good performance (100 successive successes in a maximum duration 50 timesteps each) on the task. Other than box-spot distance, the position of the various elements of the task is randomized for each shaping and test instance. For jump-and-peck, the box is fixed in place underneath a banana, and for push-extinction the box is present with no reward is available. The three shaping tasks are interleaved.

Artificial pigeons trained in this way did not succeed at the test on their first try in an "insightful" manner, unlike real pigeons. Instead, we present results for repeated tests, in which, after training, the pigeons face a succession of randomized test problems (with the box and banana placed randomly).

"Pigeon Insight" Model

Learning is modeled using deep Reinforcement Learning (Sutton & Barto, 2018), specifically an actor-critic algorithm. Reinforcement Learning is learning what to do in order to maximize a reward signal, where obtaining a reward often requires multiple successive actions. To know whether an action was good, it is therefore useful to evaluate the resulting situation, without waiting for the reward itself: if the new situation is promising (as opposed to dire), the tendency to repeat that action in similar contexts should be reinforced (as opposed to weakened). Many reinforcement learning algorithms exploit these ideas by making use of an actor which selects actions, and a critic which evaluates situations and generates a learning signal.

A technical description of these ideas and their implementation is given below in order to make the present work reproducible. Readers who wish to familiarize themselves further with Reinforcement Learning are encouraged to consult the article by Kaelbling, Littman, and Moore (1996) or the more expansive book by Sutton and Barto (2018). For a discussion of the connections between Reinforcement Learning approaches in AI and in psychology, see chapters 14 and 15 of Sutton and Barto (2018, accessible online).

The simulated environment is a Markov Decision Process, where images count as states s from a set $\mathcal{S}$ ($s \in \mathcal{S}$), pigeon behavior as actions $a \in \mathcal{A}$, with rewards $r \in \mathcal{R}$ (10 on successful completion, 0 otherwise), and a transition function $p : \mathcal{S} \times \mathcal{A} \times \mathcal{S} \to [0,1]$ defining the dynamics of the environment. In an actor-critic algorithm, the agent, with no prior knowledge of the environment dynamics, learns from experience a policy $\pi_\theta : \mathcal{S} \times \mathcal{A} \to [0,1]$ (mapping states to a probability of selecting each action, based on the parameters θ of the *actor*) and a value function $v_w : \mathcal{S} \to \mathbb{R}$ (which denotes the agent's future prospects, or return, assuming it follows its policy from the current state; it is approximated as $\hat{v}_w$ based on parameters w of the *critic*). Actor-critic systems are considered more plausible models for biological agents (Sutton & Barto, 2018, pp395-402).

Two convolutional neural networks are used to approximate the value function v as $\hat{v}_w$ (critic network) and to implement the policy (actor network). The architecture is shown for the actor network in figure 3; the critic network is identical save for the last layer, which has only one output and no nonlinearity. Learning proceeds online by gradient descent, according to the update rules:

$$w \leftarrow w + \alpha_w \delta \nabla \hat{v}_w(S')$$
$$\theta \leftarrow \theta + \alpha_\theta \delta \nabla \log \pi_\theta(A|S)$$

Where S is the state, A is the action chosen (according to the policy π), R is the reward, S' the following state, and $\delta = R + \gamma \hat{v}_w(S') - \hat{v}_w(S)$ is the one-step time-difference error. We use a discount γ (0.9) and learning rates α_w and α_θ (0.003 and 0.0003). Thus, by way of the time-difference error, the critic adjusts its estimate of the value of a state based on that of the next state. Meanwhile, the actor learns to preferentially select actions which lead to surprisingly high-valued states (states with positive time-difference errors). The interleaved processes of estimating the value of states and improving the policy leads (demonstrably under certain conditions) to a locally optimal policy. In our implementation, the actor was regularized based on the entropy of its output to ensure continued adequate exploration (as in Mnih et al. (2016)), and learning and acting was parallelized (16 concurrent agents) to accelerate computation time.

A first cohort of 20 agents was given shaping training up to a performance of 90% completion within 50 time-steps, and then continued learning in the test condition; we call this *condition 1*. A second cohort of 20 was given more extensive training (150,000 additional timesteps after meeting the criteria for condition 1); we call this *condition 2*. The expectation was that additional training would result in overfitting and render transfer more difficult (as observed for human insight in the work of Wiley (1998)). A third cohort was directly given the test without any prior training; we call this *condition 3*. In all cases, the primary measure is the rate of success: how likely each simulated pigeon is to succeed at its task within 50 time-steps. This is measured as a running average (cf. figure 4).

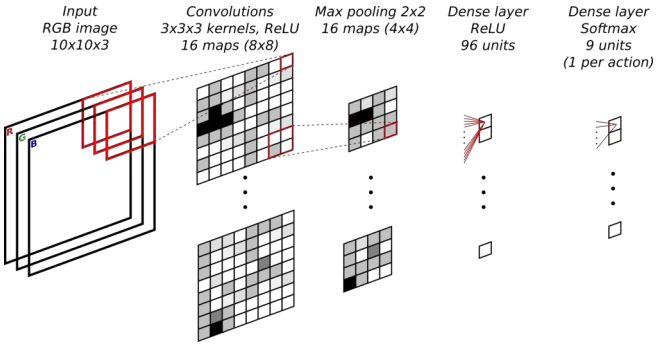

Figure 3: The neural network architecture used for the actor. For illustrative purposes, example activations are given in shades of grey, and example connections in red.

Results

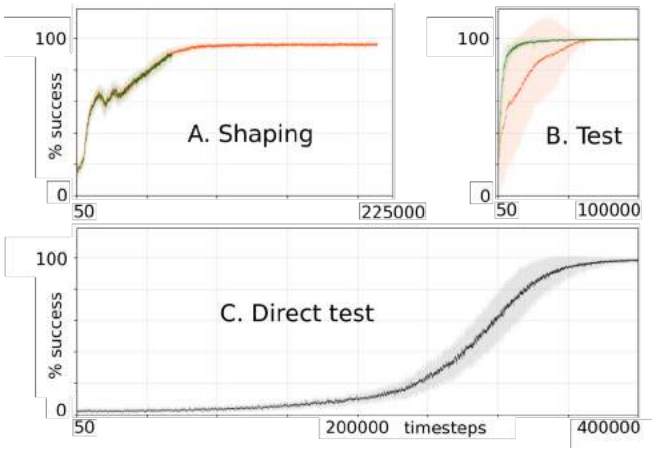

Figure 4: Performance of the actor-critic model. All graphs show the success rate for 20 runs, smoothed over 100 timesteps; color bands show the standard deviation. Note that the success rate is initially high during shaping because the shaping tasks are easy in the beginning, and progressively made more difficult as performance increases. Graphs A and B show the performance for conditions 1 (dark green) and 2 (lighter orange) for the shaping and test, whereas Graph C shows the performance for condition 3 (naive agents). Condition 2 had worse average performance on the test, with greatly increased variance.

The shaping program was successful in improving performance. Agents in conditions 1 and 2 transferred successfully to the final task, rapidly learning the new task in condition 1, although there was often a delay for those of condition 2 who had been given more extensive training. Agents in condition 2 showed considerable variance in the transfer - some of them necessitating a much longer time than others. Condition 1 and 2 both showed substantially better performance than condition 3 on the test. These results are shown in figure 4.

In condition 1, agents adapted rapidly to the new task. However, in condition 2 there often was a period of "impasse" during which the agents displayed low performance; individual curves are shown in figure 5. These impasses remained short compared to condition 3, but were substantial compared to condition 1 (see figure 5b); impasse was followed by a rapid performance increase, which was accompanied by an increase in expected value as estimated by the critic components of the agents. There was also an increase in positive time-difference errors, which correspond to unexpected progress, from the agent's perspective.

Discussion

Did the simulated pigeons experience "insight"? Unlike the real pigeons, few solved the test situation on their first try, suggesting that out-of-the-box RL is not sufficient for insight. However, especially for condition 2, they displayed patterns that are reminiscent of findings on the insight process. Recall the characteristics of insight enumerated in the background section. Many of them are reflected in the behavior of the deep RL agents:

1. The insight sequence: in condition 2 especially, one can distinguish a fruitless search/impasse phase from a sudden resolution.

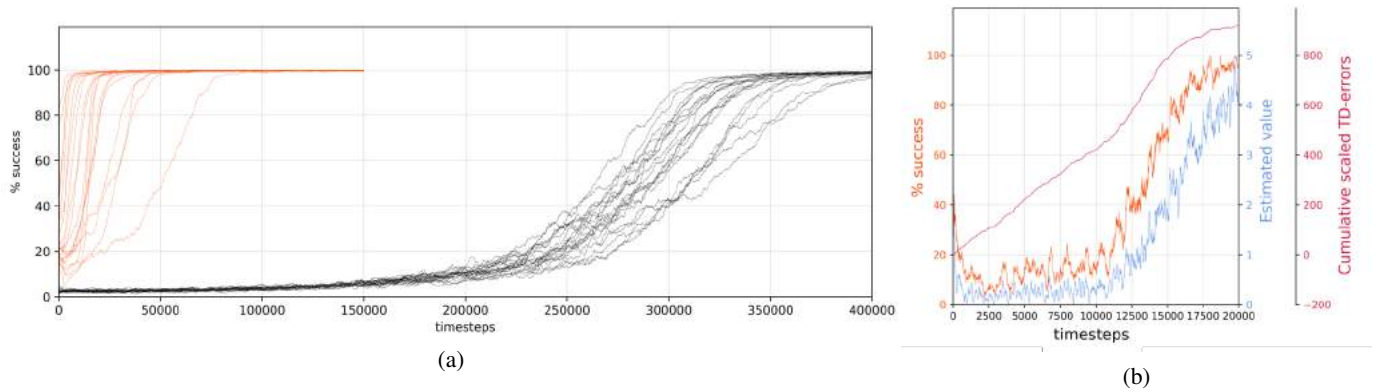
2. Sudden and surprising solution: the sudden increase of "feelings of warmth" in humans Metcalfe and Wiebe (1987), i.e. their subjective appreciation of how close they are to solving the problem, resembles the sudden increase of the estimated value function in the agents. (Recall that the value function, estimated by the critic component of the agents, measures their expectation of acquiring reward; it is thereby analogous to the "feelings of warmth" measure.) The steepness of the learning curve for shaped agents (conditions 1 and 2) is sudden by comparison to naive agents (condition 3).

3. Restructuring: the agents ought to behave "as if" the yellow objective is the green spot with which they trained. We conjecture that when the agent learns this, the rest of the correct solution "falls into place" rapidly due to prior learning[4].

4. Role of experience: "insight" is made possible by prior experience, with extensive experience having an ambiguous role – too much experience being detrimental to performance, as in Wiley (1998).

Additionally, we note several associations between the concepts of reinforcement learning and those of psychology, which are known in RL and cognitive psychology, but have received little attention in the insight literature. Readers familiar with RL may have recognized transfer and curriculum learning techniques used for instance in robotics; those well-read in psychology noticed that the overfitting of condition 2

[4]The distributed nature of neural networks makes this difficult to verify; we reserve such investigations to future work.



(a) (b)

Figure 5: **(a)** All "overfitting" transfer curves (orange, left), compared to learning from scratch (black, right), over 20 runs. (All curves have been smoothed for readability, showing the average over 4000 timesteps.).
(b)A single learning curve on the test (one of the 20 shown in orange in subfigure (a)). The top curve is the cumulative TD-error, the middle curve is the % of success, the bottom curve is the estimated value.

is reminiscent of the Einstellung effect, by which prior experience gets in the way of finding an optimal solution to a new problem (Luchins, 1942).

Thus although the artificial pigeons needed a considerable amount of interaction with the test by trial and error (note that both pigeons (Epstein et al., 1984) and chimpanzees (Köhler, 1921; Birch, 1945) also showed some amount of trial and error even during the test), they also presented learning patterns resembling those of insight: namely (1) a comparatively sudden increase of performance, accompanied by (2) an increase in expected return, which (3) was made possible by a "just-right" amount of prior experience.

The proposed model thus displays some characteristics of insight while being limited in other respects. The most notable of these limitations is the time needed to discover the full solution during the test. This might be a matter of learning quickly from limited data during the test (this is the solution favored by Epstein (2014)), or of making use of more profound regularities in the shaping tasks, e.g. via temporal abstraction as suggested by Colin, Belpaeme, Cangelosi, and Hemion (2016). Alternatively, they might identify new regularities between old and new tasks on the fly (Friston et al., 2017), or use off-policy learning to make use of prior experience (as suggested by Richard Sutton in personal communication; cf. Tolman and Honzik (1930)). Finally, perhaps the use of model-based reinforcement learning allows for trial and error to occur in subconscious simulation "in the agent's mind" (Hamrick et al., 2016; Hélie & Sun, 2010). These various approaches are not mutually exclusive - indeed, all of them are compatible, and perhaps only some (yet-to-be-realized) combination of all of these methods can produce behavior truly comparable to animal and human insight.

Conclusion

Insight problem-solving was historically presented by Köhler as a challenge for Thorndike's concepts of animal learning. Nowadays Aha!-moments, due to the sheer speed of the phenomenon in human beings and animals, remain puzzling for modeling approaches that rely on statistical trial-and-error. However, their apparent reliance on learning and thereby generalization, and their representational component, has made them equally challenging for traditional cognitive models. Both symbolic and statistical approaches have difficulty explaining insight.

We suggest that the statistical approaches offer, after all, a promising avenue of research for explaining insight. The established importance of learning for insight (Birch, 1945; Wiley, 1998) suggests a model based on learning. Our results show how transfer learning can accelerate the resolution of a new problem to the point of making it seem, in contrast to solving it "from scratch", rather sudden. This and the focus of contemporary machine learning techniques on representation designates them as clear candidates for modeling insight.

We have presented a simulation of a psychological experiment on insight, with the aim of proposing a model of the cognitive processes underlying animal behavior in the experiment. Our artificial pigeons were not a match for the real pigeons performance-wise: they required more experience to solve a simplified version of the task; their "insights" were slower and clumsier. However the proposed model showed qualitative properties reminiscent of those seen in pigeons. It is a long way to recreating the insights of chimpanzees, let alone humans; we have given some directions for future research, and we hope that the methodology presented here (replicating insight studies on non-human animals) can serve as a basis for future investigations of the creativity of great apes - such as ourselves.

Epistemic drive and memory manipulations in explore-exploit problems

Nicolas Collignon n.collignon@ed.ac.uk

Abstract

People often navigate new environments and must learn about how actions map to outcomes to achieve their goals. In this paper, we are concerned with how people direct their search and trade off between selecting informative actions and actions that will be most immediately rewarding when they are faced with new tasks. We find that some people selected globally informative actions and were able to generalize from few observations in order learn new reward structures efficiently. These participants also displayed the ability to transfer knowledge across similar tasks. However, a consistent proportion of participants behaved sub-optimally, caring more about observing novel information instead of maximizing reward. Across four experiments, we present evidence that participants' motivation to explore was influenced by 1) how much they already knew about the underlying task structure and 2) whether their observations remained available. We discuss possible explanations behind people's exploratory drive.

Keywords: active learning; generalization; exploration-exploitation; transfer learning; data-availability;

Introduction

In order to act, plan, and achieve goals, people must learn about their environment and the outcome of possible actions. One reason for human successes in developing new theories and strategies when confronted with new problems is that people are not passive observers. Indeed, children ask informative questions and can adapt their strategies when inquiring about things they don't know (Ruggeri & Lombrozo, 2014), and play with new toys in ways that help them disambiguate uncertain causal relationships and gather information (L. Schulz & Bonawitz, 2007; Cook et al., 2011). The idea that humans learn and interact with their environment by performing intuitive experiments, maximizing information gain, is a popular one (Coenen et al., 2017; Gureckis & Markant, 2012; Nelson, 2005; Gopnik et al., 2004).

In this paper, we are interested in how people learn to select actions that are most rewarding when faced with a sequence of novel but potentially related tasks. We designed experiments to better understand people's exploration and reward maximizing strategies across a sequence of tasks. Do those strategies evolve over time, as they encounter related tasks? Can people transfer structural knowledge and improve their performance by leveraging similarities between tasks? What is the relationship between people's search strategies, their ability to learn and generalize from observations, and how well they do?

When encountering new situations, people are often faced with the decision of either gathering more information about the task to improve the quality of their decision, or choosing an action that has been shown to be rewarding (Hills et al., 2015). A doctor might, for example, want to run more tests to have a better diagnosis for their patient or give them the treatment they believe will best relieve them from their symptoms. To better understand human decision strategies when dealing with the explore-exploit trade-off, Multi-armed Bandits (MAB) have been used extensively. In these experiments, participants have to select between different possible actions (e.g. the arms of a bandit) yielding stochastic rewards, so as to maximize their rewards. In the real world, an essential part of solving problems lies in discovering the underlying structure of the problem, where each action can be represented as a set of continuous and discrete features. In a Contextual MAB (CMAB), there are observable feature that provide information about the arms' reward distributions. Learning how features relate to rewards allows for an efficient representation of the environment, and enables the learner to generalize to new events. Previous studies of human behavior in CMAB problems have shown that people are able to generalize across observations when faced with a large number of options, and make use of uncertainty to direct their search (E. Schulz et al., 2017; Wu et al., 2018; Borji & Itti, 2013). These experiments have assumed the basic structure of the underlying problems to be static, or known in advance. When confronted with unknown task structures, Teodorescu and Erev (2014) showed that people were able to adaptively learn purely exploratory or purely exploitation-oriented policies. However, in their experiment there was no systematic relationship between an option's features and its reward, aside from whether it had been previously explored.

Unlike a CMAB-type task, the tasks we presented to participants were deterministic, meaning that re-selecting an option would always yield the same reward. This was done to ensure a clear distinction between exploration and exploitation in participant decisions. To examine people's ability to use generalization to guide their search we presented them with tasks that contained a large number of choices and a relatively limited number of actions, meaning that generalizing over previous observations is necessary for optimal performance. We chose a simple structure to ensure it would be possible for participants to learn and exploit it when maximizing rewards.

Our first two experiments focus on sequential tasks where participants had no prior information about the underlying reward structure, and where a combination of exploration – to discover task structure and discover optima – and exploitation is necessary to do well. The next two experiments provided participants with training about the reward structures before the task itself. In all of these experiments, we found that some participants selected actions that resolved uncertainty about the underlying structure of the task, and traded off between exploration and exploitation in order to maximize

reward. These participants were also able to transfer knowledge across tasks and gradually improved their performance. We also found a significant number of participants engaged in purely exploratory behavior, consistently preferring to choose novel actions, even when these actions were relatively unrewarding. These results highlight the importance of studying individual differences to better identify the multiple factors that influence human behavior, and of accommodating these differences in models of learning and exploration.

Experiment 1

Across our four experiments participants were given a sequence of grids composed of 9-by-9 arrays of tiles (see Figure 1), with each tile corresponding to a possible action. In this paper, we limit our analysis to the first three grids presented to participants (out of nine), as the latent task structure changed after that point. The grids studied here shared a similar underlying task structure: they had the same kind of relationship between features and rewards, but details of those relationships varied. In our experiment an action consists of selecting an individual tile, which has two features: its horizontal (x), and vertical position (y). Participants had to select tiles to maximize their cumulative rewards over 20 choices in each grid. The task presents a classical explore-exploit tradeoff: Succeeding requires carefully balancing between choosing new tiles to learn about the underlying reward structure or re-selecting tiles that were observed to be rewarding. In Experiment 1, participants received no prior knowledge about the reward structure of the tasks, nor about whether the tasks were related to one another in any way.

We predicted participants would be able to generalize from previous observations and improve by using their growing knowledge of the underlying task structure to select better actions. We measure this by looking at whether participants were able to select more rewarding tiles as they collected more information, and whether they demonstrated confidence in their knowledge by repeatedly selecting (i.e., exploiting) optimal actions. Our second hypothesis was that participants would be able to re-use knowledge across grids, since they shared the same structure, and thus improve their performance from one grid to the next.

We also studied the distance between participants' selections throughout the task to better understand their behavior. Distance between selections is a useful marker of different exploration strategies. For example, participants who seek to reduce uncertainty about the task structure are likely to select tiles that are far apart from each other, as these tend to yield more information about the broad shape of the reward function, in addition to having more uncertain rewards themselves. We call these selections *globally informative* actions. In contrast, participants might sample tiles adjacent to their previous observations, e.g., because they believe they are close to a maximum or because they want to observe local gradients. We call this kind of selection *local search*.

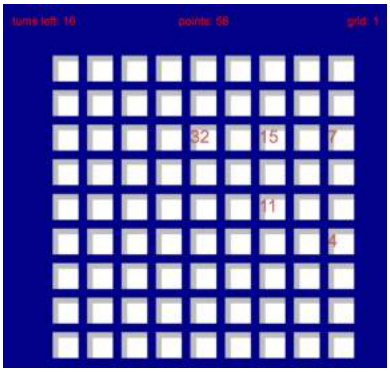

Figure 1: Screenshot of grid presented to participants after 5 observations. Note that in Experiment 1, the rewards disappear shortly after a tile has been selected.

Methods We recruited 79 participants using Amazon's Mechanical Turk service. They received \$0.75-\$1, which was doubled for participants whose final scores were in the top 10 percent. Following the instructions given to participants, we excluded participants whose performance was worse than chance ($n = 3$). We also excluded participants who failed to select more than 2 different tiles on the majority of grids ($n = 5$), as it showed a lack of engagement with the task.

The three grids analysed here used a reward structure where one location (x_m, y_m) was sampled uniformly at random in each grid, and the grid's maximum reward m was sampled from $(\mathcal{N}(\mu = 200, \sigma^2 = 50))$. The reward r for a given tile location (x, y) was exponentially decreasing with its Euclidean distance d from that maximum-reward tile: $r(x,y) = C \cdot e^{-k \cdot d((x,y),(x_m,y_m))}$, rounded to the nearest integer. We chose an exponential relationship between features and rewards to ensure there would be a clear advantage for participants who discovered the maximum-reward tile. We chose a constant $(k = 0.4)$ that led to large differences between the maximum and its closest neighbors while making it unlikely that any tiles would have rewards of zero or one. We used a random maximum reward in order to make it difficult for participants to know they had found the most rewarding tile without knowing the reward structure of the task.

When a tile was selected, the reward was displayed on the tile for 1.5 seconds and added to the cumulative score on the current grid. Participants could re-select tiles they had previously chosen. Participants were given no information about the underlying structure of the grid prior to the task, and were not informed that the tasks were related in any way, apart from a note that there could be patterns behind the rewards.

Results and Discussion For this and all subsequent experiments, we report the normalized scores (between 0 and 1), by dividing each reward by the maximum reward in that grid. We were first interested in seeing whether participants were able to recognize similarities between tasks. We use a general linear model (GLM), with the reward as outcome variable. The turn and grid index were used as predictor variables. Both the turn ($b = 0.02, se = 0.001, p < 0.001$) and the grid ($b = 0.05, se = 0.005, p < 0.001$) were significant factors. Following our hypothesis, participants selected better

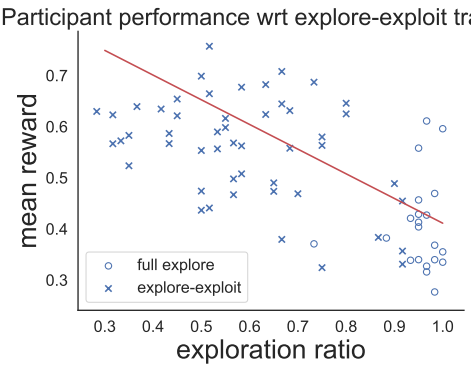

Figure 2: Each point represents a participant. The y-axis is the average reward across all three grids. The x-axis is the proportion of novel selections across all three grids. A value of 1 would mean only selecting new tiles, 0 only selecting the previously-selected tiles.

tiles over time, suggesting that they were able to exploit the underlying reward structure. Participants also improved their performance across grids, suggesting they were able to transfer structural knowledge across tasks (see Figure 3).

As a simple measure of a participant's propensity to explore, we used the proportion of actions that selected a previously-unseen tile ("exploration") versus re-selecting a previously-seen tile ("exploitation"). This distinction is more natural in our tasks than in a traditional stochastic bandit task, as in the latter it can be informative to re-select previously-seen tiles to learn about their reward distributions. There were significant behavioral differences indicated by how people traded off between exploration and exploitation among participants, and in the cumulative rewards they collected ($M = 0.49, SD = 0.30$) (see Figure 2).

Twenty-two participants (31 percent) never re-selected tiles more than twice in the majority of grids. We call these participants *full explore* (FE) participants. We call the other participants (n=49), that traded off exploration and exploitation, *Explore-Exploit* (EE) participants.

EE participants improved across tasks ($b = 0.07, se = 0.006, p < 0.001$) (see Figure 3), supporting our hypothesis that participants who used the underlying task structure to direct their search and maximize reward were able to re-use what they had learned to a new task.

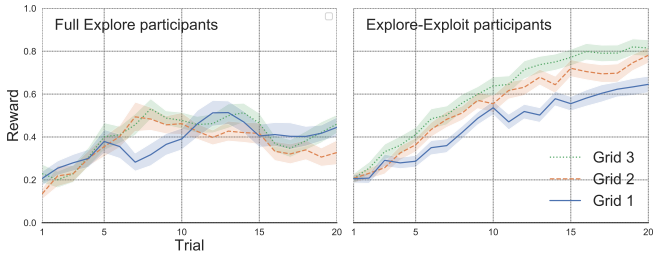

Figure 3: Performance of FE participants (n=22) and EE participants (n=49) in Experiment 1 across all three grids. Error bars in this and all subsequent plots reflect standard errors of the mean.

Across all participants, the proportion of exploratory selections correlated negatively with score ($r(140) = -0.71, p < 0.001$), and FE participants earned lower scores than EE participants ($t(69) = 5.77, p < 0.001, d = 0.15$). Their average scores barely improved from one grid to the next (Figure 3; $b = 0.02, se = 0.008, p = 0.06$).

We used a logistic regression model to evaluate participants' ability to find the maximum across grids. More participants found the maximum as they went on with the grids, hinting that they were better at utilising the underlying task structure ($b = 0.64, se = 0.11, p < 0.001$). Whether participants were engaging in *full exploratory* or *explore-exploit* strategies did not predict if they found the maximum in the tasks ($b < 0.001$). Participants were significantly better than chance at finding the maximua (0.65 of grids, vs. upper bound chance proportion of 0.25; $\chi^2(1, N = 1174) = 188.1, p < 0.001$). Furthermore, participants had overall a strong 'local bias' in their sampling, where they choose tiles close to their last choice more often than chance given the distribution of inter-tile distances ($t(151) = -50.8, p < 0.001, d = -2.34$) (see Figure 4). This suggests that participants engaged in local search strategies, rather than globally informative actions. Both EE and FE groups showed this bias, with adjacent tiles selected in 49% of FE participants' exploratory choices ($SD = 0.17$) and 39% for EE participants ($SD = 0.17$).

In conclusion, Experiment 1 showed that some participants were able to learn the underlying task structure when it was new and traded off between exploration and exploitation to maximize their rewards. These participants transferred knowledge across tasks that shared similarities in their underlying structure. However, a large proportion of participants had a strong tendency to explore in circumstances where exploitation would have yielded much higher scores, preferring unobserved tiles over known tiles with a high reward value. FE participants presented some evidence for learning the underlying structure, but this was not reflected in their score. Why did so many participants adopt such an extreme exploratory policy? One possibility is that they were motivated to learn more about the reward structure, or ensure they had found the maximum possible reward, in line with the inherent curiosity bias observed in people (Kidd & Hayden, 2015; Gottlieb et al., 2013).

We also observed a locality bias in participants' choices. This may have been due to the memory demands of the task. Wu et al. (2018) presented evidence that participants displayed an ability to use generalization to direct their search. Unlike the task used in their study, our task had the rewards disappear after participants selected a tile. Remembering past observations when generalizing might be difficult, and could have led participants to adopt policies that alleviated the complexity of the task. For example, if participants tracked local gradients in rewards and followed increasing rewards, this would only require tracking 2-3 past observations while being less demanding than computing a surrogate model over the general task structure. This would be consistent with the local search strategies exhibited in other domains such as causal learning (Bramley et al., 2015) and category learning (Markant et al., 2016), and the idea that people adapt their high-level strategies to make the most of limited resources (Lieder et al.,

2014). For FE participants, the local bias during exploration could reflect a systematic and memory-efficient policy for exhaustively searching a subset of the tiles for a maximum.

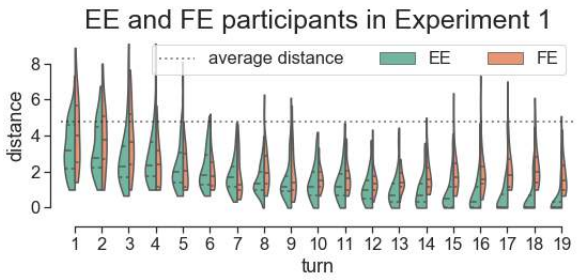

Figure 4: Average distance between selections of EE and FE participants in Experiment 1 presented with quantiles and kernel density estimations. We use Euclidian distance between selections, with 0 counting for a re-selection of the previous click. The dotted line represents the average distance between all tiles in a grid. The shape of the distribution is drawn using a (normal) Gaussian Kernel Density Estimate cut at 0.

In Experiment 2, we presented participants with the same task structure as in Experiment 1, but with changes designed to understand and potentially reduce their strong tendency to explore new tiles. These included persistent indicators of explored tiles' rewards, checks of participants' understanding of the instructions, and different incentives.

Experiment 2

In this experiment, the reward associated with a given tile is displayed continuously once it has been observed. We hypothesized that with participants observations remaining visible, the overall reward pattern would be more evident. We predicted that participants would be able to make more globally informative actions (i.e. exploratory selections would be more distant from each other). Because the underlying structure is made more evident, we also assumed fewer participants would engage in *full exploratory* behavior.

Methods We recruited 72 participants using Amazon's Mechanical Turk service identically to Experiment 1. Participants all received a base payment of $0.75. The reward scheme differed from that in Experiment 1: rather than granting bonuses to the top 10 percent, we gave all participants a bonus proportional to their cumulative score, up a maximum of $0.75. We excluded participants who failed to select more than 2 different tiles on the majority of grids ($n = 4$). In Experiment 2 when a tile is selected by a participant the reward is continuously displayed on the tile and is added to the current cumulative score on the current grid.

In another change from Experiment 1, tiles' rewards were persistently visible after they had been selected, under the logic that it might improve participants' ability to learn the underlying reward structure and increase their ability to find and exploit the maximum. We also added explicit instructions that participants could re-select tiles, and added a pre-task questionnaire to make sure participants understood these instructions. The questionnaire also required participants to understand that their goal was to maximize reward (as opposed to discovering the underlying pattern, or finding the maximum. Participants were not allowed to proceed with the task until they answered all questions correctly.

Results and Discussion Contrary to our predictions that participants would be less prone to *full exploratory* behavior, a significantly larger proportion of participants showed FE behavior in Experiment 2 as compared with Experiment 1 (.47, $n = 32$ vs. .31, $n = 22$; $\chi^2(1, N = 139) = 18.6, p < 0.001$). As in Experiment 1, the proportion of exploratory selections correlated negatively with performance ($r(134) = -0.75, p < 0.0001$). In Experiment 2, EE participants also performed significantly better than FE participants ($t(66) = 9.31, p < 0.0001, d = 0.23$) and improved significantly across tasks ($b = 0.04, se = 0.007, p < 0.0001$), whereas FE participants did not ($b = 0.01, se = 0.006, p = 0.14$).

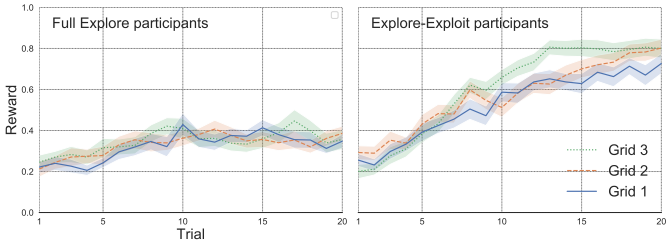

Figure 5: Performance of FE participants ($n = 49$.) vs EE participants ($n = 36$).

To understand the effect of having observations available throughout the task, we compare the performance of EE participants in Experiment 2 (n=36) to the performance of EE participants in Experiment 1 (n=49). Overall, EE participants in Experiment 2 (M=0.58) did slightly better than EE participants in Experiment 1 (M=0.56) ($b = 0.04, se = 0.008, p < 0.001$). This was most pronounced in the first grid ($t(84) = 2.18, p = 0.03, d = 0.08$). We conjecture that EE participants in Experiment 2 learned the reward pattern faster, and EE participants caught up in subsequent grids. This supports the hypothesis that visible observations allowed participants to generalize better, by supporting more global strategies. To test this idea, we looked at the inter-selection distances between the first 5 selections of participants. EE participants' choices in Experiment 2 were more global, with greater distances than EE participants' choices in Experiment 1 ($t(84) = -2.25, p = 0.03, d = 0.66$) (see Figure 6).

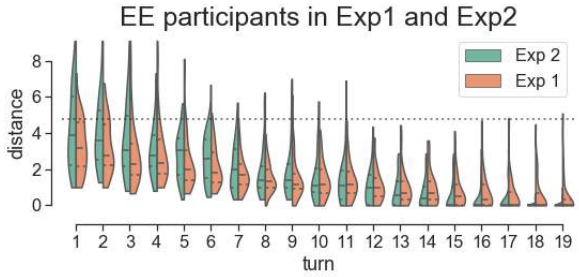

Figure 6: Comparison of distances between selections of EE participants in Experiment 1 and Experiment 2 (see Figure 4 for details). EE participants in Experiment 2 selected more "global" actions (longer distances between selections) during their first actions.

Why did more participants engage in FE behavior in Ex-

periment 2? We conjectured that participants were more motivated to observe rewards for new tiles when previous rewards remained visible, because the overall pattern – and the possibility of better understanding it – might have been more salient to them.

In Experiment 3, we sought to understand why some participants might want to select new tiles almost exclusively, rather than occasionally exploiting what they had learned to earn greater rewards. After Experiment 1, we hypothesized that this might have been due to an intrinsic epistemic drive in participants. Experiment 2 showed that for EE participants were able to leverage visible observations to conduct more global exploration, and led to a better overall performance. However, the observable rewards also seemed to add an incentive for many participants to exclusively choose novel actions, rather than maximising rewards. We hypothesized that this would only be the case for new tasks when participants had no prior knowledge about the underlying reward structure of the tasks, since new observations would not be very informative if participants had a prior about the underlying reward structure.

Experiment 3

We designed Experiment 3 to control explicitly for the potential epistemic drive of FE participants by familiarizing them with the underlying reward structures prior to the task. By making the structure clear to participants prior to the tasks, our primary prediction for Experiment 3 was that fewer participants would engage in FE behavior. We presumed the intrinsic motivation of observing new observations would be attenuated when participants did not gain new information about the task from those observations.

We also hypothesized there would be weaker or no progress across grids since participants would already be familiar with the reward structure when they engage with the first grid. Because of the training, we predicted participants would be more efficient at finding and re-selecting tiles with high values, and would thus perform better overall than in Experiment 1 and 2. Experiment 3 was set up identically to Experiment 2. Participants were told about the underlying pattern and given three practice grids so they could learn the reward structure prior to the task.

Methods We recruited 43 participants using Amazon's Mechanical Turk service, identically to Experiment 2, with the following changes: Participants were only recruited for three grids rather than nine, following the same reward pattern discussed in Experiment 1 and Experiment 2. Because of the shorter duration, participants were paid a base reward of \$0.2. We used a proportionally larger bonus of \$0.6 under the logic that this would further reduce the effects of epistemic drive. Apart from the training grids presented prior to the task, instructions were identical to Experiment 2. During the training, participants were told that each grid had one maximum tile, and the closer a tile is to the maximum the higher the reward. The first training grid had all rewards displayed and participants were instructed to familiarize themselves with the nature of the task. The next two grids were similar to the grids in the actual task (i.e. only observed tiles display reward values) but participants were encouraged to learn the pattern as well as they could. Throughout the task, instructions regarding reward maximisation and the possibility of reselecting tiles were also displayed. We excluded one participant who failed to select more than two different tiles on the majority of grids and one participant who reported not following the instructions upon completing the experiment.

Results and Discussion Surprisingly, 37 percent (15 out of 41) of participants engaged in *Full Exploration* (FE) in Experiment 3. The proportion of FE participants in Experiment 3 was significantly less than the 47 percent we observed in Experiment 2 ($\chi^2(1, N = 109) = 8.82, p = 0.003$), but was nonetheless a higher proportion than anticipated.

As expected, EE participants in Experiment 3 did not improve significantly across grids, since they had been trained extensively on the rule before the assessed task started ($b = -0.01, se = 0.008, p = 0.112$). The average performance of EE participants was significantly better than EE participants in Experiment 2 ($t(61) = 2.29, p = 0.03, d = 0.07$) and EE participants in Experiment 1 ($t(74) = 3.11, p = 0.003, d = 0.09$, suggesting that participants were able to learn the rule during the training and relied on this knowledge when faced with new grids in the task.

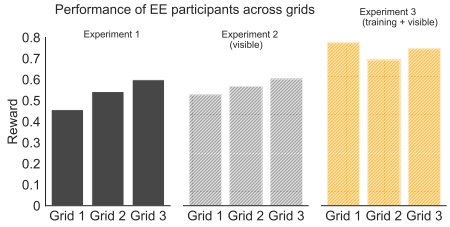

Figure 7: Average performance of EE participants (participants that traded off between exploration and exploitation) across all three grids in Experiment 1, 2 and 3.

To understand the effect of prior knowledge on participants' exploratory patterns, we compared how EE participants explored compared to EE participants in Experiment 2. Participants in Experiment 3 were significantly more locally biased in their initial five selections ($t(359), p < 0.001, d = 1.19$). Participants in Experiment 3 were already familiar with the *Location rule*, and it is probable that they were able to find the maximum by ascending towards the maximum through small incremental steps. EE participants in Experiment 3 had a significantly lower proportion of reselections (0.19 in Experiment 3 vs 0.28 in Experiment 2) ($\chi^2(1, N = 1367) = 17.16, p < 0.001$). Given their higher performance scores, EE participants in Experiment 3 were likely to have a strategy more adapted to the task than in Experiment 2, where participants were still learning the reward structure. Indeed, EE participants in Experiment 2 had a tendency to settle on a sub-optimal tile, finding the maximum tile in 0.62 of grids. EE participants in Experiment 3 took smaller exploratory steps but found the maximum in 0.81 of the grids

($\chi^2(1, N = 185) = 6.69, p = 0.01$).

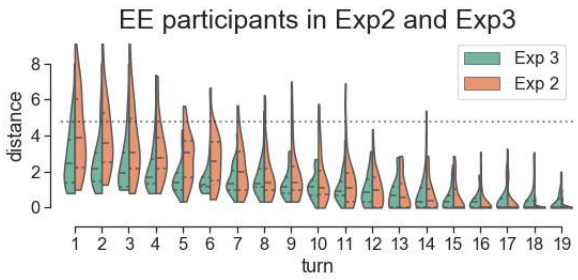

Figure 8: Distance between selections of participants (see Figure 4 for details). EE participants in Experiment 2 had more global observations than EE participants in Experiment 3. This can be explained by that fact that they had no prior knowledge about the task structure.

Contrary to our hypothesis, many participants still engaged in full exploratory behavior. Given this result, we hypothesized that participants might be motivated by observing new rewards rather than learning the underlying reward structure *per se* and that this effect might be emphasized when rewards remain visible after having been observed. Indeed, in Experiment 2, where rewards remained visible, significantly more participants engaged in full-exploratory behavior than in Experiment 1. We designed Experiment 4 to account for these two factors of epistemic motivation: 1) wanting to learn about the underlying reward structure and 2) wanting to attend novel information.

Experiment 4

Experiment 4 followed the design details of Experiment 3, except that rewards were not displayed continuously after they had been selected - they are displayed on the tile and disappear shortly after, like in Experiment 1.

Our main hypothesis for Experiment 4 was that fewer participants would engage in *full exploratory* behavior, since the epistemic reward is attenuated by not having the tiles visible after they have been selected and having training grids prior to the task. We predicted EE participants would perform similarly or slightly worse than in Experiment 3, because of the constraints of not having previous observations visible, but better than in Experiment 1 and 2. We also predicted we would observe little or no transfer effect across grids.

Methods 39 participants were recruited using Amazon Mechanical Turk. One participant was excluded for failing to select more than two different tiles, and one was excluded because their performance was worse than chance.

Results In agreement with our hypothesis, only one participant out of 37 engaged in *Full Exploration*. This was significantly less than in any other experiment. This supports the idea that participants' strategies were driven by an epistemic drive which was twofold:

First, participants were motivated to reveal the underlying reward structure, e.g., reducing the entropy about the structure of the task, or about the location of the maximum. Indeed, participants were less likely to engage in FE behavior in Experiment 4 (known structure and disappearing observations) than Experiment 1 (unknown structure and disappearing observations), and significantly less in Experiment 3 (known structure and visible observations) than Experiment 2 (unknown structure and visible observations).

Second, participants were motivated to observe the outcomes of individual actions. In Experiment 1,2 and 3 a significant proportion of FE participants selected the maximum but consistently opted for selecting novel options rather than re-selecting a previous maximum observation, with a preference for actions that were local to their last one. Participants' drive to select novel actions was enhanced by the fact that information did not need to be kept in working memory. They were less engaged in FE behavior in Experiment 1 (non-visible observations) than Experiment 2 (visible observations), and, similarly, less in Experiment 4 (non-visible observations) than Experiment 3 (visible observations). Though EE participants in Experiment 3 performed slightly better than in Experiment 4, this was not significant ($t(61) = 0.93, p = 0.35, d = 0.04$). Participants in Experiment 4 improved their average performance slightly across tasks ($b = 0.02, se = 0.007, p = 0.02$).

The average distance between the initial five exploratory selections of EE participants was not significantly different in Experiment 3 and Experiment 4 ($t(309) = -0.90, p = 0.37, d = -0.15$). EE participants in Experiment 4 explored significantly more locally than EE participants in Experiment 1 ($t(374) = -2.73, p = 0.007, d = 0.47$). Like in Experiment 3, this supports the hypothesis that participants who were familiar with the underlying structure of the grid were able to find the maximum by taking local exploratory steps until they eventually found the maximum.

Conclusion

In this paper, we focused on the behavioural analysis of participants across four experiments to study how people learn to select rewarding actions in a sequence of novel tasks. We found that some participants were able to learn the underlying structure while balancing exploration and exploitation to maximize their rewards across tasks. They improved their performance from one task to the next by transferring abstract knowledge about their environment. However, consistently across tasks, we observed that a significant proportion of participants engaged in purely exploratory behavior, largely ignoring the reward incentive. We showed that this behavior could be manipulated by controlling the availability of information as the learner selected actions, and by giving prior knowledge before participants engaged with the task. We suggest that people are motivated by two types of epistemic drives: 1) to reduce uncertainty and learn about the structure of the task and 2) to observe new evidence, regardless of its informativeness about the global task structure. The latter was evident when participants continued valuing new actions over maximising rewards, even when they were familiar with the task structure.

Different mechanisms for curiosity have been discussed in the literature, and could be connected to how people learn

in new environments when combined with trying to achieve goals or maximising utility. One such strategy is to entirely dismiss reward feedback, giving rise to a strong novelty drive. This *novelty search* mechanism has been been shown to be very successful in the context of Evolutionary Strategies for tasks with tricky reward functions (Lehman & Stanley, 2011). Some studies have shown that people are biased towards surprise (Gottlieb et al., 2013; Itti & Baldi, 2006). Selecting new actions would make sense under the assumption of possible change, or if one believes that the environment is trying to fool us. Third, the idea of *epistemic actions* could explain part of people's strong drive to select new actions, especially under the constraint of cognitive load, when storing observations is expensive or unrealistic. Epistemic actions refer to actions *in the world* that help solve problems by changing the mental state of the agent, as opposed to performing computations in the head (Kirsh & Maglio, 1994). An example of this behavior is the use of sticky-notes, or of arranging documents in a way that makes it easier to retrieve them rather than by memory alone. In the case of our experiment, observing new information might have been perceived as much cheaper than the possibility of generalizing from few observations.

In our study, we highlight that studying individual differences amongst participants can help us better understand the complex mechanisms at play during active learning in new environments. We hope that by pointing out surprising facets of human behavior, this empirical study can guide the design of better computational models of human learning and exploration. We are currently investigating how computational models of memory, generalization and search (León-Villagrá et al., 2018; Wu et al., 2018; Lucas et al., 2015) can give us further insight into people's representations and strategies when learning in new environments.

Abstract

Kinematic specification of dynamics (KSD) states that full-body kinematic patterns of daily activities are reflective of a person's plans, goals, and intentions. Furthermore, it has been shown that observers of those activities are well attuned to differences between those kinematic patterns. However, despite a substantial body of research on the identification of intentional motion, it is not yet clear what the essential kinematic information is required to perceive the intention from the kinematic pattern. Therefore, we analyzed four different intentional full body motions (sit-to-stand transitions: stand, press-stand, press-sit, and reach-up), to determine the essential kinematic information that differentiates them. We utilized principal component analysis (PCA), linear mixed models, and hierarchical multinomial logistic regression to create two predictive regression models that allow us to successfully identify and distinguish the four intentional motions.

Keywords: Intention Recognition; Kinematic Specification of Dynamics; Sit-to-Stand Transition; Point-Light Displays;

Introduction

Activities that people perform in their daily lives are reflected in a person's full body kinematic patterns (Johansson, 1973). Moreover, human observers can easily perceive even small differences in the patterns of a person's motion profile (Ansuini, 2005; Becchio, Manera, Sartori, Cavallo, & Castiello, 2012; Richardson & Johnston, 2005). It has therefore been argued that the information humans derive from another person's biological motion profile can be used to establish successful coordination with others (Pezzulo, Donnarumma, & Dindo, 2013; Sartori, Becchio, Bara, & Castiello, 2009) and with intelligent machines, such as robots (Vernon, Thill, & Ziemke, 2016).

Kinematic Specification of Dynamics

In order to study biological motion, Johansson (1973) created the first point-light displays by attaching small lights to his participants and limiting the exposure of his camera recording to capture only those lights. Johansson called these recordings point-light displays and discovered that when he placed the lights on key joint centers, observers of the displays could identify that the moving points represented a person performing a specific action.

Runeson (1994) framed the findings behind point-light displays in his principle of kinematic specification of dynamics (KSD). The KSD principle postulates that because movement kinematics are lawfully related to the dynamics that produce a movement, the movement specifies the dynamics from which it arose. In other words, the relations among a person's joint centers and joint angles specify the action that they are performing.

Specification of Action Capabilities

Overall, kinematic information has been shown to be remarkably rich. For example, point-light displays of an actor pretending to lift a heavy box are noticeably different from displays of the actor actually lifting a heavy box (Runeson, 1994). Furthermore, observing the kinematics of a person can not only specify the action that is being performed, it can also carry rich information about the action capabilities of the observed person. For example, Ramenzoni, Riley, Davis, Shockley, & Armstrong (2008) have shown that after observers view another person walking, they become more accurate at estimating the walker's maximum reach-with-jump height. Additionally, after watching another person walk while wearing (unseen) ankle weights, observers are sensitive to reductions in the walker's maximum reach-with-jump height caused by the additional weight. These findings indicate that a person's general movement pattern provides sufficient information to make an educated judgment of a person's action capabilities.

Specification of Intention

Although it is evident that people can distinguish another person's activities based on the kinematic structure of the displayed motion, there has been some debate about the richness of KSD in terms of social interaction and

intentions. In general, it is hypothesized that the intentionality as reflected in human motion can be used to understand another person's action plans. Thus, one's own actions can subsequently be adjusted in response to this understanding and smooth action coordination can be executed (Becchio, Sartori, Bulgheroni, & Castiello, 2008). However, Jacob & Jeannerod (2005) argued that the kinematics involved at the start of a chain of movements might not reflect the end goal of that chain of movements, meaning the kinematics might not accurately reflect the intention. They proposed a thought experiment involving the story of Dr. Jekyll and Mr. Hyde; the two identities belong to the same person, but the former is a renowned surgeon who performs surgeries on anesthetized patients. The latter is a dangerous sadist who performs the same hand movements on his non-anesthetized victims. Jacob & Jeannerod argued that if someone were to witness one of the two identities reaching and grasping for a scalpel, then it would be impossible to specify the social nature and intention through the grasping motion.

Several studies were performed in response to Jacob and Jeannerod's thought experiment and found evidence against their claim. Ansuini, Giosa, Turella, Altoè, & Castiello (2008) showed that prior intention shapes kinematics by measuring prior-to-contact grasping kinematics for reach-to-grasp movements performed toward a bottle filled with water. By comparing hand shaping across tasks involving different subsequent actions such as pouring the water into a container, throwing the bottle, and moving the bottle from one spatial location to another, the authors demonstrated how prior intention in grasping an object strongly affected the positioning of the fingers, the duration of the reaching, and the contact phase of the movement. Becchio et al. (2008) performed a similar experiment investigating differences between grasping an object to move it to another location and grasping an object to hand it to another person. The velocities and shapes of participants' hands for both the opening and closing phases of the grasping movement were significantly different between the two conditions, as well as the trajectory of the movement during the passing phase. While Becchio and colleagues demonstrated that movement kinematics differ based on the social or operational intention, Manera, Becchio, Cavallo, Sartori, & Castiello (2011) showed that observers can also differentiate between distinct reaching intentions. They presented point-light displays of different grasping movements including a slow grasping movement, a fast grasping movement, a grasping movement with the cooperative intention of passing an object to another person, and a grasping movement with the competitive intention of grabbing an object before another person. With only access to the kinematic information of the initial forward movement, observers were able to accurately classify which of the four actions was being presented 72% of the time, indicating that the observed kinematic patterns may be used for action coordination during joint activities (see also Sartori et al., 2009).

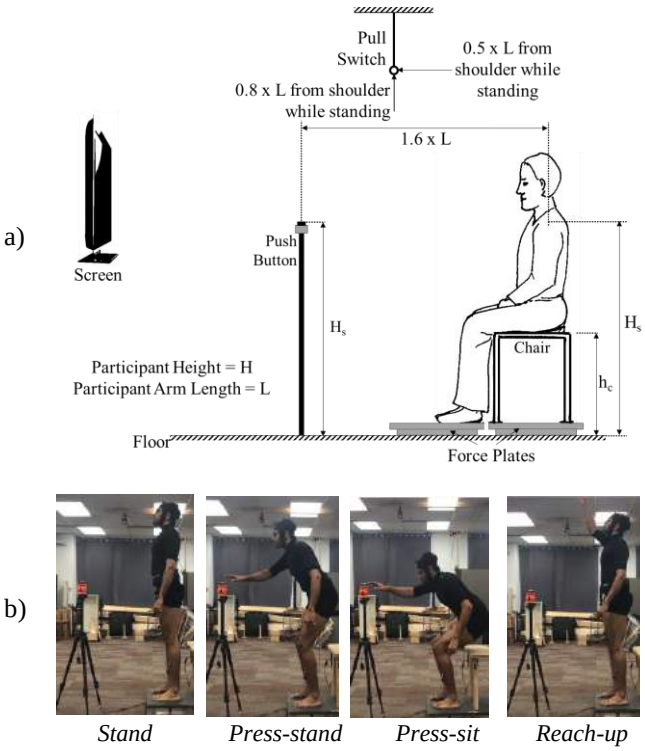

Figure 1: a) Experimental setup for data collection as established and published in Patil et al. (2018). b) Intentional sit-to-stand transitions.

Kinematic Specification of Action and Intention

Although it has been shown that one's movement kinematics provide the information necessary for another person to identify one's action capabilities and intentions, the informational basis for this ability has not been identified (though see Ansuini, Cavallo, Bertone, & Becchio, 2015). Therefore, in the current study, we adopted a similar approach to Weast-Knapp et al. (2019) who used Principal Components Analysis (PCA) to decompose the kinematic data of walking movements to isolate the informational basis for an observer trying to perceive a person's action capabilities. However, rather than focusing on the informational basis to estimate a person's action capabilities, here we explore a different type of full-body movement (sit-to-stand transition, STS) that was executed with different intentions that altered the basic STS motion (see Figure 1b) in order to identify the essential kinematic information of a full-body motion with varying intentions. To gain insight on how people can perceive intention from motion, we must first confirm if the essential kinematic information is different between the motions. If the differences exist, the next goal will be to confirm that humans can extract the same information. Therefore, this paper tackles the first goal of clarifying the essential kinematic structures for STS intentional motion.

Method

In order to enable the analysis of intentional motion, we utilized one subset of a larger data set that was originally collected in context of understanding joint angle variations for exoskeleton control (Patil et al., 2018). The data subset was taken from a healthy, 28-year old male participant.

Setup and Procedure

In order to induce four different intentional STS transitions, a setup was created by Patil et al. (2018) as shown in Figure 1a. A button was placed in front of participants at the shoulder height while sitting and 1.6-times the arm length from the shoulder. A pull switch was positioned above the participant at a height of 0.8 times the arm length and at a distance of 0.5 times the arm length from the shoulder while standing. Motion data was recorded using a 20-camera 3D motion capture system (Motion Analysis Corporation, Santa Rosa, CA). A 29-marker set based on the Helen Hayes body marker placement protocol (Kadaba, Ramakrishnan, & Wootten, 1990) was used to track the motion. A screen was positioned at eye level in front of the participant to provide instructions for the specific trial. Every trial started with the participant sitting at a stool (height 45.72 cm) without any hand or back rests.

The participants were shown a "ready" signal on the screen and, after 3 seconds, the instruction to perform any of four randomized tasks marked the go-signal. The participants performed 100 trials of four intentional STS transition tasks (25 trials per intention): *stand* - the participants were asked to stand up at a comfortable speed without any intention of subsequent activity, *press-stand* - the participants were asked to stand up from the chair while pushing the button in front of them and finish standing up; *press-sit* - the participants were asked to stand up from the chair while pushing the button in front of them and to then immediately sit back down; *reach-up* - the participants were asked to stand up to pull on the switch above their head and after pulling the switch finish standing up. For all trials, the participants were instructed not to use their hands to push down on the chair or their thighs during STS and not to lift their feet from the heel or toes during the trial. The participants were allowed to take breaks whenever they felt fatigued. For the purpose of the current analysis, we included the first four trials of each performed intentional sit-to-stand transitions within the data subset.

Data Analysis and Results

Determining Essential Principal Components

Seven of the original 29 markers (corresponding to the head, right shoulder, right elbow, right hip, right knee, right ankle, and right hand) were selected to form a simple sideview configuration of each motion with the right side of the body represented. We cut off each time series using the furthest point forward in the motion of the hip marker as shown in Figure 1b. This served to truncate the movement to the initial intention-expressing forward portion of rising from a seated position and excluded the stand-to-sit backwards transition. In the future, we plan to use this motion data to explore how human observer respond when viewing it. The Y and Z coordinates of the recorded 3-dimentional motion data were used to perform a Euclidean transformation which provided one value for each marker for each frame of the data set (cf. Weast et al., 2019). The data was then submitted to PCA via R (*base package: prcomp*). PCA is a statistical tool that allows for the reduction of high-dimensional data with the goal of revealing hidden structure in the underlying relationship between variables. For example, previous research has utilized PCA to uncover the most important factors contributing to variation in movement kinematics in gait (Vallery & Buss, 2006), juggling (Post, Peper, & Beek, 2003) and even the movements of cooperating actors (Ramenzoni, Riley, Shockley, & Baker, 2012). Here, we used PCA to reduce the seven-marker data set to a subset of principal components (PC) that captured the dynamics of the kinematic movements. We decided to use PCA rather than machine learning techniques, as we are interested in which joint centers hold the essential kinematic information to differentiate the motions. Though machine learning can help determine the presence of differences and classify each motion, it will not offer insight as to which body segments participate in providing the structure that differentiates movements. Subsequent analyses were performed on this subset to identify the activity of key markers for discriminating between intended movements.

We completed 16 PCA analyses, one per STS motion file (4 intentions × 4 repetitions). Each PCA analysis yielded a **7** (markers) × **7** (PC dimensions) matrix of coefficients, as well as a vector of the amount of total variance accounted for by each PC. The variance vectors were used as criteria to reduce the original data to those PCs that (1) accounted for at least 10% of the total variance in the motion pattern, and (2) provided sufficient variation between intentional movement profiles to be a useful candidate for future discrimination. PC1 and PC2 reliably met criteria (1), suggesting that the data could be reduced to the first two PCs without much loss in information. To determine (2) we submitted the percent explained variance of each PC to a linear mixed effects model (R package: lme4) with intention as a fixed effect and instance (each intentional motion was performed four times) as a random effect. For the sake of brevity, we only report the *F*-tests (Satterthwaite's degrees of freedom method) for overall significance of the models. Only models for PC1, $F(3,12) = 47.49$, $p < .001$, and PC2, $F(3, 9) = 54.51$, $p < .001$, were significant, suggesting that the amount of explained variance for both PC1 and PC2 differed by intentional movement. For the remaining PCs this relationship was non-significant, supporting our choice to further analyze PC1 and PC2.

Elimination of Non-significant STS Markers in PC1 & PC2

Having reduced the data to the first two PCs, two additional sets of linear mixed model analyses (7 per PC1 and PC2; 14 total) were completed to establish whether the PCA coefficients for each marker systematically varied as a function of the intentional motion.

Table 1. Results of linear mixed model for STS markers on PCs 1 and 2

Marker	Model PC1	Model PC2
M1 (Head)	$F = 86.10$, $p < .001$ *	$F = 4.82$, $p = .03$ *
M2 (Shoulder)	$F = 100.44$, $p < .001$ *	$F = 9.37$, $p = .004$ *
M3 (Elbow)	$F = 8.52$, $p = .003$ *	$F = .57$, $p = .65$
M4 (Hip)	$F = 132.40$, $p < .001$ *	$F = 19.64$, $p < .001$ *
M5 (Ankle)	$F = 3.10$, $p = .08$	$F = .09$, $p = .96$
M6 (Knee)	$F = 1.07$, $p = .41$	$F = .08$, $p = .97$
M7 (Hand)	$F = 3{,}132$, $p < .001$ *	$F = 2.86$, $p = .10$

** candidate markers*

Again, intentional motion was entered into the model as a fixed effect with instance as a random effect. The purpose of this series of analysis was to further reduce the dimensionality of the data by identifying candidate markers, whose activity might be used to build a parsimonious model for predicting the intended motion. In short, we sought to determine *which markers* might qualify for submission to a predictive model for intention, as well as *how few* may be used to build a model that reliably discriminates between the intentional movements.

As can be seen in Table 1, the analysis on PC1 revealed that the coefficients corresponding to markers M1, M2, M3, M4, and M7 varied systematically as a function of intentional motion; repeating this analysis for the coefficients in PC2, we found significant systematic variability for markers M1, M2, and M4. These sets of markers provided a list of variables to enter into subsequent regression analysis for PC1 and PC2.Table 2. Results of linear mixed model for STS markers on PCs 1 and 2

Regressing Intention Categories onto Candidate Markers

Using our candidate markers, we performed two hierarchical multinomial logistic regressions (one for each PC) to determine which combination of markers was most parsimonious in reliably discriminating between the intentional movements. For the analysis along PC1, a single marker per hierarchical step was loaded into the regression model in order from largest to smallest PCA coefficient mean. This resulted in a statistically significant model containing markers M7 (hand) and M3 (elbow), which improved the likelihood of determining the corresponding intentions, above and beyond the null (chance) model, as well as all models formed by prior steps in the analysis (see Table 2).

Table 2. Summary of model results for hierarchical multinomial regression for STS markers in PC 1. Only models that yielded a significant improvement are reported.

Step	Variables Entered	df	Likelihood Ratio	*p*
1	**M7**	42	35.81	< .001
2 *final*	**M7 + M3**	39	7.85	.049
	M7 = hand, M3 = elbow			

We followed an identical method for PC2, hierarchically entering each marker into the regression model beginning with the marker possessing the largest PCA coefficient mean. The resulting model was statistically significant, containing M1, M2, and M4, and improved the likelihood of determining the corresponding intentions, above and beyond the null (chance) model, as well as all models formed by prior steps in the analysis (see Table 3).

Table 3. Summary of model results for hierarchical multinomial regression for STS markers in PC 2.

Step	Variables Entered	df	Likelihood Ratio	*p*
1	**M1**	42	6.37	< .001
2	**M1 + M2**	39	13.10	.004
3 *final*	**M1 + M2 + M4**	36	14.88	.002
			M1 = head, M2 = shoulder, M4 = hip	

Examining Improved Accuracy from Model 1 to Final Model

Finally, we compared the accuracy in intention categorization for each of the regression results by calculating the predicted probabilities derived from the fitted values of the Step 1 and final models. For brevity, we report the predicted probability of the true (correct) intentional movement given the PC coefficients for each marker. As expected, we observed significant improvement in predictive probabilities from the first to the final models. For both PC1 and PC2, the predicted probabilities of the final model that corresponded to the correct intention was greater than 95%. Moreover, this was achieved using relatively few markers (PC1: 2 out of 7, PC2: 3 out of 7). Our results suggest that, for PC1, hand and elbow marker activity appear to provide the essential kinematic information to differentiate movement categories (see Table 4).

Table 4. Correct predicted probabilities of multinomial regression models using PC1.

	PC 1: Predicted Probabilities	
Intention	Model 1	Final Model
Stand	97.99%	100%
Press-stand	70.20%	97.03%
Press-sit	86.50%	98.70%
Reach-up	58.22%	95.78%

For PC2, the reduction to head, shoulder, and hip suggests that these markers may contain the essential kinematic information to further differentiates movement categories (see Table 5).

Table 5. Correct predicted probabilities of multinomial regression models using PC2

	PC 2: Predicted Probabilities	
Intention	Model 1	Final Model
Stand	44.50%	100%
Press-stand	62.07%	100%
Press-sit	52.35%	99.99%
Reach-up	22.58%	100%

Discussion

We aimed to identify the essential kinematic information available to observers for distinguishing intentional STS transitions.

Overall, the results suggest that, while the four intentional STS transitions (stand, press-stand, press-sit, reach-up) are built upon similar motion profiles, there are distinct differences regarding the essential kinematic information along the first two PCs, which allows for the accurate differentiation of each intention by means of a specific subsets of markers. Analyses of the coefficients in PC1 and PC2 sufficiently capture the majority of the variance attributed to differentiating the four intentional STS transitions. Additionally, the stratification of specific markers within the two PCs allows us to specify (and differentiate) the essential kinematic structure of each intentional motion. This provided the opportunity to formulate regression models that were capable of accurately predicting intention, above and beyond chance level. Both predictive models allowed for the classification of each intentional STS transition with 95-100% accuracy.

Thus, within each PC, there exists essential kinematic information that can be extracted from the time series of similar, yet distinct, intentional motions. Each marker in the final model, can then be understood as *one of the essential communicators of intention* for each STS transition. In turn, the variation in coefficients indicates *how* each marker contributes to the overall movement pattern of each intention.

For example, analyzing PC1 showed that the majority of variance in the motion data can be explained by the markers reflecting the arm motion (i.e.: elbow and hand marker). Considering that the arm motion differed significantly across intentions (e.g. reaching up vs. reaching forwards), this result is consistent with expectations. Subsequently, analyzing PC2 indicated the presence of additional essential kinematic information in the head, shoulder, and hip markers, which distinguishes suprapostural differences in the kinematics of the full-body motion.

Ultimately, our results reinforce empirical findings showing that humans are capable of visually distinguishing different intentional motion patterns (c.f. Ansuini, 2005; Becchio, Manera, Sartori, Cavallo, & Castiello, 2012; Pezzulo, Donnarumma, & Dindo, 2013; Sartori, Becchio, Bara, & Castiello, 2009) by revealing the essential information that defines and differentiates the kinematic structure of intentional motion.

Working Memory and Co-Speech Iconic Gestures

Seana Coulson (scoulson@ucsd.edu) and Ying Choon Wu (yingchoon@gmail.com)

Department of Cognitive Science

9500 Gilman Drive, La Jolla 92093 USA

Abstract

The importance of verbal and visuospatial working memory (WM) for co-speech gesture comprehension was tested in two experiments using the dual task paradigm. Healthy, college-aged participants encoded either a dot locations in a grid (Experiment 1), or a series of digits (Experiment 2), and rehearsed them as they performed a discourse comprehension task. The discourse comprehension task involved watching a video of a man describing household objects, and judging which of two words probes was most related to the video. Following the discourse comprehension task, participants recalled either the verbally or visuo-spatially encoded information. In both experiments, performance on the discourse comprehension task was faster when gestural information was congruent with the speech than when it was incongruent. Moreover, performance on the discourse comprehension task was impacted both by increasing the load on the visuospatial WM system (Experiment 1) and the verbal WM system (Experiment 2). However, in both studies effects of WM load and gesture congruency were additive, suggesting they were independent.

Keywords: depictive gesture; discourse comprehension; iconic gesture; multimodal meaning; representational gesture; verbal working memory; visuospatial working memory

Introduction

Co-speech gestures, which are produced spontaneously in co-ordination with speaking, offer an exciting opportunity to explore the relationship between body movement and higher order cognitive functions, such as language comprehension and conceptualization (for review, see Goldin-Meadow, 2003). To date, little research has addressed the cognitive resources that allow us to understand these gestures and to relate their meaning to that conveyed by the accompanying speech. Because gestures relate to linguistic information at varying levels of granularity, including the word-, phrase, and sentence- levels (Kendon, 2004), one fairly straightforward possibility is that working memory (WM) plays an important role in these processes, allowing listeners to maintain information conveyed in the gestural stream until it can be integrated with relevant information presented in the speech.

Previous research has contrasted the *verbal resources hypothesis*, that speech gesture integration primarily recruits verbal WM, with the *visuo-spatial resources hypothesis*, that speech gesture integration recruits the visuo-spatial WM system. That work employed a discourse comprehension task in which participants viewed a multi-modal discourse prime of a speaker describing everyday objects, followed by a picture that participants judged as either related or unrelated to the prime (Wu &Coulson, 2014). Reaction times for related picture probes are typically faster following discourse primes with congruent gestures that match the concurrent speech, relative to incongruent gestures that do not, suggesting congruent iconic gestures help convey information about the discourse referents (Wu & Coulson, 2014).

Consistent with the visuo-spatial resources hypothesis, the magnitude of these congruity effects has been shown to be larger in participants with greater visuo-spatial WM capacity (Wu & Coulson, 2014). Moreover, imposing a concurrent verbal load during this task yielded additive effects of gesture congruity and WM load, while a concurrent visuo-spatial load yielded interactive effects, as gesture congruity effects were greatly attenuated under conditions of high visuo-spatial load (Wu & Coulson, 2014). Prior research thus suggests that speech-gesture integration recruits cognitive resources shared by visuo-spatial WM load tasks.

One shortcoming of research by Wu and Coulson (2014) is that their measure of speech-gesture integration involved participants' responses to picture probes that followed videos of multimodal discourse. Given that responding to pictorial stimuli presumably imposes a load on participants' visuospatial processing resources, this task may overestimate the importance of visuospatial WM for the comprehension of co-speech gestures.

The present study explored the role of verbal versus visuospatial WM in speech-gesture integration by utilizing a dual task paradigm similar to that in Wu & Coulson (2014). However, rather than using performance on a picture probe task to index comprehension of the gestures, we asked participants to choose which of two words was most related to the preceding discourse video. Experiment 1 paired this

discourse comprehension task with a visuospatial WM task, and Experiment 2 paired it with a verbal WM task.

Experiment 1

Experiment 1 tests how increasing the load on participants' visuospatial WM system impacts their sensitivity to the meaning of co-speech gestures in multimodal discourse. The logic of the dual task paradigm is that if the two tasks recruit shared cognitive resources, engagement in the secondary task will impair performance on the primary one. In Experiment 1, the primary task is that of discourse comprehension, as indexed by a word probe task, while the secondary task involved memory for a sequence of dot locations in a grid. We manipulated the difficulty of multi-modal discourse comprehension by varying the semantic congruity of the gestures and the speech in our discourse videos. The difficulty of the visuospatial recall task was varied by asking participants to remember a sequence of either four locations (high load), or to remember a single location (low load). Consequently, if the recall task diverts cognitive resources from speech-gesture integration, it would be reflected in a change in the congruency effects as a function of visuospatial load – that is, either the amplification of congruency effects, the reduction of congruency effects, or their elimination altogether.

Methods

Participants Participants were 51 healthy undergraduates who, in exchange for participation, received extra credit for a course in cognitive science, linguistics, or psychology.

Materials A total of 84 discourse primes were kindly provided by Dr. Wu. These primes were derived from continuous video footage of spontaneous discourse centered on everyday activities, events, and objects. The speaker in the video was naïve to the experimenters' purpose and received no explicit instructions to gesture. Short segments (2-8s) were extracted in which the speaker produced both speech and gesture during his utterance. Topics varied widely, ranging from the height of a child, the angle of a spotlight, the shape of furniture, swinging a golf club, and so forth. For congruent primes, the original association between the speech and gesture was preserved. To create incongruent counterparts, audio and video portions of congruent clips were swapped such that across all items, all of the same speech and gesture files were presented; however, they no longer matched in meaning.

In an independent norming study using a five point Likert scale, the degree of semantic match between speech and gesture in the congruent trials was rated on average as 1.6 points higher than in the incongruent trials (congruent = 3.8, sd=0.8 versus incongruent = 2.2, sd = 0.7). Because of the discontinuity between oro-facial movements and verbal output in incongruent items, the speaker's face was blurred in all discourse primes (i.e. both the congruent and incongruent version of each).

Each discourse prime was followed by the presentation of two word probes arrayed vertically in the center of the monitor. The *related* probe was a word related to the audio content of the video, and was intended to specifically highlight the semantic content of the congruent gesture. The *unrelated* probe was intended to be unrelated to any aspect of the audio or video. The same two word probes followed the congruent and the incongruent version of each audio file. The location of the related probe (i.e. at the top or the bottom of the array) was chosen randomly on each trial.

Half of the trials (n=42) were accompanied by a low load version of the visuo-spatial recall task, and half with a high load version of the same task. The visuospatial recall task was similar to the dot movement task employed by Wu & Coulson (2014), in which participants were asked to remember a single location in a 4 x 4 grid on low load trials, and an ordered sequence of four locations on high load trials. The gesture congruity and memory load manipulations were fully counterbalanced.

Procedure Each trial began with a fixation cross (1s), followed by the encoding phase of the secondary task (visuospatial WM). Secondary encoding involved the visual presentation of a sequence of dots in a 4x4 grid. High load trials involved a sequence of four distinct locations, while low load trials involved the presentation of a single dot. Each dot remained visible on the grid for one second. A 500ms pause concluded the encoding phase.

The discourse comprehension portion of each trial began with a discourse video, presented at a rate of 30ms per frame in the center of a computer monitor. Immediately following the video offset, the probes appeared above and below the fixation cross. The mouse cursor was initialized to a location equidistant between the two. Participants were asked to respond by clicking the mouse in the square that contained the word that best matched the scenario described by the speaker. No feedback was given.

After a 250ms pause, participants were prompted to recall the location of dots in the grid in the order that they had been presented. Written feedback ("correct" versus "incorrect") was provided following each trial for 500ms. Between trials, the screen was blank for half a second and the mouse cursor was reset to a neutral hidden position.

After completion of the dual-task portion of the experiment, verbal and visuo-spatial WM capacity were assessed through two short tests – an auditory version of the Sentence Span task (Daneman and Carpenter, 1980) and a computerized version of the Corsi Block task (Milner, 1971). The Listening Span task involved listening to sequences of unrelated sentences and remembering the sentence final word in each. All trials contained between two and five items, and were presented in blocks of three. An individual's span was the highest consecutive level at which all sentence final words were accurately recalled (in any order) on at least two of the three trials in a block.

In the Corsi Block task, an asymmetric array of nine squares was presented on a computer monitor. On each trial, between three and nine of the squares flashed in sequence, with no square flashing more than once. Participants reproduced patterns of flashes immediately

afterwards by clicking their mouse in the correct sequence of squares. An individual's Corsi span was the highest level at which at least one sequence out of five was correctly replicated (Conway et al., 2005). The entire experimental session lasted approximately two hours.

Results

Visuospatial Recall Task Performance on the visuo-spatial recall task was indexed by the number of trials in which the participant correctly recalled all of the to be remembered locations. These values were subjected to repeated measures ANOVA with factors memory load (High, Low) and gesture congruity (Congruent, Incongruent). This analysis revealed only an effect of Load, $F(1, 67) = 130.2$, $p < 0.05$, $ges = .24$. Figure 1 shows the average number of correct trials in each condition and clearly indicates better performance in trials with a low load (1 dot location) than in the high load trials (4 dot locations). These data suggest the memory load task was more difficult in the high than the low load condition.

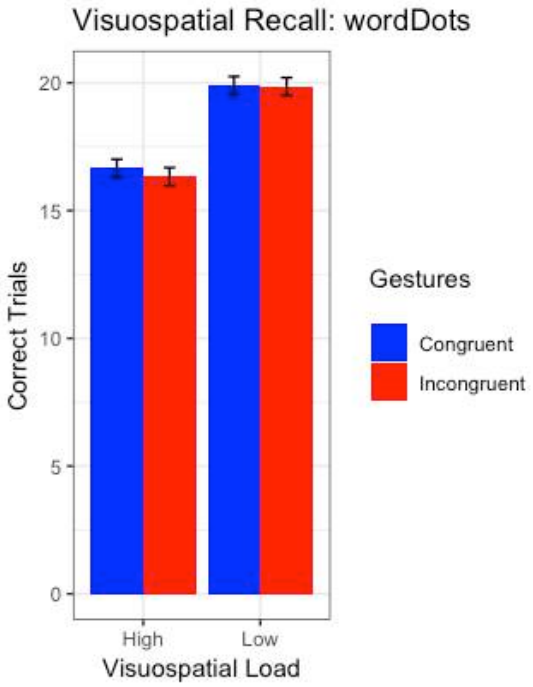

Figure 1: Mean number of correct trials on the recall task in each condition of Experiment 1.

To test the importance of WM capacity for sensitivity to our memory load manipulation, we computed the difference between each participant's accuracy on the high and low load trials. We then constructed a linear model to predict this difference due to the load manipulation as a function of participants' scores on the Corsi Block and Listening Span tasks. This model significantly predicted accuracy on the recall task, F (2, 64) = 5.18, p < 0.01, accounting for 13.95% of the variance. ANOVA on the output of the model suggested scores on the Corsi Block Task served as significant predictors, F (1, 64) = 10.3, p < 0.01, while scores on the Listening Span did not, F (1, 64) = 0.03, n.s. The systematic relationship between scores on the Corsi Block Task with the visuo-spatial load effect supports our contention that the dots task recruits visuo-spatial WM.

Discourse Comprehension Task

Accuracy on the discourse comprehension task was scored by counting the number of correct trials in each condition for each participant. Figure 2 shows the mean scores in each condition. These values were subjected to repeated measures ANOVA with factors gesture congruity (congruent/incongruent) and memory load (high/low). This analysis revealed a main effect of gesture congruity, F(1, 66) = 3.4, p < 0.05, ges 0.08, as participants were more accurate when speech was accompanied by congruent than incongruent gestures. Memory load was not significant, either as a main effect, F(1, 66) = 2.5, n.s., or as an interaction with gesture congruity, F(1, 66) = 1.08, n.s.

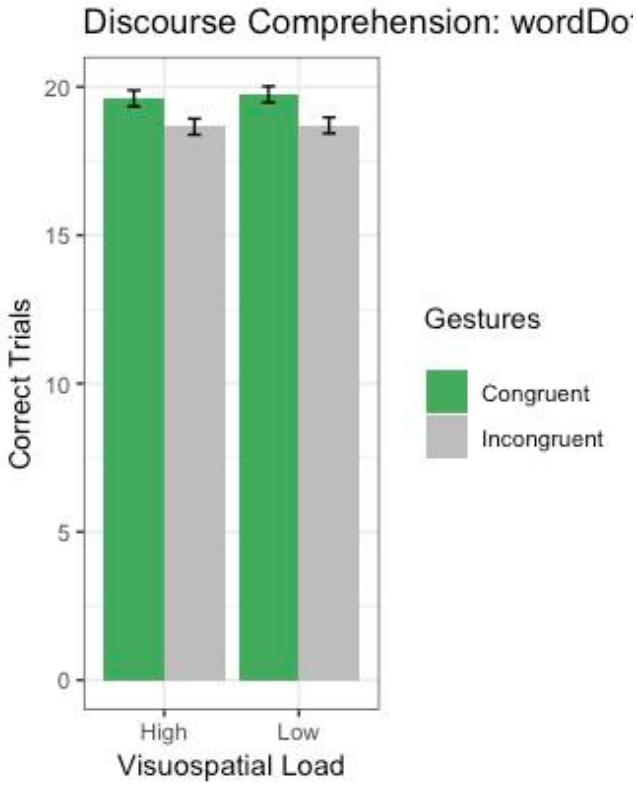

Figure 2: Mean number of correct trials in the discourse comprehension task in Experiment 1. Error bars represent 95% confidence intervals.

To explore the relationship between sensitivity to gestures and our individual difference measures, we computed the difference between the total number of trials each participant responded to correctly in the congruent gesture condition and the incongruent gesture condition. A linear model was constructed to predict this difference score from the Corsi Span score and the Listening Span score. This model accounted for 10.4% of the variance in difference scores, F(2, 64) = 3.72, p < 0.05. ANOVA on the output of

the model suggested only Corsi Span scores served as a significant predictor, $F(1, 64) = 5.3$, $p < 0.05$.

Response times for correct trials on the discourse comprehension task were analyzed with linear mixed effects models with fixed effects for gesture congruity and visuospatial load, and random effects for subject and item (viz., the audio file held constant across congruent and incongruent gesture versions of each stimulus). Random effect structure was determined via backwards model comparison using the step function in lmerTest, beginning with the 'maximal' structure allowed by the design.

Mean response times in each condition are shown in Figure 3. Performance on this task was an additive function of gesture congruity, $t = -6.84$, $p < 0.001$, with responses that were on average 383ms faster following congruent than incongruent gestures, and memory load, $t = -3.95$, $p < 0.001$, with responses an average of 170ms faster in high load trials than low load trials. The latter presumably results because participants desire to rush through the discourse comprehension task in order to 'unload' memory items in the recall task that immediately followed.

Discussion

Experiment 1 suggests a relationship between visuospatial WM capacity and sensitivity to speech-gesture congruity, but fails to support a causal link between visuospatial WM and the comprehension of gestures.

First, did the visuospatial recall task (viz. the dot task) serve to divert visuospatial resources from the primary task? Indeed, recall performance was worse under conditions of high than low load. Moreover, participants' performance on the dot task was systematically related to their visuospatial WM capacity as indexed by their scores on the Corsi block task. These data suggest that the dot task did indeed recruit our participants' visuospatial processing resources, thereby making them less available for primary task performance.

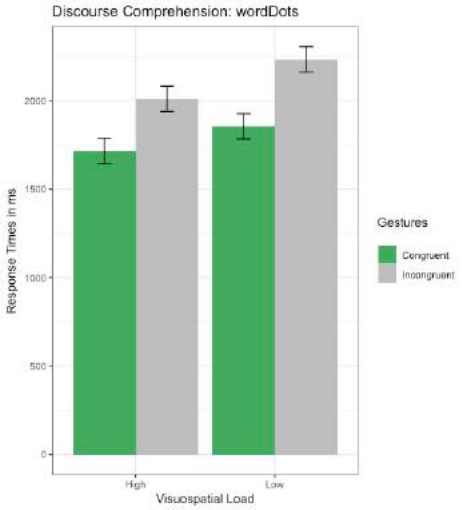

Figure 3: Mean response times in the discourse comprehension task in Experiment 1. Error bars depict 95% confidence intervals.

Second, was the discourse comprehension task employed here sensitive to the relationship between the gestures and the speech? Participants responded more quickly and more accurately on trials preceded by discourse with congruent gestures than incongruent ones. Experiment 1 thus extends results reported in Wu & Coulson (2014), showing that the facilitative impact of congruent gestures can be detected with the word probe paradigm employed in the present study. Moreover, as in the report by Wu and Coulson (2014), the participants who scored the highest on our independent assessment of visuospatial WM capacity were those who showed the largest gesture congruity effects.

Finally, how was performance of the discourse comprehension task impacted by the diversion of visuospatial processing resources? Apart from the gesture congruity effect noted above, the discourse comprehension task was also impacted by visuospatial load. Load had a somewhat paradoxical impact on responses as participants responded faster but less accurately on high load trials. Importantly, though, these two effects were additive, suggesting the discourse comprehension task proceeded somewhat independently of the visuo-spatial recall task.

Experiment 2

Experiment 2 paired the discourse comprehension task with a verbal WM task to explore how reducing the availability of verbal resources impacted participants' sensitivity to iconic co-speech gestures.

Methods

Audio and video materials were identical to those used in Experiment 1, as were the word probes. As in Experiment 1, half of the trials were accompanied by a low load recall task, and half with a high load recall task. The secondary recall task was similar to the digit recall task employed by Wu & Coulson, in which participants were asked to remember a single digit on low load trials, and an ordered series of four digits on high load trials. As in Experiment 1, the gesture congruity and memory load manipulations were fully counterbalanced.

During the encoding phase of the verbal task, a series of four numbers (each ranging between one and nine) were selected pseudo-randomly, and presented via digitized audio files while a central fixation cross remained on the computer screen. As for the visuospatial WM task in Experiment 1, the stimulus onset asynchrony for to-be-remembered items was 1 second.

During the recall phase of the task, an array of randomly ordered digits from 1-9 appeared in a row in the center of the screen, and participants clicked the mouse on the numbers that they remembered hearing in the order that they were presented. Written feedback (either "Correct" or "Incorrect") on the recall task was shown on the monitor for half a second after the final mouse click.

Results and Discussion

Verbal Recall

Performance on the verbal recall task was indexed by the number of trials in which the participant correctly recalled all of the to be remembered digits (see Figure 4). These values were subjected to repeated measures ANOVA with factors memory load (High/Low) and gesture congruity (Congruent/Incongruent). This analysis revealed only an effect of memory load, $F(1, 47) = 35.9$, $p < 0.05$, $ges = .13$. Figure 4 shows the average number of correct trials in each condition and clearly indicates better performance in the low load (1 digit) trials than in the high load trials (4 digits). These data suggest the task worked as intended to occupy verbal WM.

To test the importance of WM capacity for sensitivity to our verbal memory load manipulation, we computed the difference between each participant's accuracy on the high and low load trials. We then constructed a linear model to predict this memory load effect as a function of scores on the Corsi Block and Listening Span tasks. This initial model only approached significance, F (2, 45) = 2.92, p = 0.06. Backwards model selection via the step function in the MASS package in R indicated that the best model of memory load effects was one that included a single factor, participants' Listening Span scores.

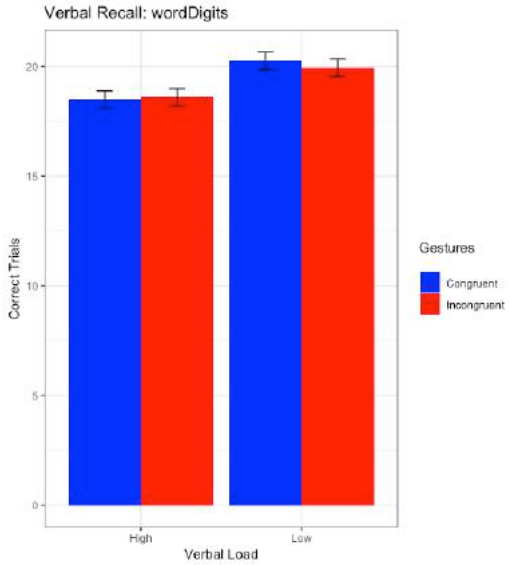

Figure 4: Mean number of correct trials in the verbal recall task for each condition in Experiment 2. Error bars represent 95% confidence intervals.

Accordingly, Corsi Span scores were dropped. The reduced model was significant, F(1, 46) = 5.81, p < 0.05, predicting 11.2% of the variance. The coefficient on the Listening Span factor was -1.2, indicating the load effect was most pronounced in participants with the lowest Listening Span scores. These data indicate a relationship between sensitivity to the digit load manipulation with our independent assessments of participants' verbal WM capacity, consistent with our assumption that the digit recall task diverted verbal WM resources. The systematic relationship between scores on the Listening Span Task with the verbal load effect supports our contention that the digit recall task recruits verbal WM resources.

Discourse Comprehension

Accuracy on the discourse comprehension task was scored by counting the number of correct trials in each condition for each participant. Figure 5 shows the mean scores in each condition. These values were subjected to repeated measures ANOVA with factors gesture congruity (congruent/incongruent) and memory load (high/low). This analysis revealed a main effect of gesture congruity, F (1, 47) = 3.4, $p < 0.05$, ges 0.12, as participants were more accurate when speech was accompanied by congruent than incongruent gestures. Memory load was not significant, either as a main effect, F (1, 47) = 0.03, $ges < 0.01$ or as an interaction with gesture congruity, F (1, 47) = 1.34, n.s, $ges < 0.01$.

To explore the relationship between sensitivity to gestures and our individual difference measures, we computed the difference between the total number of trials each participant responded to correctly in the congruent gesture condition and the incongruent gesture condition. A linear model was constructed to predict this difference measure from the Corsi Span score and the Listening Span score. However, neither this model nor any of the models explored with backwards model selection provided a significant account of these effects, indicating the absence of a systematic relationship between working memory capacity and this measure of sensitivity to gesture congruity.

Response times were analyzed in the same manner as in Experiment 1. Analysis involved the construction of linear mixed effects models with fixed effects of memory load and gesture congruity, and random effects of subject and item. As in Experiment 1, backwards model selection was used to simplify the random effects structure and choose the best model.

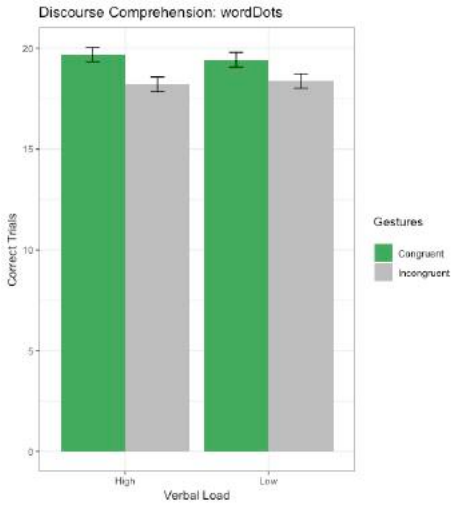

Figure 5. Number of correct trials on the discourse comprehension task in each condition of Experiment 2. Error bars depict 95% confidence intervals.

As in Experiment 1, the memory load effect results due to a 122ms faster responses in the high load trials than in the low load ones, $t = -2.55$, $p < 0.05$. Further, responses were 327ms faster in the congruent trials than the incongruent ones, $t = -5.21$, $p < 0.001$. Figure shows mean response times in each condition.

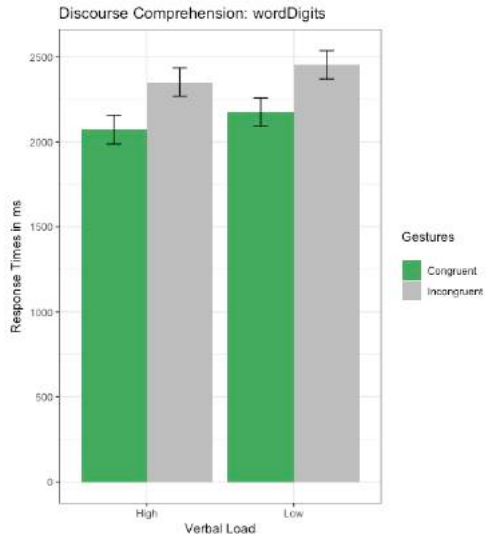

Figure 5: Mean response times for the discourse comprehension task in each condition of Experiment 2. Error bars represent 95% confidence intervals.

General Discussion

Results of the present study provide only modest support for the visuospatial resources hypothesis, and no support for the verbal resources hypothesis. Reducing the availability of visuospatial resources impacted multimodal discourse comprehension, but did not modulate participants' sensitivity to the semantic congruity of co-speech gestures. Likewise, reducing the availability of verbal resources impacted the discourse comprehension task, but did not modulate participants' sensitivity to the semantic congruity of co-speech gestures. In Experiment 1, however, sensitivity to gesture congruity was systematically greater among participants with the greatest visuospatial WM capacity. Thus, while we find no support for a direct causal role of visuospatial WM and speech-gesture integration, visuospatial resources may be relevant to some aspect of gestural processing.

Results of the present study stand in stark contrast to those reported in Coulson & Wu (2014) using the same discourse materials, the same secondary memory task, but that utilized a picture probe to test gesture comprehension rather than the word probes employed here. In tests with picture probes, Coulson & Wu (2014) found that participants were less sensitive to gesture congruity when visuospatial resources were taxed. In the present study, responses to word probes were significantly impacted by gesture congruity, but sensitivity to gestural information was similar under conditions of high and low visuospatial load. This discrepancy might result because the discourse comprehension task in Wu & Coulson (2014) was more taxing than that in the present study. Alternatively, it might be more related to the extent that the picture probe task draws more on the visuospatial resources shared with gesture processing than does the word probe task.

Indeed, the latter interpretation is consistent with the similarity between the impact of verbal memory load in Experiment 2 of the present study with that in the parallel study in Wu & Coulson (2014). Using a picture probe to assess discourse comprehension, they found that performance was impacted both by gesture congruity and by verbal memory load, although the two factors did not interact. Similarly, here we find that performance on the word probe task was independently influenced by gesture congruity and by verbal memory load. The similar impact of verbal versus visuospatial memory load on discourse comprehension as assessed with the word probes employed here also mitigates the concern raised by Wu & Coulson (2014) that the two secondary tasks differ in their demands on central processing resources.

We suggest that the greater impact of the dots task on the processing of picture probes than word probes may be indicative of the role that iconic co-speech gestures play in communication. Congruency effects on the word probe task suggest that speakers readily exploit the information in gestures to detect semantic relationships between novel words and the extant discourse context. However, perhaps because gestures are habitually used to interpret words, this process exerted minimal enough cognitive demands as to resist interference from concurrent demands on either verbal or visuospatial memory systems. By contrast, the picture probe task used by Wu & Coulson (2014) suggested that visuospatial resources were particularly important for detecting a relationship between the pictures and multimodal discourse about concrete topics.

Future research should increase the demands of either the discourse comprehension task or those of the secondary memory tasks in order to elucidate the reason for our failure to observe a differential impact of memory load on sensitivity to gestures. Perhaps titrating memory load demands individually (as in Frank, et al., 2012) will allow us to better estimate its impact on discourse comprehension.

Abstract

Cognitive tests used to measure individual differences are generally designed with *equality* in mind: the same "broadly acceptable" items are used for all participants. This has unknown consequences for *equity*, particularly when a single set of linguistic stimuli are used for a diverse population of language users. We hypothesized that differences in language variety would result in disparities in psycholinguistically meaningful properties of test items in two widely-used cognitive tasks, resulting in large differences in performance. As a proxy for individuals' language use, we administered a self-report survey of media consumption. We identified two substantial clusters from the survey data, roughly orthogonal to *a priori* groups recruited into the study (university students and members of the surrounding community). We found effects of both population and cluster membership. Comparing item-wise differences between the clusters' language models did not identify specific items driving performance differences.

Introduction

Cognitive tests are increasingly used in research on individual differences. For example, a number of recent studies reported correlations between speech perception in noise and working memory (for meta-analysis, see: Dryden, Allen, Henshaw, and Heinrich 2017). Widely used tests for both (Daneman & Carpenter, 1980; Kalikow, Stevens, & Elliott, 1977) were developed without much regard for potential individual differences in language experience, however. This raises the possibility that at least some of the variability in these tasks is related to differences in participants' language experience, as demonstrated in studies of higher-level language processing (Moore & Gordon, 2015; Wells, Christiansen, Race, Acheson, & MacDonald, 2009). Currently, it remains unclear how much this robust correlation between the two tasks – found in 26 of the 30 studies surveyed by Akeroyd (2008) – reveals a correlation between the target constructs or a latent variable of language experience.

Linguists have long considered the communicative capacities of every language to be equal and equally expressive (Joseph & Newmeyer, 2012; Pellegrino, Coup, & Marsico, 2011). Guidelines from the American Speech-Language-Hearing association on cultural competence encourage clinicians to take cultural variables into account in assessing and treating language disorders and differences (American Speech-Language-Hearing Association (ASHA), n.d.). Despite these commitments in allied fields, and the demonstrable existence of multiple American Englishes (e.g. see for review: Labov, Ash, and Boberg 2006; Schneider and Kortmann 2004), most cognitive tests assume "Mainstream" American English (MAE) as a default in the construction of stimuli, potentially confounding cognitive test performance with experience and fluency in MAE. Conversely, language experience is not deterministically related to the usual features that define distinct "dialects" – region, ethnicity, class, etc. People are cosmopolitan and idiosyncratic in the language experiences they seek out, and as a result, may be familiar with multiple language varieties, with potential consequences for their performance on cognitive tests.

Statistical learning, hypothesized to underlie much of language development (Elman, 2001; Seidenberg & MacDonald, 1999), is driven by patterns in language input. Given different input, then, language learners will necessarily construct different distributional models to generate and process speech and language. Online speech and language processing relies heavily on learned statistical regularities to facilitate top-down anticipatory processes. This is evidenced by the effects of surprisal observed when these anticipations are violated (Federmeier, Mai, & Kutas, 2005; Kutas & Hillyard, 1980, 1984). Given the highly demanding nature of online speech and language processing, anticipatory mechanisms help lessen the cognitive effort needed to accomplish the task. The greater the difference between the listener or reader's language model and the statistics of the language material they are processing, the greater the cognitive burden on the listener. For example, intelligibility levels in noise are better for one's own dialect than for a familiar, but less commonly encountered dialect (Clopper & Bradlow, 2008). In children who prefer a non-mainstream English, familiarity with "school English" is associated with performance on literacy tests (Charity, Scarborough, & Griffin, 2004).

The current research examines the effect of variability in language experience on cognitive tests. We hypothesized that measuring people's language experience indirectly, by having them complete a "media diet" survey, would allow us to identify distinct clusters of individuals based on their viewing, listening, and reading habits. We expect these clusters to only loosely covary with the demographic factors that commonly define distinct "dialect" groups. This new measure

of language differences between participants thus provides a novel aspect of individual variability that we expect to moderate performance on language-based cognitive tasks. As this measure probes the role of language directly, it may be more informative in predicting task performance variability than standard demographic information. To test this we recruit from two populations that differ along traditional demographic lines: USC undergraduates – typically high-SES students pursuing higher education (*Facts and Figures | About USC*, n.d.) – and members of the downtown Los Angeles community – mostly African American and Latinx lower-SES individuals, many of whom not pursuing education beyond high school (e.g. the zip code 90062: US Census Bureau n.d.). We administer the aforementioned functional hearing and working memory tasks and expect survey responses to at least partly predict variability in task performance. As we expect this effect to be linguistic, we also predict that language models trained on the media sources will predict participants' behavioral performances.

Methods

Participants

We recruited participants from the USC undergraduate population (N=70) and on a local community college campus (Los Angeles Trade-Technical College, N=25). USC students participated in exchange for course credit and community participants were compensated for their time at $15 per hour, prorated at 20 minute intervals. No requirements were placed on age, but due to recruitment populations, 80% of participants were between the ages of 19 and 26 (mean=22, std=6.25).

Cognitive Tests

To test participants' language abilities, we used the reading span task (Daneman & Carpenter, 1980) that was developed to assess verbal working memory and the speech perception in noise task (SPiN, Kalikow et al. 1977) that was developed to assess functional hearing. The reading span task presents sets of sentences to be read aloud while participants maintain the last word of each sentence in memory. At the end of a set, participants are tested on how many sentence-final words they can recall, and set length is increased until they cannot complete the task. Testing is terminated when participants cannot completely recall any of the three sets of sentences at a particular set length. The SPiN consists of short sentences presented over headphones in 12 talker babble (6 female, 6 male). Participants must identify the final word of the target sentence. We used recordings from the Nationwide Speech Project (Clopper & Pisoni, 2006) to create the stimuli and present trials at +6dB SNR which produced large individual differences in accuracy in pilot results. We choose these tests due to their importance as widely used individual difference measures in clinical populations to diagnose age-related decline (Byrne, 1998), aphasia (Caspari, Parkinson, LaPointe, & Katz, 1998), Alzheimer's (Kempler, Almor, Tyler, Andersen, & MacDonald, 1998), and schizophrenia (Stone, Gabrieli, Stebbins, & Sullivan, 1998). We also choose these tests for the important – but often unacknowledged – role language processing is likely to play in both.

Survey

We constructed an online survey (approx. 20 minutes long) that probes participants' current and formative media consumption habits, elicits short language production passages, and collects basic demographic information. We use this tool to glean each participant's media diet, which forms the basis for later linguistic grouping and analysis. We use the language obtained from the sources participants report as a model for participants' actual language input and a proxy of language experience.

Equipment

Subjects sat in a noise attenuating booth and participated in the survey and behavioral tasks on a desktop PC computer. USC participants were allowed to complete the survey online prior to their lab session. Participants first completed the reading span task, followed by the SPiN, and finally the survey. The reading span task was administered and scored by a researcher to ensure subjects read aloud continuously. Upon completion of each sentence, the researcher advanced the display to the next sentence in the set and solicited verbal responses at the end of each set. After a brief training phase, participants were not given feedback on their performance and were not told their failure had caused the end of the test, simply that it had ended. The SPiN test was administered using Paradigm experiment software; participants typed their responses into a free-response text box. Trials began after a 500ms delay once participants had submitted their response. Stimuli were presented at a comfortable level, standard across participants.

Clustering

We create a media source space in which each dimension represents a reported source (e.g. movie) collected in our survey. Each participant is thus represented as a binary vector in this space, with 1s in dimensions corresponding to sources they consume, and 0s in those they do not. To ensure each dimension is informative (and reduce the dimensionality), we only represent sources reported 10 or more times – thus avoiding dimensions that would only differentiate a few participants (i.e. the rest would all receive 0s in that dimension). This leaves 314 dimensions along which participants were clustered using the k-means algorithm (Lloyd, 1982). Figure 1 shows the distortion values for different numbers of clusters, revealing 3 clusters to be the inflection point at which more clusters provide only marginal returns. The algorithm takes this point as the true number of clusters because increasing the number of clusters beyond this simply subdivides the true clusters, thus over-fitting.

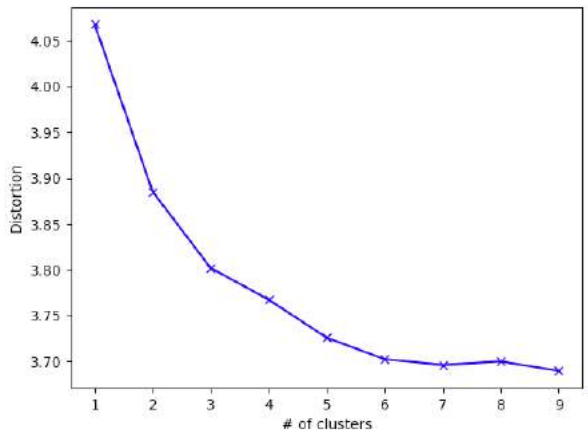

Figure 1: K-means clustering reveals 3 clusters of participants in our media consumption space. This is evidenced by the inflection in distortion decrease that occurs at $k = 3$.

Corpora Construction

We aggregate language data from the sources participants reported in our survey for further linguistic analysis. This produces two corpora (one for each cluster) that allow us to model their language differences. We fully acknowledge the difference between consuming sources as text, as our models do, and speech, as our participants do. Despite this, however, text fully captures the regularities of lexical and supra-lexical features we expect to influence performance on our behavioral tasks.

We collected each corpus by scraping repositories of television scripts (*Springfield! Springfield!*), movie subtitles (*YIFY Subtitles*), and song lyrics (the *Genius API*). For TV and music, we collected all the content for one show (e.g. all the scripts from *Law & Order*) or one artist (e.g. all the songs by *Bruno Mars*). We then pre-process these sources by removing anything the viewer would not hear (e.g. stage directions) and anything non-linguistic (e.g. non-alphanumeric characters or non-verbal noises).

Language and Surprisal Modeling

To model the language statistics of each cluster's corpus, we use 5-gram language models with backoff (Katz, 1987). These models estimate the likelihood of a sentence as the product of the conditional probabilities of its words given the words that precede them. Thus for a sentence of length L, the likelihood is:

$$\prod_{l=1}^{L} P(w_l | w_{l-(n-1)} \ldots w_{l-1}) \tag{1}$$

where n is a hyperparameter set to control the number of preceding words considered for context ($n = 1$ is simply the marginal probability). Because the probability of encountering the preceding string of words in training decreases as the length of the string increases, backoff allows the algorithm to decrease n until the preceding string *has* been seen in training (thus allowing the conditional probability to be estimated). Therefore, while we initially set our $n = 5$, probabilities may be calculated given less prior context.

In addition to the 5-gram model which proceeds from the beginning of a sentence seeking to model its probability, we also model the surprisal associated with encountering the final word of the sentence. This is a particularly important quantity considering both our behavioral tasks use sentence final words as their testing target. While in theory the model aligns with the concept of cloze probability – the probability of the sentence-final word given every preceding word: $P(w_L | w_1 \ldots w_{L-1})$ – this rarely occurs in practice given the sparseness of a training corpus. To model this, we adopt a similar method to n-gram models with backoff. We calculate the conditional probability of the last word given the $n-1$ preceding terms:

$$P(w_L | w_{L-(n-1)} \ldots w_{L-1}) \tag{2}$$

where we initialize $n = 5$ and reduce its value until the preceding string has been encountered in the training corpus ($n = 1$ is simply the marginal probability of the word occurring sentence-finally).

Results

Clustering

The clustering included all reported media sources and revealed three clusters based on participants' consumption habits. Despite a substantial drop in distortion from 2 clusters to 3 (see Fig. 1 for distortions), cluster 0 proved too small to analyze: it contains just 2 participants. Its size precludes both behavorial analysis, which requires an adequate number of samples to be statistically feasible, and computational modeling, which requires a corpus built from an adequate number of reported sources (aggregated across a cluster). Given these limitations, the following analyses will only use clusters 1 and 2 as the sample population (still 98% of the original sample). This clustering, far from an artifact of random seed, proved stable across random restarts. Over 1000 iterations, on average 75% of participants were re-clustered in the same groups (see **Behavioral Data** for the effects on statistical tests).

Regarding cluster membership, we expected USC students and community members to be unevenly distributed between clusters, and this was true, although not categorically. As seen in Table 1, the two are relatively balanced across clusters. Thus, cluster membership and *a priori* group membership are treated as orthogonal in the following analyses.

In addition to the a priori population, we examined the distribution of traditionally considered covariates across the clusters. We wanted to test whether self-reported media consumption provided new information beyond existing measures (i.e. we were not just capturing an existing highly correlated dimension of variance). As seen in Table 1, typical demographic variables were fairly evenly distributed across the clusters. One-way chi-square tests revealed that none of the demographic variables significantly differed from an even

split across clusters (i.e. the expected values if cluster and variable were independent).

Variable	Level	Cluster Ns		Cluster %	
		1	2	1	2
Population	USC	34	24	59%	41%
	LATTC	7	13	35%	65%
Gender[1]	Female	33	21	61%	39%
	Male	7	16	30%	70%
Schooling	High School	10	10	50%	50%
	Associate	4	4	50%	50%
	Some College	19	15	56%	44%
	Bachelor's	7	6	54%	46%
	Master's	1	2	33%	66%
Mono-lingual	True	10	11	48%	52%
	False	31	26	54%	46%
SES Self-Report[2]	High	13	13	50%	50%
	Medium	16	10	62%	38%
	Low	12	14	46%	54%

Table 1: The distribution of traditionally considered covariates across clusters is fairly even. We observe no obvious imbalance between clusters along any demographic dimensions our survey measured. One-way chi-square tests confirm this.

Given the orthogonality of self-reported media consumption to traditional demographic variables, we hereafter focus on the observed dimension of variance: media diet. We probe how the clusters differ in their media habits in order to delineate their makeup. We examine the clusters' centroids to calculate which dimensions (i.e. sources) they differ maximally along. This provides a measure of which media sources are most distinct between clusters. We find the following sources to be the 5 most different between clusters 1 and 2 and provide the difference in mean consumption between the two (i.e. $\bar{x}_1 - \bar{x}_2$) in parentheses: Star Wars (.64, specific films reported in the series were less powerful, on the order of .11-.17), Yes! (-.47), CNN (-.26), People (-.12), and Harry Potter (-.12). We hesitate to draw any conclusive generalities on the two clusters' media diets, but at a glance it appears that cluster 1 consumes lots of high fantasy (Star Wars, Lord of the Rings, The Chronicles of Narnia, etc.) while cluster 2 consumes more nonfiction (Yes!, CNN, People, etc.).

Behavioral Data

As seen in Figure 2, the SPiN task revealed a main effect of cluster, $F(1,74) = 7.30$, $p < .01$, but no main effect of population and no interaction between the two. In the reading span data, we again find a main effect of cluster, $F(1,74) = 4.05$, $p < .05$, and a main effect of population $F(1,74) = 13.57$, $p < .001$, and no interaction between the two. In our 1000 clustering iterations, 63% of iterations revealed statistically significant effects of cluster on the SPiN task (at $\alpha = .05$). This was not replicated with the span task, however: only 4% of our iterations found statistically significant effects.

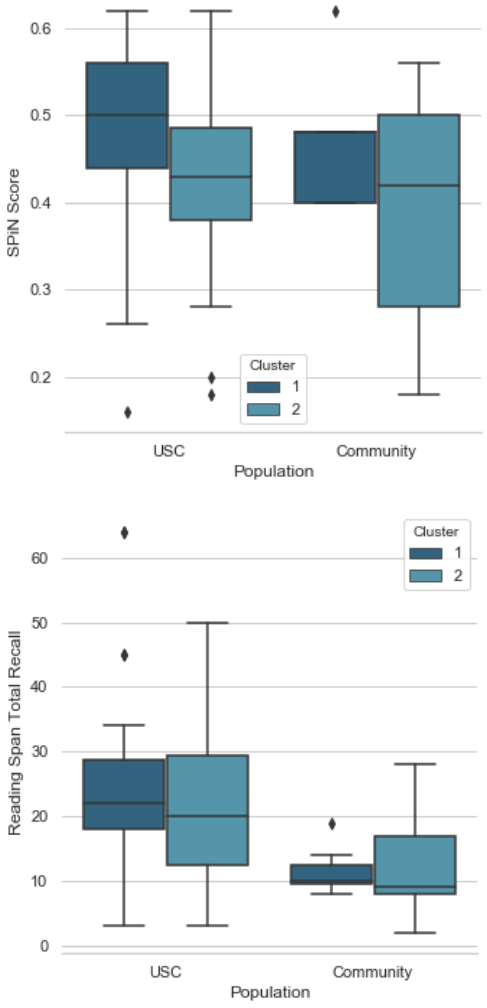

Figure 2: Results from the SPiN test reveal a significant difference between clusters but not populations. Reading span also shows an effect of cluster, but a larger effect of population. We observe no significant interactions.

The span test will play a minor role in further analyses, due to the difficulty in handling test result data and its scoring. Because the span task is terminated whenever participants fail to recall a set, participants provide unequal numbers of observations. The analyses are additionally constrained by the small number of items a typical participant completes. While observations exist for items later in the test, they are for a few extraordinary participants. This presents a problem not only in the paucity of observations, but also in the fact that these participants are unrepresentative of the general sample in their task abilities. As such, both item-level statistics and graphical representations are challenging.

Our survey obtains several pieces of demographic infor-

[1] One participant in cluster 1 chose not to report gender.

[2] Participants reported their SES on a continuous scale. Here, we bin responses into 3 quantiles to report distribution across clusters.

mation that are traditionally considered relevant covariates of performance on our cognitive tasks, such as socioeconomic status (SES, self-reported), age, education level, and monolingual status. None of these correlated significantly with performance on either task.

Language Media Input Modality

The above findings of differences between cluster performances motivated us to explore differences between clusters' survey behavior (other than the categorical responses which were used in clustering) to explain their performance data. In particular, we wondered whether the stronger task performances of cluster 1 might be due to increased experience with the tasks of speech perception and reading.

To probe this, we tested whether cluster 1 reported significantly more speech sources (TV, Movies, Music, and News shows) and significantly more text sources (Books, Newspapers, Magazines, Online News, and other online reading) than cluster 2. Indeed, we find that cluster 1 participants report significantly more listening on average than cluster 2: $t(42.82) = 3.09, p =< .005, d = 0.67$ (a medium effect). We also find that cluster 1 participants report significantly more reading on average than cluster 2: $t(72.6) = 5.10, p < .001, d = 1.13$ (a large effect). This may indicate an effect of modality-specific training on task performance. To probe this, we test the correlation between the number of speech sources a participant reports and their SPiN task performance. We test rank correlation rather than linear correlation as we are unsure of the linearity of the relationship between number of sources and modality-specific benefit, as well as to control for the effect of outliers in both performance and reporting volume. We observe a significant correlation between the two: $\rho(76) = .31, p = .005$. We do not, however, observe a significant correlation between number of text sources and span performance.

We also tested whether past modality preference (solicited with "when you were growing up...") would relate to current modality preference. We find a strong correlation between the amount of spoken language items reported growing up and amount of current items reported: $r(76) = .91, p < .001$. This correlation extends to the number of written language items, although not as strongly: $r(76) = .49, p < .001$.

Language Models

To evaluate the claim that our language models were capturing meaningful statistical regularities in the language of each cluster's corpus, we tested whether the log-likelihood produced by a model for each of the test items would correlate with mean performance on those items for the cluster. We do not observe a significant correlation between cluster 1's 5-gram model and performance on either the SPiN ($r(48) < 0.01$) or span ($r(25) = -0.01$). We also observe no significant correlation between cluster 2's 5-gram model and its performances on SPiN ($r(48) = -0.02$) or span ($r(25) < 0.01$). Additionally, we tested the correlation between cluster 1's 5th-order surprisal model and its performance and found no correlations with SPiN ($r(48) = 0.07$) or span ($r(25) = -0.09$). Similar results were obtained for cluster 2 (SPiN: $r(48) = 0.21$, span: $r(25) = 0.02$).

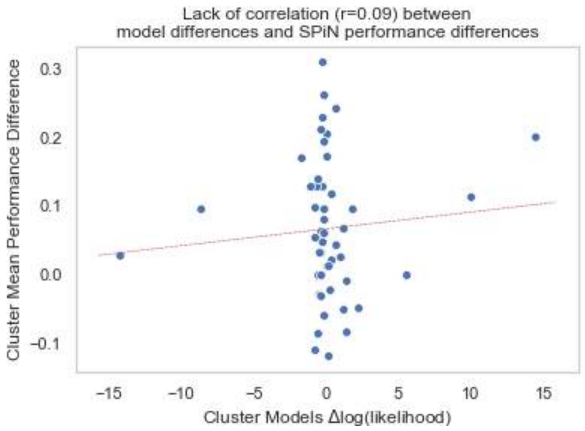

Figure 3: The non-correlation of cluster performance differences with model likelihood differences indicates the statistical information captured by the models is a poor predictor of behavioral performance. The significant cluster performance difference can be seen here by the majority of items occurring above 0-difference on the y-axis. A LMS-Regression line is drawn in red for reference.

In addition to modeling statistical properties of particular items, we also tested whether the difference between the language and surprisal models might capture the significant differences we see on our behavioral tasks. This method avoids any idiosyncrasies of particular items (as comparisons are within item) and instead captures any language differences of media sources. We again find a lack of significant correlation between 5-gram likelihood differences and task performance for both the SPiN ($r(48) = 0.09$) and span ($r(25) = .25$). Similar results are observed for the 5th-order surprisal model (SPiN: $r(48) < 0.01$, span: $r(25) = 0.08$). As shown in Fig. 3, differences between the model likelihoods are close to zero for most items, with a few outliers.

To examine the non-correlations and clustering around 0 on Fig. 3's x-axis, we tested the correlation between models and found strong correlations for both the SPiN ($r(48) = 0.94, p < .001$) and span ($r(86) = 0.97, p < .001$) test. These strong correlations, coupled with linear regression slopes of $\beta_1 = 0.96$ (SPiN) and $\beta_1 = 0.94$ (span) imply nearly identical log-likelihood scores between models despite training on categorically different sources. While the results reported here are specific to 5-gram language models and 5th-order surprisal models, other lower-ordered models of both yielded similar results.

Discussion

We observed significant performance differences on a speech perception in noise task and a working memory task between

clusters of participants derived from self-reported media consumption. These differences were above and beyond differences driven by *a priori* participant groups – students at a university vs. participants from the surrounding community. This clustering was robust to randomness and orthogonal to any traditionally considered demographic variables. As we have no reason to believe that the tests' target constructs systematically vary between our clusters, we conclude that media diet represents an uncorrelated latent variable moderating task performance. To our knowledge, our identifying media consumption as a significant orthogonal predictor of cognitive task performance is a novel contribution of this work.

This novel predictor is surprisingly powerful at explaining language test performance considering its complete lack of explicit linguistic information. In pursuing a linguistic explanation for our finding, we used statistical language models trained on sources participants reported consuming to analyze test items. These models did not identify particular stimuli driving performance differences, and we found no obvious differences in how well stimuli fit our models. However, a follow-up study we performed with more complex recurrent neural models did in fact reveal a correlation between models trained on our media corpora and behavioral performance (Courtland et al., 2019). This implies the statistics used here are not sophisticated enough. Cloze probability, for example, is computed as a simple ratio of the tokens of a word in context to all tokens in that exact context in the corpus.

Also of note is the highly significant difference in the number of sources reported by cluster 1 compared with cluster 2. It is possible that the greater number of sources indicates that cluster 1 contains more voracious consumers of media than cluster 2. This increased media consumption in the modalities of our tests may be providing cluster 1 members with modality-specific training they leverage at test time. Indeed, the correlation we observed between number of speech sources reported and SPiN performance supports this explanation. This is especially plausible given that watching a TV show or movie involves perceiving character dialog often obscured by various sources of noise (soundtrack, sound effects, etc.). It is also possible, however, that the increased responses and performance from cluster 1 is indicative not of their increased modality-specific training but rather a latent variable such as attentiveness or enthusiasm at participating in all aspects of the study.

It should be mentioned that participants' responses may reflect a (possibly implicit) choice to make specific habits known in the context of the survey. Given the importance of shared experience in forming relationships, what pieces and types of information people share and what they keep private often acts as a type of signaling that forms the basis of social cohesion. Thus, media diet survey responses may be more appropriately interpreted as signalling membership in a language community than literally reflecting the language practices of that community. Indeed, the vast majority of items in the corpora are professionally produced texts, which are likely to differ less than spontaneous spoken and written communication. In future work, we plan to obtain rich, naturalistic language samples in addition to the media corpora included so far to strengthen the evidence found here.

The identification of a dimension (other than the target construct) that test performance differs significantly along brings into question not only specific test validity probed here, but also the validity of the entire practice of test item standardization. This is true whether this dimension is categorical media consumption, shown here, or the linguistic content of the media, shown in Courtland et al. (2019). Tests that use language to probe target constructs must take the language of their test into account – not as a static entity to be standardized, but as the diverse and dynamic communication medium that it is. Test validity relies on the ability to generalize a test's result to participants' everyday behavior. This is only valid if the test is representative of the language they encounter in their daily lives (Coleman, 1964). Thus, tests employing standardized language not only contain inherent inequity for those less familiar with the test language, they are also less valid.

Here we aim to show that participants' diverse language experiences must be taken into account when diagnostic tools like those tested here are designed. Ideally, given the unique nature of language experience, test creators should strive to create tests that present equal difficulty to each participant by using personalized test language. This step to ensure equity is especially important given that test scores cannot simply be adjusted for using traditionally defined dialectal boundaries – as demonstrated here by the uninformativeness of the demographic variables that define these boundaries.

Generating equitable stimuli is a difficult or possibly infeasible task for human researchers, but could potentially be automated using generative models. If such models were driven by statistics that are highly representative of participants' language experience, they may do a better job of capturing cognitive constructs without smuggling in variability resulting from differences in language experience. Perhaps the most exciting future direction of this research will be to facilitate using more representative language statistics in designing stimuli for cognitive tests. The study of how language experience influences test performances that we take here represents a first step to understanding and mitigating this test inequity.

Abstract

Learning to read English requires learning the complex statistical dependencies between orthography and phonology. Previous research has focused on how these statistics are learned in neural network models provided with as much training as needed. Children, however, are expected to acquire this knowledge in a few years of school with only limited instruction. We examined how these mappings can be learned efficiently, defined by tradeoffs between the number of words that are explicitly trained and the number that are correct by generalization. A million models were trained, varying the sizes of randomly-selected training sets. For a target corpus of about 3000 words, training sets of 200–300 words were most efficient, producing generalization to as many as 1800 untrained words. Composition of the 300 word training sets also greatly affected generalization. The results suggest directions for designing curricula that promote efficient learning of complex material.

Keywords: reading; efficient learning; generalization; computational modeling; human and machine learning

Introduction

Generalization—the ability to apply existing knowledge to novel cases—is an important capacity observed, with varying complexity, in many species (Santolin & Saffran, 2018). Human generalization encompasses a broad range of behaviors, ranging from generalizations about the properties of three dimensional space to ones based on physical appearance. The behavioral and neurobiological bases of generalization are a focus of much research (e.g., Goldberg, 2009; Zhang, Bengio, Hardt, Recht, & Vinyals, 2016).

Generalization is especially important in language acquisition and learning to read. Children rapidly acquire knowledge that allows them to generalize beyond the limited sample of utterances they experience (Chomsky, 1965). The classic demonstration is the WUG Test (Berko, 1958). A child who has learned about plural formation can generalize to novel cases: one wug, two wugs. Similarly, a beginning reader who has learned correspondences between spelling and pronunciation can read aloud nonce words such as NUST and GLORP (Seidenberg & McClelland, 1989). Generalization has traditionally been taken as evidence for symbolic rules, but it is also observed in neural networks of varying complexity (Seidenberg & Plaut, 2014; LeCun, Bengio, & Hinton, 2015).

Our research examined generalization from a different perspective, efficiency of learning. Efficiency is a concern in real-world contexts in which, unlike most machine learning applications, learning opportunities are constrained. For example, children's vocabulary development depends on their time- and context-limited exposure to spoken language, which varies considerably (Hart & Risley, 1995; Gilkerson et al., 2017). The resulting differences in vocabulary size and quality have an enormous impact on learning to read and other aspects of schooling (Seidenberg, 2017). Knowledge gaps cannot be closed solely through explicit instruction because there isn't sufficient classroom time. The same holds for learning mappings between written and spoken language. Instruction ("phonics") is helpful, but only a small subset of patterns can be taught. In these and other knowledge domains, children learn from relatively limited data and generalization is paramount.

In the classic WUG test generalization is assessed by performance on nonce forms or, in machine learning, withheld words. The exact composition of the examples that support generalization is not the focus of attention, but is critical in experience-limited domains. We therefore re-formulated the generalization question as follows, using spelling-sound knowledge as a test case:

- Children need to acquire the ability to generate pronunciations for many written words (the target set);
- They are explicitly taught the correspondences between orthography and phonology for a much smaller subset of words (the training set);
- Generalization is assessed in terms of correct performance on untrained items from the target set, rather than nonce forms. This shifts the focus of generalization to acquiring real-world knowledge.

The research question is then how the size and composition of the training set affects generalization to untrained items. Learning is efficient if the ratio between the number of trained items and the number of generalization items is low. We examined efficiency of learning as a function of the size of the training set using simple, well-studied models of learning orthography-phonology correspondences (Seidenberg & McClelland, 1989; Harm & Seidenberg, 1999). We also examined how efficiency was affected by the composition of a training set of a given size. The results suggest that it may be possible to structure children's reading experiences in ways that promote more efficient learning.

Materials and Methods

Words

The simulations used a set of 2881 monosyllabic English words employed in previous research (Harm & Seidenberg, 1999). Word length ranged from 2–8 letters and 1–7 phonemes.

Model architecture

The model was a simple feedforward network with an input orthographic layer (102 units), an output phonological layer (66 units) and a single hidden layer (100 units). It was structured and trained in standard ways, with weights updated with gradient descent and backpropagation after accumulating cross-entropy error over all words in the training set.

Orthographic representations were generated as follows. Words were centered on the vowel (or the first vowel in a digraph), adding empty letters to the onset as necessary. If the first vowel was followed immediately by a consonant, an empty letter was also added between them, except in cases where the consonant is voiced as part of the vowel (e.g., the letter *w* in SAW). The letter *y* was treated as a consonant when it began a word and a vowel otherwise. Finally, empty letters were added to the end of each word, resulting in orthographic codes of uniform length (14 letters including empty ones).

Each letter was represented by one unit in a 26 element vector, with no units activated for the empty letter. The 14 vectors were concatenated to represent each word. To make these representations more concise, they were stacked to create a 2881×364 matrix, and all-zero columns were dropped, leaving 102 units.

Phonological word forms were represented using 41 phonemes (26 consonants, 15 vowels). They were aligned on the first vowel, adding empty phonemes at the beginning or end to produce phonological representations of equal length (10 phonemes including empty phonemes). Each phoneme was defined by 25 phonetic features (Harm & Seidenberg, 1999). The 10 phoneme by 25 feature vectors were condensed by eliminating nodes for unused features, resulting in an output layer with 66 features.

The model was implemented using scikit-learn in Python 3.6 using a multilayer perceptron, and training was executed in parallel using HTCondor (Thain, Tannenbaum, & Livny, 2005) and computational resources maintained by the Center for High Throughput Computing at UW Madison.

Model training

One million models were run, each using a set of words sampled randomly without replacement from the 2881 word target set. Training sets ranged from 100 to 1000 words in increments of 100, with an equal number of each size.

Each model was trained for 3000 weight updates with a constant learning rate (0.1). The model was exposed to the whole training set before each update. Each model was then tested on the untrained remainder of the target corpus to evaluate generalization. An output pattern was scored as correct if all unit activations were within 0.5 of their target state.

Model evaluation

Using all untrained words as the holdout set to evaluate generalization performance for each model means that the holdout set is not held constant. This is a deliberate design decision: when a word is explicitly trained, it no longer needs to be generalized to. Training on exceptional, irregular words may be the only way to accurately produce them—that explicit training not only develops the model to encode that orth-phon relationship, but also removes that exceptional word from the generalization set. On the other hand, this exceptional word may not teach the model anything generally useful. The give and take between what is in the training set or test set is central to the research question.

An alternative approach is possible, where a single test set is constructed a priori and used for all generalization. This has the advantage of serving as a true benchmark, but poses a critical challenge. It requires composing a representative test set that expresses all relational othographic and phonological structure. Our attempts at dimensionality reduction on the model representations that map between orthography and phonology for the full corpus indicate that 50 dimensions are necessary to express 80% of the variance in that structure. Sampling representatively from that high dimensional space would be necessary for constructing a useful benchmark test set. The problem of constructing this test set is the same as the problem of constructing a representative and efficient training set, and does not have a simple solution.

Results

Training set size and generalization

Figure 1A shows generalization to untrained items as a function of training set size. Smaller training sets afford more opportunities for generalization, but are less able to provide representative coverage of the corpus. Increasing the size of the training set produced diminishing generalization returns. Increasing training sets beyond 500 words did not yield greater

Size	Mean	(Ratio)	Max	(Ratio)
100	333	(3.33)	590	(5.90)
200	889	(4.45)	1252	(6.26)
300	1240	(4.13)	1546	(5.15)
400	1404	(3.51)	1634	(4.08)
500	1469	(2.94)	1668	(3.34)
600	1484	(2.47)	1654	(2.76)
700	1470	(2.10)	1618	(2.31)
800	1438	(1.80)	1566	(1.96)
900	1395	(1.55)	1510	(1.68)
1000	1344	(1.34)	1444	(1.44)

Table 1: Mean and maximum generalization performance over 100k models fit with each training set size. Ratios divide the previous descriptive statistic by the training set size.

generalization.

Figure 1B shows total number of words correct (trained and generalized). No model produced correct performance for all words. Some words were only learned if they were included in the training set; they were never produced correctly by generalization. These include words with highly atypical spellings and pronunciations such as SIXTH, DRAUGHT, SCHEME, COUPS, and JINX.

Figure 1C shows an index of *training set efficiency*, defined as the number of words correct by generalization divided by the number of words trained. Training sets with 100 words are less efficient than those with 200 words on average and in the limit, indicating that the larger set captures more of the structure relevant to untrained words. Training sets of 300 words are somewhat less efficient than those with 200, but after 300 words efficiency drops rapidly. Taking all three metrics into account, 300 words appears to be a sweet spot (see also Table 1).

Analyses of training environments containing 300 words show that they yielded reading vocabularies of 1540 words on average ($SD = 76.62$) and 1846 words at best (failing to decode 1035). Given that efficiency is a primary concern for early reading curricula, it is noteworthy that this is 75.5% of the largest reading vocabulary achieved with any training set (2444 words, achieved after training on 1000 words). Note that this 598 word increase required growing the training set by 700 words. If we subtract the training set from all reading vocabularies and just focus on words that were generalized to, the best model trained on 300 words (1546) achieves 92.7% of the maximum amount of generalization achieved with any training set (1668, achieved after training on 500 words).

These results indicate that nearly all systematic structure relating English orthography and phonology within our corpus of 2881 monosyllabic words can be learned from an appropriately constructed 300 word subset. It is possible to establish a reading vocabulary of over 1800 words based on explicit training on only 300 words, a 6-fold return on instructional investment. However, achieving this level of performance is highly dependent on the composition of the training set: the best and worst models trained with 300 words are separated in performance by over 600 accurate generalizations (min: 906; max: 1546). Thus, in future work it will be important to understand how properties of training sets are related to generalization.

What makes a word likely to be correct by generalization?

The rates at which individual words were correct by generalization across training sets varied greatly, forming a roughly bimodal distribution (Figure 2).

At one extreme are words that are correct by generalization with almost any random selection of training words; at the other are words that for which generalization is highly sensitive to training set composition. The former contain spelling patterns and orthography-phonology mappings that occur more often in this corpus; the latter words have less common patterns and more idiosyncratic mappings.

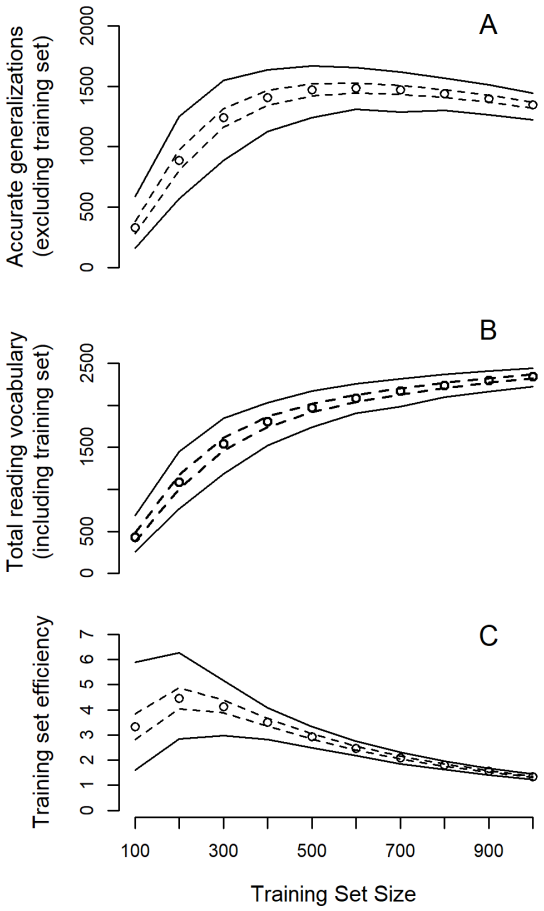

Figure 1: Reading vocabulary size and generalization ability for increasing training set sizes. A) The number of accurate generalization peaks at lower training set sizes and B) the rate of reading vocabulary growth slows. No model trained on a subset of words is capable of reading all words. C) The ratio of generalization performance and training set size, efficiency, is highest with training sets with 200–300 words. Dots indicate the mean; dotted lines are $\pm 1SD$; solid lines are minimum and maximum values.

Whether a word was likely to be generalized to was related to quantifiable measures of orthographic, phonological, and relational (mapping) typicality. We examined several lexical factors that have been employed in previous research:

- Word length: number of letters
- Orthographic neighborhood: number of words whose spelling differs from a word by a one letter substitution, deletion, or addition ($D_{Levenshtein} < 1$).
- Phonological neighborhood: number of words with the same rime (e.g., for "must", the "ust" words like "dust" and "lust").

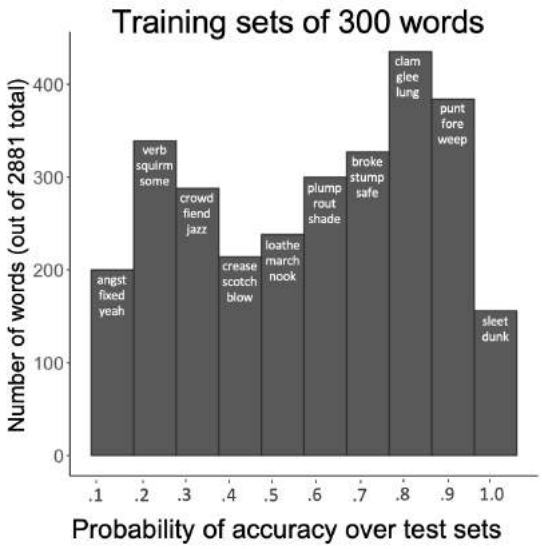

Figure 2: When aggregating over the 100k 300-word model training environments, each word occurs in many test sets. The proportion of times a word occurs in the test set and is accurately generalized to corresponds to how difficult that word is to learn. Representative words belonging to each bin are displayed.

- Consistency: the proportion of words with a given word body (the orthographic equivalent of the rime) and the same phonological rime (e.g., for GAVE, the proportion of -AVE words pronounced "ave"; (Plaut, McClelland, Seidenberg, & Patterson, 1996).

The correlations among these variables, and between these variables and the probability of accurate generalization, are reported in Table 2. The number of orthographic neighbors tends to decrease as word length increases ($r = -0.65$); a similar but weaker trend applies to the size of phonological neighborhoods ($r = -0.28$). This is representative of the English language in general. There is also a moderate relationship between neighborhood size across modalities, such that words that belong to large othographic neighborhoods are expected to belong to large phonological neighborhoods ($r = 0.35$). That this correlation is not higher demonstrates the asymmetry of structure across the modalities. The consistency of a word's pronunciation given its orthography, however, is uncorrelated with the modality-specific metrics. Words are more likely to be generalized to if they are short, belong to large phonological and (especially) orthographic neighborhoods, and have consistent pronunciation given their spelling (Table 2, bottom row).

Given the high correlations among variables, and to gain perspective on how jointly-predictive these factors are of the probability of accurate generalization, we regressed the probability of accuracy over test sets on all four variables in an additive linear model (no interaction terms). This simple model accounts for 39% of the variance in generalization accuracy. Of the variables we considered, the consistency metric accounted for the most unique variance ($\Delta R^2 = 0.15$), but orthographic neighborhood size was a close second ($\Delta R^2 = 0.13$). Once accounting for other variables, phonological neighborhood size and word length did not appreciably improve the model.

These results are broadly consistent with previous research. Effects of spelling-sound consistency have been observed in many behavioral studies of skilled and beginning readers (Jared, McRae, & Seidenberg, 1990), and simulated in earlier models that examined performance over the course of learning many words (Seidenberg & McClelland, 1989; Plaut et al., 1996). Our results suggest that factors that affected ease of learning in the earlier models also affect probability of generalization as studied in the present work.

Out of the variables we considered, phonological neighborhood size is the most studied in the context of word acquisition, where it is understood to influence the order in which words are acquired (Storkel, 2003). Orthographic neighborhood size is often studied in terms of performance, specifically visual word recognition and lexical access (Andrews, 1997). It is also negatively correlated with age of acquisition norms, which indicates that words with more dense orthographic neighborhoods tend to be learned earlier (Cameirão & Vicente, 2010). Words with consistent orthographic to phonology relationships are also processed more efficiently (Ziegler, Ferrand, & Montant, 2004).

	WL	ON	PN	Con.
Word Length	1.00			
Orth. Neighbors	-0.65	1.00		
Phon. Neighbors	-0.28	0.35	1.00	
Consistency	-0.03	-0.02	-0.02	1.00
P(accuracy)	-0.27	0.47	0.28	0.38

Table 2: Correlation among lexical measures. The bottom row reports the pairwise correlation of each variable with the probability of generalization accuracy for each word, defined as the number of times accurately generalized to divided by the number of test sets a word appeared in.

regressor	η_p^2	$\Delta\mathbf{R^2}$
Word length	0.01	0.00
Orth. Neighbors	0.17	0.13
Phon. Neighbors	0.03	0.02
Consistency	0.20	0.15

Table 3: Effect sizes for the regressors that account for variance in the probability of accurately generalizing each word. These effect size metrics are perspectives on the unique variance explained by each variable. Because of collinearity among the regressors, the sum of the ΔR^2 values will be less than total $R^2 = 0.39$.

What makes a good training set?

The word-level features reviewed above give some insight into which words will tend to be generalized to, and which will not, in the context of any given training set. The deeper question pertains to the qualities of the training set foster the most efficient generalization to untrained words in the language. One angle on this question is to consider that the word-level features are in fact reflective of how the word is situated relative to the broader linguistic environment. While we did not test this directly, it is plausible to assume that neighborhood size predicts how likely a word is to be generalized to. Good training sets are *representative* of the broader environment. If a neighborhood is split across training and test sets, the consequence is that the neighbors in the test set have representation within the training set. Given that we randomly split our corpus into training and test sets, there is no guarantee that neighborhoods are efficiently split in this way. However, words that belong to larger neighborhoods are more likely to be split across training and test sets by chance, so we might expect that training sets with larger orthographic and phonological neighborhoods on average will foster more generalization. It is clear that words with no orthographic neighbors ($n = 271$) are generalized to far less often (median probability 0.10) than words with at least one neighbor (median probability 0.56).

Such a crude metric, however, would be largely insensitive to the relative composition of the two sets. For instance, training sets that contain many words with large neighborhoods may simply contain all the words belonging to those large neighborhoods. Such a training set would be unrepresentative of the test set, and unlikely to foster generalization. What we would rather know is each word's neighborhood size relative to the number of its neighbors that also belong to the training set.

On the other hand, orthographic and phonological neighborhood structure is only helpful to the extent that they are aligned. An orthographic neighborhood populated with words with irregular and idiosyncratic pronunciations is not likely to foster generalization on a reading-aloud task. Thus, training sets that have a large and varied collection of words with consistent pronunciations may be expected to generalize well. While it is easy to determine the mean consistency of a training set, it is less clear how to account for the variability across consistent relationships and determine the representativeness of such relationships to the target environment.

We regressed the generalization performance of the 100,000 models trained on 300 word training sets on the mean word length, orthographic and phonological neighborhood sizes, and consistency over all 300 words in each set. The effect sizes are reported in Table 4. We see that, despite being a very crude measure, mean orth-phon consistency accounts for about 13.6% of the variance unexplained by the other variables, indicating that item level characteristics may provide insight on how to construct efficient training sets. However, the vast majority of variance remains unexplained and provides fertile ground for continued research.

regressor	η_p^2	$\Delta\mathbf{R^2}$
Word length	0.002	0.001
Orth. Neighbors	0.006	0.005
Phon. Neighbors	0.000	0.000
Consistency	0.137	0.136

Table 4: Effect sizes for the regressors used to account for variance in generalization accuracy over the 100,000 models fit to random 300 word training sets. Generalization was to all untrained words in the corpus. Because of collinearity among the regressors, the sum of the ΔR^2 values will be less than total $R^2 = 0.14$.

Discussion

We have established a computational procedure for investigating two aspects of generalization in learning basic reading skills: how many words need to be learned to generalize to real English words yet to be learned, and what aspects of reading vocabulary promote this transfer. Our findings indicate that while printed vocabulary continues to grow along with the number of words taught, the efficiency of learning does not grow along with it.

These findings are relevant to real-world learning conditions. As a human teacher grows the number of words they would like to teach, the amount of learning time needed grows along with it. Our findings suggest a trade-off where a smaller number of words could be taught, increasing efficiency of learning and teaching for sake of near-optimal generalization capacity. This has potentially important implications for reading education where there is a need to teach spelling-sound patterns (phonics) but only enough time to sample from the large set of patterns. Many educators oppose teaching phonics because it is seen as requiring "drill and kill" amounts of instruction and practice. This may be less of a concern if, as our results suggest, patterns can be selected in a way that maximizes generalization.

The problem of maximizing generalization with the smallest possible training set can be formalized as a *machine teaching* optimization problem (Zhu, 2015). We have drawn on this literature by manipulating the learning environment while holding the abilities of the learner constant, and then performing careful analyses of the outcomes to identify the factors that contribute to training the most proficient models. In doing so we have demonstrated systematic relationships between the composition of the training set and generalization performance that machine teachers may be able to discover and exploit.

These results are empirical; our next step will be to identify properties of words and word-sets responsible for better generalization both at the word- and set-level. As indicated in our regression model reported, item-wise measures of phonology, orthography, and especially orth-phon consistency account

for non-trivial amounts of generalization error. Next steps will be oriented towards accounting for more of the variance in generalization accuracy, and to scale up analyses to model-wise characteristics that promote generalization. It may also be possible to improve efficiency even further by using training sets attuned to children's vocabulary development, and by optimizing the sequence of learning experiences. Ultimately the aim is to discover the principle axes of the orth-phon mapping space, and exploit that structure in a theory-driven way to construct idealized training environments.

The reported models were trained on representations of the orthography with 14 "slots" for letters and tested on phonology with 10 "slots" for phonemes. This has consequences for learning that are artificial relative to how a child learns to decode orthography. Most salient is that each slot has an independent set of weights that project to the hidden layer. This means that what is learned about letters in one slot is not necessarily transferred to other slots—once the model has learned to pronounce the consonant *K* in the third slot, it will fail to generalize that knowledge when presented with a *K* in the fifth slot. This and other limitations of the slot based representation scheme contribute to our focus (and the focus of the modeling literature, generally) on monosyllabic words. Monosyllabic words are short and fairly consistent in length with a single vowel phoneme. After vowel-centering, the limits of using slots are effectively attenuated in the monosyllabic context, but it is not a solution that scales up. Models of reading that attempt to reflect more plausible visual processes and accommodate disyllabic words are needed. The slot-based approach may add some complexity to the decoding problem while simplifying the "visual" experience of our models.

Though preliminary, these simulations demonstrate that it is possible to be more efficient with curricula that attend to the number of words taught and the words that are prioritized in teaching.

Iconic Prosody is Rooted in Sensori-Motor Properties: Fundamental Frequency and the Vertical Space

Abstract

The iconic cross-modal correspondence between fundamental frequency and location in vertical space ("high is up") has long been described in the literature. However, an explanation for this relationship has not been proposed. We conducted an experiment in which participants shot at cans projected on the wall in different vertical positions. We found that mean fundamental frequency was significantly influenced by vertical head position. Moving the head upwards changes the position of the larynx, which pulls on the cricothyroid muscle and changes the fundamental frequency. We thus propose that the iconic relationship between fundamental frequency and vertical space is grounded in the body.

Keywords: iconicity; prosody; fundamental frequency; vertical space; sensori-motor properties; embodied cognition

Introduction

Iconicity refers to the resemblance between the linguistic *form* and the intended *meaning* (Blasi, Wichmann, Hammarstrm, Stadler, & Christiansen, 2016; Dingemanse, Blasi, Lupyan, Christiansen, & Monaghan, 2015). The evidence brought forward in the last decade suggests that iconicity is an essential part of language (Perniss, Thompson, & Vigliocco, 2010; Perniss & Vigliocco, 2014). The origin of iconicity, however, is far from clear (cf. e.g., Imai & Kita, 2014, p. 9). This article brings together earlier work in phonetics and cognitive sciences by discussing the relationship between iconicity and prosody in speech.

The term prosody has often been used interchangeably with intonation, though these terms are used in different ways by different authors (for a discussion, cf. Hirst & Di Cristo, 1998). Here, we use prosody as an umbrella term for the suprasegmental stress, rhythm, and intonation properties in speech (Bussman, 1996; Trask, 2004). We investigate a single basic aspect of prosody, fundamental frequency, which is an acoustic correlate of intonation. Fundamental frequency expresses the rate at which the vocal folds vibrate during speech. It is most frequently measured in hertz. Pitch expresses how fundamental frequency is perceived. It is quantified by listeners' judgments. In this paper we use f0 in reference to production studies and pitch in reference to perception studies.

Previous research has shown that there is a relationship between location in vertical space and pitch (in speech perception) or f0 (in speech production), though little in the way of explanation has been proposed. In the literature, iconicity is mainly considered to be both a finding and the explanation for the finding: there is a form–meaning mapping, because the relationship is iconic. However, no explanation is given for why iconicity is present in natural language. Therefore, the aim of this study is to investigate a potential origin for iconicity. Using an experimental approach, we demonstrate that there is a link between vertical head movement and f0. We propose that the iconic correspondence between location in vertical space and f0 is rooted in head movement required to look at objects that are higher up. In other words, the origin for the relationship between f0 and location in vertical space lies in bodily constraints, namely vertical head movement.

Evidence for Iconic Pitch in Speech Perception

Researchers have long been interested in how people localize sounds in vertical space and what kind of cognitive processes are involved (e.g., Seashore, 1899). Pioneering work by Pratt (1930) and Trimble (1934) and later experiments by Mudd (1963) and Roffler and Butler (1968) show that, regardless of the actual vertical position of the sound source, participants tend to locate high-pitched sounds higher in the vertical plane and low-pitched sounds lower in the vertical plane (i.e., the Pratt effect, cf. above). Recent work by Parise, Knorre, and Ernst (2014) provides an insight into the possible source of this "frequency–elevation mapping." The authors recorded sounds in different natural environments with directional microphones mounted at various heights. They found a strong correlation between the frequencies of the noises in the environment, especially in the 1–6 kHz range, and the sound location in the vertical space. After accounting for the filtering properties of the outer ear, Parise et al. conclude that the ear is fine-tuned to the statistics of the noises in the environment. Thus, the relationship between a given sound's frequency and its vertical position is not language-specific. Apart from that, their results suggests that the listeners' expectations of an object's location in vertical space may be grounded in the statistical probabilities in the natural environment. It has to be noted that the noises in the environment come from both animate, like birds, and inanimate sources, like wind in the trees.

In 1994, Ohala proposed the *frequency code* as a possible cause of prosodic iconicity (Ohala, 1994). He argued that in various species, low-pitched vocalizations are associated with a large-sized animal, since the mass of the vocal folds correlates with body mass and, thus, size. Both body mass

and the size of an animal are crucial to estimate a potential threat, which in the animal kingdom is a matter of life and death. The lower the perceived pitch of a given animal, the more threatening, dominant, or aggressive the animal is assumed to be. And conversely, the higher the perceived pitch emitted by the sound source, the smaller its size is estimated to be, thus the source itself is interpreted as less threatening, dominant, and aggressive.

Keeping in mind the studies mentioned above and Ohala's frequency code, when we consider humans, it is apparent that there are two main, possibly contradictory, factors that affect pitch estimation. The first is vertical position – higher pitch is located higher in vertical space. The second factor is body size – higher pitch is associated with smaller body size. If two people of different size (height) stand beside each other, the larger person's mouth will always be higher in the vertical plane. On the one hand, according to Ohala's frequency code, we would expect the larger person to emit lower-pitched sounds. On the other hand, according to, e.g., Parise et al. (2014), the larger person, because their mouth is higher up in the vertical plane, should sound higher-pitched. This contradictory predictions have, to our knowledge, only been addressed by one study (Pisanski, Isenstein, Montano, O'Connor, & Feinberg, 2017).

Pisanski et al. (2017) explicitly investigated body size estimation based on pitch vs. vertical location. Their results show that low pitch was associated with a large body size even when it was played from a low vertical position. This suggests that pitch cues override spatial cues in the body size estimation. However, this finding may be due to the task, which was to estimate the body size of an animate being. Hence, animacy and the experimental task may also have influence on the perception of different frequencies.

Evidence for Iconic F0 in Speech Production

There is considerably less work on iconic f0 in speech production. Although the effects found in the studies mentioned below are mostly subtle, nevertheless they provide evidence for the use of iconic pitch with regard to location in vertical space. Items that are located higher up in vertical space (whether they are actual objects or mental concepts located in a metaphorical plane) are marked with higher fundamental frequency than item that are located lower in space.

In a series of experiments, Clark, Perlman, and Johansson Falck (2014) asked the participants to read stories related to vertical motion (up vs. down), emotions (positive vs. negative), and perceived sound (high-pitched vs. low-pitched). The authors expected that the participants would produce higher fundamental frequency in stories with higher elevation in the physical space, positive emotions, and high auditory pitch in contrast to stories reporting lower vertical space, negative emotions, and lower auditory pitch. A significant effect was found only for stories describing a vertical motion in which the f0 was on average 5 Hz higher in the "up" condition than in the "down" condition.

Nygaard, Herold, and Namy (2009) investigated prosody of adjective antonym pairs (e.g., *happy/sad*, *big/small*, *tall/short*). The adjectives were embedded in carrier sentences next to novel non-words and the participants were asked to use infant-directed speech. Their analyses suggest that the fundamental frequency was higher in the adjectives *happy*, *big*, *hot*, *tall*, *yummy* and *strong*, compared to their antonym counterparts. Depending on the item, f0 differences were between 20 and 90 Hz. However they might have been affected by how engaged the participant was in the infant-directed speech task.

Another study that tackles the problem of iconic f0 with regard to vertical space is that of Shintel, Nusbaum, and Okrent (2006). The authors analyzed the fundamental frequency of participants saying if an animated dot was moving up or down. The data revealed a significantly higher f0 for the "up" condition. The f0 differences were, however, relatively small, similarly to those reported by Clark et al. (2014).

The reviewed previous literature, both in perception and production, documents the relationship between f0 and location in vertical space that is proposed to be iconic. But the only explanation given for this relationship is iconicity itself. The purpose of this study is to test one potential origin of iconicity and thus also the origin of the relationship between f0 and location in vertical space.

Potential Anatomical Explanations for the Relationship between F0 and Vertical Space

The control of fundamental frequency is anatomically complex. It involves a difference in the subglottal pressure between the lungs and the oral cavity, in addition to the tensing of the vocalis muscles (the vocal folds). Moreover, different extrinsic muscles can indirectly influence the vocal folds. For example, activation of the cricothyroid muscle (CT) leads to the rotation of the crycoid cartilage, which in turn tenses the vocal folds, and thus increases f0 (Honda, 1996). Apart from that, fundamental frequency can be lowered by the actions of the external strap muscles (Erickson, Baer, & Harris, 1982).

But additional factors may come into play in f0 control by causing a change within the other parameters affecting f0, e.g., by varying the muscle tension around the larynx. Anatomically, muscle tension around the larynx can be changed by head movement. To the best of our knowledge, only one empirical study exists showing the influence of head motion on f0 in speech production (Munhall, Jones, Callan, Kuratate, & Vatikiotis-Bateson, 2004). Their sentence-by-sentence multiple regression analysis revealed that 63% of the variation in the fundamental frequency could be explained by speaker's head movement during speech production. The upward head motion raises the larynx, thereby pulling on the CT muscle, which elongates the vocal folds and thereby increases f0. Still, it has to be noted that the analyses were carried out on recordings of only one speaker.

The aim of this study is to investigate the potential anatomical origin of the iconic relationship between f0 and location in vertical space. Our first hypothesis is that the fundamental frequency is affected by the position of the head. Changes in

the position of the head influence the placement of the larynx, and simultaneously affect the fundamental frequency. We assume that people look at an object, the head follows the gaze. When an object is located higher up in space, people move their head upwards and when it is located lower, they move their head down. Thus, if an object is located at the higher position in space, we expect a higher f0 within the utterance produced at this head position. Our second hypothesis is that the size of an object has an impact on the fundamental frequency when referring to that object. We expect a higher f0 for smaller objects and lower f0 for larger objects.

Methods

Experimental Design

In the experimental task, participants were asked to "shoot" cans, which were projected onto the wall in front of them, with a laser pointer. Additionally, the participants had to say the word written on the can. One of two words was written on each can: *piff* [pɪf] or *paff* [paf], both of which are German onomatopoeic words imitating the sound of shooting, like English 'bang' or 'pow'. To measure the hypothesized effect of size of the object referred to, we used two sizes of cans in the experiment – a small and a large one, which was approximately twice as large. The cans appeared on five equidistant positions on the vertical and horizontal axes, resulting in 25 possible positions. The varying vertical position of the can enabled us to elicit the head movement, expected to have an influence on fundamental frequency – according to the first hypothesis. All conditions sum up to a total of 100 tokens per participant: two words x two can sizes x five vertical positions x five horizontal positions.

During the task, the participants stood at a landmark on the ground, at approximately 1 m distance from the wall. The projection surface measured 130 x 130 cm, with the lowest edge starting at 145 cm above the ground. When a can appeared, the participants were instructed to (1) point at the can with a laser pointer, and (2) say the word written on the can. After the participant successfully pointed at the can and uttered the word written on it, an animation of the can falling down was played and, after a short blank screen, a new can in a different position appeared. The presentation of cans and their animation was manually controlled to prevent the participants from predicting when the next can would appear.

Five datasets with prerandomized order of presentation were created to avoid order effects. For technical reasons, the presentation of the stimuli was divided in two sections, both of which consisted of 50 items. The whole experiment took 15–20 minutes, though the experimental task itself lasted no longer than 5–6 minutes. This was highly relevant in order to avoid boredom and its potential effect on fundamental frequency. The main task was preceded by a short familiarization trial, which consisted of five items – cans with different words written on them, than those that were used in the main task. The participants were given no specific instructions regarding the alignment of their movements. If one of them asked about it, they were told to act naturally, in a way similar to pointing a laser pointer at a particular word or image while giving an oral presentation.

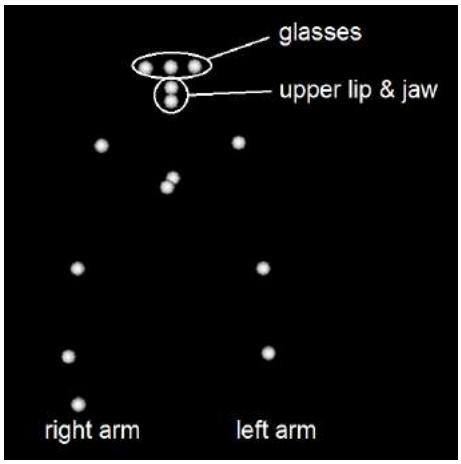

Figure 1: The placement of markers for the motion capture.

Acoustic and motion data were recorded simultaneously using a Sennheiser ME 64 cardioid microphone and an Optitrack motion capture system (Motive, version 1.9.0) with 12 cameras (Prime 13). Motion data was captured at 120 Hz sampling frequency and acoustic data at 44.1 kHz. In total, 15 markers were placed on different body parts of the participants: three on the glasses (center, left, and right); one each on the upper lip and the lower lip (jaw); one at the position of the sternum; one approximately at the location of the fourth thoracic spine vertebra; one on the laser pointer; and symmetrically two on the shoulders, elbows, and wrists. The placement of all markers is illustrated in Figure 1.

Due to technical problems with the recording equipment, the data of one participant had to be excluded.

Participants

Since males have an on average lower fundamental frequency than females, including different sexes would have yielded an additional factor in the experimental design. To avoid this, we focused on females as a participant group. A total of 31 German native speakers took part in the study (mean age = 27.84; mean height = 167.7 cm, with min = 152 cm and max = 183 cm). Twenty-six participants were monolingual and five reported being bilingual; all apart from one were right-handed. The participants were all recruited using a participant database. At the beginning of the session, they were given information about the experiment and signed a consent form. They received monetary compensation after the completion of the task. The project was approved by the ethical board of the DFGS and preregistered at Open Science Framework[1].

[1]The OSF repository can be visited under the following address: https://osf.io/ysr75/

Data Preprocessing and Annotation

The acoustic data were automatically labeled at the phoneme level using WebMAUS (Kisler, Reichel, & Schiel, 2017) and subsequently manually corrected using Praat (Boersma & Weenink, 2018). The on- and offset of the vowel were defined as the onset and offset of vocal fold oscillations, respectively. So far, we have annotated and corrected the data for 20 participants (mean age = 29.45; mean height = 165.5 cm, with min = 152 cm and max = 177 cm). Mean fundamental frequency was calculated for the whole vowel interval. The fundamental frequency range was set to 150–400 Hz to avoid octave jumps of the pitch tracker due to creaky voice.

The motion capture data were first extracted and processed with Mokka version 0.6.2 (Barré & Armand, 2014), and subsequently converted to be further processed with MATLAB (version R2017b). The maximal vertical position of the pointing wrist and of the center of the glasses were calculated within the vowel interval, provided by the annotated acoustic data.

Statistical Analyses

All statistical analyses were carried out within the R environment, version 3.5.1 (R Core Team, 2018), using the following packages: `plyr` (Wickham, 2011) for data wrangling, `car` (Fox & Weisberg, 2011) and `lme4` (Bates, Mächler, Bolker, & Walker, 2015) for statistical modelling, `RePsychLing` (Baayen, Bates, Kliegl, & Vasishth, 2015) for model evaluation, and `stargazer` (Hlavac, 2015) for the output table.

After the initial data exploration, we were forced to exclude the data of one participant (id7) from subsequent analysis. Her behavior during the experiment was atypical; she shrieked and laughed a lot during the experiment. This later had a negative effect on the reliable parameter extraction. Thus, all results refer to the group of 19 female participants.

Results

General Remarks

Though we did not explicitly investigate the coordination between the head movement (gaze), articulation (lip and jaw movement), and the pointing gesture, their temporal organization is shown in Figure 2 for reference. The speaker first visually locates the target and elevates the head (in the example shown in Figure 2, the target is situated higher in the vertical space). Then she starts the pointing gesture by visibly lifting the wrist. Finally, the speech itself begins. It can be observed in the acoustic signal itself, but also in the larger maximal distance of the upper lip and jaw.

Statistical Hypotheses Testing

The parsimonious mixed model approach was used to more reliably analyze data that are highly variable between subjects (Bates, Kliegl, Vasishth, & Baayen, 2015, p. 2). This approach starts by calculating a maximal model, as suggested by Barr (2013). Subsequently, a principal component analysis of the random effects' structure is run using the `RePsychLing`

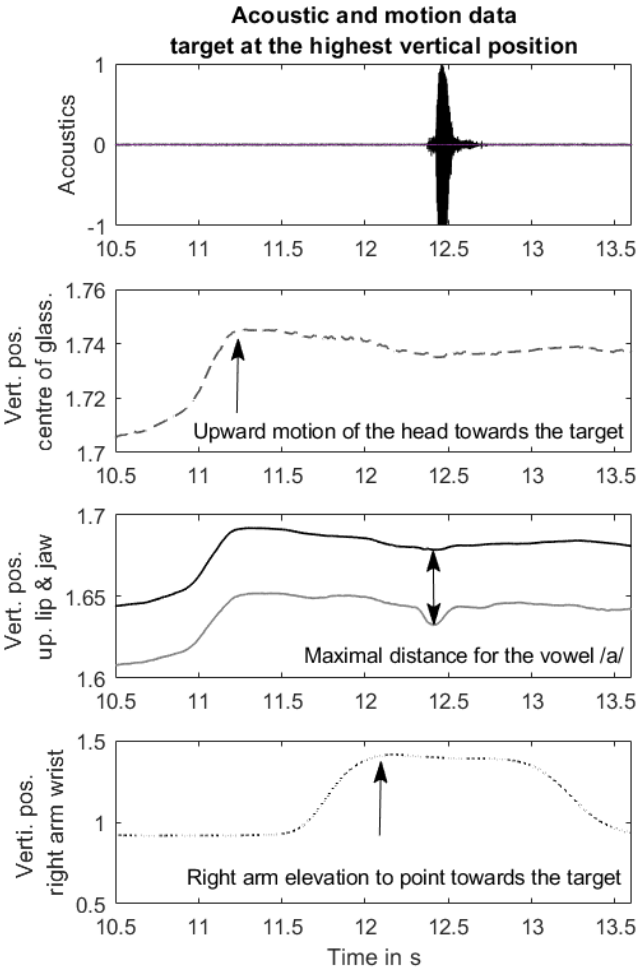

Figure 2: An example of acoustic and motion data for a trial with the stimulus located high in the vertical plane. Plots from top to bottom: (1) acoustic signal; (2) vertical head position (dashed line), determined by the marker in the middle of the glasses; (3) upper lip (black line) and jaw (gray line) markers; (4) marker on the pointing arm wrist (dashed line). All motion data are in meters. Note that the arrows in charts 2–4 only illustrate the coordination among different body parts, but all positions are calculated within the vowel interval.

package (Bates, Kliegl, et al., 2015). This procedure allows to reduce the random effects structure to the necessary components, according to the variance in the data. It is done by an iterative reduction of the model's structure and step-by-step comparison of subsequent models. In the current analysis, the parsimonious best-fit model was in fact not significantly different from the maximal model ($p = 0.54$).

All computed models consisted of the same set of fixed factors: vowel in the uttered word, subject's height, subject's head position, can's vertical position, can size, and the interaction of vowel and can size. Random intercept for subject was included in the random effects structure to account for intersubject variability. The random slopes after the iterative model reduction consisted of vowel in the uttered word, and the interaction of vowel and can size.

The results of the the linear mixed effects model presented in Table 1 reveal four main effects on the mean fundamental frequency, namely that of: the vowel segment, participant's body height, participant's head position, and the size of the can. The first two effects have been described in the past. No effect on the mean f0 has been found for either the can's vertical position or the interaction of vowel segment and can size.

The effect of the vowel on the mean f0 is in line with previous reports on the intrinsic f0 in vowels (Whalen & Levitt, 1995; Whalen, Gick, Kumada, & Honda, 1999). This is the most robust effect found in our data and it shows that higher mean f0 values were found for the high vowel /ɪ/ and lower values for the low vowel /a/. Furthermore, the data show that the taller the participant is, the lower her fundamental frequency is. This negative effect found for participant's height corroborates with the frequency code (Ohala, 1994) and the work by Pisanski and Rendall (2011).

Most importantly, both hypotheses put forward earlier gain support from our analysis. The model shows that the mean f0 increases with the elevation of the head, which is consistent with the first hypothesis. In addition, the size of the can had a significant impact on the mean f0 – participants produced lower mean f0 when referring to larger cans. This result is in line with the second hypothesis. However, it has to be pointed out that the mean f0 differences found between smaller and larger cans are rather small at only 2–3 Hz. Figure 3 illustrates that the effect found for size is the strongest in the highest can positions (1 and 2) and it diminishes or disappears completely at the lower positions (3–5).

Discussion

The analysis presented above demonstrates that in our data the mean fundamental frequency is influenced by the vertical head position rather than the vertical position of the object referred to. In the computed best-fit model with mean fundamental frequency as a dependent variable, we found that the tested anatomical factor – head position – plays a crucial role for the mean f0. In contrast, a factor depicting a purely iconic relationship in the location on the vertical plane – can's ver-

Table 1: The results of the linear mixed model analysis. The table shows the effect of fixed factors, listed on the left, on the dependent variable: mean f0. The estimated effect size is given for each factor, with the standard error given in brackets in the line below.

tical position – did not significantly account for the variance in the mean f0. Thus, we propose that the origin for the relationship between f0 and location in vertical space in speech production is rooted in the body and its sensori-motor properties. The cross-modal relationship between f0 and vertical space, as discussed in the framework of iconicity, is not simply a result of an iconic form and meaning mapping ("high is up"). It is a result of embodiment, driven by the sensorimotor properties, which are influenced by the changes in the head position.

Furthermore, we found that the size of an object had a significant impact on mean f0 values in the current experiment (cf. Figure 3). In speech production, a correspondence between fundamental frequency and size of an object has been previously found in a story reading task by Perlman, Clark, and Falck (2015), apart from other studies mentioned in the introduction. In this study, participants were asked to read stories with concepts of *fast/slow* and *big/small*. Reading pace and f0 were measured and it was found that (1) the stories with "fast" concepts were read faster than those with "slow" ones, and (2) the stories with "big" concepts were read with lower pitch than those with "small" ones. Our study supplements previous findings on f0–size symbolism by showing that participants reliably signal a difference in size of an inanimate object by adapting their fundamental frequency. There is a large body of work on the iconic f0–size relationship on the segmental level (cf. e.g., Shinohara & Kawahara, 2010; Tsur, 2006; Ultan, 1978). It has been shown in various cross-linguistic analyses that high vowels are more frequently used in words depicting smaller objects, and low vowels in words depicting larger objects. Therefore it was highly relevant to control for the interaction of vowel and can size in the current analysis, though no significant effect was found.

We would like to point out that even though vertical head movement does affect the f0 in our data, it is not the only thing that affects f0 in speech production. Speakers have a high degree of control over f0 and it is often employed to signal prominence in speech (Terken, 1991), such as word stress and sentence accent. Speakers can manipulate their pitch according to the needs of the communicative situation. We found that speakers varied greatly in how they completed the task. Some participants barely moved their head, while others did, even if it did not seem necessary. Even though a small number of participants showed very little head movement, we still found that the head position was one of the strongest predictors of mean f0 variance in our data.

The degree of the vertical head movement varied not only between the participants, but also between the vertical positions of the cans. It can be seen in Figure 3 – lower vertical positions (3–5) yield smaller or no differences in mean f0 between one another. This can be a side effect of a sufficient body size to visually process lower targets. A thorough analysis of speaker behavior is yet to be conducted.

The present study proposes a potential origin for the iconic relationship between f0 and object location in vertical space. Our data show that head movement influences f0: upward head movement leads to higher f0, which is most likely a result of the larynx pulling on the cricothyroid muscle. We thus propose that the iconic relationship between f0 and vertical space is rooted in the body: when looking at an object located higher on the vertical plane, head movement generally reflects the location of the object. In this case, the head movement itself could be considered iconic, because the form is aligned with the meaning – the head moves upwards toward an upward target. Previous literature has already established an iconic relationship between f0 and object location. Our study supplements previous interpretations of this iconic relationship with evidence that the correspondence stems from bodily constraints. The upward movement of the head causes physiological changes that influence f0. In this way, we argue that the correspondence between f0 and vertical space is both embodied – because it is rooted in the body – and iconic – because the form and the meaning correspond. "High is up", because the head moves upwards and the effect is thus an embodied form–meaning correspondence.

Sample-based Variant of Expected Utility Explains Effects of Time Pressure and Individual Differences in Processing Speed on Risk Preferences

Abstract

While previous models of economic decision-making offer descriptive accounts of behavior, they often overlook the computational complexity of estimating expected utility. Here, we seek to understand how both environmental and individual constraints on cognition shape our daily decision. Informed by the predictions of a recently-proposed resource-rational process model of risky choice, *sample-based expected utility* (SbEU; Nobandegani, da Silva Castanheira, Otto, & Shultz, 2018), we reveal that both time pressure and individual differences in processing speed have a convergent effect on risk preferences during a risky decision-making task. Under severe time constraints, participants' risk preferences manifested a strong framing effect compared to little time pressure in which choice adhered to the classic fourfold pattern of risk preferences. Similarly, individual differences in processing speed, measured using an established task, predicted similar effects upon risk attitudes as extrinsic time pressure. These findings reveal a converging contribution of environmental and individual limitations on risky choice, and provide empirical support for SbEU as a resource-rational process model of risky decision making. Notably, SbEU serves as a single-process model of two well-established biases, and the transition between the two, in risky choice.

Keywords: Behavioral economics; Risky decision-making; Time pressure; Processing speed; resource-rational process models

1 Introduction

Our capacity to adapt our decision-making strategies—financial or otherwise—to environmental demands such as time pressure is an invaluable asset for successful behavior. From an online sale which expires in a few minutes, to the rapid trading of stocks in volatile financial markets, our decisions are inevitably constrained by time pressure. Furthermore, internal limitations in processing speed—that is, the speed with which an individual can perform any cognitive operation—should interact with these environmentally imposed limitations (Gigerenzer & Selten, 2002; Salthouse, 1985) as making a choice is widely thought to require a computation of the relative values of the options under consideration (Kahneman and Tversky, 1979). In light of these constraints, one might wonder if our apparent failures to abide by rational decision-making frameworks (e.g., expected utility theory) could reflect a strategic use of limited cognitive resources. To this end, a number of recent theories have proposed that human cognition, with all its apparent biases, can in fact be understood as optimal response—subject to computational and cognitive limitations (*rational minimalist program*, Nobandegani, 2018; Griffiths, Lieder, & Goodman, 2015; Icard, 2014).

Thus, it is of interest to better understand both how we have adapted our decision-making processes to meet these demands and to what extent our ostensibly irrational choices are shaped by these limitations. While previous work has investigated the effects of environmental constraints like time pressure on irrational choice (Guo, Trueblood, & Diederich, 2017), here we seek to corroborate the contributions of both environmental and individual limitations on risky decision-making.

Perhaps one of the most studied departures from rational theories of decision-making is the violation of *description invariance*, which posits that preferences should remain consistent across choices, regardless of the context in which available options are presented. For example, according to expected utility theory (von Neumann & Morgenstern, 2007), whether a decision is made to avoid a loss or seek gains, it should not change one's choice. However, this assumptions is challenged by a wealth of data supporting the framing effect: people tend to be risk seeking for losses and risk averse for gains (Tversky & Kahneman, 1981). Sensitivity to choice framing has been documented in a variety of real-world circumstances including consumer (e.g., Levin & Gaeth, 1988; Loke & Lau, 1992), and medical decisions (e.g., McNeill, Pauker, Sox, & Tversky, 1982; Moxey, O'Connell, McGettigan, & Henry, 2003). This classic pattern of choice—risk-seeking in the domain of losses and risk-aversion in the domain of gains—is perhaps most famously explained by the S-shaped utility function posited by prospect theory (Kahneman & Tversky, 1979; Tversky & Kahneman, 1992)—a well-known descriptive model of choice behavior.

Prospect theory also explains another choice phenomenon: a decision-maker's risk preference depends not only on the framing of the problem (gains vs. losses), but also the probability of the outcome (small vs. large) associated with the risky option. For example, people buy lottery tickets for which winning in unlikely (low probability gain) but prefer to pay to insure their houses against unlikely disasters (low probability loss). On the other hand, when faced with highly probable outcomes, people prefer to select a sure gain over a probabilistic one—"something is better than nothing"—but prefer to risk it all when faced with two unfavorable options—"Ive got nothing to lose" (Di Mauro & Maffioletti, 2004; Fehr-Duda et al., 2010; Kahneman & Tversky, 1979; Markowitz, 1952; Scholten & Read, 2014; Tversky & Kahneman, 1992). According to prospect theory, the fourfold

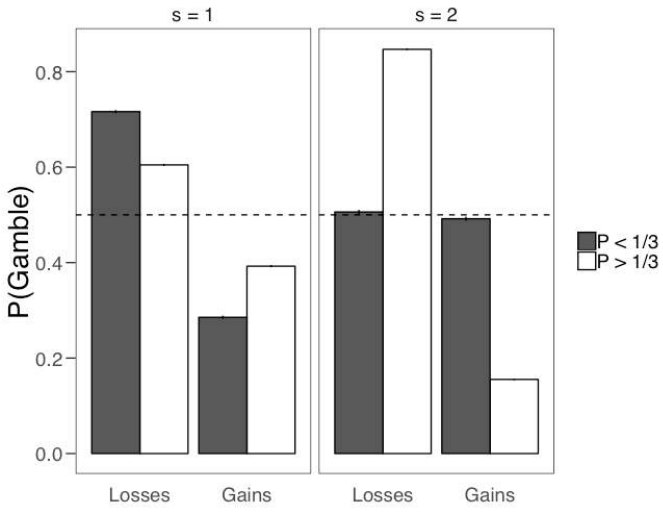

Figure 1: Sample-based expected utility (SbEU; Nobandegani et al., 2018) model predictions for the differential effect of the number of samples on choice. With limited samples (Left) model predicts a framing effect whereas, with more samples, the model predicts more of a fourfold pattern.

pattern of choice arises from the interplay between the S-shaped utility function and the subjective over-weighting of small probabilities (below 1/3) and underweighting of large probabilities (above 1/3) (Tversky & Kahneman, 1992).

While prospect theory offers a descriptive account for the framing effects, it fails to explain either how the decision-making process evolves over time, or how time constraints might bear upon the decision-making process. In order to answer questions about the role of time in these risky choices one must turn to dynamic models of choice. Sequential sampling models are a class of models which assume that choice preferences are estimated by the simulation of an action's potential consequences and where samples are simulated outcomes (Shadlen & Shohamy, 2016). In such models, each simulation takes a non-negligible amount of time and cannot be run in parallel, making time a valuable resource for the decision-maker (Lieder, Griffiths, & Hsu, 2018; Nobandegani, da Silva Castanheira, Otto, & Shultz, 2018). Thus, both total available time and the speed at which these simulations (i.e., samples) are run are directly proportional to the total number of potential outcomes considered (i.e., samples).

If sampling is costly in terms of elementary mental processes, then the number of effective 'samples' an individual is able to draw in a fixed amount of time should also vary in accordance with individual differences in the speed at which an individual processes information—a well-documented capacity limitation termed "processing speed"—which varies considerably across individuals (Kail & Salthouse, 1994). Accordingly, we leverage time pressure manipulations and these individual differences in processing speed to investigate the effect of limiting the number of samples on risky decision-making. Using these two manipulations, will test the effect of varying the number of samples on risky decision-making. Our hypotheses on the directionality of the effect of the time pressure are chiefly informed by a recently-proposed resource-rational process-level model of risky decision-making, *sample-based expected utility* (SbEU; Nobandegani et al., 2018). Extending an earlier model by Lieder et al. (2018), SbEU posits that an agent rationally adapts their strategies depending on the amount of time available for deciding.

Recently, Lieder et al. (2018) proposed a rational process model of risky choice. This model estimates the difference in expected utility of two prospect by using importance sampling, whereby outcomes are sampled in proportion to both its objective probability and its utility (e.g., important outcomes are overrepresented). Lieder et al.'s model, however, was developed under restrictive technical assumptions, making it only optimal when a large number of samples can be drawn. Fortunately, recent developments have determined an optimal sampling distribution which holds for both small and large number of samples (Nobandegani et al., 2018). This is of particular importance as mounting empirical evidence suggests that decision-makers draw very few samples (e.g., Vul, Goodman, Griffiths, & Tenenbaum, 2014); thus, providing an opportunity to explore the effect of limiting cognitive resources (i.e., available samples) on risk preferences.

Accordingly, we used SbEU to generate predictions of people's behavior for a mixture of gambles (i.e., both gains and losses and large and small outcome probabilities) under both conditions of time pressure—in which they can draw very few samples ($s = 1$)—and less constrained conditions—in which they can draw more samples ($s = 2$). Both prospects and time conditions modeled are conceptually identical to those experienced by participants during the task. As depicted in Fig. 1, drawing more samples to estimate the expected utility results in moving from a 'pure' framing effect (Fig. 1a) to the classic fourfold pattern of risk preferences (Fig. 1b). This prediction is in line with the empirical work which suggests that time pressure reduces the amount of information one can process (Miller, 1960; Zur & Breznitz, 1981), as the fourfold pattern requires integrating both outcome and outcome probability information (Kahneman & Tversky, 1979, 1979). Thus, informed by the SbEU's predictions, we sought out to test whether the effects of time pressure on economic choice would conform to the hypothesized pattern. Furthermore, as these predictions are not specific to external time pressure, but any internal constraint on the amount of information that can be processed per unit time, we simultaneously test if differences in cognitive capacity (i.e., processing speed) can also predict a similar pattern of results.

Method

Participants

Data were collected online using Amazon's Mechanical Turk; 100 (41 Female) US-based adult volunteers (mean age =

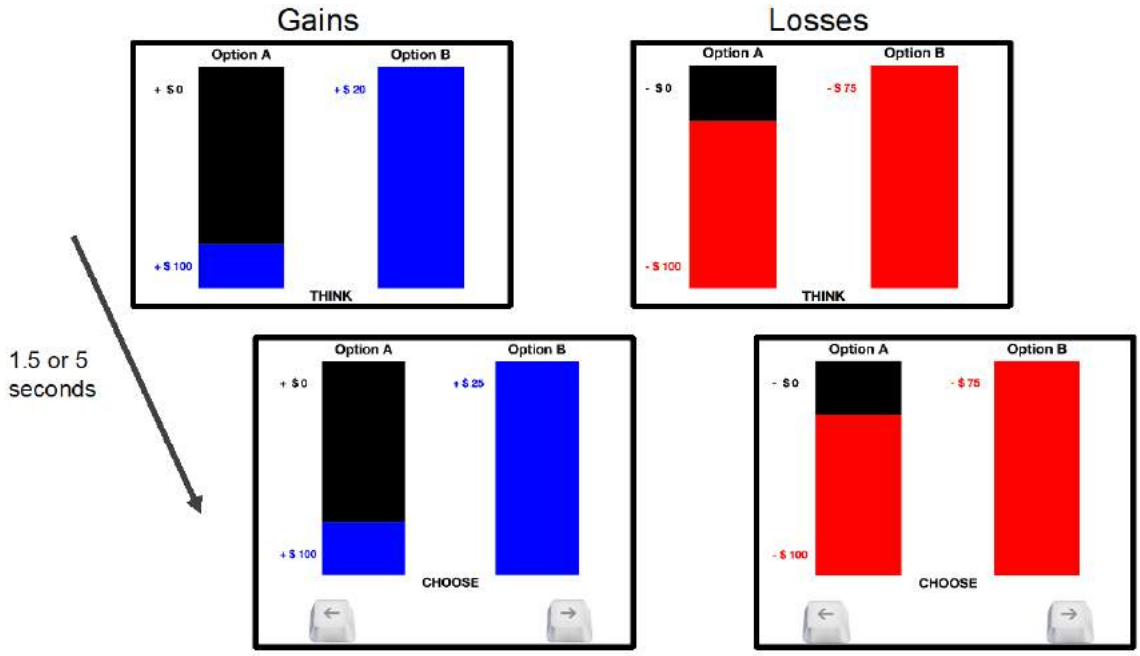

Figure 2: Screenshots of the Gambling task. Participants were given instructed to think about the gamble presented to them before being prompted to respond. The time allotted to think about the problem varied between time pressure conditions: under severe time pressure participants were given 1.5 second to think whereas under light time pressure participants had 5 seconds. Gambles were represented as bar charts where the probability of an outcome was depicted as proportional to the size of the colored portion. Color was used to emphasize the frame of the problem: red represented losses and blue represented gains.

34.77, SD = 9.88), recruited via Amazon's Mechanical Turk (Crump, McDonnell, & Gureckis, 2013), participated in the experiment for a base remuneration of $3.00 USD and a cash bonus—computed in proportion to the outcomes of all trials, with a mean overall payment of $5.85 USD. This study was approved by the McGill University Research Ethics Board.

Processing Speed Measurement

Individual differences in processing speed were assessed using a computerized Digit-Symbol Coding task (Mathias et al., 2017; Salthouse, 1985) which we adapted for use online. Participants were asked to indicate whether or not the digit-symbol pair presented in the center of the screen matched according to the key of associations presented to them. In order to asses processing speed, participants were given 90 seconds to respond to as many trials as correctly and quickly as possible. To ensure participants were taking the task seriously and to minimize exclusions due to random responding, participants were asked to complete the task a second time if their accuracy was below 70%. We subsequently only analyzed the data from a participant's final attempt at the task.

Risky Decision-Making Task

Participants were presented with 120 pairs of binary choices, 60 of which were presented during the light-time pressure (LTP) block and the remaining 60 were presented in the severe time pressure block (STP). Time pressure was manipulated by allowing the participants either 1.5 seconds (STP blocks) or 5 seconds (LTP blocks) to think about their choice. After this lock-out period, participants had a 1 second window to respond in both time pressure conditions; this response window was implemented to minimize the variability in response times and isolate the effects of processing speed on decision-making. Participants were prompted to think about their choice before the response window opened which was signaled by a switch in the cue—from "think" to "choose"—and the image of two arrow keys. The order of presentation of the two time pressure blocks was counterbalanced across participants.

Each pair of options involved a certain option and a risky option with probability p of winning the indicated amount and probability $1 - p$ of winning nothing; all gambles were of equal expected value except for 12 "catch" trials in which the expected value greatly favored an option (expected value = ± 90). Half of the stimuli were framed as losses and half of the stimuli were framed as gains. In both frames, the outcome probability of the risky options varied between extremely likely (0.90, 0.95 or 0.99) or extremely unlikely (0.10, 0.05, 0.01).

Information about each pair of options were presented in a manner similar to that used by Tymula et al. (2012): at the start of each trial participants were presented with two stacked bar-graphs where framing was depicted by the color of the bars (red for losses, and blue for gain) and the outcome probability was depicted by the proportion of the bar which

was colored (either red or blue), while the amounts ranged from $1 to $200 (see Fig. 2). The outcomes of gain trials were added to total earnings while the outcomes of loss trials were subtracted from total earnings—making the task incentives compatible. Participants were paid a bonus in proportion to their total earnings.

Data Analysis

In order to ensure that participants' choices were not made randomly but were based on the information presented, participants with less than 75% accuracy on catch trials across both conditions (operationalized as the proportion of choices which maximize expected value) were excluded from the sample, resulting in the exclusion of 21 participants. Participants who also failed to score above 70% accuracy during the last run of the digit-symbol task were also excluded from the sample—one in total. Finally, six participants were excluded for failing to meet the specified deadline resulting in a total exclusion of 28 participants of the 100 collected.

We used a mixed-effects logistic regression to predict risky versus certain choice on the basis of 1) the framing of the problem (losses or gains) 2) the outcome probability (coded as >0.5 or <0.5), and 3) time pressure condition (light or severe), and all two- and three-way interactions between these predictors. This regression model then gives us two terms of interest: the two-way interaction between probability and framing—an estimate of the fourfold pattern of choice effect since it represents the extent to which mean differences between gain and loss frames depend on outcome probability (large or small), and the three-way interaction between probability, framing and time pressure, which indicates the extent to which the presence of fourfold pattern is modulated by time pressure. Similarly, two additional regression models were run to test the effects of individual differences in processing speed on choice within each time pressure condition. Specifically, to assess the influence of individual differences in processing speed on choice, a similar regression was run for each time pressure condition except with normalized processing speed score added as an independent variable instead of time pressure condition. For all regressions, all categorical independent variables were effect coded and entered as both fixed and random effects. These regressions were estimated using the lme4 package (Pinheiro & Bates, 2002) for the R programming language.

Results

As predicted, under little time constraints participants exhibited a fourfold pattern of choice: they were both sensitive to the framing of the problem ($\beta = 1.44$, SE = 0.10, $p < .001$), and the interaction between the outcome probability and the framing of the problem ($\beta = -0.37$, SE = 0.18, $p = 0.04$).

However, under strong time pressure participants exhibited a marked framing effect, becoming less sensitive to outcome probability ($\beta = 0.28$, SE = 0.08, $p = 0.001$). Thus, the effect of time pressure on risky choice, surprisingly, changed participant's preferences from one ostensibly irrational pattern to another (see Fig. 3).

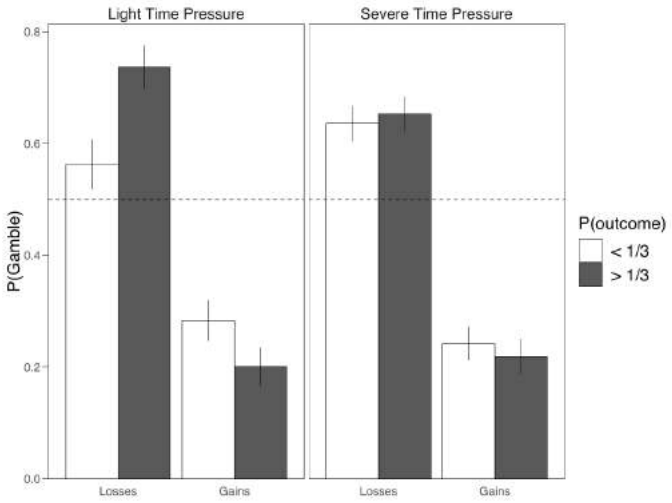

Figure 3: The effect of time pressure on risky decision-making. Under the light time pressure condition (LTP; 5 sec) participants showed more of a fourfold pattern compared to when under the severe time pressure condition (STP; 1.5 sec).

However, it remains unclear if this change in preference is a result of a reduction in the participant's ability to comprehend the gambles offered and correctly respond. It is possible that time limitations would lead to a nonspecific increase in choice randomness, as opposed to the proposed reduction in cognitive resources used. To test this alternative account, we compared the percentage of correct responses to the catch trials in the strong time pressure condition to test if it was significantly higher than chance. Using an Exact Binomial test, we were able to confirm that participants were capable of responding to the catch trials well above chance (Accuracy = 0.91, $p \leq 2.2 \times 10^{-16}$). This is to be expected as those participants who did not respond accurately in general—either due to lack of attention or understanding—were excluded from the analyses.

Finally, individual differences in processing speed were found to be related to risk preference in the predicted direction. Under light time pressure (LTP condition), individual differences in processing speed interacted with both framing of the problem ($\beta = 0.29$, SE = 0.13, $p = 0.02$) and the interaction between outcome probability and the framing of the problem ($\beta = -0.51$, SE = 024, $p = 0.03$). As processing speed increased, the extent to which participants exhibited a fourfold pattern also increased. Put another way, as processing speed decreased they were less likely to endorse a fourfold pattern (see Fig. 4). Moreover, these changes in risk preferences were not likely due to random performance on the task as processing speed and catch trials accuracy was not correlated ($r = -0.0081$, $p = 0.94$). Similarly, under severe time pressure (STP condition), both the two-way interaction between processing speed and the framing of the problem ($\beta = 0.24$, SE = 0.09, $p = 0.01$) and three-way interaction

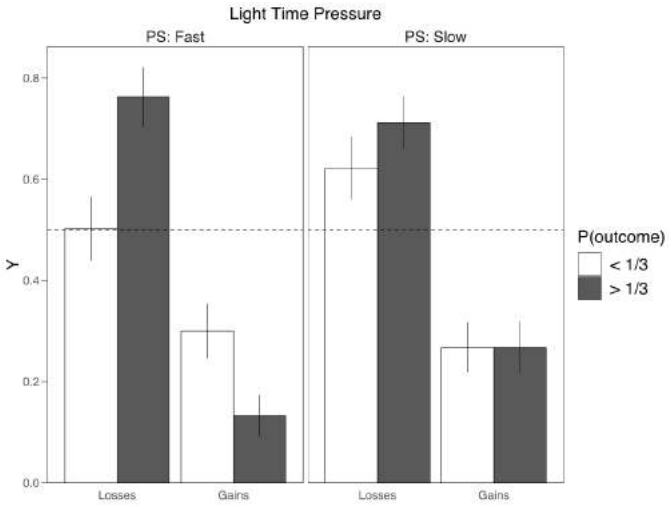

Figure 4: Under the light time pressure condition individual differences in processing speed (PS) predicted the extent to which participants endorsed a fourfold pattern. Processing speed conditions were assigned based on a median split.

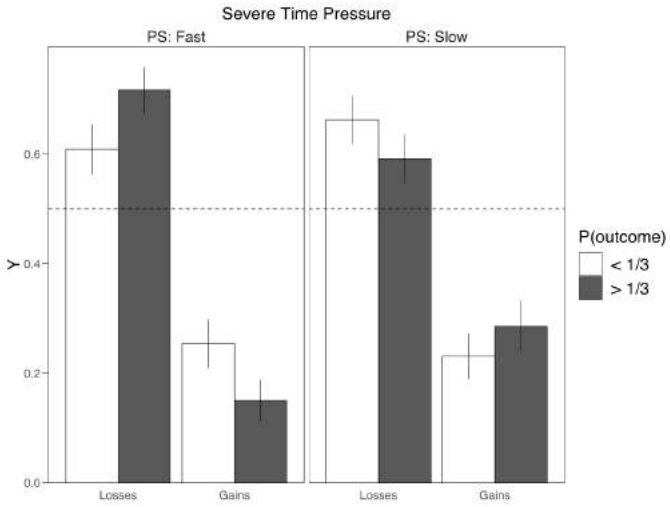

Figure 5: Under the severe time pressure condition individual differences in processing speed predicted the extent to which participants endorsed a fourfold pattern. For ease of exposition, processing speed scores (PS) were split based on the median.

between outcome probability, framing, and processing speed ($\beta = -0.30$, SE = 0.12, $p = 0.01$) were statistically significant (see Fig. 5).

General Discussion

The results presented here show that both situational and personal factors which limit cognitive resources contribute to changes in participants' risk preferences. Under little time constraints, participants produced a fourfold pattern of risk preferences—consistent with prospect theory (Kahneman & Tversky, 1979; Tversky & Kahneman, 1992). However, as predicted by a recently-proposed sample-based variant of expected utility theory, SbEU (Nobandegani et al., 2018), limitations in available cognitive resources—induced either through time pressure or measured by individual differences in processing speed—lead participants to go from showing a fourfold pattern to a framing effect.

While, descriptive models like prospect theory describe the risk preferences when selecting between gambles, this provide no account for how these preferences evolve over time or how limiting cognitive resources affects preferences. Thus, our results surprisingly reveal that the ostensibly irrational framing effect, fourfold pattern, and the demonstrated transition between the two, can all be explained as resulting from rational use of limited cognitive resources.

Interestingly, Stanovich and West (1998) demonstrated that performance on classic reasoning and judgment tasks and relationships to measures of academic achievement, correlates within individuals. Taken together with the results presented here, there is mounting evidence that the use of heuristics and biases may reflect the rational use of limited processing resources, thus suggesting that future models of choice should take into consideration individuals' cognitive abilities (or limitations). However, more work needs to be done to identify which specific cognitive capacities (e.g., processing speed or working memory) significantly contribute to the use of certain heuristics, thus providing an opportunity to better understand the cognitive mechanisms required for the performance of a given task.

Recent empirical work has also found time pressure to produce a similar pattern of results—severe time pressure lead to stronger framing effects—but failed to observe a fourfold pattern; instead they found individual preferences to reflect a weaker framing effect under light time pressure (Guo et al., 2017). However, the results were interpreted to arise from using a fast, intuitive systemas opposed to a slow, deliberative system.

Some have suggested that heuristics and biases are more than merely a result of flaws in human reasoning but are adaptive strategies to deal with conditions of limited time, knowledge or computational capacities (Simon, 1956; Todd & Gigerenzer, 2012) or take advantage of the structure of information in the environment (Todd & Gigerenzer, 2012). In fact, both experimental work (Goldstein & Gigerenzer, 2002), and theoretical work (e.g., Nobandegani & Shultz, 2019) has shown that fast and frugal algorithms can outperform standard integrative algorithms when knowledge is limited. Our results are in accordance with this compromise between normative and heuristic views of cognition as we show that biases like the framing effect can be explained as a strategic use of limited cognitive resources.

While previous work has also interpreted the framing effect as being a result of quick and intuitive thinking, these explanations make appeal to dual-process theory (De Martino, Kumaran, Seymour, & Dolan, 2006; Guo et al., 2017; Kah-

neman & Frederick, 2005; Sloman, 1996; Stanovich & West, 1998). Surprisingly, here we show that a rational *single-process* model can account for the observed results: an apparent framing effect can arise from limiting the number of samples in a resource-rational, sample-based expected utility model, SbEU (Nobandegani et al., 2018). A single-process framework is favorable over dual-process models as it provides a more parsimonious account of the observed effect.

Interestingly, unlike dual process theory would suggest, our results reveal that even when using a slow, deliberative system one can produce ostensibly irrational behavior. Concretely, according to our findings, deliberation takes us from one ostensibly irrational bias (framing effect) to another (the fourfold pattern of risk preferences)—and, as our work suggests, all of this can be understood as the optimal use of limited cognitive resources.

Lifting the Curse of Knowing: How Feedback Improves Readers' Perspective-Taking

Abstract

Previous studies have shown that readers often overestimate the similarity between their perspective and the perspective of protagonists in a story. This egocentric projection is argued to originate from readers' tendency to use their own knowledge as a frame of reference from which they (insufficiently) adjust away to account for protagonists' less informed perspective. This experimental study demonstrated that readers use feedback about protagonists' knowledge status to draw inferences that are more accurate on future perspective-taking trials. Readers who were given the opportunity to learn through feedback not only *adjusted* their perspective-judgment more than those who did not receive feedback, these readers also showed less egocentric projection on future assessments.

Keywords: perspective-taking; egocentricity bias; anchoring and adjustment; privileged information; feedback

Introduction

Communication processes rely on our ability to successfully reason about others' mental states. Research examining this perspective-taking, however, paints a contradictory picture with regard to communicators' *tendency* to be accurate perspective-takers. On the one hand, a large body of research suggests that communicators rapidly and accurately assess others' perspective (Brown-schmidt, Gunlogson, & Tanenhaus, 2008; Nadig & Sedivy, 2002). In contrast to this view, studies have shown that rapid (and automatic) judgments of others' mental state are often influenced by communicators' own knowledge and attentional status (Apperly et al., 2010; Keysar, Barr, Balin, & Brauner, 2000). These studies argue that perspective-taking activities follow an *egocentric anchoring and adjustment* process (Epley, Keysar, Van Boven, & Gilovich, 2004). During this perspective-taking process, communicators adopt another's perspective by using their own perceptions as a frame of reference and adjust this frame to take into account possible informational differences between their own and others' perceptions. These *perspective-adjustments*, however, are often insufficient due to the immediate accessibility or saliency of one's own perceptions. The accessibility and, hence, saliency of one's own knowledge in contrast to the seemingly impermeable nature of the other's mind makes it hard for perceivers to ignore or suppress their own perception as a possible estimate of others' perspective. The failures to inhibit one's own perspective during perspective-taking may result in egocentric projection (Ames, 2004), during which perceivers wrongly assume that their private perspective is shared by others.

Studies have shown that egocentric projection might also occur during reading when readers try to take story characters' perspective (e.g., Keysar, 1994; Weingartner & Klin, 2005, 2009). In these studies, readers overestimated the extent to which their knowledge was accessible to uninformed protagonists. That is, readers read stories in which a speaker protagonist sent an ambiguous message (e.g., "About that dancing class: I can't think of better ways to spend my Tuesday evenings") to a friend. Readers learned how to interpret the speaker's message by the clarifying event information they received beforehand. When this disambiguating information suggested counterfactual (e.g., "The dance class had been dull") rather than factual (e.g., "The dance class had been interesting) information, readers interpreted the speaker's message to be sarcastic. This disambiguating information was not accessible to the recipient of the speaker's message and, for each story, this addressee protagonist had no reason to believe that the speaker was being sarcastic. Studies showed, however, that readers were very likely to use their own interpretation of the speaker's communicative intention to judge that the uninformed addressees would perceive the speaker's message in a similar way. That is, when privileged information suggested that the speaker was being sarcastic, readers assumed addressees would also perceive this sarcasm. In these instances, readers' own knowledge about the speaker's experience "cursed" (Birch & Bloom, 2007; Keysar, 1994) their ability to suppress their own interpretation of the speaker's communicative intention while imaging the perspective of the uninformed protagonists.

Epley and his colleagues (2004) showed that this "curse of knowledge" (Keysar, 1994) effect on perspective-taking originates from an egocentric anchoring and insufficient adjustment process. In their "Sarcastic Messages" experiment, Epley et al. (2004) asked readers to read similar stories in which a speaker protagonist left ambiguous voicemail messages on the answering machine of his friends. Subsequently, readers indicated either the speaker's intention with his voicemail or how they thought the recipient of the voicemail would interpret the message. Following egocentric anchoring, Epley et al. (2004) expected readers to interpret the addressee's perception of the voicemail based on information that was accessible to themselves. Findings indeed showed that readers were more likely to indicate that addressees would perceive the speaker's sarcasm when readers' privileged information suggested the speaker was being sarcastic rather than sincere. Epley et al. (2004) further

showed that this perception of sarcasm was more moderate when readers only judged addressees' interpretation of the message rather than only their own perception of sarcasm. The more moderate perception of the speaker's sarcasm in the perspective-taking condition showed that readers acknowledged that the messages sounded more ambiguous to the uninformed addressees than to themselves. However, since readers still believed that addressees perceived the speaker's sarcasm, readers' perspective-judgments still reflected their own knowledge about the speaker's communicative intention. Even though readers adjusted their egocentric interpretation into a more moderate judgment, these adjustments were not sufficient in order to reflect addressees' true perspective.

Inhibiting Egocentric Information

Perceivers learning to inhibit their own cognitions during mental state reasoning can perhaps counter insufficient perspective-adjustments. For instance, recent perspective-switching research (Samuel, Roehr-Brackin, Jelbert, & Clayton, 2018) showed that communicators found it difficult to switch back to an egocentric judgment once they had learned to adopt another frame of reference. In addition to this, it is argued that the more cues perceivers receive about the knowledge status of others, the less likely they are expected to engage in egocentric projection (Eyal, Steffel, & Epley, 2018; Keysar, Barr, & Horton, 1998; West, 1996). However, studies have shown that directing perceivers' attention to focus on other people's knowledge and attentional status does not always improve perspective-taking accuracy (Damen, Van der Wijst, Van Amelsvoort, & Krahmer, 2018; Eyal et al., 2018). For instance, in a direct replication and extension of Epley et al.'s (2004) "Sarcastic Messages" study, Damen et al. (2018c)[1] examined whether explicit and repeated instructions to focus on addressee protagonists' *uninformed* perspective helps readers to acknowledge that their privileged information was not accessible to these addressees. However, not only did Damen et al. (2018c) replicate readers' egocentric anchoring and insufficient adjustment during perspective-taking, their findings also showed that explicit perspective-focus instructions did not stimulate the adjustment phase. Regardless of an explicit focus on addressees' uninformed perspective, readers still overestimated the extent to which the uninformed protagonists shared their interpretation of the voicemail.

Gaining Interpersonal Insight

Readers in Epley et al. (2004) and Damen et al. (2018c) were more likely to rely on privileged rather than common-ground information while interpreting protagonists' perspective. Interesting to note here is that readers' perspective-taking appertained to a "top-down process" (Eyal et al., 2018), whereby readers *selected* perspective-information that, according to them, was the most relevant to use. In turn, highlighting or enhancing the accessibility of more reliable information (i.e., protagonists' perspective) did not make readers more likely to *use* this information during mental state reasoning. This finding raises the question whether, during this top-down inferencing, readers did not see the need to *adjust* their judgment because they were unaware of its inaccuracy. In this case, increasing readers' awareness of the inaccuracy of their judgments might make them better future perspective-takers.

West (1996) found some support for this line of reasoning by showing that an awareness of inaccurate (egocentric) predictions allowed perceivers to learn from their mistake and to improve their perspective-taking skills. In West (1996), participants learned to predict a target's preference for quilt patterns through the feedback they received from the target. In each trial, agents made a prediction of the target's preference for the pattern (rated from "1 = dislike very much" to "7 = like very much"). Subsequently, the target responded by showing his actual preference (rating) for the pattern, after which agents rated their own preference. Findings showed that the agents' first predictions of the target's preferences showed egocentric projection. That is, if agents liked the pattern, they assumed the target did too. Interestingly, this egocentric projection decreased on subsequent trials due to the target's feedback. The more agents learned about the target's preferences, the less likely they were to project their egocentric preferences onto the target on subsequent perspective-taking trials. Apparently, feedback about their perspective-judgments allowed agents to disregard their own preferences and to select perspective-information that more reliably predicted the target's true perspective.

In addition, recent research by Eyal and colleagues (2018) showed that *receiving* accurate perspective-information rather than relying on existing knowledge improved communicators' perspective-taking accuracy. In Eyal et al. (2018), romantic partners who had the opportunity to discuss each other's preferences on a range of topics were able to use this gained insight on future assessments of their partner's preferences. This in contrast to the partners in the perspective-taking conditions who were not given this discourse opportunity, but who had to rely solely on their *imagination* of their partner's preferences. According to Eyal et al. (2018), the act of trying to *take* others' perspective does not necessarily lead to a more accurate insight into these imagined mental states, because perceivers are very likely to select the wrong information to base their inferences on. In this sense, providing communicators with the opportunity to *gain* reliable perspective-information of which they are also *aware* of its appropriateness should improve perspective-taking accuracy.

[1] Damen et al.'s (2018c) preregistration, materials and data are available in the Open Science Framework (doi: 10.17605/osf.io/kv5mu).

Current Study

This study investigates the role of feedback as a strategy to gain accurate insight into others' perspective. In particular, we examine whether confronting readers with the accuracy of their perspective-judgment (i.e., feedback) allows them to accurately assess protagonists' perspective on subsequent perspective-taking trials. Additionally, we aim to explore whether readers adjust their perspective differently depending on how they gain this perspective-insight. In this study, we contrast two approaches. For the first approach, we rely on perceivers' "bottom-up inferencing" (e.g., Eyal et al., 2018), through which perceives gain interpersonal insight by perceiving others' thoughts and actions. Since this strategy indirectly communicates to perceivers whether their first assessment had been correct, we will term this approach as *indirect feedback*. We contrast this approach against a strategy through which perceivers gain insight by receiving explicit feedback about the accuracy of their assessment (e.g., West, 1996). We will term this type of information as *direct feedback* and we will use this term to refer to the situation in which readers are made explicitly aware that they have made an error and why their judgment was inaccurate (e.g., Ellis, Loewen, & Erlam, 2019).

This study replicates Damen et al.'s (2018c) study in which readers judge addressees' interpretation of voicemails sent by a speaker protagonist. We extend the experimental design by adding a feedback manipulation and a subsequent second measurement of readers' judgment of addressees' interpretation of the voicemail. In line with previous egocentric anchoring findings (Epley et al., 2004; Damen et al., 2018c), we expect readers to overestimate the extent to which uninformed addressee protagonists will also perceive a speaker's sarcasm. We expect that this egocentric projection occurs more at readers' first than at their second prediction of addressees' perspective. In addition, we expect that this relationship is qualified by whether readers receive feedback about the accuracy of their first prediction. In particular, compared to a baseline in which readers do not receive feedback, we expect that both feedback types will help readers to *adjust* their first prediction into a perspective-judgment that more accurately reflects addressees' sincere interpretation of the message. Finally, we expect that readers' second predictions will be more accurate after they had been explicitly told their judgment had been wrong (direct feedback), than when readers need to infer the accuracy of their judgment from a description of addressees' response to the message (indirect feedback). This study is preregistered in the Open Science Framework (doi 10.17605/osf.io/kpw6u).

Method

Participants

A total of 149 undergraduates were invited to participate in the study. Seven participants were excluded because they recognized the voice-actor ($N = 5$) or because they were non-native speakers of the language of the experiment ($N = 2$). The remaining participants were randomly allocated to the control ($N = 48$), direct feedback ($N = 47$), and indirect feedback ($N = 47$) conditions (105 women, 37 men, $M_{age} = 21.57$, age-range 18-38).

Design

In each condition, participants read 12 scenarios in which a speaker protagonist (Tom) left a voicemail-message on the answering machine of an addressee protagonist. After hearing this voicemail, participants judged the addressee's perception of the speaker's sarcasm both before (time 1) and after (time 2) they received feedback about their first perspective-judgment. This resulted in a 3 (*Condition*: control, direct feedback, indirect feedback) x 2 (*Time*: time 1, time 2) design in which *Condition* was treated as a between-subjects factor and *Time* as a within-subjects factor.

Procedure and Materials

We replicated and extended the experimental materials and procedure of Damen et al.'s (2018c) "interpretation" condition. On a computer, participants read 12 stories describing an event in the life of Tom. For instance, in the story "The Dance Class", participants read the following:

> Tom was on his way to the first night of his ballroom dancing class when he saw Eileen, an old friend from his dorm last year. When he told her that he was on his way to a ballroom dancing class, she excitedly replied, "I'm thinking of taking that class, but I can't make it to tonight's class--I am having dinner with friends. Could you call me when you get back and tell me how it is?"

Subsequently, participants learned that Tom's experience had been either negative (e.g., "(…) the instructor spent the entire time taking attendance and filling out lengthy forms and questionnaires.") or positive (e.g., "(…) the instructor spent the entire time teaching the class fun, new dances."). Both experiences followed with Tom leaving a voicemail on the answering machine of his friend. In "The Dance Class" story, Tom left the following message:

> Eileen, this is Tom. Hope you enjoyed your dinner. About that ballroom dancing class: Judging from tonight's class, I can't think of better ways to spend my Tuesday evenings. Anyways, give me back a call and I'll fill you in on the details. Bye.

We re-used the 12 voicemails from Damen et al. (2019b) who demonstrated the validity of the voicemails. In a separate rating experiment, Damen et al. (2019b) asked listeners to rate the voicemails in the absence of clarifying (positive, negative) event information (1 = as very sincere, 7 = as very sarcastic). This rating experiment showed that the voicemails sounded truly ambiguous to the uninformed listeners. That is, participants rated the voicemails to sound neither as very sarcastic or as very sincere (M = 3.73, SD = 0.83).

We followed the experimental procedure described in Damen et al. (2019b), and asked participants to indicate – immediately after listening to Tom's voicemail – how the addressee protagonist (Tom's friend) would perceive the voicemail message (1 = definitely as sincere, 7 = definitely as sarcastic). For this study, this constituted the first measurement of participants' judgment of the addressee's perception of sarcasm (time 1). All stories were presented to participants in digital booklets, and half the stories in these booklets described a positive event, whereas the other half described a negative event. We created four versions of these booklets: The first booklet contained a random order of negative versus positive events (booklet 1), and another one contained its mirror image (booklet 2). Additionally, for each booklet, we created a version that contained a reversed order of the events. In contrast to Damen et al. (2019b), we chose to focus on participants' judgments of the addressee protagonist's perspective only for those stories in which participants' privileged information suggested that Tom was being sarcastic (negative events). We thereby treated the stories that suggested Tom was being sincere (positive event) as fillers.

Additionally to our replication procedure, we manipulated the extent to which participants received feedback about their first judgment of the addressee's perception of sarcasm. This feedback was automated in the sense that the computer provided participants with either direct or indirect feedback. In the direct feedback condition, participants' received explicit feedback about the accuracy (i.e., ranging from "You are completely right!" to "You are completely wrong!") of their judgment based on the answer they provided on the 7-point scale (see Table 1).

Table 1: Example of the direct feedback participants received after judging Eileen's perception of sarcasm (1 = definitely as sincere, 7 = definitely as sarcastic)

Answer	Direct Feedback
1	**"You are completely right!** Eileen thinks that Tom liked the class."
2 / 3	**"You are almost right!** Eileen thinks that Tom liked the class."
4	**"You are not right!** Eileen thinks that Tom liked the class."
5 / 6	**"You are wrong!** Eileen thinks that Tom liked the dance class."
7	**"You are completely wrong!** Eileen thinks that Tom liked the class."

Participants in the indirect feedback condition received feedback about the accuracy of their perspective-judgement regardless of their choice on the 7-point scale. This feedback constituted a follow-up text that described addressees' sincere interpretation of Tom's voicemail. For instance in "The Dance Class" story, participants could derive from Eileen's thoughts and actions in response to Tom's voicemail that she thought that Tom had enjoyed attending the class:

> After saying goodbye to her friends, Eileen cycled home. She decided she was going to search for her dancing shoes the minute she would arrive at home. She could hardly wait to join Tom in the dance class. If Tom had liked the dance class, she definitely would like it too.

In contrast to the two feedback conditions, participants in the control condition did not receive feedback about their first assessment of addressees' perception of sarcasm. Subsequently to their first judgment, these participants read a follow-up text that described the addressee's thoughts and actions that did not target her interpretation of the voicemail:

> After saying goodbye to her friends, Eileen cycled home. She and her friends had enjoyed dinner. They had known each other since high school and had built up a close friendship. Although they only saw each other a few times a year, it was always like they never had been apart.

In all three conditions, participants subsequently re-judged addressees' interpretation of the voicemail (1 = definitely as sincere, 7 = definitely as sarcastic). After this second assessment, participants answered a comprehension question that encouraged participants to attend to the materials. These 12 questions did not target participants' privileged information. When participants answered the comprehension question incorrectly, they were informed to attend to the materials more carefully. Participants answered almost all questions correctly (M = 10.52, SD = 1.07), but the number of correct responses differed between conditions, $H(3)$ = 9.73, p <.01. Pairwise comparisons with adjusted p-values showed that participants answered more comprehension questions correctly in the indirect feedback condition (M = 10.81, SD = 0.95) than in the direct feedback condition (M = 10.13, SD = 1.15), (p < .01). The accuracy scores did not differ between the control and the two feedback conditions (p > .05). After reading 12 stories, participants filled out their demographics and were debriefed about the purpose of the experiment.

Results

We computed a mean sarcasm score of participants' first (time 1) and second (time 2) judgment of addressees' perception of the speaker's sarcasm for the scenarios in which participants' privileged information suggested that the speaker was being sarcastic (negative events). We submitted these mean scores to a mixed analysis of variance in which *Condition* (control, direct feedback, indirect feedback) was treated as a between-subjects factor and participants' judgment of addressees' perception of sarcasm (*Time*; time 1, time 2) as a within-subjects factor. The means of participants' judgment of addressees' perception of sarcasm as a function of *Time* and *Condition* are presented in Figure 1.

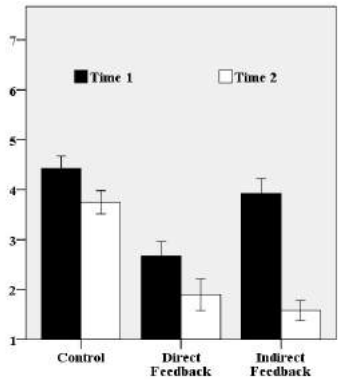

Figure 1: Mean scores of participants' judgment of addressees' perception of sarcasm (1 = definitely as sincere, 7 = definitely as sarcastic) as a function of *Time* (time 1, time 2) and *Condition* (control, direct feedback, indirect feedback).

In line with our first hypothesis, participants thought addressees would perceive the speaker's sarcasm more at their first ($M_{time\ 1}$ = 3.68, *SD* = 1.19) than at their second perspective-judgment ($M_{time\ 2}$ = 2.42, *SD* = 1.29), $F(1, 139) = 198.96$, $p < .001$, $\eta_p^2 = .59$[2].

We expected that feedback (direct, indirect) would help participants to adjust their first prediction of addressees' perspective into a judgment that more accurately reflected addressees' sincere interpretation of the voicemail than when this feedback was absent (control). Results indeed showed that the main effect of *Time* was qualified by a significant interaction with *Condition*, $F(2, 139) = 35.93$, $p < .001$, $\eta_p^2 = .34$[2]. Pairwise comparisons that compared participants' perspective-taking accuracy of their second perspective-judgment showed that participants had more successfully adjusted their first prediction after they had received both direct (*M* = 1.89, *SD* = 0.13) and indirect (*M* = 1.58, *SD* = 0.13) feedback, compared to the control condition in which this feedback was absent (*M* = 3.75, *SD* = 0.12), $p < .001$. The accuracy of participants' second prediction did not differ between the two feedback types ($p = .245$).

Interestingly, results also showed that participants' perspective-taking accuracy of their first prediction differed as a function of *Condition*. Pairwise comparison revealed that participants in the control condition (*M* = 4.43, *SD* = 0.14) thought addressees would perceive sarcasm more at time 1 than the participants in both the direct (*M* = 2.67, *SD* = 0.14, $p < .001$) and indirect (*M* = 3.93, *SD* = 0.14, $p < .05$) feedback conditions. For their first prediction, participants in the indirect feedback condition also thought addressees would perceive sarcasm more than the participants in the direct feedback condition ($p < .001$).

To examine whether the degree to which participants adjusted their perspective differed as a function of *Condition*, we computed a mean difference score between participants' first and second judgment of addressees' perception of the speaker's sarcasm and submitted this difference-score to an one-way analysis of variance. This follow-up analysis showed that participants' perspective-adjustments differed between conditions, $F(2, 139) = 35.93$, $p < .001$. Simple contrasts revealed that participants had adjusted their perspective more in both the direct ($M_{difference}$ = 0.78, *SE* = 0.16) and indirect ($M_{difference}$ = 2.34, *SE* = 0.16) feedback conditions compared to the control condition ($M_{difference}$ = 0.68, *SE* = 0.15), $t(139) = -4.63$, $p < .001$. In addition, participants who had received indirect feedback had adjusted their perspective more than those who had received direct feedback, $t(139) = 7.10$, $p < .001$.

Discussion

This study examined the influence of feedback on readers' perspective-taking. In an extension study of Damen et al. (2018c), we have shown that readers learned from the feedback they received to make better perspective-taking judgments immediately after the feedback (within the same trial) and on subsequent trials. The extent to which readers improved their perspective-taking accuracy depended on the type of feedback they received. In contrast to our expectation, we found that readers' predictions were more accurate immediately after indirect rather than direct feedback. This could have been due to the benefit these readers had from having to exert more cognitive effort to calculate addressees' interpretation. That is, readers who received the feedback indirectly not only had to infer addressees' interpretation of the voicemail from the description of addressees' actions and thoughts, these readers also had translate this information to a reliable score (i.e., 1 = definitely as sincere, 7 = definitely as sarcastic). This in contrast to the readers who were explicitly informed about the extent to which their judgment deviated from addressees' actual interpretation (direct feedback) and who, therefore, could have converted this feedback to a rating more easily.

Interestingly, the accuracy of readers' *first* predictions also differed due to the type of feedback they had received on previous trials. Although readers receiving indirect feedback made better adjustment *within* the same perspective-taking trial, their first predictions on new trials showed more egocentric projection errors than those who received direct feedback[3]. This finding needs to be interpreted with caution, because it could have been the result of task characteristics. That is, for each trial, readers receiving direct feedback could have learned that a sincere interpretation (i.e., a score of 1) was the correct response for all experimental trials, reducing egocentric projection on first predictions. This in contrast to the indirect feedback condition in which readers could have been more cautious to assume the addressees' sincere interpretation until they had actually received addressees' reaction to the voicemail. However, in all experimental conditions and for each experimental trial, the correct

[2] The findings remained unchanged when we controlled for the presentation order of the scenarios.

[3] This finding could also be an explanation as to why we see bigger adjustments in the indirect than the direct feedback condition.

response always reflected addressees' sincere interpretation of the messages. Therefore, this possible confound cannot explain why there are still significant differences within experimental trials and adjustment differences across conditions.

Although readers in the control condition did not receive feedback about the accuracy of their interpretation, these readers also adjusted their first prediction to a more accurate second prediction of the addressees' perspective. This 'positive' adjustment could have been the result of readers reflecting on their earlier assessment and subsequently coming to a more accurate conclusion (e.g., Epley et al., 2004). However, important to note is that these adjustments were still less accurate than when readers were provided with reliable information (feedback) to base their re-assessment on.

In line with findings of both West (1996) and Eyal and colleagues (2018), this study showed that providing readers with reliable perspective-information ("perspective-getting") allows them to disregard their own knowledge and to use this new information to more accurately predict others' perspective. It should be noted that readers in this experiment paid attention to the feedback they received and, therefore, could have been more aware that they could or *should* use this information to adjust their predictions appropriately. In addition, in Eyal et al. (2018), the discourse through which partners gained relevant perspective-information was demarcated with regard to the topics partners had to discuss. Therefore, an interesting question for future research is whether this "perspective-getting" effect generalizes to situations in which reliable perspective-information (and its appropriateness) is not been made explicit.

Abstract concepts and the suppression of arbitrary episodic context

Abstract

Context is important for abstract concept processing, but a mechanism by which it is encoded and re-instantiated with concepts is unclear. We used a source-memory paradigm to determine whether *episodic* context is attended more when processing abstract concepts. Experiment 1 presented abstract and concrete words in colored boxes at encoding. At test, memory for the frame color was worse for abstract concepts, counter to our predictions. Experiment 2 showed the same pattern when colored boxes were replaced with male and female voices. Experiment 3 presented words from encoding in the same or different box color to determine whether a greater advantage is conferred by context retention in memory for abstract concepts. There was instead a *disadvantage*: abstract concepts were *less* likely to be identified when the encoding color was retained at test. Concrete concepts are more sensitive to simple episodic detail, and in abstract concepts, *arbitrary* context may be suppressed.

Keywords: concepts, semantic memory, episodic memory, abstract concepts, concreteness

Introduction

Abstract concepts like *decision* are central to the human experience, yet little is understood about how they are processed. Contextual information is thought to be important to abstract concepts—the specific meaning of *decision* varies more depending on context than does the meaning of *river*. While a river in New England shares many properties with a river in Papua New Guinea, consider the case of *decision*: your decision on which beverage to buy at a café late at night differs greatly from the decision a judge might make in determining sentencing for a felon. It is the context which determines the antecedents, outcomes, and consequences in these two instantiations of *decision*. While it seems that context should be important in processing abstract concepts, the mechanism by which context is encoded and re-instantiated with the concept remains unclear. One possibility is that the episodic memory system, which supports encoding and recall of contextually detailed memories, is critical in understanding abstract concepts. Thus, here we probed a potential mechanism underpinning abstract concepts' sensitivity to context by using a source memory paradigm to test whether *episodic* context is better bound to abstract than concrete concepts.

Episodic memory is classically defined as explicit memory for unique events (Tulving, 1983, 2002), where episodic context is the detail that colors an episode. There are circumstances under which we are more likely to *encode*, and therefore, *recall* the arbitrary contents of a particular episode (e.g., the color of a frame or the identity of a speaker). A standard paradigm for assessing this ability is the source memory task (see Davachi, 2006; Yonelinas, 2001, 2002). In this task, participants are asked at test to determine whether an item (e.g., a word) was previously presented in an exposure phase, and then probed as to whether they can recognize some prior contextual detail. Greater confidence in having seen a word at exposure is associated with greater likelihood of having encoded the contextual detail (e.g., Kirwan, Wixted, & Squire, 2008; Yu, Johnson, & Rugg, 2012). Therefore, we would predict that greater confidence in having seen or heard a word during an encoding phase is associated with better memory for an arbitrary context, such as a box color or voice, at a test phase.

In addition to confidence in recollection or strength of the memory, emotionality in words, including both valence and arousal (Kensinger & Corkin, 2003), influences the likelihood of recalling the context in which something was presented, suggesting that the *content* of the stimuli at exposure can influence the likelihood that the context is identified at test. More specifically, *conceptual* or *semantic* content might affect likelihood of context encoding. In this set of experiments, we investigated whether this is true for concreteness: are we better at encoding contextual detail for abstract than for concrete concepts?

The notion that episodic context is more important for interpreting abstract concepts suggests that we should be more sensitive to the episodic context in which abstract concepts are placed and, in turn, be more accurate at retrieving even non-systematically related elements in the context. We opted to test this hypothesis by examining whether *arbitrary* contexts are better recognized when paired with abstract as compared to concrete concepts. Because memory is generally better for concrete than for abstract words (e.g., Paivio, Walsh, & Bons, 1994), we expected that although overall memory for concrete concepts would be better, *when* abstract concepts are correctly recognized, the context would be better encoded. To foreshadow the results, we find evidence *against* this hypothesis, suggesting that arbitrary episodic context may be *inhibited* in abstract concepts. In the General Discussion, we propose an alternative framework in which these results might be accommodated.

In the studies below, context is operationally defined as an aspect of a stimulus that is irrelevant to the central stimulus, such as whether a target word is presented within a red or green frame or whether stimuli are presented in a male or female voice.

Experiment 1

Methods

Participants Forty-two University of Connecticut (UConn) students with normal or corrected-to-normal vision and hearing provided informed consent and received course credit for participating. One participant was excluded for non-compliance, leaving $N = 41$. The study was approved by the UConn IRB.

Stimuli In the encoding phase, 100 (60 target, 40 non-target) abstract (e.g., *decision*) and 100 (60 target, 40 non-target) concrete (e.g., *chair*) noun concepts were used. (Non-targets were synonym words which functioned as positive responses for the synonym-judgment task described below. Targets were non-synonyms.) Stimuli were matched across all stimulus subsets on word length and word frequency based on English Lexicon Project data (Balota et al., 2007), and were sorted into abstract and concrete conditions based on Brysbaert, Warriner, and Kuperman's (2014) concreteness norms (Table 1). Half of the words were enclosed in red boxes, and the other half in green, and this was balanced across concrete and abstract words. In the test phase, an additional 50 abstract and 50 concrete words were added to the target and non-target items.

Table 1
Stimulus Characteristics

	Targets			Synonyms		
	n_{letter}	log^F	conc	n_{letter}	log^F	conc
Abs	6.7	5.0	1.8	7.3	5.7	2.1
Conc	7.0	5.1	4.9	6.2	5.7	4.8

Procedure Participants performed a two-phase source memory task. Stimuli were presented visually one at a time, in pseudorandomized order, with an arbitrary box context (either a red or a green box). On each word, participants performed a synonym-judgment 1-back task. To ensure that they did not ignore the boxes, the hand they used to make their response was determined by box color (left hand for words in green boxes and right for red). Stimuli were presented for 2000 ms with a 1000-ms interstimulus interval. Participants were told there would be a later memory test on the words, but not that source (i.e., box color) memory would be tested.

In the test phase, participants performed two tasks for each word. First, they responded whether they had seen the word at encoding, indicating their degree of confidence in the decision (high, medium, and low confidence for either "old" or "new"). Second, for old words, they indicated the color of the box on initial encoding. The task was the same for new words, except that they were asked simply to select the color they thought the box would have been had it been presented at encoding. Participants were given 6000 ms each for the old/new and the box color judgment.

Data analysis Data were analyzed using R. Memory for items (i.e., words) and their contexts (i.e., box color) was first analyzed using descriptive statistics, calculating accuracy, hit rate, miss rate, correct rejections, false alarms, and d' (calculated as z(Hit) – z(FA)) for all words, and accuracy was also assessed by level of confidence. Source (i.e., box) memory accuracy was calculated only for target hits, and was assessed across confidence levels. Source memory accuracy was analyzed as a function of word type and confidence in having seen the word at encoding. Logistic mixed effects models (lme4 package; Bates et al., 2017) were used to analyze the data, with subject and word as random intercepts, and word type (abstract or concrete), level of confidence (low, medium, high), and their interaction as treatment-coded fixed effects. Each predictor was entered in a successive model, and statistical significance was assessed by comparing the models using likelihood ratio tests. Here, p-values < .05 were considered statistically significant.

Results

Item recognition First, to provide a baseline measure of memory for concrete and abstract words, we report the accuracy and hit, miss, correct rejection, and false alarm rates across all words (Table 2). Hit rates were higher and false alarms lower in concrete words, demonstrating the mirror effect (Glanzer & Adams, 1985), which has previously been observed for concreteness (Glanzer & Adams, 1990). For overall accuracy, there were main effects of both word type and confidence. Concrete words were better recognized than abstract ($\chi^2(1) = 10.21$, $p = .001$), and accuracy increased with greater confidence ($\chi^2(2) = 571.37$, $p < .001$). The interaction was non-significant. Among targets only (i.e., non-synonym words presented at encoding), there was no main effect of word type ($\chi^2(1) = 0.29$, $p = .59$), but a main effect of confidence level ($\chi^2(2) = 675.22$, $p < .001$), with words recognized better with higher confidence. The interaction was non-significant. Means and 95% CIs for word and source (i.e., box) memory are shown in Figure 1. Finally, d' analysis showed that when considering response sensitivity, accuracy was better for concrete concepts, $t(39) = -5.37$, $p < .001$.

Table 2
Mean Item Recognition Accuracy

Word type	Acc	Hit	Miss	CR	FA	d'
Abstract	.73	.77	.23	.65	.35	1.21
Concrete	.78	.81	.19	.71	.29	1.57

Note. CR = correct rejection; FA = false alarm.

Source memory Here, we included only trials for which the word had been correctly identified. There was a main effect of word, where the box was less likely to be remembered for abstract words ($\chi^2(1) = 5.45$, $p = .02$), but not of confidence level. The interaction was non-significant. Participants were less likely to correctly remember the box color for abstract words (Figure 1).

According to d' scores, there was a baseline advantage for recognizing concrete words, which would then bias the source memory models. Correct memory trials for abstract words may have been less likely to reflect true hits where the word was in fact encoded. Accordingly, we also constructed models with d' as a predictor. A likelihood ratio test comparing the model with both d' and word type versus the model with only d' was significant, $\chi^2(1) = 5.27$, $p = .02$, suggesting that the effect of word type, where box recognition was worse in abstract than it was in concrete concepts, was significant even after accounting for the d' concreteness advantage.

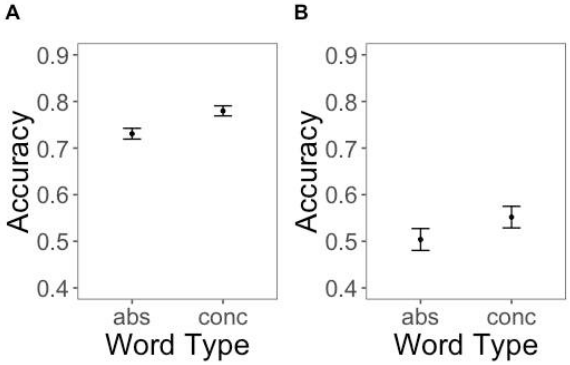

Figure 1. Effects of concreteness on (a) overall item recognition accuracy and (b) source (i.e., box) memory.

Discussion

Source memory was worse for abstract concepts, and this was true even after controlling for a concreteness advantage detected in d'. Thus, the results of Experiment 1 ran counter to our hypothesis: source memory was *worse* for abstract than for concrete words, even when participants were highly confident in having seen the word at encoding. Why did this unexpected difference emerge? It may be that concrete concepts are more amenable to a mnemonic strategy wherein a color adjective (i.e., "red" or "green") could readily be bounded to concrete objects (e.g., "table"), making source memory better for concrete words. Thus, it may be that contextual detail is better encoded in abstract concepts, but only when not systematically related to concrete objects (as may be the case for colored boxes). A second explanation is that counter to our main hypothesis, the concreteness advantage extends to memory for arbitrary contextual details. Experiment 2 evaluated these competing explanations.

Experiment 2

In Experiment 2, we utilized a variant of the source memory paradigm, where instead of the box, the context to be encoded was a male or female voice. Concepts were presented auditorily, and memory was assessed on visually presented words (e.g., Wilding & Rugg, 1996). In line with the original prediction that contextual detail is encoded to a greater extent in abstract concepts, it was predicted that source memory (i.e., male or female voice) would be better for abstract concepts. This prediction is further buoyed by the finding that person-related social properties may be more important for abstract concepts (Barsalou & Wiemer-Hastings, 2005).

Methods

Participants Forty-two UConn undergraduates with normal or corrected-to-normal vision who had not participated in Experiment 1 provided informed consent and were given course credit for their participation.

Stimuli The words were the same as those used in Experiment 1, but rather than being presented visually they were instead recorded by a male and a female speaker, with half the words presented by the male speaker and half by the female speaker. As with box color, this list was held constant across participants. There were no differences in the length of the sound files between the two speakers, and all files were normalized to a peak amplitude.

Procedure In the encoding phase, the procedure was the same as in Experiment 1. In the memory phase, the first judgment—whether the word was in the initial set (old) or not (new)—was the same. For the second judgment, participants were asked to indicate whether the person who said the word in the initial set was "Jane" or "Sid." The test phase was conducted with visually presented words, as in Experiment 1 (for a similar paradigm, see Wilding & Rugg, 1996).

Data analysis Data were analyzed in the same way as in Experiment 1.

Results

Item recognition Accuracy and hit, miss, correct rejection, and false alarm rates across all words are shown in Table 3. Among all words, there was a

significant main effect of both word type, with concrete words showing better recognition ($\chi^2(1)$ = 6.77, p = .009), and confidence level, with both medium and high showing greater accuracy than low confidence ($\chi^2(2)$ = 610.85, p < .001). The word type × confidence interaction was non-significant. Among targets, there was a main effect of confidence ($\chi^2(2)$ = 961.49, p < .001), but not of word type. The interaction was significant ($\chi^2(2)$ = 9.18, p = .01) at high confidence, suggesting that at greater memory strength, item recognition was worse for abstract words. Means and 95% CIs for the main effects of word type on word and source (i.e., voice) memory are visualized in Figure 2. Finally, d' analysis revealed that after considering response sensitivity, accuracy was better for concrete concepts, $t(40)$ = -3.49, p = .001.

Table 3
Mean Word Recognition Accuracy

Word type	Acc	Hit	Miss	CR	FA	d'
Abs	.70	.72	.28	.64	.36	1.04
Conc	.73	.77	.23	.67	.33	1.28

Note. CR = correct rejection; FA = false alarm.

Source memory Here, we again included only trials for which the word had been correctly recognized. There was a main effect of word type, with source memory for the voice context worse for abstract words ($\chi^2(1)$ = 5.70, p = .02), as well as a main effect of confidence ($\chi^2(2)$ = 25.22, p < .001). The interaction was non-significant. Thus, participants were again less likely to recognize the context correctly for abstract as compared to concrete words. Means and 95% CIs are shown in Figure 2.

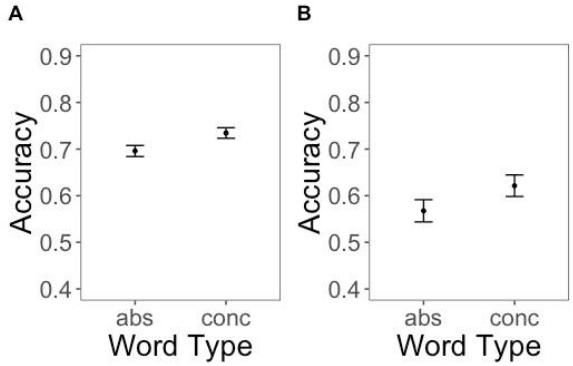

Figure 2. Effects of concreteness on (a) overall item recognition accuracy and (b) source (i.e., voice) memory.

As in Experiment 1, d' was greater for concrete than it was for abstract concepts (Table 3), and so we constructed models with d' as a predictor. A likelihood ratio test comparing the model with both d' and word type versus the model with only d' was significant, $\chi^2(1)$ = 5.75, p = .02, suggesting that the effect of word type, where source memory was worse for abstract than it was for concrete concepts, was significant even after accounting for the d' concreteness advantage.

Discussion

There was again a concrete word advantage in overall item recognition. Moreover, source memory for the voice context was worse for abstract concepts. This provides support for the interpretation that the concreteness advantage also extends to episodic memory, at least for memory for simple episodic detail. However, Experiments 1 and 2 showed a baseline memory advantage for concrete words, and thus they may have been more strongly encoded, and the strength with which the words were encoded, not concreteness, may have facilitated source memory. Accordingly, we conducted a third experiment.

Experiment 3

In Experiment 3, we simplified the memory phase by instead *only* probing recognition memory: half of the words were presented in the same box color as they were at encoding, while half of the words were presented in a different box color. The aim here was to investigate whether there is a selective advantage in recognition memory when the context is retained in abstract concepts—that is, is recognition memory facilitated to a greater extent in abstract concepts by context preservation? This would suggest that while the memory trace left by abstract concepts may be weaker, it can be strengthened when context is consistent across exposures. On the other hand, if recognition memory accuracy for abstract concepts is *worse* when the box color at encoding is preserved at test, it would suggest that arbitrary episodic detail may be *inhibited* in abstract concepts.

Methods

Participants Forty UConn undergraduates with normal or corrected-to-normal vision who had not participated in Experiment 1 or 2 provided written informed consent and received course credit.

Stimuli The stimuli were the same as those in Experiments 1 and 2, and box color assignment was counterbalanced across participants.

Procedure The encoding procedure was the same as in Experiment 1. At test, participants were asked to identify as many old words as possible, ignoring the color of the box. Words were presented in the red and green boxes. Half of the words retained the box color from encoding, and half changed color.

Data analysis Item recognition data were analyzed in the same way as in Experiments 1 and 2. However, box retention (old vs. new) was used as a second fixed effect in the mixed logit model, and the interaction was word type × box retention.

Results and discussion
